CHAPTER 193

The Genus *Borrelia*

RUSSELL C. JOHNSON and CARRIE A. NORTON HUGHES

The genus *Borrelia* is one of the four genera of the family Spirochaetaceae and is comprised of pathogenic spirochetes that are transmitted by arthropod vectors. With the exception of louse-borne relapsing fever, the borrelioses are zoonoses. In the past, due to the inability to culture the spirochetes and conduct the usual morphological and physiological studies for their classification, the borreliae have been classified into species solely on the basis of their arthropod vector. In addition, the antigenic variability associated with some of the borreliae has prevented the use of serological methods for their identification. With the formulation of a culture medium by Kelly (1971), and with subsequent improvements by Stoenner (1974) and Barbour (1984), many of the borreliae can now be cultivated in vitro and taxonomic methods based on molecular biology can be applied to their classification. Nineteen species of Borreliae have been recognized.

Borreliae are slender (0.2–0.5 μm × 8–30 μm) helically shaped bacteria (Fig. 1). They are considered to be Gram-negative, but are visualized best with Giemsa's stain. *Borrelia* shares the same basic ultrastructural features as other members of the Spirochaetaceae (see also Chapter 191). These features include an outer membrane that encloses the protoplasmic cylinder and periplasmic flagella inserted subterminally and bipolarly in the protoplasmic cylinder. An amorphous slime layer has been observed on the surface of several borreliae (Hovind-Hougen, 1976). Muramic acid (Ginger, 1963) and ornithine (Klaviter and Johnson, 1979) have been identified as components of the borrelial cell wall. The periplasmic flagella are unsheathed and overlap in the central region of the cell (Holt, 1978). The number of periplasmic flagella per cell end varies from 7 to 20 (Hovind-Hougen, 1976). Because of the internal location of the periplasmic flagella, cells maintain their motility in environments of relatively high viscosity.

Borrelia species are relatively slow-growing microaerophilic spirochetes. The cells contain an iron superoxide dismutase, but not catalase or peroxidase (Austin et al., 1981), and are resistant to metronidazole (Johnson et al., 1984a). They grow well in the temperature range of 30–35°C with generation times of 12–24 h at the latter temperature. Their nutritional requirements have not been fully defined but appear to be complex. *Borrelia* require N-acetylglucosamine (Kelly, 1971) and long-chain fatty acids, which are incorporated unaltered into cellular lipids (Livermore et al., 1978; Pickett and Kelly, 1974). They utilize glucose as a major energy source, with lactic acid as the predominant metabolic end product (Kelly, 1976).

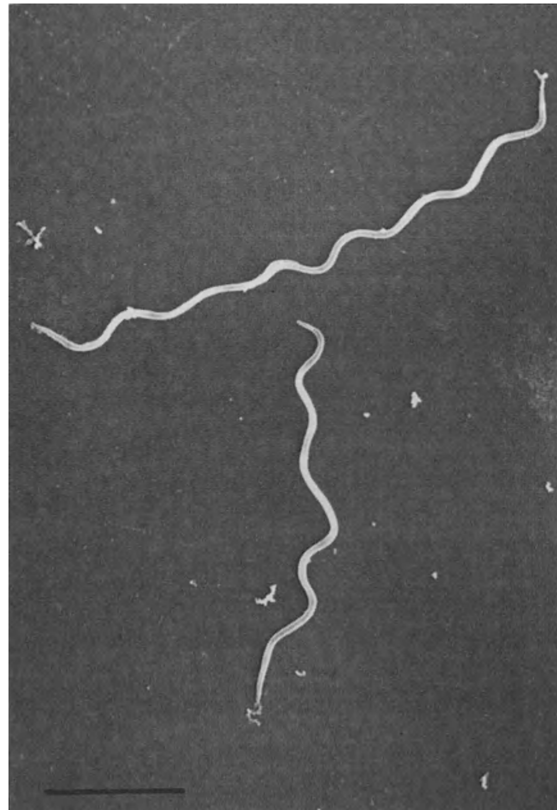

Fig. 1. *Borrelia burgdorferi* strain 297, human cerebral spinal fluid isolate, as seen by scanning electron microscopy. Bar = 5 μm.

Borrelia species do not produce any known toxins and may elicit an acute inflammatory response in the host. They are considered to be extracellular parasites, as they are predominately confined to the plasma space of their mammalian hosts. The remittent fevers characteristic of relapsing fever borreliae are due to antigenic variations among the infecting populations of spirochetes.

Habitats

All known borreliae are arthropod-borne pathogens and are transmitted by the human body louse or various species of hard and soft ticks. The principle species of *Borrelia* and their primary vectors are listed in Table 1. The validity of the assignment of some of the species of *Borrelia* is questionable. For example, on the basis of DNA homology studies, a high degree of relatedness (76% to 100%) was observed among *B. hermsii, B. turicatae,* and *B. parkeri,* indicating that these borreliae probably comprise a single species (Hyde and Johnson, 1984). Conversely, some *B. burgdorferi* isolates from the United States and Europe appear to be genetically dissimilar (LeFebvre et al., 1989).

Presence in Lice

B. recurrentis is the etiological agent of louse-borne (epidemic) relapsing fever and is the only

Table 1. Characteristics of *Borrelia* species of medical and veterinary significance.

Species	Disease	Vector	Geographic distribution
B. recurrentis	Louse-borne relapsing fever	*Pediculus humanus* subsp. *humanus*	Worldwide
B. hermsii	New World tick-borne relapsing fever	*Ornithodoros hermsi*	Canada, western USA
B. turicatae	New World tick-borne relapsing fever	*O. turicata*	Southwestern USA
B. parkeri	New World tick-borne relapsing fever	*O. parkeri*	Western USA
B. mazzottii	New World tick-borne relapsing fever	*O. talaje*	Southwestern USA, Mexico, Central and South America
B. venezuelensis	New World tick-borne relapsing fever	*O. rudis*	Central and South America
B. duttonii	Old World tick-borne relapsing fever	*O. moubata*	Central, eastern, and southern Africa
B. hispanica	Old World tick-borne relapsing fever	*O. marocanus*	Spain, Portugal, Morocco, Algeria, Tunisia
B. crocidurae, B. merionesi, B. microti, B. dipodilli	Old World tick-borne relapsing fever	*O. erraticus*	Northern and eastern Africa, Near and Middle East, southeastern Europe
B. persica	Old World tick-borne relapsing fever	*O. tholozani*	Middle East, Greece, Central Asia
B. caucasica	Old World tick-borne relapsing fever	*O. verrucosus*	Iraq, southwestern USSR
B. latyschewii	Old World tick-borne relapsing fever	*O. tartakowskyi*	Iraq, Iran, Afghanistan, southcentral and southwestern USSR
B. burgdorferi	Lyme (borreliosis) disease	*Ixodes dammini*	Midwestern and eastern USA
		I. pacificus	Western USA
		I. ricinus	Europe
		I. persulcatus	Asiatic USSR, China, Japan
B. anserina	Avian borreliosis	*Argas persicus* and other *Argas* spp.	Worldwide
B. theileri	Bovine borreliosis	*Rhipicephalus evertsi, Boophilus microplus, B. annulatus, B. decoloratus*	South Africa, Australia, Brazil, Mexico
B. coriaceae (?)	Epizootic bovine abortion	*Ornithodoros coriaceus*	California

species of borreliae that is louse-transmitted. The human is the only known reservoir of this spirochete. The human body louse, *Pediculus humanus* subsp. *humanus,* becomes infected after feeding on a spirochetemic individual and remains infected during its life span of approximately 10 to 61 days. The ingested borreliae enter the louse midgut where they penetrate the gut epithelium to gain entrance to the hemolymph, in which they multiply. They do not infect the salivary glands or ovaries of the lice. Accordingly, the infection is not passed to offspring of infected lice via transovarial transmission, nor do humans become infected via infectious saliva while the lice are feeding. Rather, infection is thought to occur when spirochetes are liberated from the lice and enter the host through the bite wound when the lice are crushed on the skin by scratching. Since body lice prefer the normal body temperature of 37°C, to higher temperatures they are likely to leave a febrile person to seek an afebrile person, which results in the rapid transmission of infection during epidemics.

Presence in Ticks

The borreliae are also parasites of both soft and hard ticks. Two human diseases caused by infected ticks are the tick-borne (endemic) relapsing fevers and Lyme (borreliosis) disease. Numerous species of *Borrelia* are responsible for the tick-borne relapsing fevers and are distributed worldwide in both tropical and temperature climates (Table 1). Argasid (soft) ticks of the genus *Ornithodoros* serve as the vectors of these spirochetes, with wild rodents being the major reservoir for the borreliae. Occassionally, lizards, toads, turtles, and owls can harbor these spirochetes. The infection is maintained in reservoir animals by tick bites. Humans are accidental hosts, with the possible exception of infections by *B. duttonii.* In East Africa, this spirochete is carried by the domestic tick, *O. moubata,* and the reservoir for the borreliae appear to be humans.

The course of development of relapsing fever borreliae in ticks varies considerably from that in lice. Ticks become infected while obtaining a blood meal from spirochetemic animals. A generalized infection ensues, and spirochetes can be found in a variety of tissues, including the salivary glands, the coxal glands on the legs, and the ovaries. Humans and animals become infected while the tick is feeding, either through infectious saliva and/or coxal fluid entering via the bite wound or skin. Ticks are durable vectors of borreliae, as they are able to survive months to years without a blood meal. In addition, the spirochetes are able to survive in the ticks for similar periods of time. In contrast to lice, female ticks can transmit borreliae transovarially to their progeny, and the spirochetes can be maintained during transition from one developmental form to another (e.g., larvae to nymph to adult).

The Ixodidae (hard) ticks are the primary vectors of *B. burgdorferi,* the etiological agent of Lyme disease (Table 1). The association between *B. burgdorferi* and *Ixodes dammini,* the vector of this disease in northeastern and north-central USA, has been studied extensively (Benach et al., 1987; Burgdorfer et al., 1982; Burgdorfer et al., 1989; Ribeiro et al., 1987). This relationship is similar to that occurring in other ticks of the *I. ricinus* complex. The larval and nymphal forms of *I. dammini* commonly become infected with *B. burgdorferi* when obtaining a blood meal from infected rodents. The white-footed mouse, *Peromyscus leucopus,* is a primary reservoir for the spirochete. In contrast to the tick- and louse-borne relapsing fever borreliae that egress from the midgut a few days after ingestion and invade the hemolymph, *B. burgdorferi* remains in the midgut until the next blood meal (Burgdorfer, 1989; Ribeiro et al., 1987). At that time, it penetrates the basal membrane of the midgut, invades the hemolymph and various tissues, including the salivary glands, and is transmitted to the host via infectious saliva. Transovarial transmission occurs less frequently in the *Ixodes* ticks as compared to the *Ornithodoros* ticks.

Several species of *Borrelia* are of veterinary importance. However, little information is available on the development of these borreliae in their tick vectors.

Medical Importance of Borreliae

Relapsing Fevers

Subsequent to exposure to an infected louse or tick, the relapsing fever borreliae gain access to the blood and the lymph. After an incubation period of 4 to 18 days and after the spirochetes have multiplied to levels of 10^6 to 10^8 cells per ml of blood, the illness begins abruptly with shaking chills, fever, headache, and fatigue, which persist for 3 to 7 days. Following an afebrile period of 5 to 10 days, a second symptomatic episode may occur. Additional relapses of decreasing time and intensity are characteristic of the tick-borne disease but are uncommon in the louse-borne disease. The relapses

are the result of antigenic variation in the borreliae. The borreliae are able to undergo a number of cyclic antigenic variations. When antibodies to the prevailing antigenic type appear, the organisms "disappear" from the peripheral blood and are replaced by a different antigenic variant in a few days. If the host is untreated, this process may be repeated several times, depending upon the infecting strain of *Borrelia.*

During the acute phases of the illness, borreliae may be seen in blood smears stained with Giemsa or Wright stain and counterstained with crystal violet (Felsenfeld, 1971). The mortality rate in louse-borne relapsing fever ranges as high as 40% in untreated cases, but can be less than 5% following antibiotic treatment. Oral tetracycline (30 mg/kg of body weight), given in four divided doses at 6-h intervals for 10 days, is considered the drug of choice (Foster, 1977). Shortly following the initiation of antibiotic therapy, a Jarisch-Herxheimer reaction occurs, manifested by chills, fever, headache, and joint and muscle pains. This reaction is quite pronounced in louse-borne relapsing fever. Clinical descriptions of relapsing fever in humans have been detailed by Bryceson et al. (1970).

Louse-borne relapsing fever has been reported primarily from African countries, particularly Ethiopia and Sudan. Some outbreaks have occurred in the South American Andes. Tick-borne relapsing fevers are more sporadic in occurrence. In North America, most of the cases occur within the distributional area of *Ornithodoros hermsi* or *O. turicata* (Table 1). In the United States, tick-borne relapsing fever is underreported because it is seldom diagnosed. Unless a patient history of wilderness exposure or camping in rodent-infected areas is given and the patient is aware of a tick bite, the illness is usually not suspected during the initial period of fever (Fihn and Larson, 1980).

Lyme (Borreliosis) Disease

Lyme disease is a multisystem illness that primarily affects the skin, nervous system, heart, and joints (Steere, 1989). The disease was brought to the attention of the medical community as the result of an outbreak of arthritis in adults and children in Lyme, CT, USA, and the adjacent communities of Old Lyme and East Haddam. The resulting epidemiological and clinical investigations led to the identification of a new disease entity, Lyme disease (Steere et al., 1977).

The hallmark skin lesion of Lyme disease, erythema chronicum migrans, was first described in Europe in 1908 (Afzelius, 1921) and in the USA in 1969 (Scrimenti, 1970). According to the CDC, Lyme disease is the most common vector-borne infection in the USA. Cases have been reported in 43 states, with three areas of concentration: from Massachusetts to Maryland in the northeast; Wisconsin and Minnesota in the midwest; and California and Oregon in the west. Most European countries have also reported cases, as have republics in the USSR. In addition, the disease has been reported in China, Japan, Africa, and Australia.

Lyme disease can be divided into early and late infection. Approximately 7 to 9 days following the initial tick bite, the early (localized) infection is marked by the pathognomonic skin lesion, erythema migrans (in 60 to 80% of patients), and accompanied by fever, regional lymphadenopathy, or minor constitutional symptoms (Steere, 1989). The erythema migrans lesions usually fade within 3 to 4 weeks, even when untreated, but they may recur. Weeks to months later (disseminated disease), patients may develop meningoencephalitis, Bell's palsy, myocarditis, migrating musculoskeletal pain and intermittent attacks of arthritis, especially in the large joints such as the knee. As the infection progresses (late or persistent infection), the episodes of arthritis last for months rather than weeks. Also, syndromes of both the central and peripheral nervous system may occur more than a year after the initial infection. Persistent infections in Lyme disease may also develop as acrodermatitis chronicum atrophicans (ACA), the late skin manifestation of the disease, which has primarily been observed in Europe (Asbrink and Hovmark, 1988; Kaufman et al., 1989). The skin lesion typically begins as a bluish-red discoloration of swollen skin on an extremity. This lesion may occur at an earlier site of erythema migrans. The inflammatory stage of ACA may persist for years or decades and may lead to atrophy of the skin. Transplacental transmission of *B. burgdorferi* has been reported; however, congenital infection with adverse outcome, such as perinatal death, appears to be unusual (Schlesinger et al., 1985; Weber et al., 1988).

After the first several weeks of infection, most patients have a positive antibody response to the spirochete. The specific IgM response is detectable after the third week and peaks after 6 to 8 weeks (Steere et al., 1983). The *B. burgdorferi*-specific IgG response peaks during the second to third month of infection and may persist for years. Since the direct visualization and culture of *B. burgdorferi* from patient specimens is difficult, serologic determinations are currently the most practical mode of laboratory

diagnosis. False negative results occur early in the disease, whereas false positives may occur in patients with a variety of other diseases, including syphilis, Rocky Mountain spotted fever, autoimmune disease, and neurologic disorders. Differential diagnosis is difficult.

Early Lyme disease usually responds well to antimicrobial therapy. However, cases with persistent joint or central nervous system complications tend to be more resistant to treatment. Adults with the early manifestations generally respond to doxycycline (100 mg orally, 2× daily, 10–30 days) or amoxicillin (500 mg orally, 4× daily, 10–30 days). Children younger than 8 years of age are generally treated with amoxicillin (250 mg orally, 3× daily, 10–30 days). Neurologic manifestations and other abnormalities are treated with ceftriaxone (Rocephin) (2 g, intravenously, 1× daily, 14 days). Treatment failures have occurred with all of these regimens, and retreatment may be necessary. Since patients who have already developed a mature anti-borrelia IgG response often remain seropositive after apparently successful antibiotic therapy, the presence or absence of circulating antibodies to *Borrelia* following treatment is not a reliable indicator of cure (Dattwyler et al., 1989). Descriptions of clinical presentations and the medical progress of Lyme disease have been reviewed by Steere (1989).

Veterinary Diseases

Borrelia anserina, the type species of the genus, is the etiological agent of avian borreliosis, a highly fatal disease of geese, ducks, turkeys, and chickens. Mammals are resistant to this infection. The disease is widespread, occurring in many countries including Europe, Asia, Australia, and South, Central, and North America. The vectors of *B. anserina* are species of *Argas* ticks. The disease begins with a high fever; then the birds become cyanotic and develop diarrhea. Spirochetes are present in the blood early during the disease and relapses do not occur.

Borrelia coriaceae is the putative etiological agent of epizootic bovine abortion, a disease of major economic importance in California (Lane et al., 1985). This recently recognized species of *Borrelia* (Johnson et al., 1987) is carried by the soft tick *Ornithodoros coriaceus* (Lane et al., 1985).

Borrelia theileri is responsible for a mild disease of cattle, horses and sheep. The illness is characterized by one to two episodes of fever, weight loss, weakness, and anemia. The vectors of this spirochete are species of the hard ticks *Rhipicephalus* and *Boophilus.* The disease has been reported in South Africa and Australia.

Isolation

The study of *Borrelia* was greatly facilitated by the development of a culture medium by Kelly (1971) that would support the growth of the spirochetes. Stoenner enriched the basic formulation of Kelly with the addition of yeast extract and tissue culture medium (Stoenner et al., 1982). Subsequent modifications by Barbour (1984) resulted in BSK (Barbour-Stoenner-Kelly) medium, which has allowed the isolation of borreliae from a variety of tissues. The success of in vitro culture of *Borrelia* is usually dependent on the quality of the animal serum or albumin used in the media preparation (Callister et al., 1990).

Liquid BSK II Medium for Growth of *Borrelia* (Barbour, 1984)

1. To 900 ml of glass-distilled water, add the following:

N-2-hydroxyethylpiperazine-N-2-ethanesulfonic acid (HEPES, Sigma)	6.0 g
Neopeptone (Difco)	5.0 g
Sodium citrate	0.7 g
Glucose	5.0 g
Sodium bicarbonate	2.2 g
TC Yeastolate (Difco)	2.5 g
Sodium pyruvate	0.8 g
N-acetyl glucosamine (Sigma)	0.4 g
Bovine serum albumin, fraction V	50.0 g

2. Adjust pH of medium at 20–25°C to 7.6 with 1 N NaOH.
3. Sterilize by filtration with air pressure (0.2-μm membrane filter).
4. Add 100 ml of sterile 10X concentrate CMRL 1066 without glutamine (Gibco).
5. Add 200 ml of sterile 7% gelatin (Difco), which has been dissolved in boiling water.
6. Add 64 ml of sterile, heat-inactivated rabbit serum (Pel-Freeze Biologicals, Inc., Rogers, AR).
7. Dispense to glass or polystyrene tubes or bottles. Fill to 90% capacity and cap tightly.
8. Store complete medium at 4°C.

Semisolid medium is prepared by the addition of 100 ml of sterile 1.89% Seakem LE agarose (Gibco), which has been dissolved in boiling water. The agarose solution is added just prior to dispensing the medium.

Borrelia can be isolated from *Ornithodoros* and *Ixodes* ticks using semisolid BSK medium. The hemolymph and most tissues of *Ornithodoros* ticks can be used as a source of the relapsing fever borreliae and *B. coriaceae.* In contrast, *B. burgdorferi* is usually restricted to the midgut of *Ixodes* ticks. Susceptible animals (young mice, rats, or hamsters) can be used for the isolation of borreliae by inoculation of tick tissue suspensions or by allowing infected ticks to feed on the animals. The borreliae may be isolated from the blood during the first 7 days

of infection and from the kidney, spleen, and bladder after 14 days using the procedures described below.

Borrelia strains are isolated from blood by inoculating one to two drops per 10 ml of semisolid BSK medium. Tissue samples are homogenized in liquid BSK medium (10% wt/vol) with a Stomacher Lab Blender (Tekmar, Cincinnati, OH). Larger tissue debris is allowed to settle and duplicates of 1:10-dilutions of the supernatant are made in the semisolid BSK medium. Cultures are incubated at 30—35°C and examined by darkfield microscopy for spirochetes at weekly intervals.

B. burgdorferi has been isolated and subcultured from blood, CSF, synovial fluid, and skin specimens from Lyme disease patients. In contrast to relapsing fever, very few borreliae are present in the acute stage of Lyme disease. They cannot be detected visually in the blood, and most isolation attempts have been unsuccessful (Rawlings et al., 1987; Steere et al., 1983). Only one successful isolation and subculture has been reported for the synovial fluid (Schmidli et al., 1988). Spirochetes are more readily isolated from the CSF when central nervous system involvement occurs and from biopsy specimens of the skin lesion of erythema migrans and acrodermatitis chronicum atrophicans (Asbrink and Hovmark, 1988; Berger et al., 1985; Rawlings et al., 1987). *B. burgdorferi* has not been isolated from the urine of patients with Lyme disease. Despite successes in isolating *B. burgdorferi* from patient specimens, no standard method for processing samples can be recommended at this time. Although borreliae usually can be detected in culture media within 1 to 3 weeks of incubation, some isolates may not be visible for several months.

Borreliae are best preserved by the addition of glycerin (final concentration, 10%) to blood or plasma from infected animals, or to culture media, and stored at −70°C or in liquid nitrogen.

Identification and Characterization

Members of the genus *Borrelia* have been identified by ecological and biochemical characteristics. All species in this genus are transmitted to vertebrates by hematophagous arthropods. In most cases, borreliae differentiation was based on identification of the specific vector that transmits the spirochete, on the host (humans, animals, or birds), and on the variable infectivity of isolated borreliae for different species of laboratory animals (Burgdorfer, 1976; Davis, 1956; Felsenfeld, 1971). More recently, genetic techniques have been used to characterize these spirochetes.

Borrelia DNA has a GC content of 27 to 32 mol%, which is lower than that reported for *Treponema* and *Leptospira* (Hyde and Johnson, 1984). DNA homology studies have shown that the three North American relapsing fever borreliae, originally speciated on the basis of vector specificity, constitute a single species of *Borrelia* (Hyde and Johnson, 1984). In addition, the Lyme disease spirochete and the *O. coriaceus* spirochete were determined to be new species of *Borrelia* (Johnson et al., 1984b; Johnson et al., 1987). Through the use of restriction endonuclease analyses and hybridization studies, it has been possible to detect similarities and differences among strains of *B. burgdorferi* (LeFebvre et al., 1989). The detection and identification of *Borrelia* has also been accomplished through the use of DNA probes (Schwan et al., 1989).

Molecular Biology

The DNA organization of the *Borrelia* appears to be unique in the Spirochaetaceae and perhaps among the prokaryotes as well in having linear DNA plasmids. In contrast to other spirochetes, the *Borrelia* species were found to contain plasmids (Hyde and Johnson, 1984). Plasmids were detected in all of the *Borrelia* examined, which include *B. hermsii, B. parkeri, B. turicatae, B. crocidurae, B. burgdorferi, B. coriaceae,* and *B. anserina,* the type species of this genus (Hyde and Johnson, 1986). A small 9.2-kb supercoiled plasmid present in a fresh tick isolate of *B. burgdorferi* was found to exist as a stable dimer and to contain methylated DNA (Hyde and Johnson, 1988). In addition to circular plasmids, *Borrelia* species contain linear plasmids, a form of DNA that was previously thought to be unique to eukaryotes (Barbour and Garon, 1987; Plasterk et al., 1985). Also, the linear plasmids of *B. burgdorferi* were shown to have covalently closed termini, another form of DNA thought to be restricted to eukaryotes and viruses (Barbour and Garon, 1987).

Linear plasmids of *B. hermsii* are believed to carry silent copies of serotype-specific variable major proteins (VMP) of the organism (Meier et al., 1985). The expression locus and the active copies of the VMP genes are located on different linear plasmids of the cell (Plasterk et al., 1985). Antigenic variation (switching) occurs due to the transposition of the structural genes to the expression locus. In contrast, the DNA of *B. duttonii,* another agent of relapsing fever, was reported to consist of a number of distinct segments (Hayes et al., 1988). DNA sequences that

coded for the VMPs of *B. duttonii* appeared to be present on high-copy-number segments. However, recent experiments using in situ lysis procedures provide evidence that *B. duttonii* contains a circular chromosome, in addition to at least two linear plasmids and one supercoiled plasmid (Perng et al., 1990). *B. burgdorferi* is similar to *B. hermsii* in that they both have the genes for surface proteins located on a linear plasmid. Genes encoding outer-surface protein A and outer-surface protein B are present on a 49-kb linear plasmid of this spirochete (Barbour and Garon, 1987). The organization and expression of these genes have been studied extensively (Bergstrom et al., 1989; Bundoc and Barbour, 1989; Howe et al., 1986). *B. burgdorferi* will lose plasmids, as a result of in vitro cultivation (Barbour, 1988), as well as infectivity for hamsters (Johnson et al., 1984c). Schwan et al. (1988) reported that a fresh *B. burgdorferi* tick isolate carried nine plasmids, including seven linear plasmids ranging in size from 49 to 16 kb and two circular plasmids of 27 and 7.6 kb. Continuous cultivation of this strain in BSK medium resulted in the loss of both a 7.6-kb circular plasmid and a 22-kb linear plasmid, in addition to a corresponding loss of infectivity in mice. Other genes of *B. burgdorferi* that have been isolated and characterized include those encoding a 60-kb common antigen (Hansen et al., 1988) and a major flagellin protein (Gassman et al., 1989).

Ferdows and Barbour (1989) examined the genome of *B. burgdorferi* cells using pulsed-field gel electrophoresis. The results of their studies indicated that *Borrelia* spirochetes have linear chromosomes. However, similar studies conducted at another laboratory concluded that members of the genus *Borrelia* contain the circular chromosome typical of prokaryotic organisms (Perng et al., 1990).

The Genus *Leptospira*

SOLLY FAINE

Bacteria of the genus *Leptospira* are ubiquitous, associated with most mammals, and with marsupials and certain amphibia, or found free-living in soil and surface waters. Some strains of leptospires can cause an acute generalized infection, characterized by fever and hemorrhages, called leptospirosis. Leptospires may remain and grow in the kidneys of animals that recover from the acute infection but remain renal excretors or carriers, shedding leptospires in their urine. Humans may be infected but do not remain carriers and are thus not natural hosts.

The disease leptospirosis is economically important because it causes loss of productivity in livestock. It also causes loss through illness and death in humans in contact with either domestic livestock or wildlife carriers. It is thus a significant occupational hazard for people in rural or agricultural communities and in selected occupations in direct or indirect contact with animals (see "Economic Importance of Leptospirosis").

The leptospires are unusually thin, coiled, aerobic or microaerophilic bacteria, which cannot be stained easily for light microscopy, do not grow as surface colonies on conventional media, and are usually observed in wet preparations by darkfield microscopy. They are thus studied almost exclusively in fluid cultures, leading to special difficulties in characterization, identification, and nomenclature, many of which have now been overcome with the development of techniques that are independent of culture on solid media.

As a result of hesitation to define the genus and its species in inappropriate and nondefinitive terms, a system of classification and nomenclature based on serology was adopted, linked with primary division into animal pathogens and nonpathogens. This system has been satisfactory, if not ideal, for diagnosis, prognosis, epidemiology, and treatment of leptospirosis in animals and humans. The pathogenic leptospires were grouped into an "interrogans" complex, later the *interrogans* species, comprising numerous serovars with individual names, arranged by serological relationships into serogroups. The nonpathogens were part of a "biflexa" complex, later the *biflexa* species, similarly grouped by serovar (Faine and Stallman, 1982). The official description is thus of two species, *Leptospira interrogans,* and *L. biflexa.* The names of the component serovars of each species are conventionally written in italics. Serologically related serovars are grouped for convenience into serogroups, which have no formal taxonomic status, and whose names are written in capitalized Roman letters. Yasuda et al. (1987) classified leptospires into genospecies, based on the GC content of the DNA and on DNA homology groups. Some of the genospecies were given new names while existing names were used for others. This classification is still incomplete because the GC content and consequent genospecies status of many serovars has not yet been published. Among those strains designated by Yasuda et al. (1987), there are relationships which do not correspond entirely with their serological classification (see "Genetic Composition, and Classification," below, and Table 2).

A third species, believed to be nonpathogenic, formerly described as *Leptospira illini* (Hanson et al., 1974), was reclassified into a new genus, *Leptonema,* according to its morphology, genetics, and growth characteristics (Hovind-Hougen, 1979). Another species, *L. parva,* was defined by Hovind-Hougen et al. (1981b) on the basis of morphology, growth, and DNA composition. In addition, there are halophilic water leptospires, classified as members of *L. biflexa,* which differ from other biflexa type leptospires mainly in their salt tolerance (see Table 1). Table 1 lists characteristics of a number of species of *Leptospira.*

Most studies assume that all leptospires are similar, that findings on any strain can be compared with any other of the same or different serovars, and that any differences related to serovar truly reflect serovar classification. The hypothesis that differences may be related to geno-

species rather than serovar remains to be explored.

Ecophysiology

Cell Structure

Members of the genus *Leptospira* (Faine and Stallman, 1982; Johnson and Faine, 1984) are thin helicoidal bacteria with a coil amplitude of approximately 0.1 to 0.15 μm and a wavelength of about 0.5 μm. Frequently one or both ends are hooked in fluid cultures, but straight variants occur (Faine and van der Hoeden, 1964). Unspecified nuclear material, ribosomes, and mesosomes are enclosed in a peptidoglycan complex wound in a helix and surrounded by an outer envelope (OE). An outer membrane, (variously described as three or five layers depending on the method of fixation), totally enclosing each leptospire, is composed of protein, lipid, and lipopolysaccharide (LPS). Extrusions, presumably of LPS, and blebs can be seen to originate from the OE in some preparations. Heat (Faine et al., 1964), ethanol, sodium deoxycholate (Yanagawa and Faine, 1966), lysozyme, detergents (Auran et al., 1972), and NaCl all can remove OE to produce spherical sacs approximately 1.5–2 μm in diameter, sometimes seen as granules in aging cultures. The OE is necessary for leptospiral integrity; in intact organisms antibodies react only with surface antigens of the OE, which prevents access to subsurface antigens. OE preparations are immunogenic and have been used as vaccines. Nothing is known of the details of membrane structure.

Leptospiral flagella (previously known as "axial filaments"), presumed to mediate motility (see Chapter 191), are inserted into the cell wall in a manner typical of a Gram-negative cell, with insertion of a knob, two pairs of discs connected by a rod, and a hook area. However, *Leptonema* has a Gram-positive type of flagellar insertion with a single pair of discs (Hovind-Hougen, 1979). Each leptospire or leptoneme has two flagella within the helix, apparently in a groove in the cell wall, each originating near one end, closer to the tip in straight forms of leptospires compared with hooked forms. Flagella removed mechanically (Nauman et al.,

[h]*L. wolbachii* (Yasuda et al., 1987).
Data from literature sources including Yasuda et al. (1987) and Kmety and Dikken (1988).

1969; Chang and Faine, 1974) and purified by differential centrifugation (Kelson et al., 1988) appear as coiled structures, approximately 15–18 nm in cross-sectional diameter and of variable length, some of which are sheathed. The core contains presumably protein globular structures arranged regularly, either linearly or helically, for the length of the flagellum. Flagellar antigens, assumed to be peptides, cross-react widely in contrast to the high specificity of LPS agglutinating antigens (Kelson et al., 1988).

A cell wall (Yanagawa and Faine, 1966) surrounded by a cytoplasmic membrane (Hovind-Hougen, 1979) contains the cytoplasmic contents and determines the helical leptospiral shape. Microfibrils originating in the cell wall (Yanagawa and Faine, 1966) were isolated from *L. biflexa* and characterized by Yanagihara and Mifuchi (1968) as a 72-kDa homogeneously migrating protein, which also contained carbohydrates in a protein:CHO ratio of 1:0.8. Cytoplasmic microtubules are characteristic of *Leptonema* (Hovind Hougen, 1979). Inclusions of NaCl were seen in a halophilic strain (Muggia) of *L. biflexa* (Hovind-Hougen et al., 1981a).

Chemical Composition

The chemical composition of leptospires, which includes a relatively high proportion of lipids (Johnson, 1976) and long-chained fatty acids (including the unusual positional isomer *cis*-11-hexadecanoic acid) (Johnson et al., 1970), is influenced by strain, growth conditions, and culture medium. Various pentoses, hexoses, heptoses, and hexosamines are found; fatty acids include hydroxylauric, palmitic, and oleic acids as major constituents in *L. interrogans* serovar *copenhageni* (Johnson, 1976; Vinh et al., 1986a). The cell wall contains diaminopimelic acid and 4-*o*-methyl mannose (Yanagihara et al., 1983). Some of the constituent lipids are responsible for the endotoxin-like properties of a specific cytotoxic glycolipoprotein (GLP) obtained from *copenhageni* leptospires with lysozyme and acetic acid precipitation (Vinh et al., 1986b).

LPS and surface protein antigens (Nunes-Edwards et al., 1985) are found in OE, along with variety of OE proteins, with significant differences among the strains of the serovars *copenhageni, pomona,* and *hardjo.* A group of non-agglutinating monoclonal antibodies to *copenhageni* reacted solely with a 37-kDa protein localized in the OE (Jost et al., 1988).

Leptospiral LPS prepared by hot phenol-water methods and extracted from either water or phenol phases or both, differs from the LPS of many other Gram-negative bacteria because it is not toxic and was reported not to contain authentic 2-keto-3-deoxyoctonic acid (KDO) (Shimizu et al., 1987; Vinh et al., 1986a), although electron microscopically it had a similar

ribbon form and globular ultrastructure. Significant variation in LPS occurs among serovars; the LPS of *hardjo bovis* contains KDO, which needs prolonged acid hydrolysis to release it in at least some serovars or genospecies, possibly because of the presence of substituted sugars (Vinh et al., 1989). Equivalents to "rough" or "smooth" type bacterial morphology are not recognized in leptospires, but their LPS bands in electrophoretic gel patterns are analogous to those of either rough or smooth organisms (Vinh et al., 1986a). The lipid A fraction analog has not been studied in detail, but preparations from the serovars *copenhageni* and *hardjo* lack hydroxymyristic acid.

Alkali treatment of LPS produces soluble erythrocyte-sensitizing antigenic and protective polysaccharides (Hindle and White, 1934; Faine et al., 1974), whereas antigenic and immunogenic polysaccharides, including oligosaccharides comprising four or more residues, were derived by acid hydrolysis. Among them, mannosamine has been characterized as an epitope reacting with monoclonal antibodies to serovar *hardjo* (Vinh et al., 1989; Jost et al., 1989).

Metabolic Activities

Various metabolic enzymes, not in use as differentiating criteria, have been identified in leptospires, including catalase, originating intracellularly; oxidase, which can be used to identify colonies in agar; fatty-acid desaturating enzymes; β-oxidative enzymes; lipases and phospholipases; aminopeptidases; tricarboxylic acid cycle enzymes; glyoxylate cycle and isoleucine deaminase enzymes; glycosidases; esterases; and various arylamidases. Four strains of halophilic leptospires were all oxidase-positive, but otherwise variable in enzyme activities (Cinco et al., 1975).

Phospholipases specific for erythrocyte membrane phospholipids (sphingomyelin, lecithin, and phosphatidyl choline) have been identified both by enzyme and hemolytic activities in *L. interrogans* serovars *bataviae, canicola, grippotyphosa, pomona,* and other pathogens, as well as in *L. biflexa* serovars; (Kasarov, 1970). Saprophytic leptospires contain phospholipases A and C, while the pathogens have only phospholipase A. There are two phospholipase groups among pathogenic leptospires: those containing a calcium-dependent sphingomyelinase and lecithinase, and those with neither; saprophytes produced a calcium-independent lecithinase alone (Kasarov and Addamiano, 1970). A sphingomyelinase C hemolysin from serovar *hardjo* (del Real et al., 1989) and an uncharacterized hemolysin from serovar *pomona* (Dain et al, 1988) have been cloned recently. Lipase activity groups have also been recognized (sec Table 1).

Lipases may allow leptospires attached to surfaces to "graze" on nutrient fatty acids at a solid-liquid interface (Kefford et al., 1983), to which they are attracted by a chemotactic gradient.

Genetic Composition and Variation

Leptospiral DNA may be used in genetic studies like other bacterial DNA. Cloned DNA or nucleotide sequences complement enzyme defects or deletions (Zuerner and Charon, 1988; Yelton and Cohen, 1986), or are expressed as antigenic leptospiral proteins (Doherty et al., 1989); either DNA fragments or specific sequences (Zuerner and Bolin, 1988; Yelton and Peng, 1989) have been used as probes for identification or diagnosis (see below), and leptospiral protein antigens have been cloned and expressed in recombinant *Escherichia coli* (Doherty et al., 1989).

Neither bacteriophages nor plasmids have been identified in *Leptospira* or *Leptonema,* but transformation between leptospires in fluid culture has been reported. The absence of an understood means of genetic transfer between leptospires handicaps research and knowledge of leptospiral genetics.

The GC content of leptospiral DNA falls in the range of about 33.5–40.7% (Yasuda et al., 1987). On the basis of genetic and other characterisitics (Table 1), six new species were defined among leptospires classified serologically in the species *L. interrogans.* These were named *L. borgpeterseni, L. inadai, L. interrogans, L. noguchii, L santarosai,* and *L. weilii.* Three new genospecies, *L. biflexa, L. meyeri, L. wolbachii,* were also identified by DNA-DNA homology and similarity in GC content of their DNA among leptospires classified serologically as *L. biflexa* (see "Classification and Nomenclature," this chapter) (Table 2). *Leptonema illini* and *Leptospira parva* each fell into separate new species (Table 1).

Closely related or apparently identical serovars may have different restriction endonuclease patterns (Hathaway et al., 1985), especially when a variety of restriction endonucleases is used, and conversely, antigenic variants selected by monoclonal antibodies may have similar endonuclease profiles (Yamaguchi et al., 1988) compared with their parent strains. Nevertheless, grouping of leptospires by their restriction

endonuclease patterns broadly follows the conventional serological groups.

Classification and Nomenclature

The genus name *Leptospira,* given by Noguchi in 1917, means a "very thin spiral (= helical)" form (Faine and Stallman, 1982). As new types of *Leptospira,* obviously different pathogenically and ecologically but indistinguishable morphologically or culturally with the methods then available, were recognized in the 1920s and 1930s, the only criteria for identification and classification of these slowly growing, metabolically sluggish, hard-to-see bacteria, was serology. The serovar was adopted as the basic taxon, and an arbitrary criterion—10% residual titer of standardized hyperimmune rabbit sera after carefully controlled cross-absorption—was adopted for definition of a new serovar. There is currently sufficient partial cross-reaction to be able to group different but similar serovars together in 23 serogroups which have ecological, diagnostic, pathogenic, and epidemiological significance, but no formal taxonomic status. (Dikken and Kmety, 1978; Faine, 1982; Faine and Stallman, 1982; Johnson and Faine, 1984; Kmety and Dikken, 1988). In general, pathogenic leptospires are in separate groups on the basis of their genotype, serotype, lipase, and other characteristics from saprophytes (Table 1). The pathogenic leptospires are all placed in a single provisional species, *L. interrogans,* and all non-pathogenic types in a provisional species, *L. biflexa.* Within these are over 200 individually-named serovars, resulting in a cumbersome if unavoidable trinomial nomenclature (Table 2). Some serovars identical by serotyping are not homogeneous when compared by DNA-DNA homology, GC content, and DNA restriction endonuclease patterns, and sometimes also by lipopolysaccharide composition and structure (Le Febvre and Thiermann, 1986; Vinh et al., 1989). This causes as yet unresolved problems in identification, nomenclature, and classification, particularly because of the practical relevance of serological classification. Taxonomic applications of monoclonal antibodies (Terpstra et al., 1985; Ono et al., 1987) reveal one or more serogroup-specific epitopes in some serogroups (Farrelly et al., 1987; Vinh et al., 1989), while in others there appears to be a mosaic of epitopes whose relative quantitative distribution corresponds with and probably mediates serovar specificity (Adler et al., 1989). Common serogroup antigens, identified qualitatively by the techniques of ELISA or immunoblotting, are useful for broad classification.

Physiology

Growth

Leptospires grow by elongation of the cell body followed by a constriction and pinching off at a flexible joint in the middle of the cell. Eventually, the two halves separate. A new flagellum develops at the new free end and grows in toward the middle of each daughter cell. Pairs are common. Under some poorly-understood culture conditions, separation fails and chains of leptospires are formed. Very long forms also occur, sometimes in chains, particularly where amounts or types of fatty acid in the medium are inadequate. Thus, there are different requirements for cell division and for separation.

Leptospires well adapted to their environment grow with a doubling time of 6–8 h in fluid or solid laboratory media at 28–30°C, or in vivo. Freshly isolated pathogens or environmental strains may take days or weeks to adapt to laboratory conditions, with doubling times as long as 14–18 h. The lag phase may last for days, especially for new isolates, but is short or imperceptible with laboratory cultures grown from relatively large inocula (approximately 5–10% of culture volume) subcultured from vigorously growing cultures. The stationary phase is reached at culture densities of approximately 10^8 cells/ml in serum media and 10^8–10^9 cells/ml or more in cultures in Tween-albumin media. The culture density is especially enhanced if the culture is well aerated, and it can persist at these levels for days or weeks. The growth rate in solid or semisolid medium is not known. Cultures stored in the dark at room temperature may be viable for years.

L. biflexa and related saprophytic strains tend to grow faster. *Leptonema illini* grows to maximum culture densities of about 10^9 cells/ml in about 24–48 h at 30°C in trypticase soy broth or leptospiral media.

Nutritional Requirements

The basic nutritional requirements for the growth of leptospires include nitrogen in the form of ammonia, derived from its salts or from the deamination of asparagine by asparaginase in serum in the medium; carbon in the form of long-chain (C_{15-18}) fatty acids; thiamine; cyanocobalamin; and oxygen. Pyruvate enhances growth from small inocula in some strains. In general, sugars are not metabolized, and short-chain fatty acids cannot be utilized unless long-chain fatty acids are also available. Although these are general requirements throughout the genus, there are differences between the sapro-

phytic and the parasitic members, and some variability within the latter.

Some of the parasitic leptospires, identified so far by serovar rather than species, require long-chain unsaturated fatty acids, while all the others and the saprophytic group utilize saturated fatty acids. Members of the latter group also produce lipases, while only some of the parasitic ones do. Long-chain fatty acids are required for growth, but are broken down by β-oxidation; leptospires contain relatively high concentrations of long-chain saturated, and some unusual unsaturated, fatty acids, mainly as constituents of their lipopolysaccharides.

Energy requirements of leptospires are derived from oxidation of fatty acids. End products of metabolism are undefined. The metabolic enzymes described are assumed to act as mediators of conventional metabolic pathways, but there is little direct evidence, virtually none of it recent. In addition to a need for thiamine (5–25 mg/1) and cyanocobalamin (20 μg/1), optimum iron concentrations (10^{-5}M) and traces of copper and manganese are required. Leptospires synthesize their own pyrimidine bases, allowing 5-fluorouracil (100 mg/1) to be used as a selective agent in culture media (Johnson, 1981).

Metabolism

Leptospires have an aerobic or a microaerophilic metabolism. Addition of approximately 1:100,000 concentration of a redox indicator, such as 1-naphthol-2-sodium sulfonate indo-2,6-dichlorophenol (Eh −0. 180 mV at pH 7.2) or 2,6-dichlorophenol-indophenol (Eh −0.200 mv at pH 7.2) (Lawrence, 1951), to semisolid or solid media results in discoloration of the medium below the disk, or at and for a few mm around the subsurface colony sites before and when colonial growth appears. The optimum pH for growth of leptospires and leptonemes is in the region 7.2–7.4. Acid, even at pH 6.8–6.9, is rapidly lethal, whereas alkaline conditions up to pH 7.8–7.9 are tolerated. Growth in laboratory media at those extremes is poor. An acid urinary pH, as in some carnivores or omnivores, will prevent the urinary excretion of live leptospires, but not necessarily their continued growth in renal tubules. Soil composition and pH have important ecological effects on the survival of excreted pathogenic leptospires and their spread to new hosts via surface waters (Elder et al., 1986).

Leptospires and leptonemes appear to be essentially aquatic organisms. Dry conditions are lethal, and they cannot be recovered from cultures, body fluids or tissues, or surface waters after drying under normal conditions. They will survive rapid freezing as in lyophilization, at −20 to −70°C in blocks of tissue, or for a few days in chilled meat (Peet et al., 1983). They do not survive for long under anaerobic conditions, nor do they appear to survive intracellularly following ingestion by phagocytes. Nevertheless, they appear to flourish in nature in reducing environments where oxygen levels are low, as in swamp water, soil, the renal tubules of mammalian hosts, and intercellularly or interstitially in the tissues of a host animal during the acute stages of infection.

Leptospires are very sensitive to the action of detergents, including sodium deoxycholate and soaps. Since long-chain fatty acids essential for growth and metabolism are also toxic, they must be made available to the leptospires at nontoxic concentrations. They are usually absorbed to a detoxifying absorbent such as serum albumin, charcoal, or, in nature, particles or surfaces from which they are released to the leptospire. Leptospires may be attracted to such surfaces by a nutrient gradient. In laboratory media serum albumin used as an additive in powder form or in animal serum serves as the absorbent.

Saprophytic leptospires and leptonemes will grow at temperatures as low as 11–13°C, a property useful for identification (Table 1). Their optimum temperature for growth is in the range 25–28°C. Pathogenic serovars will not grow at 13°C, and have an optimum around 28–30°C after adaptation in the laboratory. Recent mammalian isolates can be maintained at 37°C for many subcultures, provided they are transferred frequently while growing vigorously. Non-pathogens and avirulent pathogens do not survive 0.85% NaCl in Korthof medium at 37°C but can grow at 30°C. Halophilic leptospires require sodium concentrations from 0.22–0.44 M and can tolerate up to 0.65–0.75 M (Cinco et al., 1975). Under these conditions, their oxidases and tributyrinases are active, and they are otherwise similar to other *biflexa* serovars.

None of the leptospires survive in the laboratory at temperatures above 41–42°C. Leptospires have been preserved in liquid nitrogen for at least 3 years (Alexander et al., 1972). All the non pathogens, including the halophiles, can grow in the presence of 10 mg/1 of $CuSO_4$. The salt concentration of optimum culture media for leptospires contains only about one-10th of the salt concentration of physiological saline, which is lethal to many strains. Very low salt concentrations are well tolerated; leptospires survive long periods in stream or tap water, but washing in water or dilute buffer accompanied by strong centrifugation for laboratory studies

removes the outer envelope. All the nonpathogens will grow in the presence of 225 mg/l of 8-azaguanine or 5–10 mg/l of 2-6–diaminopurine; some of the pathogens will also grow in the latter.

Most leptospires are susceptible in vitro to a wide variety of antibiotics at low, therapeutically useful, levels (Faine and Kaipainen, 1955; Broughton and Flack, 1986; Oie et al., 1983; Alexander and Rule, 1986). Resistance to neomycin allows its use as a selective agent. Resistance to penicillin or streptomycin develops readily in culture but is not considered to be a problem clinically. Mutual antagonistic activity between leptospires in solid media in petri dishes has been described but not characterized.

Sera from animals apparently never infected with pathogenic leptospires contain IgM molecules capable of reacting with surface receptors in the OE of nonpathogens (biflexa type) (Johnson and Muschel, 1966) and avirulent pathogens (Faine and Carter, 1968). This reaction may determine survival after entry to an animal host. Immunoglobulins appear in the animal urine in the acute stage of infection and in early convalescence, as a result of overflows of serum antibodies through damaged kidneys. Urinary antibodies may also occur in animals which are renal carriers, even though they are excreting leptospires, in the absence of detectable structural or functional renal abnormality. Leptospires excreted in urine may be coated with host immunoglobulin and be refractory to agglutination by serum antibodies.

Pathogenicity in Relation to Habitat

The reason why some leptospires are pathogenic and some are not is still unclear. It has not been proven that all the biflexa type leptospires isolated from animal urine were pathogenic. All the recognized pathogens and nonpathogens fall into distinct genetic groups. (Table 1). Among the pathogenic varieties there are unanswered questions of why some animals are resistant, or conversely, why they are susceptible to infection with certain serovars. Ecological considerations will determine the chances of leptospires surviving in the environment after excretion from their hosts, and thus the chances of infection of a fresh susceptible animal.

After entry and growth in the host animal, pathogenic leptospires must have mechanisms to evade host defenses and to produce the sometimes severe damage to host tissues. Both virulent and avirulent leptospires attach to cell surfaces (Vinh et al., 1984), and virulent leptospires may attach preferentially by their ends to fibronectin, collagen, and laminin in the extracellular matrix of cells (Ito and Yanagawa, 1987a and 1987b). Details of leptospiral attachment to the surfaces of renal tubular epithelial cells and the relationship of the mechanisms to those described by Kefford et al. (1983) for attachment of *L. biflexa* to noncellular surfaces are obscure (Ballard et al., 1986), but the issue remains central to the understanding of the pathogenesis, epidemiology, and prevention of leptospirosis.

Among pathogens, virulence for any or all animals may be lost on culture passage, because avirulent organisms better able to grow in culture conditions are selected. Virulence may be regained by animal passage, or by selecting organisms better adapted to survive and grow in vivo (Faine, 1957). Susceptibility to serum-innate IgM antibody may be a mechanism determining virulence. The effector on the leptospire may be a carbohydrate found in virulent organisms.

Although leptospiral LPS is not significantly pyrogenic and lacks some other typical endotoxic properties, a glycolipoprotein from *L. interrogans* serovar *copenhageni* was toxic for mice and cytotoxic for cultured cells, acting by means of constituents that were uniquely leptospiral long-chain fatty acids, possibly by competitively inhibiting the incorporation of naturally occurring lipids in the cell membrane. The toxicity in vitro was obscured in the presence of serum albumin, which absorbed the toxic lipids (Vinh et al., 1986b). A similar action of this or another toxin on platelet membranes could account for platelet aggregation and consequent coagulation defects, which are features of severe leptospirosis. Phospholipase activity is related to selective hemolytic activity for various animal species, consistent with the host range of pathogenic leptospires being determined by the specificities of their phospholipases for the phospholipids of the cell membrane of the host species. While hemolytic activity in vivo has not been proven directly, the hemolysins are specifically neutralized by post-infection immune serum. Changes resembling punched-out holes were found by electron microscope in erythrocytes of calves with leptospirosis and are consistent with either cytotoxin or hemolysin activity (Thompson and Manktelow, 1986), and autoimmune hemolysis may occur from the absorption of complement and antibody binding to leptospiral antigens on erythrocytes (van der Ingh and Hartmann, 1986).

Specific immunity in leptospiroses is mediated by humoral (antibody) means alone. Very low levels of specific immunoglobulins are

protective if they are surface-active (agglutinating) on leptospires and are opsonic. Increased resistance with age in animals parallels maturation of the B-cell immune response. The rate at which antibodies are formed in relation to the rate of growth of the leptospires in the host is a major determinant of the outcome of infection (Faine, 1957, 1962).

The only known determinants of immunity in leptospirosis are opsonization and phagocytosis. In both cases, the only leptospiral components recognized as reacting are LPS and its constituents; the reacting molecules, identified using opsonic and protective monoclonals, are polysaccharides of the side chains of the LPS and are located in the outer envelope (Jost et al., 1988, 1989). Serovar specificity depends on the nature of the LPS antigen polysaccharides.

Isolation

Special techniques are used for the isolation of any type of leptospire from environmental or clinical sources (Johnson, 1981; Faine, 1982, 1988) because leptospires grow comparatively slowly and are relatively susceptible to acids and other metabolic products of accompanying and contaminating bacteria or fungi. Fluid media are usually used, with filtration or selective agents to eliminate contaminants. Growth is less reliable in solid media which can be used in some circumstances but are likely to dry out during prolonged incubation.

Leptospires (including pathogenic varieties) and leptonemes have been isolated from surface waters (rivers, streams, lakes, soil water, mud). In these sites they pose a hazard to anglers, farmers, military personnel, and boaters. There are sometimes suprisingly high concentrations even in fast-flowing rivers. Sensitive culture methods and freedom from contamination are essential for isolation from these sources. Suitable specimens are water, soil, or mud samples collected into dry containers (to avoid contamination with leptospires in water in the containers). Although direct inoculation into selective culture medium, with or without prior serial dilution, may be used, it is usually desirable to concentrate the specimen and necessary to remove or reduce contaminating microorganisms. Cultures need to be checked in case more than one type of leptospire is present.

In general, leptospires, but not other bacteria, will pass through a membrane filter of 0.22 μm pore size; the filtrate is cultured. Preliminary passage through a prefilter or a 0.45 μm membrane will facilitate filtration. An older, effective, but less acceptable, method is to use rapid biological filtration of leptospires into the bloodstream from the peritoneal cavity of mice, hamsters, or guinea pigs (Faine, 1982). The same methods of filtration, growth on solid media, or animal inoculation may be used to purify contaminated cultures.

Leptospires may be isolated from the kidneys of renal carriers or from alkaline urine, as well as from blood and all other tissues and body fluids of acutely infected animals or humans. Autolysed or contaminated specimens or acid urine are unsuitable for examination. Specimens collected aseptically are desirable. The urine is centrifuged, and the sediment inoculated into fluid standard or selective medium.

Blood taken aseptically from human or animal sources in the acute stages of infection may be cultured by adding 0.1–0.5 ml to 10–50 ml of EMJH medium and incubating at 30°C. Blood specimens for culture may be transported after aseptic addition of EDTA or other anticoagulants (see below). Tissues removed aseptically at autopsy can be ground and extracted with buffered saline or culture medium, and the supernatant, after settling, can be used for inoculation of culture media or animals (whose blood can then be cultured). Details of methods can be found in the references cited above. (Alexander, 1985; Faine 1982, 1988).

Culture Media—Principles and Preparation

Traditional leptospiral media were dilutions of 8–10% v/v serum, usually from rabbits, in a diluted nutrient broth or peptone solution. The development of bovine albumin detoxicant and polysorbate 80 (Tween 80) as a nutrient source (Johnson, 1981) allowed the isolation of more exacting strains and the maintenance of cultures under reproducible conditions. Water used to dissolve nonautoclavable filter-sterilizable additives must be previously heat sterilized, and containers used for filtration should be dry and preferably sterilized by heat to avoid contamination from filter-passing leptospires.

Details of the composition, recipes, and methods of preparation of commonly used culture media may be found in recent references (Johnson, 1981; Faine, 1982; Alexander, 1985; Faine, 1988). Serum media, e.g., Korthof medium, Stuart medium, or Schüffner-Verwoort medium, commonly contain approximately 0.8–1.0 g/l peptone and 8–10% pooled slightly hemolysed rabbit serum, phosphate-buffered at approximately 0.01M to a final pH in the range 7.2–7.6. The serum is added to the autoclaved base medium and the final mixture sterilized by passing through a 0.22 μm filter membrane, or sterile serum may be added aseptically to the

autoclaved base. Protein media without serum use bovine serum albumin (BSA) as a detoxicant and are based on the oleic-acid-albumin media of Ellinghausen and MacCulloch, modified by Johnson and Harris (EMJH medium) (Johnson, 1981). The quality of the water and the albumin (fatty acid content, dryness) are critical. Albumin should be from batches tested for suitability, from known manufacturers. In an extreme, the albumin and the Tween may be purified before use by extraction with solvents (Adler et al., 1986).

Growth is indicated by a birefringent swirl in the medium on shaking; some strains never achieve greater density, while others reach visible turbidity, seldom opacity, indicating growth to approximately 10^9 cells/ml or greater. Cotton plugs should not be used because toxic fatty acids may be leached from the cotton into the medium.

Many laboratory strains will grow in protein-free medium (Bey and Johnson, 1978; Adler et al., 1986) with careful attention to water quality, if the Tweens are purified by extraction of free fatty acids, their further oxidation minimized, and the proportions of different Tweens (Tween 20, Tween 40, Tween 80) are balanced for the specific strain. Frequent subculture is necessary during growth on protein-free medium. In cultures without protein detoxicants, some strains produce lipases whose end products are especially toxic to leptospires, including themselves. Strains need to be subcultured in gradually reducing protein concentrations to adapt to protein-free media, which are generally not suitable for attempts at fresh isolations from clinical or environmental sources. A limited range of adapted strains are maintained under protein-free conditions and used for vaccine production. *Leptonema* can grow in trypticase soy broth to reach concentrations approximating 10^9 cells/ml in 24–48 h at 30°C, although there are no studies of growth rates or nutritional requirements. Sodium-dependent leptospires were grown in a medium containing 0.25 g NH_4Cl, 0.25 g Tween-85, 10.0 g BSA, 10 mg thiamine, and 1 mg cyanocobalamin in 1 liter of artificial sea water (Cinco et al., 1975).

SOLID MEDIA AND SEMISOLID MEDIA. Most leptospires will grow in or on media solidified with agar (Faine, 1982), provided the agar is not toxic and fungal contamination and dehydration during storage and incubation are avoided. Following surface or stab inoculation of semisolid or solid media (0.2–0.8% agar), leptospires grow in disks (Dinger disks) below the surface, although colonies may appear at first in the depths. In solid medium (0.8–1% agar), poorly visualized colonies appear in the depths of the medium in 2–20 days, depending on the leptospire and the quality of the medium, and the colonies may spread centripetally as gray transparent spheres up to 2 mm in diameter with defined edges. In shallow media, as in a petri dish, a colony may form a white-edged ring covering several centimeters, representing a spreading, inverted hemispherical colony. The advancing edge of the spreading growth, which can be stained with oxidase reagent, is dense with leptospires, and can be picked as a plug with a sterile pasteur pipet for transfer or for microscopic examination. These colonies, which are the analogs of the Dinger disks, were first described by Larson and Cox (1957). Growth on or in solid media is brownish-grey by transmitted light, but whitish by reflected light and very hard to detect in uncolored media. Incorporation of a 1:100,000 concentration of a redox indicator (see "Physiology," this chapter) enhances visibility. The potential of growth in colonies on the surface of solid (2%) agar (Wood et al., 1981) has not been exploited.

L. biflexa strains will grow at a lower concentration of serum or BSA, more quickly (visible or even maximum growth in 24 h at 30°C), and more densely, than most *L. interrogans* strains. The reasons for these differences have not been elucidated.

SELECTIVE AND DIFFERENTIAL MEDIA. Knowledge of special growth requirements has allowed the development of selective culture media, containing 2-6-diaminopurine, 8-azaguanine, or neomycin, for growing leptospires in the presence of contaminants (Faine, 1982, 1988). An enriched medium for better isolation of leptospires from animals was described by Ellis et al. (1982).

Tissue cultures may be contaminated with filter-passing *L. biflexa* in solutions made with unheated tapwater used for culture media or with pathogenic leptospires introduced with primary cultures of animal kidneys, inadvertently derived from carrier animals.

Techniques of Culture and Subculture

Recent accounts and full details of special techniques demanded by the special characteristics of leptospires and their media are given in Johnson (1981); Faine (1982, 1988). Culture purity and density may be checked under darkfield microscopy (see below).

Identification

Methods and Techniques

Leptospires are poorly visualized after staining with strong carbol fuchsin or other dyes. Silver

may be deposited on the surface but the techniques are exacting and details are easily obscured. Stains are not used for light microscopy, except silver, although immunofluorescence or immunoperoxidase can be used in sections of human or animal tissues. The usual routine method is darkfield microscopy. Electron microscopy is useful for identification and classification, and immunoelectron microscopy, especially with immunogold, has been used for experimental identification of structures whose antigens have been recognized serologically.

Low-power darkfield microscopy using a dry condenser is the standard method for checking growth in cultures, and for reading agglutination tests (Faine, 1982). To observe fine details of morphology at the limits of optical microscopy, it is necessary to use a high-resolution oil immersion objective (N.A. 1.25–1.3) equipped with a diaphragm or funnel stop to match the corresponding oil immersion condenser (N.A. 1.2–1.4). A thin slide, a very thin cover glass, both extremely clean, and a thin preparation sealed against movement resulting from drying currents are necessary for technically satisfactory conditions. Phase contrast, which can reveal some detail in leptospires and the spherical "granules" (Faine et al., 1964) derived from them, is unsuitable for routine observation of cultures. Immunostains are useful for both cultures and tissue or environmental specimens if the serovar is known or if a broadly cross-reacting antiserum is used, and also as a tool for research on the specificity of antigens, on monoclonal antibodies, and for localization of antigenic sites. Electron microscopy is not usually used for the routine identification of leptospires or related genera (except for *Leptonema*) but combined with negative staining and immunogold-labeled polyclonal or monoclonal antibodies, it has demonstrated the location of antigens and epitopes corresponding to flagella (Kelson et al., 1988), lipopolysaccharides, and the outer envelope (Jost et al., 1989).

Characteristics and Criteria

There are no reliable criteria to differentiate various types of *Leptospira* from one another or from *Leptonema* by darkfield microscopy (Faine and Stallman, 1982; Johnson and Faine, 1984). Leptospires are typically thin, bright, beaded, motile, rodlike structures, about 0.2 μm in diameter, ranging from approximately 8–25 μm in length; when viewed with very high magnification they are seen to be helical. The rod appears rigid except at the ends distal to the flagellar insertions where it is flaccid. There is rapid, but sometimes irregular and erratic, translational movement in either direction. Rapid rotation on the long axis causes the ends to bend against the direction of translational movement to give a hooked appearance at one or both ends. Straight (not hooked) variants have a much shorter flaccid portion and flagellar inserts much closer to the end. Flagella, the outer envelope, and other structures cannot be seen by light microscopy, but can sometimes be visualized with difficulty following specific immunostaining with appropriate selective antibodies. Internal contents in granular forms can be seen by darkfield and by phase contrast microscopy; electron microscopy shows that these are rolled-up, protoplasmic cylinders within a membrane.

In semisolid media, leptospires move with a characteristic screw-like motility, flexing and winding around obstacles. The rigid form is resumed immediately in fluid media. Motility is enhanced proportionately with the viscosity of the medium.

Leptospira can be differentiated from *Leptonema* by electron microscopy and by growth in trypticase soy broth (TSB) medium, and *Leptospira interrogans* serovars from those of *L. biflexa* by growth at 13°C and in 8-azaguanine (Table 1). All *Leptospira* require long-chain fatty acids, usually detoxified with serum albumin in culture, but *Leptonema illini* grows in TSB medium. A monoclonal antibody reacting exclusively with nonagglutinating antigens in members of the *Leptospira interrogans* group in ELISA tests (Jost et al., 1988) is useful for rapid identification. Other genera of spirochetes (see Chapter 191) are readily differentiated from *Leptospira* and *Leptonema* by their morphology, motility, and number of flagella, and by serology (Johnson and Faine, 1984; Baker-Zander and Lukehart, 1984; Magnarelli et al., 1987).

"Bacterial restriction endonuclease analysis" (BRENDA) (Robinson et al., 1982) is useful for relatively rapid presumptive identification and classification of isolates and for subclassification and revision of taxonomic categories, as is the determination of the GC content and DNA homology grouping.

The officially recognized classification is serological (Faine and Stallman, 1982; Johnson and Faine, 1984; Kmety and Dikken, 1988) measured by agglutination of live cultures, with antibodies against heat-labile antigens (Dikken and Kmety, 1978). Details of the serological methods are in the references above and in Faine (1982). For the microscopic agglutination test (MAT), serial dilutions of sera are mixed with an equal volume of culture, incubated at 30–37°C for 1 h or longer, and a loopful of each

dilution examined by darkfield microscopy for agglutination, taking 50% agglutination as the endpoint. Cross-reactions between serovars are common. The strain reacting to the highest titer is not necessarily the homologous serovar for the antiserum being used. Serovar classification cannot be done without cross absorption. LPS patterns after gel electrophoresis and immunoblotting may assist in identification of serologically apparently identical strains. (Vinh et al., 1989).

Mouse monoclonal antibodies produced against most of the main serogroups of *Leptospira* following immunization with whole leptospires, sonicated suspensions, or chemical fractions include all classes of murine immunoglobulins, with cross-reacting serovar specificities often different from rabbit, human, bovine, or other animal immunoglobulins. Generally, these reactions confirm taxonomic relationships that have been revealed by agglutination absorption studies (Ono et al., 1982; Farrelly et al., 1987; Terpstra et al., 1987; Jost et al., 1988). Species-reactive antigens *(L. interrogans)* and serogroup- as well as serovar-specific and other epitopes, some of them not involved in agglutination, have been identified by ELISA, thus solving some classification problems. Judiciously chosen monoclonals can expedite the tedious serological identification of isolates.

Applications

Diagnosis of Leptospirosis

The same diagnostic principles apply for human or animal leptospirosis. Ideally, the infecting agent should be recognized, cultivated, and identified, but this is infrequently achieved because of inadequate or late clinical suspicion, slow growth, and the need for specialized techniques. Indirect, usually serological, evidence of infection is commonly used, but tests of molecular diagnosis by DNA or RNA probes are currently being explored. Additional, nonetiological tests such as histological, hematological, and biochemical changes may assist diagnosis.

The diagnosis of illness requires different techniques from screening for epidemiological surveillance. Rapid, generic diagnosis is often urgently required in humans or animals to decide whether or not an illness is leptospirosis, and, if so, which type (for management, therapeutic, prognostic, and epidemiological reasons) at a time when therapeutic intervention and management can affect the progress of the disease. Screening tests provide evidence of an underlying level of subclinical infection in a population, in addition to those diagnosed as clinical cases, but speed is seldom vital in these cases. Low titer reactors are significant because they indicate previous infection.

The techniques of specimen selection, microscopy, cultivation, agglutination, immunofluorescence, ELISA, and identification are described above and in Faine (1982) and Faine (1988).

CULTURE OF SPECIMENS. Usually blood, urine, and cerebrospinal fluid (CSF), but sometimes necropsy and biopsy tissues are cultured. A significant dilution of at least 1:50 of blood in medium is recommended. Urine should not be acid. Growth is seen as a birefringent swirl, confirmed by darkfield microscopy, with care to ensure that similar looking fibrin threads are not mistaken for leptospires.

Tissues such as kidney or liver should be cut or ground aseptically into very small fragments, and no more than approximately 5% (w/v) inoculated, to avoid anaerobiosis in the medium. Fragments or suspensions of tissues may also be inoculated directly onto the surface of solid medium in plates. Growth is recognized by the appearance of small gray-white subsurface colonies or by a ring of growth around the inoculum site.

MICROSCOPY. Darkfield microscopy is generally used for direct examination of specimens; electron microscopy is seldom valuable. Properly controlled and interpreted histological examination of tissues stained for leptospires by silver, immunofluorescence, or immunoperoxidase assay offers a presumptive, though frequently accurate, diagnosis. Attempting direct identification of leptospires in body fluids or tissues by darkfield microscopy is not recommended, especially for novices, although certain identification of leptospires by microscopy can speed diagnosis and management.

SEROLOGICAL DIAGNOSIS. Most leptospirosis is diagnosed by serology, using MAT. ELISA tests for IgM or IgG or both, sometimes used in parallel, or immunoblots or immunobeads have not yet gained acceptance as substitutes for agglutination because their diagnostic interpretation is still unclear. MAT antibodies react with LPS polysaccharides and are relatively specific for the infecting serovar and serogroup, although the highest titer does not necessarily indicate the infecting serovar because there are cross-reactions between serovars and individual differences in immunoglobulin response to the antigens. Only isolation and identification of the

infecting leptospire can prove its identity. Unless the infecting serovar is known, it is necessary to test sera against a battery of serovars representative of the serogroups known to exist locally, preferably using locally isolated strains.

A titer of 1:400 or higher in a single serum specimen or a rising 4-fold titer between consecutive specimens is considered significant in an acute infection, although there are extreme differences in titers in acute leptospirosis caused by different serovars. Very high titers of 10,000 or more with the serovars *icterohaemorrhagiae* or *copenhageni* and low responses of 800–1600 with *hardjo* are typical both in humans and animals. Antibodies in humans last for months to years. There is little reliable data on persistence in animals. Effects on persistence of antibody titers of antibiotic treatment, initial height of titer, infecting serovar, immunoglobulin class, or possible continuous or repeated exposure to the same or other leptospires have not been adequately assessed, although this information is vital for understanding immunity and for evaluating immunization.

ELISA tests have been more valuable in screening than in diagnosis, possibly because of the current lack of standardization and experience in interpretation. Serum IgM antibodies in carrier pigs correlate with urinary shedding (Ballard et al., 1984). The immunoblot test using culture or LPS on nitrocellulose is a sensitive method now being developed for rapid diagnosis (Watt et al., 1988), and DNA restriction endonuclease patterns expedite preliminary classification of isolates. Direct diagnosis by using gene probes, including polymerase chain reaction, for recognition of leptospires in tissues or body fluids, or for identification of isolates has been explored recently (Millar et al., 1987; van Eys et al., 1988, 1989; Zuerner and Bolin, 1988).

PROSPECTS FOR IMPROVED SERODIAGNOSIS. Serological diagnosis always depends on the presence of detectable antibody. No tests, however sensitive, can detect antibody in the first day or two of infection in a novice patient before it has been produced, yet when diagnosis is needed most urgently. Monoclonal antibodies with either genus or serovar specificity can aid identification of isolates. Their main potential use in diagnosis is primarily in research for characterizing specific or generic antigens for faster, more sensitive, or more appropriate tests. Genotypic classification of leptospires by DNA homology is discussed above.

Vaccines: Principles of Immunity and Immunization

All evidence shows that immunity to initial infection or to reinfection is humorally derived and is specific for the serovar (sometimes serogroup). Such immunity is mediated by any class of immunoglobulin with the appropriate epitope specificity (Jost et al., 1989). Immunity follows both infection and vaccination; its duration is uncertain, but experimentally it coincides with detectable agglutinating antibody, even at very low levels. Killed vaccines of whole leptospires are widely used for animals (dogs, pigs, cattle), and, in Asia, for humans, conventionally in two initial injections about a month apart, followed by an annual booster. Vaccines of outer envelope preparations and leptospires grown in protein-free media are effective and believed to cause fewer side effects, but still probably owe their efficacy to their LPS content. Experimentally, both leptospiral LPS alone (Jost et al., 1989; Masuzawa et al., 1989) and a derived polysaccharide containing the protective antigen (Jost et al., 1989) are effective vaccines. At present there is no evidence of any protein or peptide protective antigen; none of the proteins cloned into recombinants have been protective. Conversely, none of the genes for the known protective LPS or polysaccharide antigens have been cloned. The biological disparity between the leptospires and the expression vectors tested makes expression of cloned genes especially difficult.

Economic Importance of Leptospirosis

The main economic importance of *Leptospira* lies in their ability to produce infection in animals and humans. The economic factors in leptospirosis (Faine, 1982, 1990) include direct or indirect costs of

- abortion, failure to thrive, loss of milk production, and associated veterinary costs in domestic and commercial livestock and dogs, with potential for malnutrition and impoverishment in individuals and communities dependent upon animal sources of protein, especially in subsistence economies;
- vaccination and surveillance (vaccines, veterinary attention, laboratory tests, evaluation and administration), including testing and certification of serum samples from large numbers of livestock before international transport;
- human illness, suffering, medical care, and loss of productive working time and capacity;
- production and evaluation of vaccines and vaccination programs for animals and humans;
- rodent control in livestock management, pastures (including sugar cane plantations and ricefields), and food processing;
- occupational disease surveillance and control, protective clothing, and insurance for work-

ers in industries where there is a significant risk (e.g., milkers of cows, slaughterers, assistants, inspectors, and laborers at abbatoirs, military personnel).

Biotechnological applications are confined to the production and development of vaccines and diagnostic reagents at present.

CHAPTER 195

The Family Chlorobiaceae

HANS G. TRÜPER and NORBERT PFENNIG

The species and genera included in the physiological and ecological group of the green sulfur bacteria (*Chlorobium* and related genera; the Chlorobiaceae) share a number of particular characteristics which suggest that these genera may be genetically related. However, until now only a few strains have been studied with respect to the similarities of the oligonucleotide sequences of their 16S rRNA (Woese, 1987) and their 5S rRNA (van den Eynde et al., 1990). Thus, the Chlorobiaceae cannot yet be considered as a family of genetically related genera comparable to the Chromatiaceae (Fowler et al., 1984) (see also Chapter 170). The closest relatives of the Chlorobiaceae analyzed so far form a cluster containing *Bacteroides fragilis* and other *Bacteroides* species; with respect to all other groups of anoxygenic phototrophic bacteria, the Chlorobiaceae appear to be a well-isolated group (S_{AB} value < 0.25).

Habitats

Freshwater Habitats

In contrast to bacteria of the Chromatiaceae, visible, mass accumulations of green sulfur bacteria are rare in freshwater habitats. The first reports are from Szafer (1910) and Strzeszewski (1913) who described layers of green bacteria in the effluents of sulfur springs in Poland. Chlorobiaceae occurred at the highest sulfide concentrations, while purple sulfur bacteria appeared downstream at lower sulfide concentrations. Nonetheless, *Chlorobium* species are widely distributed in the anoxic mud and sediments of all freshwater habitats where their presence can be established, using an appropriate enrichment culture method.

The largest blooms of green sulfur bacteria in freshwater enrichments occur at the chemocline of stratified holomictic or meromictic lakes. Czeczuga (1968) reported that the green layer at the chemocline in Wadolek Lake, Poland, was dominated by *Chlorobium limicola*. In the Bolschoje-Kichier Lake, USSR, the green layer was formed by *Ancalochloris perfilievii* and *Pelodictyon luteolum* (Gorlenko and Lebedeva, 1971). A very dense layer of a green *Pelodictyon* species at a depth of 2m in Knaak Lake, Wisconsin, was studied by Parkin and Brock (1981). In many lakes, green and purple sulfur bacteria occur together in the layer, for example, in the Pluss-See (Northern Germany; Anagnostidis and Overbeck, 1966) and in the Schleinsee and Buchensee (Lake Constance region, Vetter, 1937; Overmann and Tilzer, 1989). In these lakes, the Chlorobiaceae are represented by species of *Ancalochloris* and *Pelodictyon,* and by the Pelochromatium and/or Chlorochromatium consortium. It is not uncommon for the green sulfur bacteria to proliferate just below the Chromatiaceae (Caldwell and Tiedje, 1975; Gorlenko et al., 1983). This can be understood if it is considered that the Chlorobiaceae, with their highly effective light-harvesting chlorosomes, are unique with respect to their modest radiation requirements. In order to grow at comparable growth rates, Chlorobiaceae require only about one-fourth of the light intensity of the purple bacteria (Biebl and Pfennig, 1978).

Lakes with Chromatiaceae and brown Chlorobiaceae species have also been studied by Bergstein et al. (1979) and Veldhuis and van Gemerden (1986).

Symbiotic Consortia of Green Sulfur Bacteria in Freshwater Habitats. One of the outstanding features of the green sulfur bacteria is their participation in the only known symbioses between bacteria. In these so-called consortia, a central chemoorganotrophic, usually motile, bacterium is covered by synchronously dividing, green sulfur bacteria. Although these consortia were originally given binominal names, such names are illegitimate as long as they are applied to symbiotic associations (Pfennig and Trüper, 1974; Trüper and Pfennig, 1971). At present the following consortia are known: Chlorochromatium aggregatum, Chlorochromatium glebulum, Cylindrogloea

bacterifera, Pelochromatium roseum, and Pelochromatium roseoviride (Gorlenko and Kuznetsov, 1971).

The Chlorochromatium consortium (Lauterborn, 1915; Chloronium mirabile, Buder, 1913) consists of a single, rod-shaped, polarly flagellated, motile, colorless, central bacterium which is covered by 6–12 regularly attached, rod-shaped, nonmotile, green cells of the *Chlorobium limicola* type. A high degree of metabolic interdependence is indicated by the synchronous growth and division of all cells of the consortium. Furthermore, the nonmotile phototrophic *Chlorobium* symbionts produce a positive phototactic response in the motile central bacterium: the consortia are capable of accumulating at the illuminated side of the culture vessel. Thus, because of the symbiosis, the nonmotile *Chlorobium* cells attain the ecologically significant capacity to respond to different light intensities, as do the motile Chromatiaceae (Pfennig, 1980).

In addition to the green Chlorochromatium consortium, there are two other brown ones. Lauterborn (1915) and Utermöhl (1925) first described the brown Pelochromatium roseum consortium. Here, the symbiotic phototrophic bacterium is a strain of *Chlorobium phaeobacteroides*. For the Pelochromatium roseoviride consortium (Gorlenko and Kuznetsov, 1971), the motile central bacterium is surrounded by an inner layer of 6–12 cells of *Chlorobium phaeobacteroides* and a second outer layer consisting of *Pelodictyon luteolum*-like cells.

Until now, the symbiotic consortia have only been studied in enrichment cultures. While the phototrophic components can readily be isolated in pure culture, all attempts to grow or identify the motile chemotrophic central bacteria have been unsuccessful (Pfennig, 1980).

The symbiotic consortia thrive in all kinds of freshwater habitats containing anoxic, sulfide-bearing mud and water: ditches, pools, ponds, and stratified lakes. Usually, they occur together with motile and/or gas-vacuole-containing, purple sulfur bacteria (Anagnostidis and Overbeck, 1966; Caldwell and Tiedje, 1975; Dubinina and Kuznetsov, 1976; Gorlenko et al., 1983).

MEROMICTIC LAKES. A special environment between holomictic freshwater lakes and shallow marine habitats are the deeper meromictic coastal lakes. Since the interface between the stagnant anoxic and sulfide-containing seawater and the overlying fresh or brackish water is very stable, the blooms of phototrophic sulfur bacteria are almost permanently present throughout the year. In many of these lakes, the brown Chlorobiaceae, in particular, *Chlorobium phaeobacteroides* and *C. phaeovibrioides*, are the dominant species. Examples are Lake Faro, Messina, Sicily (Trüper and Genovese, 1968); Lake Mogilnoye, Kildin Island, USSR (Gorlenko et al., 1978); Spanish Mediterranean coastal lakes (Guerrero et al., 1987); and Bietri Bay of Ebrie Lagoon, Ivory Coast (Caumette, 1984). Other meromictic lakes with reddish-brown layers are Fayetteville Green Lake (USA; Culver and Brunskill, 1969) with *Chlorobium phaeobacteroides*, and Repnoe Lake (USSR; Gorlenko et al., 1973) with the brown *Pelodictyon phaeum*.

Montesinos et al. (1983) determined the selective conditions under which the brown Chlorobiaceae compete successfully with the green species for the formation of blooms in lakes, studying the ratio between the green *Chlorobium limicola* and the brown *Chlorobium phaeobacteroides* in eight Spanish lakes. The results were compiled, together with data from 22 other lakes from around the world; the presence of the green or the brown species was compared with the depth at which the phototrophic bacterial plate was located. It is obvious from their list that green Chlorobiaceae were dominant in lakes with blooms near the surface (2–4 m) whereas, in blooms between 5- to 9-m depth, green and/or brown species developed. If the blooms occurred between 9- and 25-m depth, they were exclusively formed by the brown species.

Water selectively removes certain wavelengths of light and Montesinos et al. (1983) confirmed the distributions seen in their field data by laboratory experiments with pure and combined cultures of green and brown *Chlorobium* species in filtered light. The brown Chlorobiaceae have a selective advantage over the green species in the narrow band of blue-green radiation (450–550 nm) that penetrates deepest in the water column. Only the light-harvesting carotenoids of the brown species, isorenieratene and β-isorenieratene have a broad absorption band between 450 and 550 nm, allowing these species to effectively absorb the available blue-green radiation (Pfennig, 1989). The carotenoids of the purple sulfur bacteria also absorb in this region. However, these bacteria require higher radiation intensities for comparable growth rates (Biebl and Pfennig, 1978) and, therefore, cannot compete with the brown Chlorobiaceae at limiting light intensities.

Marine Habitats

An impressive example of the capacity of brown *Chlorobium* species to survive on incredibly low

amounts of blue-green radiation is the recent discovery of bacteriochlorophyll (bchl) *e* at an 80-m depth in the Black Sea. On the RV *Knorr* cruise 134, leg 9 in May 1988 (US-Turkish Oceanographic Expedition to the Black Sea), hydrogen sulfide was detected at depths of 80 m in the western basin (42°50'N, 32°00'E). In the acetone extracts of filtered samples from the sulfide interface between 68- and 92-m depth, four homologs of bchl *e* and the carotenoids isorenieratene and β-isorenieratene were identified (Repeta et al., 1989). These pigments indicated the presence of brown *Chlorobium* species. From cultures prepared from parallel membrane-filter samples of water from the 80-m depth, bacteria resembling *Chlorobium phaeobacteroides* have been obtained by N. Pfennig and J. Overmann (unpublished observations).

In shallow marine lagoons, stagnant seawater pools, and salt marsh environments, mass developments of green sulfur bacteria may occasionally occur. Even if not bloom-forming, the typical marine green sulfur bacterium, *Prosthecochloris aestuarii* (Gorlenko, 1970), can almost always be isolated from anoxic water and mud. Two other typically marine species have been described: *Chlorobium vibrioforme,* (Trüper, 1970; Caumette, 1984, 1986) and *Chloroherpeton thalassium* (Gibson et al., 1984).

Isolation

Preparation of Culture Media

Suitable culture media for the Chlorobiaceae are very similar to those for the Chromatiaceae. The medium composition and preparation procedures given in Chapter 170 for the Chromatiaceae can be used. Instead of trace element solution SL 12, however, the following EDTA-free solution SL 10 has also been successfully used (Overmann and Pfennig, 1989).

Trace element stock solution SL 10

Distilled water	1 liter
HCl (37%)	8.5 ml
$FeCl_2 \cdot 4H_2O$	1.5 g
H_3BO_3	6 mg
$CoCl_2 \cdot 6H_2O$	190 mg
$MnCl_2 \cdot 4H_2O$	100 mg
$ZnCl_2$	70 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg

The salts are dissolved in the order given, and the solution is sterilized by autoclaving. This solution is used at 1 ml per 1 liter of medium.

Selective Enrichment of Green Sulfur Bacteria

Water, mud, or sediment samples from anoxic sulfide-containing natural habitats (freshwater or marine samples) usually contain both green and purple sulfur bacteria, even if the color of the sample may suggest the presence of only one group. Chlorobiaceae are selectively enriched in medium 1 or 2 (see Chapter 170) at pH values between 6.6 and 6.9 (not above pH 7.0). The bottles are continuously illuminated with a daylight-fluorescent lamp at light intensities between 5 and 300 lux and an incubation temperature of 20 to 30°C. At high light intensities (500–2,000 lux) and temperatures between 30 and 35°C, green *Chlorobium* and *Prosthecochloris* species (marine; Trüper, 1970; Matheron and Baulaigne, 1972) will be selectively enriched over purple sulfur bacteria. At very low light intensities (5–50 lux), the Chlorobiaceae are selectively enriched (even with tungsten lamps) due to their unique capacity to grow at light intensities that are too low to support the growth of other phototrophic sulfur bacteria (Biebl and Pfennig, 1978).

Low-light intensities, together with diurnal light and dark changes and temperatures around 20°C, may be used to enrich for certain species of Chlorobiaceae that are outgrown by *Chlorobium* or *Prosthecochloris* at high-light intensities and high temperatures. The enrichment of the gas-vacuole-containing green sulfur bacteria of the genus *Pelodictyon* (Pfennig and Cohen-Bazire, 1967; Overmann and Pfennig, 1989) and of the Chlorochromatium and Pelochromatium consortia can be expected at low sulfide concentrations (< 2 mM) in medium 1 between 20 and 100 lux, and at 15 to 20°C.

With the amount of sulfide initially present in the medium, only very limited growth can be expected. After all the sulfide and sulfur are photooxidized, the bacteria stop growing and will be damaged by further illumination. In order to keep the enrichments growing and to obtain high cell yields, it is necessary to feed the cultures several times with a sterile, neutralized sulfide solution, as described in Chapter 170.

If the green or brown Chlorobiaceae to be isolated were first detected by microscopic observation in a water or mud sample from nature, liquid enrichment cultures should not be used. Such enrichment cultures may select for species that are not the dominant form in the sample. In order to isolate the various bacteria in the same proportions as they are present in the original sample, the latter is used directly as an inoculum for deep agar dilution series. Medium 1 (Chapter 170) is used with the addition of 3

mM acetate, which serves as an additional carbon source and results in the development of much larger colonies. The agar tubes are incubated at room temperature and at light intensities (fluorescent light) not higher than 50–200 lux to provide the least selective conditions.

Identification

The properties of the species of the Chlorobiaceae are listed in Table 1. Members of the Chlorobiaceae lack assimilatory sulfate reduction and require a reduced sulfur compound as a sulfur source. They can assimilate some simple organic carbon compounds in the presence of sulfide and carbon dioxide. Many strains need vitamin B_{12}. Cell multiplication occurs by binary fission; only *Pelodictyon clathratiforme* and *P. phaeoclathratiforme* show ternary fission leading to the formation of three-dimensional nets. *Chloroherpeton thalassium* is the only motile species of the Chlorobiaceae; it consists of unicellular gliding filaments. Fig. 1 shows the morphology of some typical species of the Chlorobiaceae.

The most conspicuous difference between the Chlorobiaceae and the purple sulfur bacteria (Chromatiaceae and Ectothiorhodospiraceae) is the bacteriochlorophyll pigments. Thus, despite their trivial names of green and purple bacteria, it is not the color of colonies or cell suspensions, because there exist green and brown species in the Chlorobiaceae as well as brown, orange, purple, red, and green species in the purple sulfur bacteria. The easiest differentiation between the Chlorobiaceae and the purple sulfur bacteria is by recording the absorption spectra of living cell suspensions, as described in Chapter 170. The wavelengths typical for the three presently known bulk (antenna) bacteriochlorophylls in living cells of Chlorobiaceae (and some of the Chloroflexaceae) are: bchl *c*, 745–755 nm; bchl *d*, 715–745 nm; and bchl *e*, 710–725 nm (Gloe et al., 1975; Pfennig and Trüper, 1977). Fig. 2 shows absorption spectra of living cell suspensions of two *Chlorobium* species. The in vivo absorption characteristics of bchls *c* and *e*, as well as of the most common carotenoids, are represented. In such spectra the typical maxima of the reaction center bchl *a* of the Chlorobiaceae does not show up due to its minute amount as compared with the amount of antenna bacteriochlorophylls.

When physiology, morphology, and pigments of a newly isolated strain have been determined, identification with a known species is possible in most cases; if not, further properties of the new strain must be studied. We recommend the determination of the GC content of the DNA and a study of ultrathin sections under the electron microscope, in order to verify the presence of chlorosomes (see later for discussion of these unique structures of the green bacteria).

The description of a new species of the Chlorobiaceae should be based on pure cultures and, if possible, on more than one strain. Besides nomenclatural items, a new description should contain detailed information about cell morphology (color, size, shape, motility, mode of division, presence of gas vacuoles, slime capsules, sheaths); occurrence of cell aggregates; fine structure; photosynthetic pigments (color of cell suspensions, types of bchl and carotenoids); and GC content. The following physiological data should be given: oxygen tolerance; sulfide tolerance; salinity requirements: optimum growth temperature and pH; sulfur, nitrogen, and carbon sources utilized; vitamins or other growth factors required; and capacity for photo-versus chemotrophy, organo- versus lithotrophy, and hetero-versus autotrophy. An indication of natural habitats is also necessary.

Finally, a type strain must be designated and deposited in one of the recognized national type culture collections, preferably ATCC, DSM, NCIB, or NTHC, as required by the International Code of Nomenclature of Bacteria (Lapage et al., 1975).

Physiology

During photosynthetic metabolism in the Chlorobiaceae, light is harvested in special organelles, the chlorosomes. These are lens- to cigar-shaped bodies that are attached to the inner side of the cytoplasmic membrane in direct association with the plasma membrane. The chlorosomes contain the antenna bacteriochlorophylls and transfer energy to the reaction center bacteriochlorophyll in the plasma membrane. The reaction center bacteriochlorophyll is always bchl *a* in the Chlorobiaceae.

Although cyclic photophosphorylation in the Chlorobiaceae works like that in the Chromatiaceae (Drews, 1989), the mechanism for NAD^+ reduction is quite different. In the Chlorobiaceae, the primary photosynthetic electron acceptor is not a bacteriopheophytin like in the purple bacteria, but an iron-sulfur protein with a reduction potential of -540 mV. This allows the green sulfur bacteria to directly reduce NAD^+ via reduced ferredoxin. The electron removed by noncyclic electron flow is replaced by external electrons entering the system at a less electronegative site via cytochrome c_{555}, which again donates them to the reaction center bac-

Table 1. Properties of the species of the Chlorobiaceae.

Species	Shape, size (μm)	Aggregate pattern	Gas vacuoles	Color of cell suspension	Predominant bchl	Predominant carotenoid[a]	GC content (mol%)	Type or neotype strain	Special requirement
Ancalochloris perfilievii	Sphere, 0.5–1.0 with prosthecae up to 2.0	Microcolonies	+	Green	ND	ND	ND	—	Vit. B_{12}

teriochlorophyll. Cytochrome c_{555} behaves in analogy to cytochrome c_2 in purple bacteria, whereas menaquinones replace ubiquinones as mobile intramembranous hydrogen carriers. For further details, see Drews (1989).

Lippert and Pfennig (1969) demonstrated that in the Chlorobiaceae, molecular hydrogen utilization occurs in the majority of species and strains. Autotrophic growth in the green sulfur bacteria is, however, dependent on the presence of a reduced source of sulfur, as these organisms are not capable of assimilatory sulfate reduction.

The uptake hydrogenases of *Chlorobium* species are not yet fully understood (Gogotov, 1986). In general, the enzymes appear to be membrane-bound and probably contain nickel and iron-sulfur clusters. The natural electron acceptors of hydrogenases in *Chlorobium* are rubredoxin or cytochromes (Gogotov, 1986).

All species of the Chlorobiaceae utilize sulfide and elemental sulfur as photosynthetic electron donors (Trüper, 1981a, 1989). The stoichiometry of sulfide oxidation with respect to CO_2 fixation is more variable than that of the Chromatiaceae due to incomplete formation of sulfate (Van Niel, 1931).

During oxidation of sulfide, hydrophilic "elemental sulfur" appears in the form of globules outside the cells.

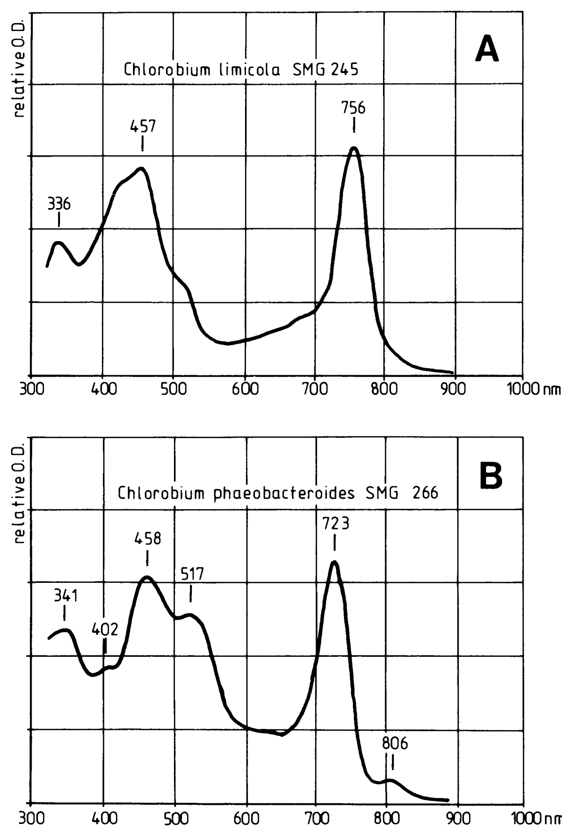

Fig. 2. Absorption spectra of living cell suspensions of green and brown *Chlorobium* species. (A) *Chlorobium limicola,* with bchl *c* (756 nm) and the carotenoid chlorobactene (457 nm). (B) *Chlorobium phaeobacteroides,* with bchl *e* (723 nm) and the carotenoids chlorobactene (458 nm) and isorenieratene (517 nm).

Utilization of thiosulfate as a photosynthetic electron donor by Chlorobiaceae is restricted to the *"thiosulfatophilum"* biovars of the two species *Chlorobium limicola* and *C. vibrioforme.* Of these, only *C. vibrioforme* biovar *thiosulfatophilum* forms extracellular sulfur globules from thiosulfate (Steinmetz and Fischer, 1982). The thiosulfate-utilizing biovars form thiosulfate as free intermediate during phototrophic sulfide oxidation, and they are able to disproportionate elemental sulfur in the light in the absence of carbon dioxide (Trüper et al., 1988).

The enzymology of sulfur metabolism in the Chlorobiaceae is not yet fully resolved. It appears that the oxidation of sulfide to "elemental sulfur" is mediated by *c*-type cytochromes. The formation of thiosulfate from sulfide is catalyzed by flavocytochrome *c* (Fischer, 1984). Adenylylsulfate reductase was shown to occur in *Chlorobium* species (Trüper and Peck, 1970) and was purified by Kirchhoff and Trüper (1974). Splitting of adenylylsulfate and liberation of sulfate is performed by ADP sulfurylase in *C. vibrioforme* (Trüper and Fischer, 1982; Khanna and Nicholas, 1983; Bias and Trüper, 1987) and exclusively by ATP sulfurylase in *C. limicola* (Bias and Trüper, 1987).

In the Chlorobiaceae, autotrophic CO_2 fixation occurs via a reverse tricarboxylic acid cycle, as was first proposed by Evans et al. (1966). Key enzymes of this cycle are the ferredoxin-dependent α-ketoglutarate and pyruvate synthases, and an ATP-dependent citrate lyase (Sintsov et al., 1980; Ivanovsky et al., 1980). The careful ^{14}C-labeling studies by Fuchs et al. (1980a, 1980b) and respective ^{13}C-NMR studies by Paalme et al. (1982a, 1982b), together with the characterization of the citrate lyase (Antranikian et al., 1982), have provided unequivocal final evidence for this distinctive mechanism of autotrophic CO_2 fixation.

With respect to the utilization of organic carbon, the Chlorobiaceae show little versatility (Trüper, 1981b). They are obligately photolithoautotrophic even when utilizing acetate or pyruvate (so far the only organic carbon sources known to be used) showing a strict dependence upon a simultaneous supply of bicarbonate and sulfide or thiosulfate.

Although the best nitrogen source for growth is the ammonium ion, the majority of strains of the Chlorobiaceae are able to fix dinitrogen (for reviews, see Vignais et al., 1985; Hallenbeck, 1987).

Further aspects of ultrastructure, energy transfer, metabolism, phylogeny, physiology, and ecology are dealt with in a book on green photosynthetic bacteria edited by Olson et al. (1988).

Applications

Chlorobiaceae have been used for the removal of the obnoxious (and poisonous) smells of hydrogen sulfide during anaerobic waste treatment (Kobayashi et al., 1983). Cork and Cusanovich (1979) presented a process for the continuous disposal of sulfate by a mutual bacterial system consisting of *Desulfovibrio desulfuricans* and *Chlorobium limicola.* Cork (1982; Cork and Ma, 1982; Cork et al., 1983, 1985) developed a system using *C. limicola* as the biocatalyst in the production of elemental sulfur and organic carbon (biomass) from acid gas (containing H_2S and CO_2), an alternative to the Claus desulfurization process used in cleaning sour natural gases.

CHAPTER 196

The Genus *Bacteroides* and Related Taxa

HAROUN N. SHAH

History

Bacteroides fragilis, type species of the genus *Bacteroides* was first described by Veillon and Zuber (1898) as *Bacillus fragilis* but was later transferred to the genus *Bacteroides* by Castellani and Chalmers (1919). *B. fragilis* has been referred to as *Fusiformis fragilis* (Topley and Wilson, 1929), Ristella fragilis (Prévot, 1938) and *Bacteroides fragilis* subspecies *fragilis* (Holdeman and Moore, 1974). Studies on more than 300 morphologically and physiologically similar isolates which were saccharolytic and showed growth stimulation with bile revealed phenotypically discernible groups within a "continum of variants" (Holdeman and Moore, 1970). As a result, *Bacteroides fragilis* was regarded as a single species which comprised the following; *B. fragilis* subspecies *fragilis, B. fragilis* subspecies *distasonis, B. fragilis* subspecies *eggerthii, B. fragilis* subspecies *ovatus, B. fragilis* subspecies *thetaiotaomicron, B. fragilis* subspecies *uniformis,* and *B. fragilis* subspecies *vulgatus* (Holdeman and Moore, 1974).

All subspecies were later shown to be genetically distinct by DNA-DNA hybridization (Johnson, 1973) and were reinstated to species rank by Cato and Johnson (1976). Similar studies by Johnson et al. (1986) led to the recognition of three additional related species, *B. caccae, B. merdae,* and *B. stercoris.* Biochemical, chemical, and molecular biological data indicate that this group of 10 species form a taxonomically coherent group of species that differs so markedly from other taxa within the currently defined genus (Holdeman et al., 1984) that they require separate generic status. Accordingly, the description of the genus *Bacteroides* was amended recently to restrict it only to the *"B. fragilis* group of species" (Shah and Collins, 1989) and includes all the above taxa.

The moderately saccharolytic, pigmented/nonpigmented organisms comprise a large group of 15 species which share many common phenotypic properties. The earliest reported member of this group, *Bacteroides melaninogenicus* was described by Oliver and Wherry (1921). Previously regarded as a single species (see Chapter 197) with one asaccharolytic subspecies (*B. melaninogenicus* subspecies *asaccharolyticus*) and two moderately saccharolytic subspecies (*B. melaninogenicus* subspecies *melaninogenicus* and *B. melaninognicus* subspecies *intermedius*), all subspecies or serogroups (Lambe, 1974) have been elevated to species rank (Holdeman and Moore, 1974). The species *B. oralis (B. oralis* var. *oralis* and *B. oralis* var. *elongatus)* was separated from *B. melaninogenicus* almost exclusively on the basis of pigment production by the latter (Loesche et al., 1964). This heavy reliance on pigmentation, together with poor circumscription of the species *B. oralis,* led to the species becoming a repository for a large and varied collection of strains which could not be accommodated elsewhere. Furthermore, the only three available reference strains of *B. oralis* (ATCC 15930 [VPI9085], 7CM, and J1) were all assigned to new species (Fig. 1). Strain ATCC 15930 was assigned to *B. melaninogenicus* because of the formation of black pigment (Holbrook and Duerden, 1974; Holbrook et al., 1977) and later to *B. loescheii* (Holdeman and Johnson, 1982). J1 was described as *"B. ruminicola-like"* due to its capacity to ferment xylose and arabinose (a specific property which *B. oralis* does not possess) while strain 7CM was transferred to *B. vulgatus* on the basis of DNA-DNA hybridization data and its growth stimulation of bile (Shah and Collins 1981). Two strains, HS4 and VPI 8906D, which conformed to the description of *B. oralis* had high interstrain DNA-DNA homology but low genetic relatedness with a newly proposed neotype strain of *B. oralis* (ATCC 33269). Strains HS4 (NCDO 2354) and VPI 8906D were shown to comprise the nucleus of a new species, *B. buccalis* (Shah and Collins, 1981), while *B. veroralis* (Watabe et al., 1983) and *B. oulorum* (Shah et al., 1985) were proposed for phenotypically similar but genetically distinct species. Biochemical and chemical studies showed that strain J1 and two related stains NP333 (NCDO 2352) and WPH61 were genetically similar but differed sufficiently from

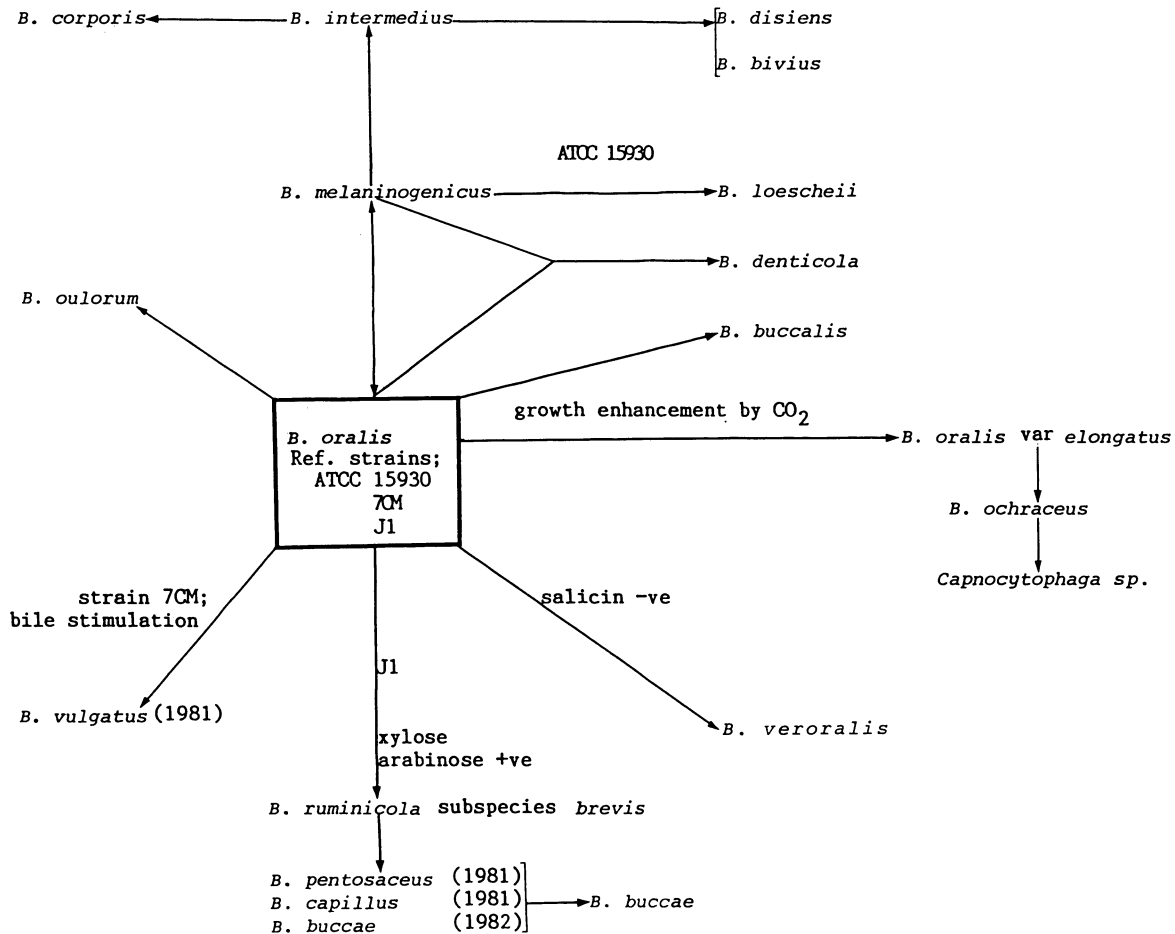

Fig. 1. Current status of isolates that previously belonged to *Bacteroides oralis.*

other species to warrant their placement in a new species, *B. pentosaceus* (Shah and Collins, 1981). Phenotypically and genetically similar strains, for which the species *B. capillus* was proposed, were isolated from localized periodontitis sites (Kornman and Holt, 1981). *B. pentosaceus, B. capillus,* and the newly proposed *B. buccae* (Holdeman et al., 1982) were reported to be genetically similar and the specific epithet *B. buccae* took precedence (Johnson and Holdeman et al., 1985). *B. oris* (Holdeman et al., 1982) and *B. heparinolyticus* (Okuda et al., 1985) share many common properties with these species but are generally less fermentative. The description of *B. denticola* (Shah and Collins, 1981) was emended to include both pigmented and nonpigmented strains (Holdeman and Johnson, 1982). The less saccharolytic pigmented species *B. intermedius* was shown to comprise another genetically distinct taxon for which the name *B. corporis* was proposed (Johnson and Holdeman, 1983). *B. bivius* and *B. disiens* are phenotypically similar to *B. intermedius* but do not form pigment on blood agar (Holdeman and Johnson, 1977). This large group of species, generally referred to as the *"B. melaninogenicus-B. oralis* group," form a biochemically related group of species which differs from *B. fragilis* and other recently proposed genera and should be assigned to a new genus (Shah and Collins, 1989). Most species of the *"B. melaninogenicus-B. oralis"* group are frequently isolated from the oral cavity and are moderately fermentative.*

In contrast to the above species, most of the remaining taxa do not colonize the oral cavity and are generally nonfermentative (Holdeman et al., 1984). They represent a diverse collection of species quite unrelated to the type species *B. fragilis* or to each other. Consequently, several new genera have been proposed, many of which are monospecific (see Shah and Collins, 1989). Examples of some species which have long been established and since reclassified, include *Tissierella praeacuta* (Collins and Shah, 1986b) for *B. praeacutus* (1908); *Anaerorhabdus furcosus*

*Recently reclassified in a new genus *Prevotella.*

(Shah and Collins, 1986) for *B. furcosus* (1898); *Sebaldella termitidis* (Collins and Shah, 1986a for *B. termididis* (1962); *Fibrobacter succinogenes* (Montgomery et al., 1988) for *B. succinogenes* (1950); *Megamonas hypermegas* (Shah and Collins, 1982a for *B. hypermegas* (1963); *Mitsuokella multiacidus* (Shah and Collins, 1982b for *B. multiacidus* (1974); *Rikenella microfusus* (Collins et al., 1985) for *B. microfusus* (1978), and *Ruminobacter amylophilus* (Stackebrandt and Hippe, 1986) for *B. amylophilus* (1956). Although several other species such as *B. capillosus, B. coagulans,* and *B. ureolyticus* have not been reclassified, biochemical and chemical properties so far examined indicate that they warrant separate generic status (see reviews by Shah and Collins, 1983, and Collins and Shah, 1987).

Recently, many new species have been proposed as members of the genus *Bacteroides.* Many of these species bear little resemblance to *classical Bacteroides* and their current taxonomic positions remain uncertain. Table 1 (from Shah and Collins, 1989) gives an overview, and where possible the taxonomic position of these species, while Fig. 2. gives the distribution of mol% GC values among these organisms.

General Characteristics

More than 50 species of *Bacteroides* are currently listed in *Bergey's Manual of Systematic Bacteriology* (Holdeman et al., 1984) and the Approved Lists of Bacterial Names (Moore et al., 1985) In the past, any Gram-negative, obligately anaerobic, nonsporeforming rod which could not be assigned to the genus *Fusobacterium* or *Leptotrichia* has been placed in the genus *Bacteroides.* Poor definition of the genus, including its wide range in DNA-base composition (about 28–61 mol% GC) (Holdeman et al., 1984) has allowed isolates which share only a few common properties to be deposited in the genus *Bacteroides.* Previously we have suggested (Shah and Collins, 1983; Collins and Shah, 1987) that the generic description should be emended to include only the type species *B fragilis* and related taxa. Thus, the genus *Bacteroides* should be restricted to those species which fulfill the following criteria:

1. Obligately anaerobic, Gram-negative, nonsporeforming rods.
2. Saccharolytic, and produce major levels of acetate and succinate as metabolic end products.
3. Contain enzymes of the hexose monophosphate shunt-pentose phosphate pathway such as glucose-6-phosphate dehydrogenase (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH), in addition to malate dehydrogenase (MDH) and glutamate dehydrogenase (GDH).
4. Have a DNA-base composition within the range 40–48 mol% GC.
5. Possess sphingolipids.
6. Contain a mixture of long-chain fatty acids with predominantly straight-chain saturated, anteiso-methyl branched and iso-methyl branched acids.
7. Possess menaquinones with MK-10 and MK-11 as major components.
8. Contain *meso*-diaminopimelic acid as the diamino acid of its peptidoglycan.

On the basis of the above criteria the following species are currently considered to constitute the revised genus *Bacteroides: B. fragilis* (type species), *B. caccae, B. distasonis, B. eggerthii, B. merdae, B. ovatus, B. stercoris, B. thetaiotaomicron, B. uniformis,* and *B. vulgatus.* This more restricted definition of the genus *Bacteroides* (Shah and Collins, 1989) contains only saccharolytic, nonpigmented species. The growth of all species is stimulated by bile and, with the exception of *B. splanchnicus,* are the only Gram-negative, anaerobic, nonsporeforming rods which possess high levels of both G6PDH and 6PGDH (Shah and Collins, 1989). Although *B. splanchnicus* superifically resembles members of the *"B. fragilis"* group, biochemical, chemical, and genetic data indicate that they are taxonomically unrelated. *B. splanchnicus* differs from the *"B. fragilis"* group in producing propionic acid as a major metabolic end product, possessing menaquinones with nine isoprene units, and containing mainly 13-methyl-tetradecanoic acid (see review, Shah and Collins, 1983). Subsequent rRNA-homology studies by Johnson and Harich (1986) revealed less than 20% relatedness between *B. splanchnicus* and the *"B. fragilis"* group, which further supports the exclusion of *B. splanchincus* from the genus *Bacteroides* sensu stricto.

The group of species referred to above as the *"B.melaninogenicus-B.oralis"* group comprises many of the species commonly isolated from the oral cavity, and which have DNA-base compositions between 40–50 mol% GC (Shah et al., 1990; Reddy and Bryant, 1977). Using the revised definition of the genus *Bacteroides,* it is evident that this group constitutes a new genus, quite unrelated to *B. fragilis,* for which the name *Prevotella* has been proposed (Shah and Collins, 1990). These species are moderately saccharolytic, produce mainly acetic and succinic acids in a glucose medium, and do not grow in media containing 20% bile. The pigmented species such

Species currently designated *Bacteroides*		
B. caccae, B. distasonis, B. eggerthii, B. fragilis, B. merdae, B. ovatus, B. stercoris, B. thetaiotaomicron, B. uniformis, B. vulgatus	*Bacteroides* (emended definition)	Shah and Collins, 1989
B. bivius, B. buccae, B. buccalis, B. corporis, B. denticola, B. disiens, B. intermedius, B. heparinolyticus, B. loescheii, B. melaninogenicus, B. oralis, B. oris, B. oulorum, B. ruminicola, B. veroralis, B. zoogleoformans	*B. melaninogenicus-B. oralis* group; (now reclassified as *Prevotella* gen. nov.)	Collins and Shah, 1987; Shah and Collins, 1983; Shah and Collins, 1990
B. levii, B. macacae, B. salivosus	Not *Bacteroides;* possibly related to *Porphyromonas*	Collins and Shah, 1987; Love et al., 1987; Shah and Collins, 1983
B. ureolyticus, B. gracilis	Not *Bacteroides;* possibly related to *Campylobacter* or *Wolinella*	Paster and Dewhirst, 1988
B. capillosus	Not *Bacteroides;* generic position uncertain	Collins and Shah, 1987; Shah and Collins, 1983
B. cellulosolvens	Not *Bacteroides;* generic position uncertain	Murray et al., 1984
B. coagulans	Not *Bacteroides;* generic position uncertain	Collins and Shah, 1987; Shah and Collins, 1983; Elleman, 1988
B. forsythus	Not *Bacteroides;* generic position uncertain	Tanner et al., 1986
B. galacturonicus	Not *Bacteroides;* generic position uncertain	Jensen and Canale-Parola, 1986
B. helcogenes	Not *Bacteroides;* generic position uncertain	Benno et al., 1983
B. nodosus	Not *Bacteroides;* generic position uncertain	Collins and Shah, 1987; Shah and Collins, 1983
B. pectinophilus	Not *Bacteroides;* generic position uncertain	Jensen and Canale-Parola, 1986
B. pneumosintes	Not *Bacteroides;* generic position uncertain	Collins and Shah, 1987; Shah and Collins, 1983
B. polypragmatus	Not *Bacteroides;* generic position uncertain	Moore et al., 1985
B. putredinis	Not *Bacteroides;* generic position uncertain	Collins and Shah, 1987; Hammann and Werner, 1983; Shah and Collins, 1983
B. pyogenes	Not *Bacteroides;* generic position uncertain	Benno et al., 1983
B. splanchnicus	Not *Bacteroides;* generic position uncertain	Hammann and Werner, 1983; Shah and Collins, 1983; Collins and Shah, 1987
B. suis	Not *Bacteroides;* generic position uncertain	Benno et al., 1983
B. tectum	Not *Bacteroides;* generic position uncertain	Love et al., 1986
B. xlanolyticus	Not *Bacteroides;* generic position uncertain	Scholten-Koerselman et al., 1986
New genera for reclassified species		
Anaerorhabdus	Formerly *B. furcosus*	Shah and Collins, 1986
Fibrobacter	Formerly *B. succinogenes*	Montgomery et al., 1988
Megamonas	Formerly *B. hypermegas*	Shah and Collins, 1982a
Mitsuokella	Formerly *B. multiacidus*	Shah and Collins, 1982b
Porphyromonas	Formerly *B. asaccharolyticus, B. endodontalis,* and *B. gingivalis*	Collins and Shah, 1987; Shah and Collins, 1983, 1988
Rikenella	Formerly *B. microfusus*	Collins et al., 1985
Ruminobacter	Formerly *B. amylophilus*	Stackebrandt and Hippe, 1986
Sebaldella	Formerly *B. termiditis*	Collins and Shah, 1986a
Tissierella	Formerly *B. praeacutus*	Collins and Shah, 1986b

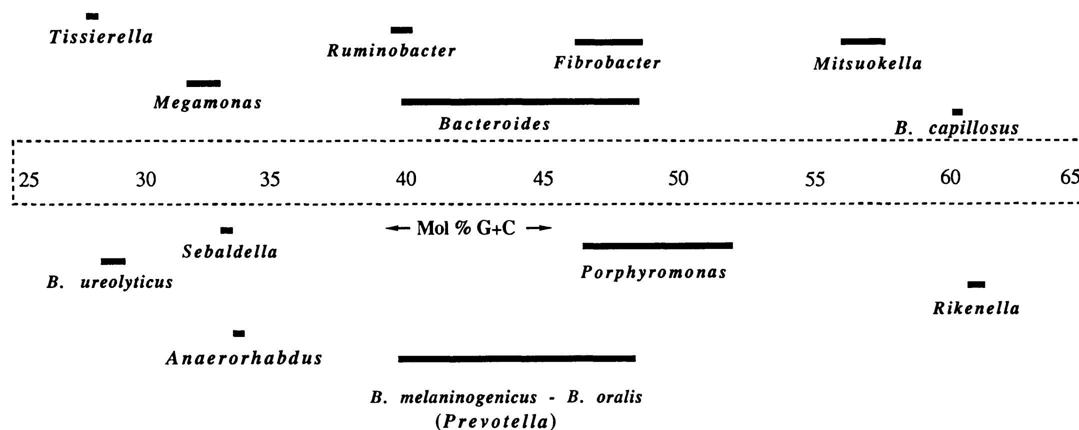

Fig. 2. Distribution of GC content of the DNA of *Bacteroides* and related genera.

as *B. melaninogenicus, B. loescheii, B. corporis, B. intermedius,* and some strains of *B. denticola* produce both protoheme and protoporphyrin pigments. *B. melaninogenicus, B. loescheii* and pigmented strains of *B. denticola* fluoresce brilliantly under ultraviolet (UV) radiation (365 nm) due to the production of mainly protoporphyrin (Shah et al., 1979). These species have the ability to demetallate the iron-containing protoheme molecule leaving a highly conjugated structure which fluoresces under UV radiation (Shah et al., 1979). The darker pigmented colonies of *B. intermedius* and *B. corporis* accumulate an excess of protoheme over protoporphyrin. Before these colonies become entirely black the nonpigmented cells at the center of the colonies also fluoresce. This property is, therefore, useful for recognizing at least some species of the *"B. melaninogenicus-B. oralis"* group and has been of major consequence in elucidating the taxonomic interrelationships of this group of species. Other members of this large cluster include *B. bivius, B. buccae, B. buccalis, B. disiens, B. heparinolyticus, B. oralis, B. oulorum, B. oris, B. ruminicola, B. veroralis,* and *B. zoogleoformans.* These species differ from the *"B. fragilis* group" in that they are sensitive to bile and lack G6PDH and 6PGDH (Shah and Williams, 1982).

B. levii and *B. macacae* resemble *Porphyromonas* species in producing mainly protoheme and possessing a similar dehydrogenases pattern (Shah and Collins, 1988). The similarity in metabolic end products (butyric and acetic acids) and a compatible GC content of 45-48 mol further reinforces the similarity between *B. levii* and *Porphyromonas* (Shah and Collins, 1988). However, like *B. macacae, B. levii* is weakly saccharolytic. *B. macacae* further differs from the rest of this group in producing mainly propionic and succinic acids as major metabolic end products and possessing a lower GC content of 42–44 mol. Two broad groups of species are further discernible by DNA-base composition: a high GC group with base compositions within the range 56–61 mol% and a low GC group of 28–37 mol%. The high GC group, which comprises *Mitsuokella multiacidus* (Shah and Collins, 1982b), *Mitsuokella dentalis* (56–58 mol%) (Haapasalo et al., 1986), *Rikenella microfusus* (60–61 mol%) (Collins et al., 1985), and *Bacteroides capillosus* (60 mol%) share few common properties with each other or *Bacteroides* sensu stricto. *Mitsuokella multiacidus* is a highly saccharolytic organism that produces major levels of lactic acid in addition to acetic and succinic acids (Holdeman et al., 1984). *B. capillosus* is asaccharolytic, producing only low levels of acetic and succinic acids, while *R. microfusus* is very weakly saccharolytic but produces major levels of similar acids (Kaneuchi and Mitsuoka, 1978).

Microorganisms with DNA-base compositions within the range 28–37 mol% GC are phenotypically and genetically so different from each other and from *B. fragilis* as to warrant their placement in several new genera. With the exception of *Megamonas hypermegas* and *Sebaldella termitidis,* all species are nonfermentative. The metabolic end products of these species/genera vary considerably, in accord with their chemotaxonomic heterogeneity (see review, Collins and Shah, 1987).

Habitat

Members of the genus *Bacteroides* and related taxa normally colonize the upper respiratory, intestinal, and female genital tracts. Normal feces for example, contains 10^{11} "*Bacteroides fragilis* group" species per gram compared to

facultative anaerobes which approximate 10^8 per gram (Drasar and Hill, 1974). Other species such as the "*B. melaninogenicus-B. oralis* group" are associated with dental plaque. Although these organisms are normally considered as part of the normal commensal flora of the mucous membranes of humans and animals, they are the most important anaerobic bacteria associated with human infections (Finegold et al., 1985). The infections caused by these organisms are often related to their primary site of isolation. Thus, species of the "*B. fragilis* group" account for between 15–54% of the anaerobic flora in intra-abdominal infections, between 32–68% in perirectal abscesses, and between 26–50% in decubitus ulcers (Finegold et al., 1985). Conversely, their numbers reach only 3% of the anaerobic flora in infections of the head and neck, do not occur in dental diseases, and are less than 4% of the anaerobic flora of transtrachael aspirates and pleural fluid (Finegold et al., 1985). In contrast, members of the "*B. melaninogenicus—B. oralis* group" can account for up to 72% of the anaerobic flora of head and neck infections and can reach up to 50% in pleural fluid (Finegold et al., 1985). However, they account for less than 10% of the anaerobic flora of infections below the waist. This pattern of infection suggests that the source of these organisms in soft tissue infections are probably derived from their natural habitat. The normal site of isolation of these species and others are given in Table 2.

Isolation

Methods available for specimen collection, transport, and anaerobic culture have been dealt with in detail by Dowell and Hawkins (1974), Holdeman et al. (1977), and Sutter et al. (1985). The following media have been selected from various recommended media (Sutter et al., 1985) for primary isolation of anaerobic bacteria, with particular reference to *Bacteroides* and Gram-negative, anaerobic bacteria of human origin.

Total Counts

This can be carried out on either Brucella blood agar supplemented with vitamin K, and hemin

Table 2. Normal site of isolation of *Bacteroides* and other Gram-negative, nonsporeforming anaerobes.

Species/genus	Normal site of isolation[a]
"*Bacteroides fragilis* group"	Colon
"*B. melaninogenicus-B. oralis* group"	Oral cavity
B. bivius, B. disiens	Female genital tract
Other species labelled "*Bacteroides*"	
B. capillosus	Mouth and colon of humans and animals
B. cellulosolvens	Sewage sludge
B. coagulans	Intestinal and urogenital tract
B. forsythus	Dental plaque
B. gracilis	Oral cavity
B. helcogenes	Swine intestinal tract
B. levii	Bovine rumen
B. macacae	Oral cavity of macque monkey
B. nodosus	Infected hoofs of sheep and goats
B. pneumosintes	Naso-pharyngeal, gingival crevice
B. polypragmatus	Sewage sludge
B. putredinis	Colon of humans and animals
B. pyogenes	Swine intestinal tract
B. ruminicola species	Rumen of sheep, cattle, and other ruminants
B. suis	Swine intestinal tract
B. tectum	Oral flora of dogs and cats
B. ureolyticus	Respiratory, intestinal, and genital tracts
"*Bacteroides*" spp. that have been reclassified	
Anaerorhabdus furcosus	Colon of humans and animals
Fibrobacter succinogenes	Rumen of sheep, cattle, and other ruminants
Megamonas hypermegas	Intestinal tract of poultry
Mitsuokella multiacidus	Colon of humans and pigs
Rikenella microfusus	Ceca of poultry
Ruminobacter amylophilus	Rumen contents of cattle
Sebaldella termitidis	Intestinal contents of termites
Tissierella praeacuta	Intestinal tract

[a]Except where stated, sites refer to humans.

Table 3. Presumptive identification of Gram-negative, anaerobic, nonsporeforming rods.

	Kanamycin (1 mg) susceptibility	Colistin (10 μg) susceptibility	Growth in 20% bile	Nitrate reduction	Urease production	Pigment/ fluorescence
B. fragilis group	R	R	+	−	−	−

solution or Wilkins-Chalgren agar. The composition of these media is as follows:

Brucella Blood Agar (BBL or Difco)

Pancreatic digest of casein	1.0 g
Peptic digest of animal tissue	1.0 g
Glucose	0.1 g
Yeast autolysate	0.2 g
NaCl	0.5 g
Sodium bisulfite	0.01 g
Agar	1.5 g
Distilled water	100.0 ml

Adjust to pH 7.0, boil agar to dissolve, then sterilize at 121°C for 15 min. The medium is then cooled to 50°C and defibrinated sheep blood (5% [v/v] added aseptically and dispensed.

Wilkins—Chalgren Agar

Trypticase	1.0 g
Gelysate	1.0 g
Yeast extract	0.5 g
Dextrose	0.1 g
NaCl	0.5 g
L-arginine-free base	0.1 g
Sodium pyruvate	0.1 g
Vitamin K	0.05 mg
Hemin	0.05 mg
Agar	1.5 g
Distilled water	100.0 ml

Boil to dissolve agar and autoclave at 121°C for 15 min.

The addition of kanamycin and vancomycin to laked blood Brucella agar medium (KVLB) inhibits most facultative anaerobic bacteria and permits the selection of mainly *Bacteroides* species. Its composition is as follows:

Kanamycin-Vancomycin Laked Blood Agar (KVLB)

Brucella agar	4.3 g
Hemin solution (5 mg/ml)	0.1 ml
Vitamin K, solution (10 mg/ml)	0.1 ml
Kanamycin solution (100 mg/ml)	0.075 ml
Distilled water	100.0 ml

The medium is autoclaved at 121°C for 15 min, then cooled to 50°C, and 1 ml of a vancomycin solution (7.5 μg/ml) and laked sheep blood (blood frozen overnight and then thawed) added.

Bile-containing media are generally used to selectively isolate members of the "*B. fragilis* group" of species. The growth of microorganisms such as those of the "*B. melaninogenicus-B. oralis* group" of species, which colonize the oral cavity, is inhibited on these media. Bacteroides Bile Esculin Agar is one such medium which is successfully used (Sutter et al., 1985) to isolate *B. fragilis* and related species. Its composition is as follows:

Bacteroides Bile Esculin Agar

Trypticase soy agar	40.0 g
Oxgal	20.0 g
Esculin	1.0 g
Ferric ammonium citrate	0.5 g
Hemin solution	2.0 ml
Gentamicin solution (40 mg/ml)	2.5 ml
Distilled water	1 liter

The pH is adjusted to 7.0, and the medium autoclaved at 121°C for 15 min and dispensed.

When successfully isolated, organisms can be maintained by weekly subculture on blood agar plates. Cultures for long-term storage are best kept at −70°C in liquid nitrogen, or lypholized.

Growth in Liquid Media

Most of the species described above use both carbohydrates and nitrogenous substrates as energy sources. Consequently, all media designed for the bulk growth of these microorganisms generally contain glucose and either proteose peptone or some other commercial protein hydrolysate. NaCl (0.5%) is generally required

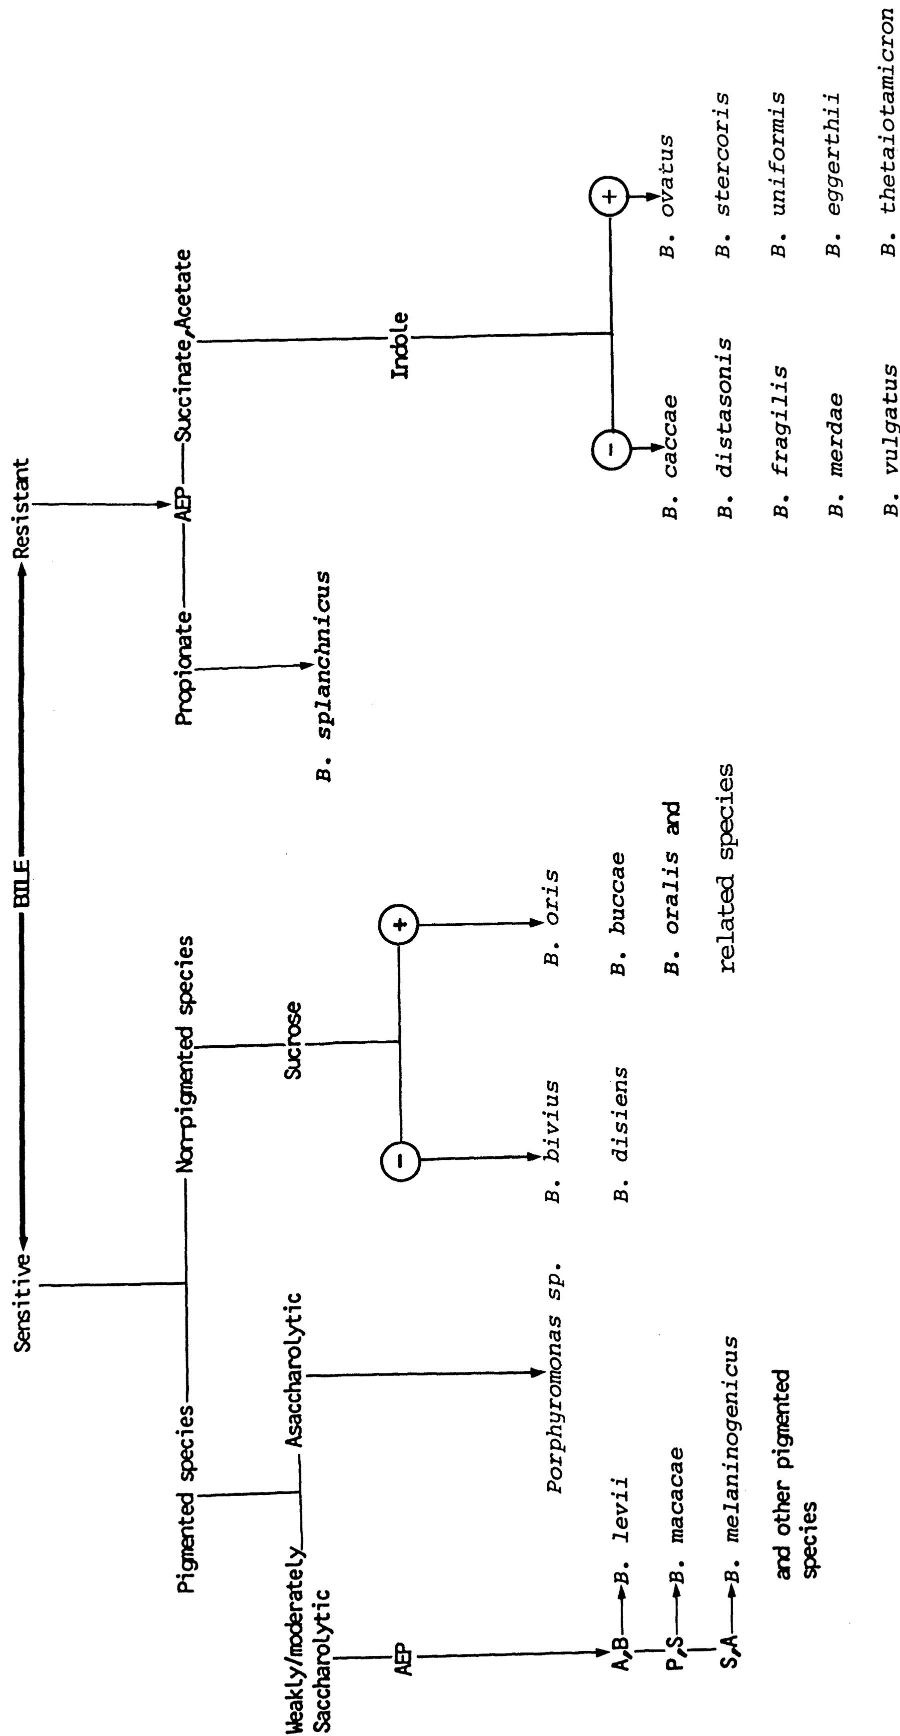

Fig. 3. Further identification of *Bacteroides* and phenotypically related taxa (see Table 7 for abbreviations).

Table 4. Differentiation of *B. fragilis* and related species by sugar fermentation and other diagnostic tests.

	Fermentation					Indole	Catalase

B. stercoris	+	+	−	−	−	+	−
B. eggerthii	−	+	+	−	−	+	−
B. splanchnicus	−	−	−	−	−	+	−

+, property present; −, property absent.

while cysteine is used both as a reducing agent and a growth requirement. Heme (for cytochrome production) replaces the need for whole blood while vitamin K is used as a precursor for menaquinone biosynthesis (Shah and Collins, 1980). Species that colonize the rumen often require either volatile fatty acids or rumen fluid. Details of culture media such as PYG or medium 10 (Caldwell and Bryant, 1966) are given by Holdeman et al. (1977). Medium BM (Shah et al., 1976), which is simple in composition and has been used very successfully for the culture of nearly all such species isolated from humans is given below:

BM

Trypticase	1.0 g
Proteose peptone	1.0 g
Yeast extract	0.5 g
NaCl	0.5 g
Glucose	0.5 g
Cysteine hydrochloride	0.075 g
Distilled water	100.0 ml

Sterilize, cool, then add 1% (v/v) of filter sterilized hemin-menadione solution (see below).

Hemin-Menadione Solution

Hemin solution is first prepared by adding 1 ml of 1 N NaOH to 50 mg of crystalline heme, followed by 98 ml of water. To this is added 1 ml of menadione solution (5 mg/ml in 95% ethanol) and the mixture filter sterilized and stored at −20°C. The hemin and menadione solution is added aseptically at 1% (v/v) to sterilized media.

Identification of Bacteroides and Other Gram-negative, Anaerobic Rods

The system of Sutter et al. (1985) involves the use of Gram stain, cell and colonial morphology, susceptibility to special antibiotic disks (placed on the first quadrant of a streaked plate), and tests for nitrate reduction, growth in bile, urease production, and observation of pigment production/UV fluorescence, This system enables a preliminary grouping of isolates (Table 3) into the following major categories:

1. *B. fragilis* group,
2. Pigmented group,
3. *B. ureolyticus*-like group,
4. Nonpigmented group,
5. *Fusobacterium-Leptotrichia* group.

Commercially available multitest systems such as API 20A and RAP-ID ANA can be used for most of the test listed above (see, for example, Hofstad, 1980). However, for many of these systems, the database for identification is still inadequate and cannot be relied upon entirely. Gas-liquid chromatography (GLC) of the acidic end products (AEP) of isolates is necessary for accurate identification to the species level and is employed in all current identification schemes.

Leptotrichia buccalis, which produces major levels of lactic acid, and *Fusobacterium* species, which produce predominantly butyric acid, could be readily separated from the remaining species, which produce mainly acetic and succinic acids and occasionally lower levels of other volatile short-chain acids. Growth in the presence of bile and pigment production on blood agar are major characteristics for delineating these taxa to recognizable groups (see Fig. 3).

Some species possess unique properties which make them readily recognizable. Thus, the growth of *B. gracilis* is stimulated by formate or hydrogen and fumarate or nitrate (Tanner et al., 1981). *B. zoogleoformans* grows as a very viscous, ropy-like mat in liquid medium (Cato et al., 1982). Both *B. ureolyticus* and *B.*

Table 5. Biochemical and chemical characteristics useful in the differentiation of Gram-negtive, nonsporeforming, rods.

Taxon	DNA-base composition (mol% GC)	Dibasic[a] amino acid of the peptidoglycan	Dehydrogenase[b] enzymes present	Predominant[c] cell fatty acid	Major menaquinone	References
B. fragilis group	40–48	DAP	G6PDH, 6PGDH, MDH, GDH	$aiC_{15:0}$	MK-10	Miyagawa et al., 1979

W, weak reaction; +, positive reaction; −, negative; V, positive or negative reaction; $+^-$, most reactions positive; $-^+$, most reactions negative.
[a]Pigment, pigment production on blood agar.
[b]NAG, *N*-acetylglucosamineidase.
[c]α-Fuc, α-Fucosidase.
[d]β-Xyl, β-Xylosidase.
[e]β-Glu, β-Glucosidase.
[f]Gly, glycine aminopeptidase.

forsythus often form pits on the surface of blood agar plates (Tanner et al., 1986); the former also possesses urease activity (Jackson and Goodman, 1978). Other species which bear the label *"Bacteroides,"* such as *B. cellulosolvens,* ferment only cellulose and cellobiose (Murray et al., 1984). *B. tectum,* an oral isolate from cats and dogs, atypically grows in the presence of bile (Love et al., 1986), whereas the swine intestinal species *B. helcogenes* grows only poorly (Benno et al., 1983). The growth of other swine colonic species *B. pyogenes* and *B. suis,* is, however, inhibited by bile (Benno et al., 1983). Some major characteristics of these taxa are given below.

Differentiation of Species

A combination of biochemical/chemical tests can be used to obtain unequivocal identification of species within the "*B. fragilis* group," the "*B. melaninogenicus-B. oralis* group," and other Gram-negative nonsporeforming, anaerobic rods. For convenience, the biochemical and chemical tests are listed separately here, but in practice they may be carried out in parallel.

The production of indole and catalase and the fermentation of sucrose, salicin, rhamnose, and arabinose can be used to differentiate members of the "*B. fragilis* group" (Table 4). Species of this group possess DNA-base compositions within the range 40–48 mol% GC, have *meso*-diaminopimelic acid in their peptidoglycan, contain enzymes of the hexose monophosphate shunt-pentose phosphate pathway, possess major levels of 12-methyl-tetradeconic acid (anteiso-C_{15}) and contain predominantly menaquinones with 10 and 11 isoprene units (Table 5). *B. splanchnicus* differs from this group in producing butyric acid as a metabolic end product, contains predominantly 13-methyl-tetradecanoic acid (iso-C_{15}), and possesses menaquinones with nine isoprene units (MK-9) (Table 5).

Members of the "*B. melaninogenicus-B. oralis* group" can be identified to the species level by a combination of fermentation reactions and the production of specific constitutive enzymes (Table 6). These species have DNA-base compositions within the range 40–52 mol% GC (Ta-

ble 5) but differ significantly from those of the "*B. fragilis* group" in the absence of the pentose phosphate pathway enzymes (G6PDH and 6PGDH). The menaquinone composition of some species are highly distinctive. Thus, the principal respiratory quinone of *B. melaninogenicus, B. intermedius* and *B. oulorum* is MK-10, whereas for *B. denticola* and *B. veroralis* it is MK-11 (Shah et al., 1985). *B. pentosaceus* possesses almost equal levels of MK-12 and MK-13, while *B. buccalis* contains predominantly MK-12 (Shah and Collins, 1981) and *B. oralis* MK-13 (Shah et al., 1985).

Members of the remaining species/genera have not been studied in such detail as the above species, but they can be readily identified from available data. Table 7 highlights the major biochemical reactions for differentiating these species. Many of these microorganisms are nonfermentative, thus the metabolic end products produced are probably derived from the fermentation of nitrogenous substrates in the medium. The DNA-base compositions, dehydrogenase enzymes pattern, cellular fatty acid composition and major menaquinones of various taxa are given where known (Table 5).

Outlook for Biotechnology

Industrially important compounds synthesized by a range of Gram-negative, anaerobic bacteria have not been exploited commercially due to difficulties encountered in genetic manipulation of these organisms, and poor expression of their genes in distantly related cloning systems such as phage lambda in *E. coli* (see Salyers et al., 1987; Shoemaker et al., 1986). *B. fragilis* is clinically the most important member of this large group of microorganisms (Finegold et al., 1985), consequently the physiology and pathogenicity of this species has been widely studied. *B. fragilis* grows on a simple defined medium, has a fast generation time (1–2 h) and several potential cloning vectors have been described. These include bacteriophages (Tartera and Jofre, 1987; Tartera et al., 1989), antibiotic resistant conjugative plasmids (Callihan et al., 1983; Shoemaker et al., 1986), and cosmids which are genetically engineered to promote the expression and transfer of genes to and from members of the Bacteroidaceae (Shoemaker et al., 1986). Thus, the shuttle vector pE5-2 has been used to transfer genes to *P. gingivalis* and *B. intermedius* (Progulske-Fox et al., 1989). It should,

Table 7. Salient features of species currently or formerly referred to as *Bacteroides*.

Species	Features
B. capillosus	NF; AEP trace, A, S; 60 mol% GC
B. cellulosolvens	NF, except for cellobiose and cellulose; 43 mol% GC
B. coagulans	NF; produces indole, gelatin digested; AEP, low levels of A
B. forsythus	NF; α-fucosidase positive, trypsin and β-galactosidase by API ZYME; 44–48 mol% GC
B. galacturonicus	WF; pectin and polygalacturonate fermented to produce F, A, and L; 36 mol% GC
B. gracilis	NF; nitrate reduced to nitrite; AEP, S
B. helcogenes	F; β-hemolysis; AEP, A, S
B. nodosus	NF; highly proteolytic; AEP, low levels of A, P, and S; 45 mol% GC
B. pectinophilus	WF; pectin and polygalacturonate fermented to F, A, and L; D-fructose positive; 45 mol% GC
B. pneumosintes	NF; AEP, low level of A
B. polypragmatus	F; motile; indole produced; trehalose positive; AEP, A
B. putredinis	NF; indole produced, gelatin digested; AEP, iV, S; Phe; 50–52 mol% GC
B. pyogenes	F; growth inhibited on bile; xylan negative; AEP, A, S
B. suis	F; growth inhibited in bile; xylan positive; AEP, A, S
B. tectum	WF; growth on bile; cellobiose positive; APE, A
B. xylanolyticus	WF; pectin and polygalacturonate fermented to F, A, and L; D-fructose positive; 45 mol% GC
Reclassified Species:	
Anaerorhabdus furcosus	NF; some strains, ferments glucose weakly cells may be Y-shaped; AEP, L
Fibrobacter succinogenes	WF; glucose, cellobiose, and lactose weakly fermented; AEP, A, S
Megamonas hypermegas	F; growth in bile, large cells 2 to 3 by 5 to 11 μm; AEP, A, P, L
Mitsuokella multiacidus	F; nitrate reduced to nitrite; AEP, A, L, S
M. dentalis	NF; AEP, A, S
Rikenella microfusus	WF; spindle-shaped cells; growth in bile; AEP, A, S
Ruminobacter amylophilus	F; ferments carbohydrate polymers such as starch (few monomers); AEP, F, A, S
Sebaldella termiditis	F; ferments xylose but not arabinose; AEP, F, A, L
Tissierella praeacuta	NF; cells motile, peritrichous flagella; gelatin weakly digested; AEP, A, B, iV
B. ureolyticus	NF; nitrate reduced; urease produced; AEP, A, S

F, fermentative; WF, weakly fermentative; NF, nonfermentative; AEP, acid end product; A, acetic; B, butyric; F, formic; iV, isovaleric; L, lactic; Phe, phenylacetic acid; S, succinic acid.

therefore, be possible to clone such genes as the elastase of *B. coagulans* or *B. nodosus* or the fibrinolysin of *B. putredinis* for clinical use, utilizing *B. fragilis* to obtain high expression of these enzymes.

Unlike the above species, genetic transfer and expression has been achieved between *B. nodosus* and the phylogenetically unrelated species *Psuedomonas aeruginosa* for the development of a pili-based *B. nodosus* vaccine (Stewart and Elleman, 1987). This approach offers a means of large-scale production of pili thus avoiding problems associated with culturing the fastidious anaerobic parent organism, *B. nodosus.*

Many of the species isolated from the rumen of sheep have important industrial properties (Bryant and Robinson, 1962; Hentges and Smith, 1985). Thus, *Fibrobacter succinogenes* or *B. cellulosolvens* may find application for the anaerobic digestion of cellulose. Recently, the cellodextrinase gene from *F. succinogenes* has been cloned in *E. coli* (Gong et al., 1989). *B. ruminicola* subspecies *ruminicola* and *B. xylanolyticus* may find useful application in the degradation of xylan while other plant macromolecules such as pectin could be fermented by *B. pectinophilus* and *B. ruminicola* subspecies *ruminicola.* The pigmented species, particularly *B. melaninogenicus, B. loescheii,* and *B. denticola* produce significant levels of protoporphyrin (see Chapter 197) from the demetallation of protoheme (Shah et al., 1979). Porphyrins are both difficult and expensive to synthesize but have important uses in biomedicine. These organisms could, therefore, be used directly to produce such compounds, or their genes could be inserted either into *B. fragilis* and then into *E. coli* to circumvent the difficulties encountered in large-scale production with anaerobic bacteria.

CHAPTER 197

The Genus *Porphyromonas*

HAROUN N. SHAH

History

Black-pigmented bacteria resembling bacteroides were first reported by Oliver and Wherry (1921). The distinctive pigment produced on blood agar was considered to be melanin and consequently the organism was called *Bacteroides melaninogenicum*. Because of its requirement for X and V growth factors, the species was described as *Haemophilus melaninogenicus* in the third edition of *Bergey's Manual of Determinative Bacteriology* (Bergey et al., 1930). However, in the fifth edition of *Bergey's Manual* (Roy and Kelly, 1939), the generic name *Bacteroides* was adopted, as suggested by Castellani and Chalmers (1919), and *H. melaninogenicus* was reclassified as *Bacteroides melaninogenicus* (Roy and Kelly, 1939).

Prevot (1938), however, considered the genus name invalid and used the generic name *Ristella;* hence *B. melaninogenicus* is often referred to in earlier literature as *Ristella melaninogenica.* Schwabacher et al. (1947) reported that the black pigment produced by this species was incorrectly identified as melanin and suggested that the specific epithet be altered to *B. nigrescens.* Wilson and Miles (1945) considered these organisms as belonging to the group *Fusiformis* and adopted the name *Fusiformis nigrescens* for the pigmented species. Subsequently, the generic name *Bacteroides* took precedence in the seventh edition of *Bergey's Manual* (Kelly, 1957).

Despite its biochemical heterogeneity (see, for example, Courant and Gibbons, 1967; Sawyer et al., 1962), it was suggested that *B. melaninogenicus* be retained as a single species with both nonfermentative and saccharolytic strains. In the eighth edition of *Bergey's Manual* (Holdeman and Moore, 1974), *B. melaninogenicus* was therefore regarded as a single species, with three subspecies based on saccharolytic potential and types of metabolic end products. Thus, saccharolytic strains were assigned to *B. melaninogenicus* subspecies *melaninogenicus,* moderately saccharolytic strains to *B. melaninogenicus* subspecies *intermedius,* and nonfermentative strains to *B. melaninogenicus* subspecies *asaccharolyticus.*

Heterogeneity within *B. melaninogenicus* subspecies *asaccharolyticus* was first demonstrated by electrophoretic mobility patterns of malate dehydrogenase (MDH) and differences in DNA base compositions (Shah et al., 1976). Strains with the slower MDH mobility and lower GC content were of oral origin whereas strains with the faster MDH mobility and higher GC content were isolated from nonoral sites. Studies of the same strains by polypeptide patterns by SDS gel electrophoresis revealed two distinct profiles (Swindlehurst et al., 1977), one with major bands in the low molecular weight region (the slow MDH, low GC group) while isolates of the other group possessed a more evenly dispersed polypeptide pattern (the fast MDH, high GC group). As a result, strains of the latter group of *B. melaninogenicus* subspecies *asaccharolyticus* were then elevated to species rank by the ICSB Taxonomic Subcommittee as *B. asaccharolyticus* (Finegold and Barnes, 1977). Genetic heterogeneity between this group of isolates was confirmed (Shah and Hardie, 1979) and oral strains were reclassified in a new species, *B. gingivalis* (Coykendall et al., 1980). Studies of their cellular fatty acids (Shah and Collins, 1980; Mayberry et al., 1982), menaquinone composition (Shah and Collins, 1980), and DNA-DNA hybridization (Shah and Collins, 1983; van Steenbergen et al., 1982) further supported the placement of these organisms into separate species.

Studies of the asaccharolytic, pigmented oral isolates from endodontal infections and infected root canals with periapical destruction (Sundqvist, 1976) led to the recognition of another genetically distinct species, *B. endodontalis* (van Steenbergen et al., 1984), and the tentative proposal of *B. dentalis* (Haapasalo et al., 1984). Both taxa appeared to be synonymous and the validly published *B. endodontalis* took precedence. The asaccharolytic, pigmented species *B. asaccharolyticus, B. gingivalis.* and *B.*

endodontalis form a biochemically and/or chemically coherent group of species quite distinct from other pigmented bacteroides or the type species of the genus, *B. fragilis.* Ribosomal RNA homology (Johnson and Harich, 1986) and 16S rRNA cataloging (Paster and Dewhirst, 1988) data have confirmed the distinctiveness of these asaccharolytic taxa, for which the genus *Porphyromonas* has now been proposed (Shah and Collins, 1988). Major contributions that led to the establishment of this genus are shown in Table 1.

General Characteristics

Members of the genus *Porphyromonas* are characterized by the production of porphyrin pigments (Shah et al., 1979). The dark brown/black pigment, originally thought to be melanin, has been identified as protoheme and the light brown, UV-fluorescent compound as protoporphyrin (Shah et al., 1979). These pigments are produced on blood agar plates from 3–10 days after subculture. Extracted as their dimethyl esters, the electronic spectrum of the brown/black protoheme dimethyl ester shows a major band (Soret) at 385 nm with additional maxima at 512, 541, and 643 nm (Fig. 1). By contrast, the UV-fluorescent, protoporphyrin dimethyl ester has its Soret band at 407 nm and additional maxima at 505, 541, 575, and 629 nm (Shah et al., 1979; Fig. 1).

Growth in a liquid medium is confluent with cells being typically coccobacilli to rods (0.4–0.8 by 1.0–3.5 μm. All members of the genus produce indole or catalase and do not hydrolyze esculin or starch (Holdeman et al., 1984). The three species are nonfermentatitive and utilize nitrogenous substrates such as trypticase or proteose peptone as energy sources (Shah and Williams, 1987a). Members of the genus produce a complex mixture of acidic end products, with butyric acid being particularly distinctive (Holdeman et al., 1984). Unlike other pigmented species or members of the genus *Bacteroides,* which contain predominantly 12-methyl-tetradecanoic acid (*anteiso*-$C_{15:0}$) as their long-chain fatty acid, *Porphyromonas* species possess mainly 13-methyl-tetradecanoic acid (iso-$C_{15:0}$) (Shah and Collins, 1980). The latter taxa also contain MDH and glutamate dehydrogenase (GDH) but differ from *Bacteroides* sensu stricto in lacking enzymes of the hexose monophosphate shunt/pentose phosphate pathway (i.e., glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase) (Shah and Williams, 1982). The peptidoglycan of all strains so far examined lacked diaminopimelic acid. The electron transport system comprises mainly cytochrome b while menaquinones are the sole respiratory quinones present. Members of the genus *Porphyromonas* possess a GC content of DNA within the range 46–54 mol%.

Habitats

Although studies of the habitat of *Porphyromonas* species are still inconclusive, current evidence indicates that these species colonize different sites in the body. The type species *P. asaccharolytica* can be isolated from a wide range of nonoral sites such as the cervix, ear, intestine, genitalia, and from a variety of infections (Dowell and Lombard, 1981; Finegold et al., 1985). Strains have been isolated from blood, amniotic fluid, umbilical cord, empyema, peritoneal and pelvic abscesses, endometritis, and wound infections (Duerden, 1980a, 1980b; Goldstein et al., 1984; Lambe, 1974; Slots and Genco, 1979). There are only very limited reports of *P. asaccharolytica* strains from the oral cavity (Mayrand et al., 1984; Shah et al., 1976). *P. gingivalis* appears to colonize solely subgingival sites of the oral cavity but has also been recovered from the tongue, tonsils, saliva, and rarely from supragingival dental plaque (Shah et al., 1976; van Winklehoff et al., 1988). *P. gingivalis* was shown to constitute less than 5% of the cultivable subgingival flora of individuals with gingivitis (Slots, 1982; Slots et al., 1978; White and Mayrand, 1981; Zambon et al., 1981) but its numbers can increase dramatically in advanced periodontitis (Duerden, 1980b; Newman, 1979; Speigel et al., 1979; Tanner et al., 1979; White and Mayrand, 1981). It is therefore widely accepted that *P. gingivalis* is present below detectable levels in periodontally healthy sites but that their numbers reach measurable levels with disease development. *P. endodontalis* appears to colonize an even more restricted niche than the two other species. Although it has been isolated from mixed oral infections, it is mainly recovered from infections of endodontal origin (Duerden, 1980b; van Winklehoff et al., 1988) and has been reported widely from root canal infections (Haapasalo, 1986). Since both *P. gingivalis* and *P. endodontalis* are recovered almost exclusively from diseased sites, its primary source of infection remains unknown. These organisms are not present in the healthy oral cavity before development of permanent teeth (Slots, 1982) but may become important with the onset of periodontitis. Phenotypically related species have been reported from a wide range of animals,

Table 1. Major contributions that led to the proposal of the separation of the genus *Porphyromonas* from "*Bacteroides*" *melaninogenicus* subspecies "*asaccharolyticus*."

MDH, malate dehydrogenase; iso-$C_{15:0}$, 13-methyl-tetradecanoic acid; MK-9 and MK-10, menaquinones with nine (MK-9) or 10 (MK-10) isoprene units.

such as cats, monkeys, jaguars, horses, pigs, guinea pigs, and herbivors, but the genetic relatedness of these microorganisms is still unknown. Among these animal isolates, several genotypes and phenotypes have been reported (Laliberté and Mayrand, 1983; Love et al., 1984). Further studies are therefore necessary to ascertain whether at least the "oral" human species are indigenous or exogenous to the oral cavity.

Isolation

Growth on Solid Media

Porphyromonas species can be isolated and maintained on blood agar base with 5% (wt/vol) horse or defibrinated sheep's blood. Neither of its normal cofactors, hemin or menadione, are required if the blood agar plates are freshly made or stored at 4°C for less than 1 week. Other media such as modified Brucella agar or Wilkens-Chalgren agar are commonly used. Prior to 1976, vancomycin-kanamycin blood agar plates (7.5 μg/ml) were routinely used for primary isolation of these organisms from dental plaque. Studies in our laboratory first showed that vancomycin inhibited the growth of the saccharolytic strains whereas colistin (10 μg/ml) inhibited the growth of the saccharolytic taxa such as *B. melaninogenicus* and *B. intermedius* (Shah et al., 1976). In subsequent studies, vancomycin was therefore excluded and colistin (10 μg/ml) was added to

blood agar plates. Other workers have confirmed the inhibitory effects of vancomycin on the growth of these organisms (van Winklehoff and de Graaff, 1983) and a selective medium containing colistin, bacitracin, and nalidixic acid has been reported for *P. gingivalis* (Hunt et al, 1986). The composition of some of these media are as follows:

Modified Brucella Agar

Brucella agar (BBL/Difco)	4.3 gm
Hemin solution (5 mg/ml)	0.1 ml
Vitamin K solution (10 mg/ml)	0.1 ml
Distilled water	100 ml

The medium is autoclaved at 121°C for 15 min and 5 ml of sterile defibrinated sheep's blood is added aseptically.

Wilkins-Chalgren Agar

Trypticase	1.0 g
Gelatin peptone	1.0 g
Yeast extract	0.5 g
Dextrose	0.1 g
NaCl	0.5 g
L-Arginine-free base	0.1 g
Sodium pyruvate	0.1 g
Vitamin K	0.05 mg
Hemin	0.5 mg
Agar	1.5 g
Distilled water	100.0 ml

The medium is autoclaved at 121°C for 15 min.

Selective Medium for *P. gingivalis* (Hunt et al., 1986)

Columbia agar base	42.5 g
Agar (BBL)	6.5 g
Colistin sulfate	10.0 mg
Demineralized water	1,000 ml
Heat to dissolve agar, then add	1.0 ml
Hemin-nalidixic acid (prepared by dissolving 5.0-mg hemin and 15.0 mg of nalidixic acid in 5 ml 1 N NaOH)	
Vitamin K, (1% (wt/vol) in alcohol)	10.0 mg

The pH is adjusted to 7.3, and the medium is autoclaved at 121°C for 15 min. The medium is cooled to 50°C, and 50 ml of defibrinated sheep blood and filter-sterlized bacitracin solution (1 μg/ml final concentration) is added aseptically and dispensed as required.

Growth in Liquid Media

Nutritional studies have shown that *Porphyromonas* species require nitrogenous substrates as a source of energy (Shah and Williams, 1987a). Peptides are the preferred energy source but limited growth is possible on amino-acid-containing media, such as casamino acids or a defined medium (Shah and Williams, 1987a, 1987b; Seddon et al., 1988). Unlike some *Bacteroides* species that colonize the rumen, *Porphyromonas* species cannot replace its nitrogen requirement with ammonia (H. N. Shah, unpublished observations). Thus, all media reported to date contain a commercial source of peptides such as trypticase, proteose peptone, yeast extract, or tryptone at approximately 1% (wt/vol). Glucose is not catabolized, but up to 50% of it can be utilized by some species as a source of carbon. Cysteine is used both as a reducing agent and as a growth requirement. Heme (for cytochrome production) replaces the need for whole blood while vitamin K is added as a precursor for menaquinone biosynthesis (Shah and Collins, 1980). Some of the commonly employed growth media include BM (Shah et al., 1976), tryptone-yeast extract broth (TYB), and proteose peptone-yeast extract glucose broth (PYG) (Holdeman and Moore, 1970). The composition of some of these media are given below.

BM Medium (Shah et al., 1976)

Trypticase	1.0 g
Proteose peptone	1.0 g
Yeast extract	0.5 g
NaCl	0.5 g
Glucose	0.5 g
Cysteine hydrochloride	0.075 g
Distilled water	100.0 ml

The medium is cooled and a solution of 1% (vol/vol) filter sterilized hemin-menadione solution is added.

Hemin-menadione solution: Hemin solution is first prepared by adding 1 ml of 1 N NaOH to 50 mg of crystalline heme, followed by 98 ml of water. To this add 1 ml of menadione solution (5 mg/ml in 95% ethanol) and filter-sterilized and store the mixture at −20°C. The hemin—menadione solution is added aseptically at 1% (vol/vol) to sterilized media.

Tryptone-Yeast Extract Broth

Tryptone	1.0 g
Yeast extract	0.5 g
Cysteine hydrochloride	0.05 g
Hemin	0.5 mg
Vitamin K	0.05 mg
Distilled water	100.0 ml

The medium is adjusted to pH 7.2 and autoclaved at 121°C for 15 min. Bovine serum (2.0 ml) is added aseptically after the medium has cooled.

A chemically defined medium for *P. gingivalis* has been described (Seddon et al., 1988). This medium yields poor growth but may be used as a basal medium for physiological studies. Minimal media can be formulated from it

by the addition of protein hydrolysates (Seddon et al., 1988). The composition is as follows.

Synthetic Medium

Aspartic acid	100 mg
Glutamic acid	100 mg/l
Phenylalanine	100 mg/l
Alanine	100 mg/l
$MgSO_4 \cdot 7H_2O_4$	700 mg/l
KH_2PO_4	200 mg/l
KH_2PO_4	1000 mg/l
$CaCl_2$	100 mg/l
NaCl	100 mg/l
L-Cysteine hydrochloride	75 mg/l
Hemin	5 mg/l
Menadione	0.5 mg/l

The pH of the medium is adjusted to 7.4 and is autoclaved at 121°C for 15 min.

Identification

The genus *Porphyromonas* belongs to the family Bacteroidaceae; a large family of Gram-negative, obligately anaerobic, nonsporing, nonmotile rods. In the current edition of *Bergey's Manual of Systematic Bacteriology* (Holdeman et al., 1984), three genera, *Bacteroides, Fusobacterium*, and *Leptotrichia*, are described on the basis of their characteristic metabolic end-product profile. Thus, *Fusobacterium* produces mainly butyric and acetic acids, *Leptotrichia* produces lactic acid, while strains that possess neither profile are assigned to the genus *Bacteroides*. Work throughout the 1980s has shown that the genus *Bacteroides* (Shah and Collins, 1983; Collins and Shah, 1987) contains an extremely heterogenous collection of species that differ significantly in cellular morphologies and are biohemically and physiologically very diverse. The host specificity of these species and their pathogenic potential vary considerably and this diversity is reflected in the wide range in GC content of the DNA approximately 28–61 mol%). The type species of *Bacteroides, B. fragilis* (42 mol% GC), differs from *Porphyromonas* species (46–54 mol% GC) in DNA base composition and in major metabolic properties (Table 2).

Porphyromonas species can be readily distinguished from other members of the family Bacteroidaceae by the distinctive black, pigmented colonies on blood agar plates after 2–5 days growth. In contrast to the pigmented saccharolytic species such as *Bacteroides intermedius, B. denticola*, or *B. melaninogenicus, Porphyromonas* species form smooth, slightly mucoid, wet, shiny, convex colonies, 1–3 mm in diameter, that darken progressively from the edge of the colony towards the center after 6–10 days incubation. Eventually the whole colony becomes black due to protoheme production. Growth in liquid media is not significantly affected by the addition of carbohydrates and the terminal pH remains near neutral irrespective of its presence. Protein hydrolysates such as proteose peptone, trypticase, or yeast extract markedly enhance growth. The optimum temperature for growth is 37°C. The major metabolic end products from BM or PYG medium are acetic and butyric acids, together with lower levels of propionic, isobutyric, and isovaleric acids (Table 2).

Malate dehydrogenase and glutamate dehydrogenase are present whereas glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase are absent (Table 2). Proteinases are produced but the range of substrates hydrolyzed varies. Amino acids, such as aspartate and asparagine, are fermented but these species generally possess only a limited ability to ferment amino acids. Indole is produced but nitrate is not reduced to nitrite nor is starch or esculin hydrolyzed.

Studies by Caroff et al. (1987), Johne et al. (1988), Kumada et al. (1988), and Brondz et al. (1989) have demonstrated the presence of 3-deoxy-D-manno-2-octulosonic acid (KDO) (previously believed to be absent) in the lipopolysaccharide of *Porphyromonas*. The peptidoglycan does not contain diaminopimelic acid as the diamino acid. The principal respiratory quinones are unsaturated menaquinones with 9 or 10 isoprene units. Both nonhydroxylated and 3-hydroxylated long-chain fatty acids are present. The nonhydroxylated fatty acids are composed of predominantly isomethyl branched types (iso-$C_{15:0}$) and lower levels of straight-chain saturated acids. The 3-hydroxylated fatty acids are the straight-chain saturated types. The GC content of the DNA ranges from 46–54 mol%. Characteristics that may be useful in distinguishing *Porphyromonas* from other commonly occuring genera of the Bacteroidaceae are shown in Table 2.

Differentiation of *Porphyromonas* Species

Though DNA-DNA hybridization clearly separates the three species of *Porphyromonas*, physiological tests for distinguishing these species are still limited. Phenotypically related taxa such as *Bacteroides levii* and *B. macacae* can be separated from these species by their ability to weakly ferment glucose, lactose, and/or mannose (Holdeman et al., 1984). *B. salivosus*, a

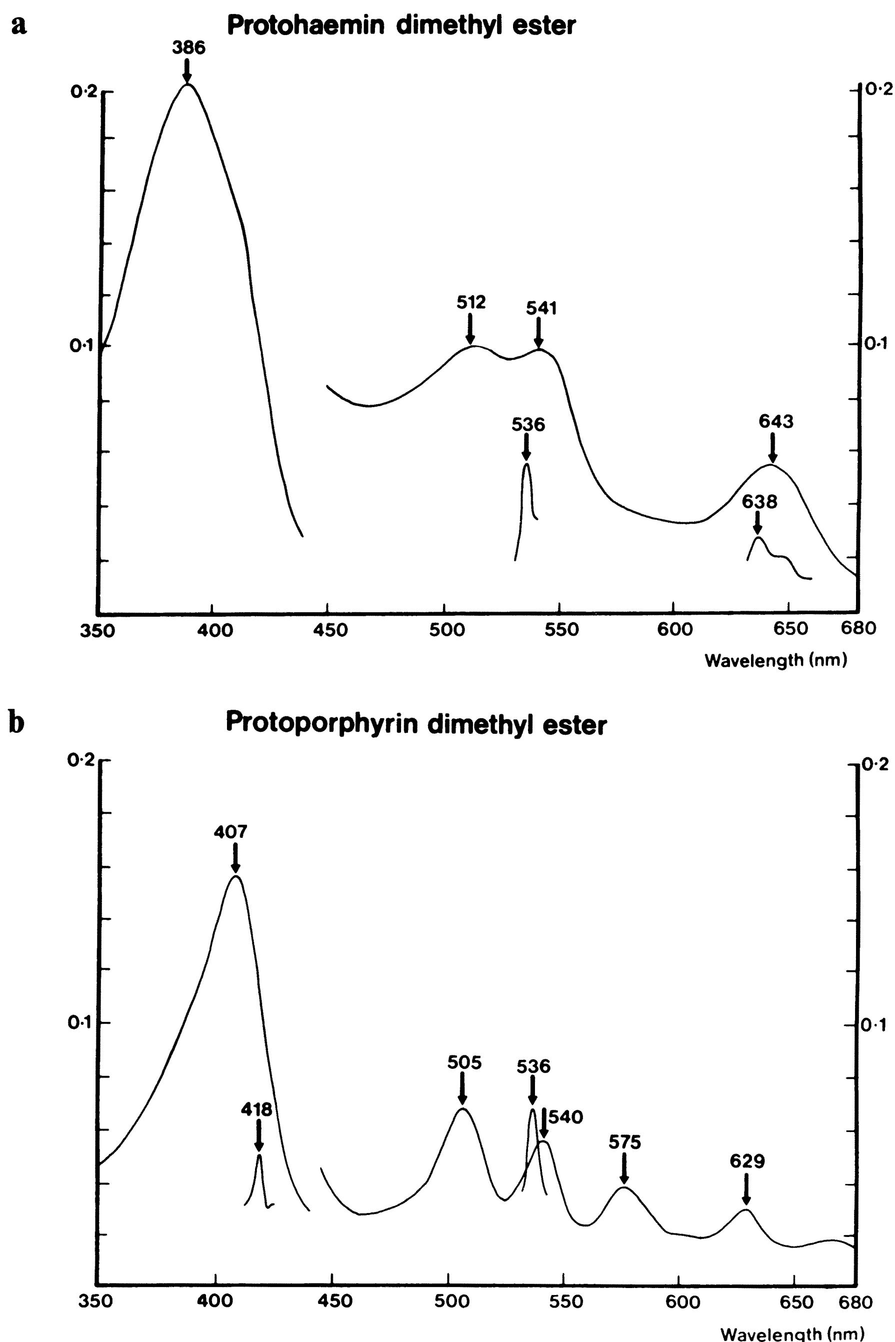

Fig. 1. Absorption spectra of *Porphyromonas* pigments (a) protohaemin dimethyl ester and (b) protoporphyrin dimethyl ester. Calibrations at 418, 536 and 638 nm were done with holmium glass.

phenotypically similar species isolated from cats (Love et al., 1987) resembles *P. gingivalis* in producing phenylacetic acid and has hydrolytic activity to α-*N*-benzoyl-L-arginine-4-nitroanalide (L-BAPNA) but differs by its low GC content (42–44 mol%) and its inability to agglutinate sheep erthrocytes. Most strains of *P. asacharolytica* so far tested possess α-fucosidase activity, thus distinguishing them from *P. gingivalis* and *P. endodontalis*. *P. gingivalis* strains are characterized by the presence of menaquinones with nine isoprene units whereas *P. asaccharolytica* possesses menaquinones with 10 isoprene units. The polyprenyl side chain of *P. endodontalis* is not yet known. The electrophoretic mobility of MDH and differences in DNA base compositions (Table 3) further differentiates the three species of *Porphyromonas*.

Table 2. Differentiation of *Porphyromonas* from *Bacteroides* and other related taxa.

Genus	Metabolism[a]	Indole production	Major metabolic end products from glucose broth[b]	Major long-chain fatty acids	Dehydrogenases present[c]				GC content (mol%)
					MDH	GDH	G6PDH	6PGDH

[b]Menaquinone present but number of isoprene units not determined.

Clinical Importance and Outlook for Biotechnology

Members of the genus *Porphyromonas* have been isolated from a wide range of infectious sites (see reviews, Moore, 1987; van Winklehoff et al., 1988). In general, animal model experiments have shown that *P. gingivalis* produces spreading lesions that nearly always result in death of the animal whereas *P. asaccharolytica* and *P. endodontalis* lesions are localized and do not cause death (see review, Mayrand and Holt, 1988). Most studies relating to virulence and pathogenicity of these species have therefore focused on *P. gingivalis* partly for these reasons and partly because of its clearer association with disease. However, despite extensive investigations throughout the 1980s, the pathogenic mechanisms involved in the initiation and development of periodontal disease, for example, are still not fully understood. Current evidence indicates that virulence is multifactorial and a broad approach to the study of this subject is necessary to elucidate the underlying mechanisms involved in periodontal disease development. Contributions have therefore come from a wide range of disciplines and a number of interesting functions have been identified (reviewed by Mayrand and Holt, 1988).

Putative virulence factors so far proposed include surface components such as fimbriae, surface receptors (e.g., hemagglutinins), capsular material, membrane vesicles/blebs, and lipopolysaccharide, in addition to a wide spectrum of both extracellular and intracellular tissue-degrading enzymes such as collagenases, proteinases, glycosaminoglycan-depolymerizing enzymes, heparinases, and nucleases (see Mayrand and Holt, 1988). Capsular material and culture supernatants of *P. gingivalis* have been shown to decrease the chemotactic response of polymorphonuclear leukocytes. Resistance to phagocytosis is strongly associated with the presence of a capsule (Okuda and Takazoe, 1973, 1988; Okuda et al., 1987) and encapsulated strains were shown to remain viable during abscess formation (Takazoe et al., 1971). Mutants that lack a capsule are rapidly phagocytosed but such mutants are pleiotrophic, being deficient in several other properties (Shah et al., 1989). Differences, however, occur in chemical composition and antigenicity of *P. gingivalis* capsules and further studies are required to demonstrate a clearer association (Okuda and Takazoe, 1988). About 50% of *P. gingivalis* strains possess fimbriae but differences in antigenic specificity occurs (Suzuki et al., 1988). Unlike many bacterial species, these structures are not associated with hemagglutinating activity but appear to function in attachment to both host and bacterial cells (Grenier and Mayrand, 1987). Fimbriae were recently shown to bind specifically to gingival fibroblasts resulting in subsequent stimulation of thymocyte activating factor, which in turn stimulated mytogen-induced thymocyte proliferation (Hanazawa et al., 1988).

Unlike that of many Gram-negative bacteria, the lipopolysaccharide of *P. gingivalis* has been shown to possess relatively low toxicity (Koga et al., 1985). Initially this was considered to be due to the absence of KDO and other core sugars but is now attributed to the lack of phosphorylation in the lipid A backbone of the molecule (Johne et al., 1988). Both *P. gingivalis* and *P. endodontalis* possess vesicles (Shah et al., 1976; Haapasalo et al., 1984; Grenier and Mayrand, 1987). Their small size (approximately 50–150 nm) allows them to cross epithelial barriers, which cannot be penetrated by whole cells. They promote bacterial attachment between homologous cells and can mediate attachment between species that do not normally aggregate (Grenier and Mayrand, 1987). Vesicles possess

many of the properties of the parent cell, such as proteinase and collagenase activities or hemagglutination, and it is now widely believed that they deliver potent hydrolytic enzymes into subgingival sites, with the potential to cause tissue damage. Furthermore, vesicle-bound enzymes may function to release peptides (from host tissue and secretions) to support the nutritional requirements of these species in vivo.

It is therefore evident that due to the multifactorial nature of virulence of this species, molecular genetic techniques must be used to investigate the role of each putitive virulence factor separately to enable assessment of their relative contribution. Such studies are now being undertaken in several laboratories.

The biotechnological potential of *Porphyromonas* species is probably limited to *P. gingivalis* because of its wide spectrum of hydrolytic enzymes. However, all species utilize protoheme and under certain conditions are able to demetallate it to produce protoporphyrin (Shah et al., 1979, Fig. 2). Porphyrin compounds have

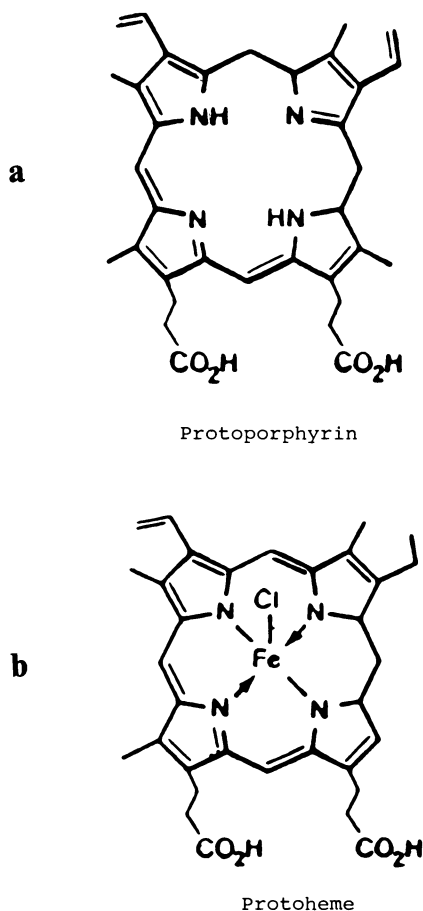

Fig. 2. Major porphyrins produced by *Porphyromonas* species (a) protoporphyrin and (b) protoheme.

wide application in biomedicine but are expensive to synthesize chemically. The potential therefore exists to utilize these organisms for the production of porphyrins to which various residues could be chemically attached.

Although the hydrolytic enzyme activity of *P. gingivalis* is now well documented, the useful biotechnological features of these enzymes are not yet fully realized. The proteinases comprise several types, of which the cysteine proteinase has now been characterized (Shah et al., 1990). Others such as the serine proteinase, the glycylprolyl peptidase, glycosaminoglycan-depolymerizing enzymes, and nucleases, have been purified but await detailed characterization before they can be commercially exploited. For example, it may be possible to treat septic thrombophlebitis (in which heparin, a naturally occurring acidic mucopolysaccharide inhibits the clotting of blood) with the heparinase of *P. gingivalis.* Several such examples exist where the hydrolytic enzymes of *P. gingivalis* may find biomedical applications. However, before this can be achieved, an understanding of the regulation and expression both in the host and in genetic vectors need investigation. Such studies on the thiol proteinase of *P. gingivalis* are in progress (Roberts et al., 1990). Recently the hemagglutinin of *P. gingivalis* has been successfully cloned into *Escherichia coli* (Progulske-Fox et al., 1989a, 1989b). This study represents the first successful transfer of *P. gingivalis* genes into a vector, and thus opens the field to further genetic manipulation of specific macromolecules.

CHAPTER 198

The Genera *Flavobacterium, Sphingobacterium,* and *Weeksella*

BARRY HOLMES

The name *Flavobacterium* was proposed in 1923 for a genus of the family Bacteriaceae, encompassing the rod-shaped, nonendosporeforming, chemoorganotrophic bacteria (Bergey et al., 1923). Most of the pigmented bacteria of the family were segregated in the tribe Chromobactereae, which contained four genera of aerobic bacteria separated from each other by differences in color. These genera were *Chromobacterium, Flavobacterium, Pseudomonas,* and *Serratia,* for the purple, yellow, green fluorescent, and red strains, respectively. This emphasis on pigmentation (a character shared by genetically diverse bacteria [Weeks, 1969]) for taxonomic assignment to *Flavobacterium* has given the genus a dubious reputation in the past (McMeekin et al., 1972; Weeks, 1969), and as a consequence the genus has served too frequently as a repository for pigmented bacteria that possess the general attributes of *Flavobacterium* but had not been subjected to detailed classification studies. Taxonomic heterogeneity and general uncertainty have characterized *Flavobacterium* from its inception, and its history is a record of proposals to achieve credibility for the genus.

Stanier (1947) recognized that the cytophagas have more than a casual phenetic resemblance to pigmented, Gram-negative eubacteria such as *Flavobacterium* and the relationship to the cytophagas has dominated the taxonomic consideration of *Flavobacterium.* Differentiation of flavobacteria from cytophagas has depended primarily upon demonstration of the gliding movement and colonial translocation characteristic of the latter bacteria, but absence of these features has not deterred assignment of flavobacterial species to *Cytophaga* (Mitchell et al., 1969). Freshly isolated cytophagas have the unusual ability to use a great variety of complex natural polymers, e.g., agar, alginates, cell walls, cellulose, chitin, DNA, keratins, lipids, pectin, porphyrins, proteins, RNA, and starch, as nutrients. This ability is not a general property of flavobacterial species, although strains of some species may hydrolyze casein, chitin, gelatin, or starch.

The problem of differentiating *Flavobacterium* from *Cytophaga* has been discussed extensively (Christensen, 1977a; McMeekin et al., 1972; Mitchell et al., 1969; Weeks, 1969). An outcome would be more nearly possible if two issues were resolved. These are the heterogeneity of *Flavobacterium* and the differentiation of nonmotile flavobacteria from cytophagas. A primary requirement for the resolution of both issues is an acceptable definition of *Flavobacterium.* The concept of *Flavobacterium* was hardly altered in successive editions of *Bergey's Manual of Determinative Bacteriology* until the fifth (Bergey et al., 1939), which eliminated from the genus the least well-described species and the polarly flagellated strains. Those known to be Gram-positive were excluded in the seventh edition (Weeks and Breed, 1957). In the eight edition (Weeks, 1974) the genus remained heterogeneous, as evidenced by the two disparate reported ranges of GC content of the DNA: 30–42 and 63–70 mol%. Only in *Bergey's Manual of Systematic Bacteriology* (Holmes et al., 1984a) did the genus at last become reasonably homogeneous by including only nonmotile low GC strains. Interspecies DNA-DNA hybridization studies of the latter organisms showed a background level of hybridization of about 20%, which may represent a common DNA complement (Callies and Mannheim, 1980; Owen and Holmes, 1981).

Despite sharing several features, the low GC flavobacteria nevertheless show some heterogeneity and fall into four natural groups (A–D, Table 1), as previously suggested by Holmes and Owen (1981). The strains of group D, so far found only on mammalian mucus membranes, are susceptible to penicillin and are nonpigmented; they now comprise the genus *Weeksella.* Strains of the remaining groups are free-living, show resistance to a wide range of antimicrobial agents and are yellow-pigmented (Table 1). These organisms constitute the genus *Flavobacterium* and they can be divided into

Table 1. Differentiation of the flavobacteria.

Character	Habitat	Resistant to antimicrobial agents	Yellow pigment	Indole production	Oxidation of carbohydrates	Proteolytic activity
Group A: *Flavobacterium balustinum, F. breve, Flavobacterium* species group IIb *(F. gleum, F. indologenes), F. indoltheticum, F. meningosepticum*	Free-living	+	+	+	+	+
Group B: *Flavobacterium odoratum*	Free-living	+	+	−	−	+
Group C:[a] *Flavobacterium mizutaii, F. multivorum, F. spiritivorum, F. thalpophilum, F. yabuuchiae*	Free-living	+	+	−	+	−
Group D: *Weeksella virosa, W. zoohelcum*	Strict saprophyte	−	−	+	−	+

+, character present; −, character absent.

[a]Yabuuchi et al. (1983) have proposed that *F. mizutaii, F. multivorum,* and *F. spiritivorum* should be placed in a separate genus *Sphingobacterium.*

groups A–C on the basis of differences in indole production, oxidation of carbohydrates, and proteolytic activity (Table 1). A detailed taxonomic study of these organisms by techniques such as DNA-rRNA hybridization is necessary to determine their phylogenetic relationships and therefore whether they all belong in the same genus. Pending such a study, it seems undesirable to divide the genus further or to admit to it taxa of uncertain affiliation, otherwise the genus is in danger once more of becoming heterogeneous. The limited data available from DNA-rRNA hybridizations (Bauwens and De Ley, 1981) indicate that *F. breve, F. meningosepticum,* and *F. odoratum* may not be closely related, and that *F. aquatile,* the type species of the genus (and itself represented by a single strain), is not closely related to the above three species. For other reasons, *F. aquatile* had been considered unrepresentative of the genus. Consequently, Holmes and Owen (1979) requested that *F. breve* be made the type species instead. Their request was subsequently denied, and thus if the genus is further subdivided in the future the name *Flavobacterium* will remain with *F. aquatile* and the majority of organisms currently recognized as *Flavobacterium* will be transferred to one or more new genera. For the above reasons, *F. aquatile* is not considered in the tables in this paper (its characters are given by Holmes et al., 1984a). Perhaps prematurely, the genus *Sphingobacterium* has been proposed by Yabuuchi et al. (1983) for organisms in group C (Table 1) based on the fact that most of these organisms have been shown to possess novel sphingolipids in their cell walls. As this character is not easily determined routinely, and pending further study and possible revision of the genus as a whole, the group C strains are here retained in *Flavobacterium.* (Although all strains in group C have valid combinations of their specific epithets with *Flavobacterium,* there has as yet been no proposal to transfer *F. thalpophilum* or *F. yabuuchiae* to *Sphingobacterium.)*

With *Flavobacterium* better defined, it is now possible to reassess the differentiation of this genus from *Cytophaga.* It has been suggested that organisms of both these genera, which share a distinctive cellular fatty acid composition, a characteristic menaquinone system, and a low GC content, should all be included in *Cytophaga* (Oyaizu and Komagata, 1981). However, this view does not take into account the heterogeneity of the *Flavobacterium-Cytophaga* group as revealed by the preliminary DNA-rRNA hybridization results of Bauwens and De Ley (1981). More recent DNA-DNA hybridization studies (Bernardet, 1989) reveal no appreciable homology between *Cytophaga johnsonae* and *Flavobacterium* species of groups A, B, and C. Oligonucleotide cataloging (Paster et al., 1985) places *C. johnsonae* and *F. aquatile* in the same group while finding that *F. breve* is only peripherally related to the same group. Cataloging also places *Cytophaga* and

Flavobacterium in the same eubacterial "phylum" as *Bacteroides.*

In summary, while *Flavobacterium* is now more homogeneous than it has ever been, further work is necessary to group the species into additional genera so as to reflect their phylogenetic relationships. Among the flavobacteria of clinical origin at least, these generic groupings may well be reflected by the groups A–C as defined in Table 1. While these organisms would appear to be distinct from *Cytophaga,* other flavobacteria, including *F. aquatile,* may be more closely related to *Cytophaga.* The latest arrangement of including the families Bacteroidaceae and Cytophagaceae plus a newly proposed family "Flavobacteriaceae" in the order Cytophagales (Reichenbach, 1989) is a good reflection of our present knowledge of the phylogenetic relationships of these organisms.

Habitats

Yellow-pigmented, nonfermentative, Gram-negative, nonmotile, rod-shaped bacteria, which have been placed in the genus *Flavobacterium* or have been termed flavobacteria, have been isolated from fresh and marine waters, soil and ocean sediments, foods and food-processing plants, and clinical materials. These bacteria are widely distributed in nature and are especially common in water, which would explain their seeming omnipresence.

Nonclinical Sources

Flavobacterial strains have been isolated most commonly from freshwater and marine environments, and many general bacteriological surveys of such habitats have reported their presence (for example, ZoBell and Upham, 1944). The numerical taxonomic studies of Hayes (1963) and of Floodgate and Hayes (1963) used marine strains isolated from fish surfaces, sea water, and marine mud; the samples were taken from the north Atlantic region, western North American coast, and Florida. Comprehensive investigations of dairy and meat-processing industries have shown numerous flavobacteria (McMeekin et al., 1971, 1972; Jooste et al., 1985), including *Weeksella*-like organisms (Botha et al., 1989). The bacteria have also been found in chlorinated cooling water of vegetable canning plants and were the cause of characteristic spoilage following post-sterilization contamination (Bean and Everton, 1969). *F. multivorum* has been isolated from soil (Hayward and Sly, 1984; Pichinoty et al., 1985).

Clinical Sources

Flavobacteria have consistently been found among the nonfermentative, Gram-negative bacteria isolated from clinical specimens such as blood, urine, infected wounds, and feces (Pickett and Manclark, 1970; Pickett and Pedersen, 1970a, 1970b; Tatum et al., 1974). Their frequency of occurrence is usually low, 1% or less, and their pathogenicity is low-grade or doubtful. They are, however, extremely resistant to many antimicrobial agents (and so may well colonize the patient on intensive chemotherapy for an infection caused by some other organism). Such resistant strains are found in each of groups A–C: *F. breve* (Holmes et al., 1978); *F. meningosepticum* (King, 1959); Group IIb of King (Tatum et al., 1974; this taxon includes *F. gleum* [Holmes et al., 1984b] and *F. indologenes* [Yabuuchi et al., 1983]); *F. odoratum* (Holmes et al., 1977, 1979); *F. multivorum* (Holmes et al., 1981); *F. spiritivorum* (Holmes et al., 1982) and *F. thalpophilum* (Holmes et al., 1983).

F. meningosepticum, the best-known pathogen in the genus, is associated with a sometimes fatal meningitis of infants and has been isolated from their throats, spinal fluid, and blood as well as from throats of normal adults (King, 1959; Holmes, 1987). *F. odoratum* has also been a cause of ventriculitis (Macfarlane et al., 1985). Both *F. multivorum* and *F. odoratum* have been reported as a cause of bacteremia (Freney et al., 1987; Potvliege et al., 1984; Prieur et al., 1988), while both *F. odoratum* and *F. thalpophilum* have been described in wound case reports (Davis et al., 1979; Hansen et al., 1988). *Weeksella virosa* appears to be almost exclusively associated with the female genital tract (Holmes et al., 1986a; Reina et al., 1989), and it seems more prevalent in sexually promiscuous women (Mardy and Holmes, 1988). *W. zoohelcum* is commonly found in the canine oral cavity and has been isolated from human dog-bite wounds (Holmes et al., 1986b). However, one strain has been reported as a cause of meningitis in a child following a dog-bite (Bracis et al., 1979) and another as a cause of septicemia (Noell et al., 1989).

Isolation

Nonclinical *Flavobacterium*

Flavobacteria are chemoorganotrophic and not difficult to isolate, although maintenance of the cultures sometimes presents a problem.

General studies do not require enrichment procedures and usually nutrient agar-type media are used. Studies of marine, pigmented bac-

teria, for example, have used seawater-agar media, such as the following:

Marine *Flavobacterium* Medium (Hayes, 1963)

Beef extract (Lab Lemco)	10 g
Peptone (Evans)	10 g
Agar (Difco)	15 g
Aged seawater	750 ml
Distilled water	250 ml

Adjust pH to 7.2–7.3.

Isolation of yellow-pigmented bacteria from food and food-processing equipment used a similar medium:

Food *Flavobacterium* Medium (McMeekin et al., 1971)

Beef extract (Oxoid L20)	10 g
Peptone (Oxoid L37)	10 g
NaCl	5 g
Agar (Oxoid No. 3)	12 g
Distilled water	1 liter

Incubation temperatures were similar to that of the environment, i.e., 20–25°C., and incubation times were about 4 days.

Weeks (1955) used medium M1, which contains lesser amounts of nutrients, for both isolation and maintenance of flavobacterial cultures.

Medium M1 (Weeks, 1955)

Proteose peptone (Difco)	5 g
Yeast extract (Difco)	1 g
Beef extract (Difco)	2 g
NaCl	3 g
Agar	12 g
Distilled water	1 liter

pH 7.2–7.4.

It is not unusual to find that media containing relatively large amounts of the individual nutrients, such as those used by Hayes (1963) and McMeekin et al. (1971), are not as well suited to maintenance of flavobacterial cultures as are media with lower concentrations. A study on maintenance by Christensen and Cook (1972) dealt primarily with the isolation of cytophagas but flavobacteria were included. In general, media such as PMYA II containing small amounts of nutrients were superior.

PMYA II (Christensen and Cook, 1972)

Peptonized milk	1 g
Yeast extract	0.2 g
Sodium acetate	0.02 g
Agar	15 g
Distilled water	1 liter

This medium was excellent for detection of cytophagal gliding and colonial swarming, which is useful in differentiating between flavobacteria and cytophagas.

Flint (1985), when developing a selective agar medium for the enumeration of *Flavobacterium* species in water, found that on nutrient agar alone less than 10% of colonies recovered were yellow-pigmented; however, when a nutrient agar medium containing kanamycin at 50μg/ml was used, this figure increased to 70%.

Clinical *Flavobacterium*

Tatum et al. (1974) have described in detail the procedures for isolation of flavobacteria from clinical sources, such as those of *F. meningosepticum* and Group IIb. Primary plating of a clinical specimen is usually onto blood, chocolate, eosin-methylene blue, or MacConkey agar, but other media may be used. Incubation temperature is 35–37°C, but the bacteria will grow at room temperatures (20–25°C). Other workers have found ordinary nutrient agar quite satisfactory (for example, Holmes et al., 1977, 1978).

Preservation of cultures

Pickett and his colleagues have used cystine-trypticase agar (BBL) for maintenance of cultures of the clinical flavobacteria. Long-term preservation was carried out using brucella broth (BBL) containing 10% glycerol and the cultures were stored at −50°C (Pickett and Pedersen, 1970a). Isolates can also be stored freeze-dried.

Identification

Assignment of a culture to *Flavobacterium* now rests primarily upon the attributes ascribed to the genus (Holmes et al., 1984a). Strains are strictly aerobic, Gram-negative, nonmotile, yellow-pigmented, free-living nonfermenters with low GC content and do not show gliding motility; clinical strains at least are highly resistant to a wide range of antimicrobial agents. Since these features are quite general, the personal judgment of the investigator is a major contribution, especially for the nonclinical strains which have not been studied as thoroughly as clinical strains.

Clinical isolates can usually be identified by assigning them initially to one of the groups A–D on the basis of the characters given in Table 1 and then using the appropriate table for spe-

cies determination. Methods for determining some characters useful in the differentiation of flavobacteria (indole formation, hydrolysis of DNA, starch, and urea, and pigment production) have been compared by Pickett (1989). Just as the flavobacteria may eventually comprise several genera, so new species are set to emerge from the existing recognized species. It is apparent from Tables 2–4 that many species are heterogeneous in phenotypic characters and such is the genomic diversity among the flavobacteria that many recognized species comprise very few known strains. Indeed, several are represented by a single strain.

Among the taxa in group A, *F. balustinum* (from heart blood of fish) and *F. indoltheticum* (from the marine environment) are represented by single strains and extensive DNA-DNA hybridization studies of phenotypically similar strains have ascribed no additional strains to the former and only three to the latter (A. G. Steigerwalt and D. J. Brenner, personal communication). Similar DNA relatedness studies reveal that in *F. breve* there is a "core" of closely related strains with other strains showing lower levels of relatedness to the "core" strains (Owen and Holmes, 1980). Owen and Snell (1976) showed that of the strains representing the then six serovars of *F. meningosepticum,* the type strain of the species, which represented serovar A, showed much lower levels of relatedness to strains of the other serovars (B–F) than did these strains to each other. Work on this species was extended by Ursing and Bruun (1987), who found only three other strains that showed appreciable homology to the type strain; the remaining 48 strains could be divided into four subgroups. Despite the genomic differentiation of these 52 strains into two major groups, no correlation of these groups could be found with

Table 2. Characteristics for practical identification and differentiation of the *Flavobacterium* taxa of group A.

The phenotypic results were derived from previous work at the National Collection of Type Cultures, as follows: *F. balustinum, F. indoltheticum, Flavobacterium* species Group IIb (Holmes, 1983), *F. breve* (Holmes et al., 1978), and *F. meningosepticum* (Holmes, 1987). The GC values were derived as follows: *F. balustinum* and *F. breve* (Owen and Holmes, 1980), *F. meningosepticum* (Owen and Lapage, 1974; Owen and Snell, 1976), *F. indoltheticum* and *Flavobacterium* species group IIb (B. Holmes and R. J. Owen, unpublished observations).

Table 3. Characteristics for practical identification and differentiation of the group C flavobacteria.[a]

Test	*F. mizutaii* (3 strains)	*F. multivorum* (28 strains)	*F. spiritivorum* (11 strains)	*F. thalpophilum* (7 strains)	*F. yabuuchiae* (2 strains)

The phenotypic results and GC values for *W. virosa* were derived from Holmes et al. (1986a) and those for *W. zoohelcum* from Holmes et al. (1986b).

antimicrobial susceptibility (Bruun, 1987), crossed immunoelectrophoresis (Bruun and Høiby, 1987), or phenotypic characters (Bruun and Ursing, 1987). The name *F. indologenes* was proposed for all strains of group IIb (Yabuuchi et al., 1983), despite the fact that it is genomically heterogeneous (Owen and Snell, 1976). The name *F. gleum* was proposed for several group IIb strains that show a high level of DNA-DNA relatedness (Holmes et al., 1984b). More recent DNA-DNA hybridization studies of group IIb strains (A. G. Steigerwalt and D. J. Brenner, personal communication) show that, while several strains display high levels of relatedness to the respective type strains of either *F. gleum* or *F. indologenes,* as many strains again remain to be assigned to one or more genomic groups. Until this problem is further investigated, it would seem prudent to continue referring to the taxon by its original designation of *Flavobacterium* species group IIb.

Group B comprises only *F. odoratum,* easily recognized by its fruity odor (Holmes et al., 1977). Although only ten strains have been studied by DNA-DNA hybridization, there is again genomic heterogeneity in the taxon with the strains falling into three genomic groups (Owen and Holmes, 1978).

With the exception of *F. multivorum,* all the other species in groups C and D have been ex-

amined for DNA-DNA relatedness (*F. mizutaii, F. spiritivorum,* and *F. yabuuchiae* [Holmes et al., 1988]; *F. thalpophilum* [Holmes et al., 1983]; *Weeksella virosa* [Holmes et al., 1986a]; *W. zoohelcum* [Holmes et al., 1986b]). These studies showed that the species were genomically homogeneous except for *F. spiritivorum,* which contained two strains showing high levels of relatedness to each other but lower levels to other strains of *F. spiritivorum;* these two strains now constitute *F. yabuuchiae* (Holmes et al., 1988).

Although there is clear evidence for additional genospecies in *Flavobacterium* (perhaps in *Weeksella* also [Botha et al., 1989]), some of these may not be recognized formally as new species unless phenotypic characters can be found to differentiate them. In addition, there are phenotypically discernible taxa which remain unnamed pending a full taxonomic study. These organisms are groups IIc, IIe, IIh, and IIi; they are all saccharolytic and the last three, at least, are indole producers (Rubin et al., 1985). They may therefore well be additional members of *Flavobacterium* group A, especially as strains of Groups IIe and IIh are known to contain menaquinone 6 and lack sphingolipids (Dees et al., 1986), which would also exclude them from group C (the sphingobacteria). Some differentiation of the flavobacteria can be achieved by gas liquid chromatographic analysis of volatile fatty acids produced in culture (Rasoamananjara et al., 1988). Serology has only been applied to *F. meningosepticum,* where types A–O are recognized; however, strains representing some of these serotypes are biochemically atypical of the species and may be strains of *F. breve* (Holmes et al., 1984a).

Identification of the nonclinical flavobacteria seems to be essentially a matter of deciding whether nonmotile flavobacteria are cytophagas. In this connection, it is a requirement to know whether or not an isolate demonstrates gliding movement and colonial translocation as defined by Henrichsen (1972). It is also necessary to know the DNA base composition and whether the culture can utilize a variety of complex macromolecules in its nutrition. Cultures that display properties of typical cytophagas do not present a problem since these would not be classified as flavobacteria; cultures not having such properties could be considered flavobacteria. Isolates that do not display cytophagal gliding but do demonstrate colonial translocation would not be cytophagas according to Henrichsen (1972). Cultures that are believed to display gliding motion but which do not show colonial translocation probably should not be assigned to the Cytophagaceae. Christensen (1977b) believed that colonial spreading would occur in such cultures if the correct experimental conditions were used.

It has already been stated that *F. aquatile* (from water) is not included in the identification scheme given in this chapter. Also not included are the more recently described species *F. thermophilum* (Loginova and Egorova, 1978) and *F. branchiophila* (Wakabayashi et al., 1989), the latter of which causes bacterial gill disease in freshwater fishes. The former is a thermophile, probably a *Thermus* species (see Chapter 205) and the latter, like *F. aquatile,* neither grows at 37°C nor grows well on nutrient agar. Two further new species, both halophiles from an Antarctic Lake, *"F. gondwanense"* and *"F. salegens,"* may be proposed (T. A. McMeekin, personal communication). Whether these more recently described organisms truly belong in the genus remains to be determined. DNA-DNA hybridization studies (Bernardet, 1989) reveal that *F. branchiophila* has higher levels of relatedness to *Cytophaga* species than to *Flavobacterium* species. The other validly published species in the genus that are not mentioned here are of uncertain taxonomic position and do not belong in *Flavobacterium* for the reasons given by Holmes et al. (1984a).

Physiological properties

Within the group A flavobacteria, the main cellular fatty acid components in *F. breve* are iso-$C_{15:0}$ and 3-OH iso-$C_{17:0}$ acids (as they are also present in *F. aquatile*); *F. meningosepticum* contains in addition, significant amounts of 2-OH iso-$C_{15:0}$ and is similar to *Flavobacterium* species group IIb (Moss and Dees, 1978; Oyaizu and Komagata, 1981). *F. odoratum* (group B) differs from members of group A in containing iso-$C_{15:0}$, iso-$C_{17:1}$, 3-OH iso-$C_{15:0}$ and 3-OH iso-$C_{17:0}$ acids (Oyaizu and Komagata, 1981). Among the group C flavobacteria (or sphingobacteria), *F. multivorum* at least contains iso-$C_{15:0}$ and 2-OH iso-$C_{15:0}$ as major fatty acid components while the main cellular lipids are sphingophospholipids (Yabuuchi et al., 1981), as indeed they also are in *F. mizutaii, F. spiritivorum,* and *F. thalpophilum* (Dees et al., 1985; Yabuuchi et al., 1983). The group C organisms also contain major quantities of menaquinone 7 but no menaquinone 6, in contrast to the flavobacteria of groups A and B which contain major amounts of menaquinone 6 but no menaquinone 7 (Dees et al., 1985). These characters further support the case for classifying the group C organisms in the separate genus *Sphingobacterium* but they rely on characters not easily determined routinely.

Cells of all *Flavobacterium* species are nonmotile in both hanging drop preparations and in soft agar; it is generally accepted that they lack flagella. However, Weeks (1955) examined the type strain of *F. aquatile* by electron microscopy and observed structures that he thought were like "pseudoflagella." By light microscopy, Webster and Hugh (1979) observed what they thought to be nonfunctional flagella on both the type strain of *F. aquatile* and that of *F. meningosepticum,* but this was not confirmed by Thomson et al. (1981) using electron microscopy (although extracellular appendages of a nonflagellar nature, like those on gliding bacteria, were seen in *F. aquatile*).

The yellow pigments produced by these organisms are nonfluorescent and insoluble in growth media; in *F. aquatile* the pigment is carotenoid (principally zeaxanthin; O. B. Weeks, unpublished observations) whereas in *F. breve* and *F. odoratum* they are not carotenoid but are probably of the flexirubin type.

Clinical strains are generally resistant to many antimicrobial agents, including amikacin, ampicillin, carbenicillin, gentamicin, kanamycin, polymyxin B, streptomycin, and tobramycin. Although an R plasmid conferring resistance to ampicillin, carbenicillin, and erythromycin has been reported in a strain of *F. odoratum* (Kono et al., 1980), detectable plasmids have been rarely reported (Owen and Holmes, 1981) and resistance in these organisms is therefore possibly associated with chromosomal genes.

Applications

No applications for strains of the genera *Flavobacterium, Sphingobacterium,* or *Weeksella* are yet known. However, suitable strains of *"Flavobacterium keratolyticus"* (isolated from soil in Japan), an organism not only without standing in nomenclature but possibly also not even a member of the genus *Flavobacterium,* naturally produce an endo-β-galactosidase. This enzyme exposes the human red blood cell cryptantigen Tk and is therefore potentially useful in blood transfusion laboratories for determining the type of end-link sugar on the red cell membrane that carries the blood group antigen (Liew et al., 1982). Growth measurements with a supposed *Flavobacterium* strain have proved useful in determining the concentration of maltose- and starch-like compounds in drinking water, where these compounds may contribute to undesirable bacterial growth in distribution systems (Van Der Kooij and Hijnen, 1985).

CHAPTER 199

The Order Cytophagales

HANS REICHENBACH

In the past decade much has been learnt about the order Cytophagales and about some of the organisms belonging to it, although the majority of its members are as unfamiliar as ever. On the basis of 16S rRNA studies, we can now delimit the group with some confidence and have a well-founded idea of its phylogenetic position (Paster et al., 1985; Woese et al., 1985). Accordingly, the Cytophagales appear to be distantly related to the *Bacteroides* group, and these two together comprise one of the main branches, perhaps a phylum, in the bacterial phylogenetic system. The substructure of the *Cytophaga* branch of the phylum is more difficult to evaluate. There is a main line on which we find unicellular gliders—*Cytophaga* (*Cy.**) *johnsonae*, *Cy. lytica*, *Cy. aquatilis* = *Flavobacterium* (*Fv.*) *aquatile*, and *Sporocytophaga* (*Sp.*) *myxococcoides*—but at a lower level unicellular nonmotile bacteria (*Fv. breve*, i.e., low GC, true flavobacteria) are also found. At a still lower level, a cluster branches off which comprises the unicellular gliders—*Flexibacter* (*Fx.*) *filiformis* = *Fx. elegans* Fx el, *Cy. heparina*, and *Taxeobacter* = Myx 2105), unicellular nongliding flavobacteria (*Fv. ferugineum*), but also filamentous, multicellular, gliding (*Saprospira*) and nonmotile bacteria (*Haliscomenobacter*). It is obvious from these data that our present definition of genera does not reflect the phylogenetic situation, and also that the grouping in families and perhaps orders needs to be reconsidered. Before that is done, however, 16S rRNA sequences of further species should be determined.

From what has been said above it is clear that only a preliminary characterization of the order is possible at present. In this chapter, the order Cytophagales is restricted to unicellular gliding bacteria; the relevant genera are listed in Table 1. Filamentous, gliding bacteria of the genus *Saprospira* may or may not belong to the order, and they are sufficiently different to justify a separate treatment (see Chapter 200); contrary to earlier suggestions, these organisms are not apochlorotic cyanobacteria (Reichenbach et al., 1986). Unicellular, gliding bacteria of the genus *Lysobacter* have been found to be closely linked to the xanthomonads and thus belong to the gamma branch of the Proteobacteria (Woese et al., 1985); consequently they are discussed separately (see Chapter 176) It should be mentioned that, in the past, lysobacters have often erroneously been classified as cytophagas; this is discussed in Chapter 176. On the other hand, the cytophagas have been regarded as myxobacteria for some time and accordingly named; *Cy. columnaris* has even been classified in the myxobacterial genus *Chondrococcus* (now *Corallococcus*). However, as pointed out above, the two groups are not phylogenetically related. The nonmobile bacteria that cluster with the Cytophagales are discussed in Chapter 198 (*Flavobacteria*) and Chapter 201 (*Haliscomenobacter*).

The Cytophagales as outlined above are all unicellular, gliding, Gram-negative bacteria. All

Table 1. Survey of the taxonomy of the order Cytophagales of the *Bacteroides-Flavobacterium-Cytophaga* branch.

Order: Cytophagales
Family: Cytophagaceae
Genera: *Cytophaga*
- *Sporocytophaga*
- Unnamed *Cytophaga*-like bacteria (several genera)
- *Flexibacter*
- *Microscilla*
- *Flexithrix*
- *Capnocytophaga*
- *Taxeobacter*
- (*Saprospira*)[a]

[a]*Saprospira* may or may not belong to the order. It is discussed separately in Chapter 200.

*In this chapter, the following abbreviations sometimes are used for the genera of the order Cytophagales: CLB, *Cytophaga*-like bacteria; *Cp.*, *Capnocytophaga*; *Cy.*, *Cytophaga*; *Ft.*, *Flexithrix*; *Fv.*, *Flavobacterium*; *Fx.*, *Flexibacter*; *Mc.*, *Microscilla*; *Sa.*, *Saprospira*; *Sp.*, *Sporocytophaga*; *Tx.*, *Taxeobacter*.

have rod-shaped cells, which may differ substantially in shape. They may be short or long, delicate or stout, with tapering or rounded ends (Fig. 1). Two genera exhibit a controlled and cyclic shape change: *Sporocytophaga* produces resting cells in the form of spherical microcysts, and some *Flexibacter* species alternate between very long and extremely agile thread cells and very short, almost spherical and nonmotile rod cells (Fig. 2). Many of the other species are more or less pleomorphic, with cell populations that consist of short and very long rods and chains of cells, particularly in older cultures.

The typical colonies are spreading swarms (Fig. 3). Sometimes they are filmlike and may cover the whole culture plate within a few days. In other cases, they only expand slowly or remain more or less compact. In a few instances there is also rhizoid growth. Many Cytophagales produce brightly colored colonies in shades of yellow, orange, or brick red. The yellow and orange colonies often change immediately into red, purple, or brown if covered with a 10% KOH solution. This color change is due to flexirubin-type pigments (Fig. 4), which have so far only been found in organisms of this group (including flavobacteria). The organisms belonging to the Cytophagales may be aerobic, microaerophilic, capnophilic (CO_2-requiring), or facultatively anaerobic. They are all organotrophs, many of them able to degrade biomacromolecules like proteins, chitin, pectin, agar, starch, or cellulose. They are ubiquitous, abundant, and probably play a major role in the turnover of matter in nature (e.g., Ruschke, 1968; Ruschke and Rath, 1966). Some may also be of practical interest.

A few reviews on the Cytophagales and their subgroups have been published since the first edition of *The Prokaryotes* and can be recommended here for further information (several chapters in *Bergey's Manual of Systematic Bacteriology*, vol. 3, 1989, for detailed discussions of the taxonomic problems; also, Reichenbach and Weeks, 1981; Shewan and McMeekin, 1983; and on practical aspects: Reichenbach, 1988; see also: Bernardet, 1989; Jooste, 1985; Kath, 1990).

Habitats

The Cytophagales are by far the most common of all gliding bacteria. They are found in enormous numbers in certain habitats, mainly those rich in organic material. They can adapt, however, to rather low nutrient levels (Höfle, 1982, 1983) and probably usually subsist on biomacromolecules, which they are specialized to degrade. The main habitats of the Cytophagales, and thus convenient sources for their isolation, are soils at or close to neutral pH, decaying plant material, and dung of animals, particularly that of herbivores. In freshwater environments, they are found on river banks and lake shores, in estuaries, aerobic bottom sediments, and algal mats. Certain *Cytophaga*-like bacteria (CLB) have also been found in large numbers freely floating in water, especially during the cold season, e.g., in Lake Constance, the Mindelsee, and the Feldsee in southwestern Germany (Gräf, 1962a; Reichardt, 1974; Ruschke and Rath, 1966). The principal cellulose decomposers in southern Canadian lakes appear to be cytophagas (Hoeniger, 1985). CLB are common in sewage plants where, in the aerobic regions, CLB may constitute 5 to 10% of the total cultivatable bacterial population (Güde, 1980). Here, too, a seasonal variation in the number of CLB can be observed, with a maximum in the winter months. Typically, the CLB are particularly enriched in those stages at the end of the purification process, where only recalcitrant organic molecules remain.

In marine environments, the Cytophagales are abundant near the shores: on living and dead seaweeds, in aerobic and anaerobic bottom sediments, and on decaying sea animals, such as crustaceans with their chitin exoskeleton. Marine cellulose degraders have been found on fishing nets in Japan where they once were a serious problem in the deterioration of the fab-

Fig. 1. Cell shape of the Cytophagales in phase contrast. (a) A brick red, marine, agar decomposer, probably a *Microscilla* species, in chamber culture; the long, flexible, thread cells have tapered ends. Bar = 25 μm. (b) CLB from soil, in chamber culture, showing the typical arrangement of cells at the swarm edge. Bar = 10 μm. (c) *Cytophaga lytica,* a yellow, marine, agar-digesting CLB, from SP2 liquid medium. Bar = 5 μm. (d) *Cytophaga succinicans,* a facultatively anaerobic freshwater CLB, from AO agar. Bar = 5 μm. (e and f) *Cytophaga aurantiaca* type strain, a cellulose-degrading true *Cytophaga,* from glucose-glutamate agar. The population in (e) consists of delicate, flexible rods, which are pleomorphic with very long and with slightly swollen cells; in (f), cells from older parts of the colony begin to produce dark, lemon-shaped inflations, which later degenerate to spheroplasts. Bar = 10 μm in both pictures. (g) *Flexibacter flexilis* type strain, from starch agar; one of the thread cells (top edge of the photograph) shows the beginning of branching at one end. Such branching is not uncommon among the Cytophagales. Bar = 5 μm. (h) *Taxeobacter* species, cells in situ on water agar with a streak of living *E. coli,* showing a characteristic palisade pattern. Bar = 5 μm.

ric (Kadota, 1956). Cellulose degraders seem, however, not to be common in marine habitats; at least we have failed so far to isolate any from European coasts. Little is known about the distribution of CLB in the open sea, and a careful investigation of this point would be desirable. As CLB are not likely to form spreading colonies on rich media, the "flavobacteria" that are often observed in ecological studies of various aquatic environments perhaps may frequently really be CLB instead.

In estuarine habitats in the upper Chesapeake Bay, CLB were found to constitute a substantial proportion of the chitin-degrading bacterial flora (Reichardt et al., 1983), among them many facultatively anaerobic, flexirubin-positive strains resembling *Cy. johnsonae* and *Cy. aquatilis*. These organisms tolerated various levels of salt, but did not depend on elevated salt concentrations.

However, the boundaries between land and sea appear in general to be rather sharp for CLB. This may be concluded from the observation that virtually all strains of CLB and *Flexibacter* isolated by us from terrestrial and freshwater habitats contain, in addition to carotenoids, flexirubin-type pigments, while strains isolated from the sea coast usually produce carotenoids exclusively and only exceptionally produce flexirubin-type pigments (Reichenbach et al., 1981). Since enormous numbers of terrestrial CLB must constantly be washed or blown into the sea, this can only mean that terrestrial strains cannot easily adapt to and become established in the marine environment. An interesting exception may be *Cy. flevensis*. This is an agar-decomposing organism that does not produce flexirubin-type pigments, both characteristics which would speak for a marine origin. It has, however, been isolated from fresh water of the Isselmeer in the Netherlands (van der Meulen et al., 1974). Since the Isselmeer is a part of the North Sea that has been separated from the open sea for decades and has gradually become constituted with fresh water, marine bacteria would have had ample time to adapt to gradually changing conditions and thus may have had a chance to survive. These observations also suggest that marine and terrestrial CLB may be less closely related than was thought before; this is indeed supported by 16S rRNA analyses (Paster et al., 1985).

In recent years, it has been discovered that CLB may also occur in milk and dairy products and perhaps occasionally contribute to deterioration (Jooste, 1985; Jooste et al., 1985). Even more serious are sporadic reports of CLB as human pathogens. CLB in the air humidifier system of a textile plant was found to be responsible for a hypersensitivity pneumonitis of workers; it was later described as a new species, *Cy. allerginae* (Flaherty et al., 1984; Liebert et al., 1984). The *Capnocytophaga* species live in the tooth pockets of humans (Leadbetter et al., 1979). Although a role for them in periodontic disorders has been discussed, it seems that the contribution of capnocytophagas to that disease is only a minor one at the most. But life-threatening septicemias and other kinds of general infections have been observed repeatedly, and not only in immunocompromised patients as has originally been thought (e.g., Forlenza et al., 1980; Paerregaard and Gutschik, 1987; Shlaes et al., 1982). Fortunately, the organisms respond well to antibiotics (Forlenza et al., 1981; Gräf and Morhard, 1966).

An economically serious problem are the fish-pathogenic CLB. These organisms are gaining even more importance as fish cultivation is intensified. First discovered in aquarium fishes in the USA (Davis, 1922), infections with CLB became a major concern in the 1940s in the western USA, where they caused severe losses among salmonid fishes in rivers and lakes and in fish hatcheries. The infections were then intensively studied, and it was discovered that more than one species of CLB was involved, causing several different diseases with diverse symptoms. The two most important diseases were columnaris disease, brought about by *Cy. columnaris* (= *Fx. columnaris* = *Chondrococcus columnaris*), and cold water disease by *Cy. psychrophila*. One factor that may have contributed to these outbreaks may have been the warming of the water by electric power plants, mainly along the Columbia River. It appears that, as a rule, unfavorable living conditions for the fish, like confinement, crowding, and sub-

Fig. 2. Cytophagales with a cyclic change in cell shape, shown in phase contrast. (a and b) *Sporocytophaga myxococcoides* from a membrane of regenerated cellulose on ST6 agar; in (a), most cells are still vegetative rods, but young microcysts and intermediary stages of cell conversion can already be seen; in (b), mature, optically refractile microcysts are present. (c to e) *Flexibacter filiformis* (formerly called *Fx. elegans* Fx el) from VY/2 agar; (c) a slide mount from the very edge of the swarm colony shows very long, delicate, flexible, and extremely agile thread cells without, or with only very few, cross walls; (d) at some distance from the edge, the thread cells have become much shorter by fragmentation; (e) finally, the cell population consists mainly of very short rods which are also clearly fatter and darker and are no longer motile. Bars = 10 μm.

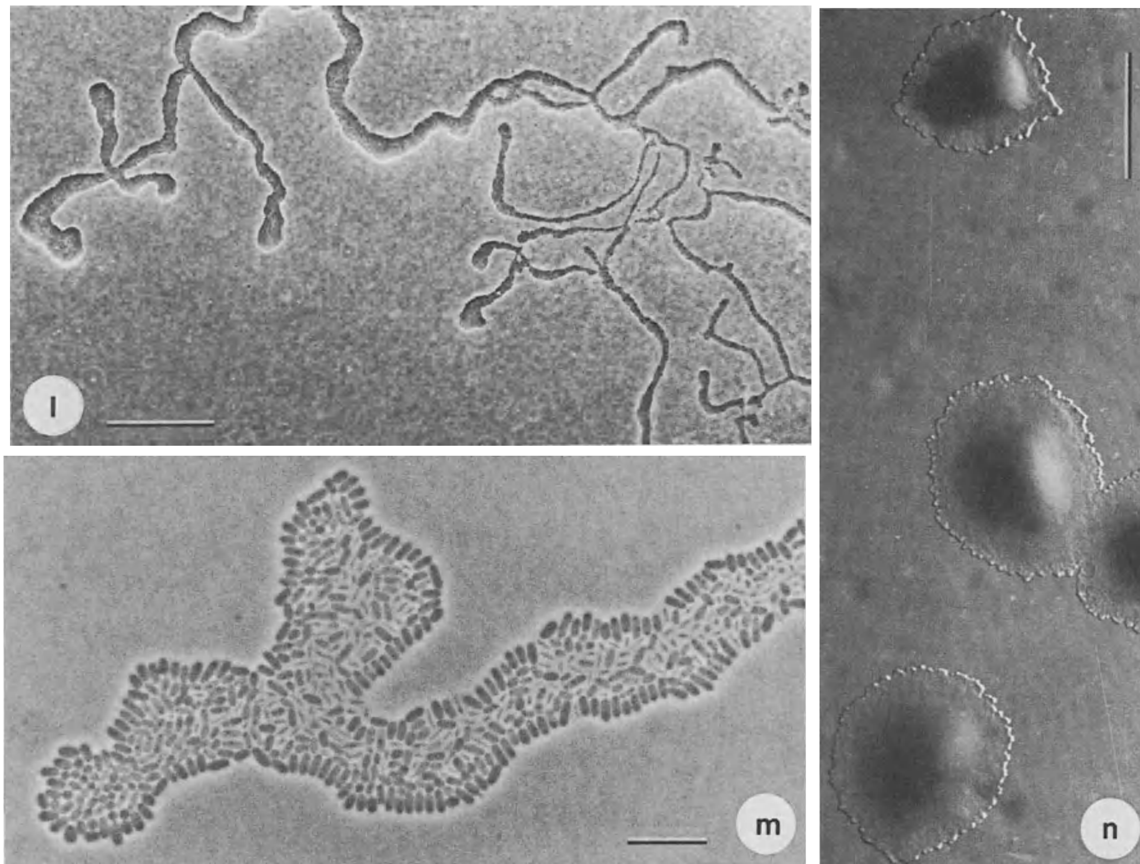

Fig. 3. Colonies of various diverse Cytophagales. (a) Spreading colony of a CLB from soil, growing in chamber culture, dark field. Bar = 100 μm. (b) *Flexibacter filiformis* Fx el, swarm colony on agar plate. Bar = 3 mm. (c) CLB from soil; typical swarm colonies emerge at the side of a streak on an agar surface. Bar = 1 mm. (d and e) CLB from soil growing on two different agar media. (d) On the poorer substrate, the colonies are relatively large and show some spreading; (e) they remain small and compact on the rich medium. Bar = 1 mm in both. (f) CLB from soil, swarm colony on CY agar showing a distinct surface pattern. Bar = 1 mm. (g) *Cytophaga flevensis,* an agar-digesting CLB from freshwater; as a relatively rich agar substrate was used, the colonies remained rather compact. Bar = 2 mm. (h) *Flexibacter filiformis* Fx el, chamber culture; dense clusters of cells are sitting in conspicuous slime tracks; phase contrast. Bar = 30 μm. (i) CLB from soil, chamber culture, edge of a swarm colony with a network of slim tracks; phase contrast. Bar = 30 μm. (j and k) *Cytophaga columnaris,* a fish-pathogenic CLB from freshwater; swarm colonies on MYX agar (j) and AO agar (k), showing the typical growth pattern of the organism. Bar = 1 mm in both. (l to n) *Taxeobacter ocellatus* Tx ol (= Myx 2105): (l and m) on water agar with a streak of living *E. coli,* the organism typically spreads out, producing long, tendril-like strips; (m) at a higher magnification, the unusual palisadelike arrangement of the cells becomes apparent; both phase contrast; (n) after plating on CY agar, relatively compact, brick red colonies begin to spread out. Bar = 100 μm in (l), 10 μm in (m), and 2 mm in (n).

optimal water temperature, favor infections by CLB (e.g., Anacker and Ordal, 1959; Becker and Fujihara, 1978; Bullock, 1972; Colgrove and Wood, 1966; Collins, 1970; Davis, 1949; Fujihara and Hungate, 1972; Fujihara et al., 1971; Garnjobst, 1945; Ordal and Rucker, 1944; Pacha, 1968; Pacha and Ordal, 1970; Pacha and Porter, 1968; Rucker et al., 1953; Snieszko and Bullock, 1976). Fish diseases caused by CLB are now known worldwide, and they often are a serious threat to fish culturists (e.g., Ajmal and Hobbs, 1967; Bootsma and Clerx, 1976; Deufel, 1974; Ghittion, 1972; Lehmann, 1978; Song et al., 1988; Wakabayashi and Egusa, 1974; Wakabayashi et al., 1970a, 1970b). In Europe, CLB diseases have been observed only since about 1965, but it is not clear whether the pathogens were there before but had previously been overlooked, or whether infections have finally become established on a larger scale because environmental conditions have deteriorated. It appears that in the past few years *Cy. psychrophila* has begun to spread through Europe; again, the reasons are not known (Bernardet, 1989; Bernardet and Kerouault, 1989). Very recently, flavobacteria have also been found to be

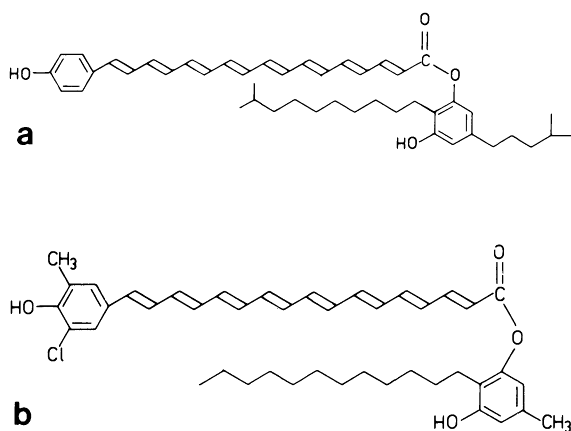

Fig. 4. Flexirubin-type pigments characteristic for members of the Cytophagales. (a) *Cytophaga*-flexirubin from CLB. (b) Chloroflexirubin from a *Flexibacter* species.

involved in fish diseases (*Fv. branchiophila*), and it will be interesting to see if they are related to fish pathogenic CLB. The data on DNA-DNA hybridization with *Cy. columnaris* were insignificant (Wakabayashi et al., 1989). Further, CLB diseases have been encountered in marine environments (e.g., Anderson and Conroy, 1969; Bullock, 1972; Campbell and Buswell, 1982; Hikida et al., 1979), apparently due to infections by *Fx. maritimus* (Bernardet et al., 1990; Wakabayashi et al., 1986). CLB and flavobacteria obviously belong to the bacterial flora that colonize the eggs of cod and halibut, but in this case detrimental effects have not been demonstrated (Hansen and Olafsen, 1989). However, CLB may have a role in disorders of other marine animals; they have been linked to the destruction of the hinge ligaments of cultivated oysters (Dungan et al., 1989). Based on what is known so far, it may be concluded that the infection mechanism of the CLB pathogenic for fish is connected to their very strong protease activity, and in some, also DNase activity.

Isolation

There are no selective methods that are universally applicable for the enrichment and isolation of the diverse members of the Cytophagales. The general strategy for their isolation is to provide conditions that promote spreading growth on surfaces, and then to pick organisms that produce spreading colonies or swarms (Fig. 3) for subcultivation. The nutrient level is usually kept low in the medium used for crude and enrichment cultures in order to stimulate gliding motility and delay development of contaminants. By combining this approach with the use of special substrates in the isolation medium, nutritional specialists among the Cytophagales may be enriched more specifically, e.g., cellulose and chitin degraders. The isolation procedure thus always requires the use of plate cultures. Liquid media have only been used successfully for baiting cellulose decomposers (see below).

With some experience, it will often be possible to recognize members of the Cytophagales microscopically, because many have a characteristic cell morphology (Fig. 1 and 2). If that is not the case, the appearance of the colonies may provide a clue. The property of swarming presents some difficulties since some organisms cannot be or, only with difficulty, can be induced to form spreading colonies, even when gliding motility can be recognized unequivocally by microscopic examination of wet mounts or by the occurrence of slime trails in chamber cultures. This is why quite a few CLB were originally classified as *Flavobacterium* species. On the other hand, spreading growth is, of course, shared by other gliding bacteria. But there are only two other groups of organotrophic, unicellular gliders: the myxobacteria, which usually show a totally different swarm morphology and typically produce fruiting bodies in crude cultures (see Chapter 188); and the lysobacters, which have a peculiar cell morphology, which is, however, shared by some CLB (see Chapter 176). In many cases, pigmentation may be a useful criterion. As already mentioned, many, although not all, members of the Cytophagales are bright yellow, orange, or red. These pigments are always cell-bound (in contrast to some or all of the *Lysobacter* pigments, which, in addition, are usually much paler). If growth is heavy, pigmentation can already be easily recognized in the colonies; alternatively it may be observed after the cells have been concentrated by scraping them together. A large group of soil and freshwater strains of *Cytophaga*, *Sporocytophaga*, CLB, and *Flexibacter* produce flexirubin-type pigments that, upon addition of alkali, turn from orange to purple (Achenbach et al., 1978; Reichenbach et al., 1974) This test can easily be applied to culture plates. In this case, the yellow or orange colonies will turn a much deeper color, either red, purple-violet, or brown, when spotted with 10% KOH solution. The color change differs from that of the pure pigments because of the presence of other pigments, usually carotenoids, which alter the flexirubin absorption spectrum. The color change reaction is reversible upon addition of HCl. If a gliding bacterium gives a positive result with this color test, one can be certain that it belongs to one of the above-mentioned groups of organisms.

The only nongliding bacteria known to contain flexirubin-type pigments are the phylogenetically related, low GC (true) flavobacteria (Reichenbach et al., 1980; Weeks, 1981). It should be understood, however, that the described color change is a phenolate reaction that can also be observed with other pigment types. In fact, a similar color reaction has been found in *Brevibacterium linens*, which contains the phenolic carotenoid 3,3′-dihydroxy-isorenieratene (Kohl et al., 1983). Nonmotile, Gram-positive *Brevibacterium*, of course, cannot easily be confused with the organisms discussed here.

Sources for the isolation of Cytophagales will be found in the section on "Habitats." If a broad representation of those organisms is desired, the samples should be processed soon after collection, especially if the samples are from aquatic or humid environments, because in such samples, oxygen depletion and desiccation in particular can quickly lead to the elimination of sensitive species. Thus, in my experience, the cellulose-degrading *Cytophaga* species are easily lost in this way. On the other hand, many species of Cytophagales are completely desiccation resistant; I have been able to isolate strains of *Sporocytophaga*, *Flexibacter*, CLB, and *Taxeobacter* from samples that had been air-dried and stored for 5 to 10 years at room temperature.

Methods for the Isolation of Cytophagales

Small samples of promising natural material are inoculated either as individual spots or as one to three well-separated streaks onto the surface of dry water agar (WAT agar) plates. For marine samples, seawater agar (MS1 or SW2 agar) is used. Alternatively, media with a very low nutrient content may be used (CYT, MS4, SP2, SP6 agar). Finely divided samples such as soil may also be sprinkled over the plate, as a way of multi-spot inoculation. This can be advantageous because the organisms tend to stick to tiny particles and thus may be distributed in the sample very unevenly. To reduce the growth of fungi, cycloheximide (2.5 mg/100 ml) should be added to the isolation medium (not necessary with marine samples).

WAT Agar and WCX Agar

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. After autoclaving, 25 μg cycloheximide may be added per ml from a filter-sterilized stock solution for WCX agar.

MS1 Agar

Agar	1.5%

In natural seawater.

The pH is not adjusted. The medium is autoclaved.

SW2 Agar

Na acetate	0.002%
NH_4Cl	0.1%
Agar	1.5%

In artificial seawater (see below).

The pH is adjusted to 7.2. The medium is autoclaved.

Artificial Seawater (Dawson et al., 1969)

NaCl	24.7g
KCl	0.7g
$MgSO_4 \cdot 7H_2O$	6.3g
$MgCl_2 \cdot 6H_2O$	4.6g
$CaCl_2$ anhydrous	1.0g
$NaHCO_3$	0.2g

Dissolve in 1 liter water. To prevent precipitation, $CaCl_2$ and $NaHCO_3$ are autoclaved as separate stock solutions.

CYT Agar

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$CaCl_2 \cdot 2H_2O$	0.05%
$MgCl_2 \cdot 7H_2O$	0.05%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

MS4 Agar

$(NH_4)_2SO_4$	0.1% (autoclaved separately)
Glucose	0.2% (autoclaved separately)
Agar	1.5%

In natural seawater.

The pH is not adjusted. The medium is autoclaved.

SP2 Agar

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.02%
Na acetate	0.002%
Agar	1.5%

In artificial seawater.

The pH is adjusted to 7.2. The medium is autoclaved.

SP6 Agar

Casitone (Difco)	0.03%
Yeast extract (Difco)	0.01%
Agar	1.5%

In artificial seawater.

The pH is adjusted to 7.2. The medium is autoclaved.

The plates are incubated at 30°C, at room temperature, or at 12°C, depending on the origin of the samples. Cultures started from aquatic sources are usually incubated at the lower temperature range because many aquatic CLB will not grow above 25 to 27°C.

The cultures are checked at regular intervals of 1 to 2 days for spreading colonies. It takes between 24 h and several weeks for spreading organisms to appear, depending on the organ-

ism, the incubation temperature, and the nutrient concentration in the culture, which may have been substantially augmented by the introduced sample material. As the spreading swarms are often filmlike and extremely delicate, the plates must be examined with a dissecting microscope equipped with a tiltable mirror so that side illumination can be used from below. Some experience is required before gliding organisms can be reliably distinguished from flagellated bacteria, which occasionally also spread out (Fig. 3b and 3d). A good distinguishing characteristic is usually the pattern of the swarm edge which, for gliding bacteria, is usually dentate with fine flamelike projections, while for flagellated organisms, it tends to be entire or coarsely lobed. However, certain *Bacillus* strains that form long filaments may also spread out with flamelike tongues at the edge of their colonies. Amebae or, in marine samples, gliding diatoms like *Nitzschia putida* may mislead the investigator. Usually a look through the microscope will quickly dispel all doubts; thus, e.g., no gliding bacterium is known that is able to swim actively (that is move without being in contact with a surface).

The baiting technique used for the isolation of myxobacteria (see Chapter 188) also often yields members of the Cytophagales. Living cells of *Escherichia coli* are streaked cross-wise or in three parallel lines onto water agar and inoculated with a suitable sample. The organisms develop along the *E. coli* streaks, often without lysing them, and spread as an extremely thin film, usually a monolayer, far out over the agar surface between the streaks. The technique is in essence nothing else than an enrichment in a low nutrient medium.

If the Cytophagales are present in sufficiently high numbers, the samples can be suspended in sterile water, diluted, and plated. Media with low nutrient concentrations, like CYT and SP6 agar, are well suited. Media with a somewhat higher nutrient concentration, like CY, SP2, and SAP2 agar may also be used. They result in higher colony counts, but spreading of the gliding bacteria may be reduced or suppressed completely (Fig. 3i and 3j). Here, the color of the colonies may provide a useful lead. It should be kept in mind, however, that dilution plating is often not very successful, because the organisms tend to stick to particles and may be lost during the first few dilution steps.

CY Agar, CYG2 Agar, and CYCX Agar

Casitone (Difco)	0.3%
Yeast extract (Difco)	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. The medium may be supplemented with 0.3% glucose, which is separately autoclaved, for CYG2 agar. If the medium is used for plating of dilution steps, 25 μg cycloheximide may be added per ml after autoclaving from a filter-sterilized stock solution, for CYCX agar.

SAP2 Agar

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Agar	1.5%

In artificial seawater.

The pH is adjusted to 7.2. The medium is autoclaved.

Water samples may be plated directly or upon dilution. Often, however, it will be necessary to concentrate the bacteria by passing the sample through a membrane filter. The filter is then incubated right-side up on a suitable culture plate, either as a whole or after having been cut into several sectors; the latter approach increases the chance of isolating several different organisms. If media with somewhat higher nutrients are used, like CY or SAP2 agar, the incubation time is shortened and, thus, the danger of overgrowth reduced. But spreading of the organisms may become more or less suppressed, so that members of the Cytophagales can only be recognized by their color and cell shape. The strategy that is best applied depends on the load of contaminants expected. Some of the smallest gliding bacteria can move through the filter pores (at 0.3- to 0.5-μm pore size) and form colonies on the agar surface below. This can be used as a selective technique. In this case, the filter should be removed from the agar surface after about one day to prevent contaminants from also moving through the filter.

Isolation of Nutritionally Specialized Organisms

AGAR DECOMPOSERS. Agar decomposers are very common in marine environments and can be obtained by the methods outlined above. They are easily recognized, because their colonies rest in shallow craters or in deep pits, and are surrounded by large, uncolored, "gelase" zones if the plate is flooded with iodine solution (Stanier, 1941; Veldkamp, 1961). Some organisms liquify the agar very quickly so that they can only be isolated if widely separated colonies are obtained after plating. Here, the filter migration technique described above is sometimes useful. A few agar-decomposing CLB have also been found in freshwater habitats near the sea coast, viz. *Cy. flevensis* (van der Meulen et al., 1974) and *Cy. saccharophila* (Agbo and Moss, 1979).

Chitin Decomposers. Chitinolytic bacteria are very common among the Cytophagales. Samples are streaked out on chitin agar, e.g., CT6 or CT7 agar (for marine strains, on CT8 or CT9 agar). The chitin is only added in a thin top layer in order to conserve chitin, which is relatively laborious to prepare, and to prevent the chitin from settling on the bottom of the dish out of reach of the organisms; in addition, superior results are obtained in this way because the cleared zones in the opaque chitin layer appear sooner and become more pronounced (Stanier, 1947; Veldkamp, 1955, 1965). Good sources for chitin decomposers are soil, material from sewage plants, and the shells of dead crustaceans. All known chitin-degrading Cytophagales can also grow very well without chitin, e.g., on CY agar, and they can be isolated by the general techniques described above. Thus, they can be purified by plating on, e.g., CY or SAP2 agar.

CT6 Agar

Top layer:

$MgSO_4 \cdot 7H_2O$	0.1%
K_2HPO_4	0.02%
Agar	1.5%

The pH is adjusted to 7.5. After autoclaving, enough chitin is added to give an easily recognizable turbidity, which should be achieved with about 0.5% chitin. The chitin is taken from an autoclaved stock suspension of reprecipitated material; the suspension must be dense enough so that the volume to be added to the medium does not exceed 30% The preparation of the chitin is described in Chapter 176. The medium is poured as a thin layer on top of the following:

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved.

CT7 Agar

Top layer as for CT6 agar. The base agar is WAT agar. On this medium only organisms that can use chitin as the only carbon and nitrogen source are able to grow.

CT8 Agar

Top layer:

K_2HPO_4 (autoclaved separately)	0.02%
Agar	1.5%

In artificial seawater.

The pH is adjusted to 7.5. After autoclaving, chitin is added, as for CT6 agar. The medium is poured on SW2 agar plates.

CT9 Agar

Top layer as for CT8 agar; base agar is SP2 agar.

Cellulose Decomposers. Decaying plant material or soil is sprinkled on filter paper that has been placed on mineral salts agar, e.g., ST6 agar (for marine organisms, SW5 agar may be used).

ST6 Agar and ST6CX Agar

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$MnSO_4 \cdot 7H_2O$	0.01%
$FeCl_3 \cdot 6H_2O$	0.02%
Yeast extract (Difco)	0.002%
Agar	1%
K_2HPO_4	0.1% (autoclaved separately)

After autoclaving, a filter-sterilized trace element solution is added, and, for crude cultures, 25 μg cycloheximide per ml from a filter-sterilized stock solution, for ST6CX agar. A recipe for a trace element solution is found in Chapter 188.

SW5 Agar

$(NH_4)_2SO_4$	0.1%
Yeast extract (Difco)	0.02%
Agar	1%
K_2HPO_4 (autoclaved separately)	0.1%

In artificial seawater.

The medium is autoclaved.

It appears that the type of filter paper used does not make much difference; we get good results with thin, moderately dense, high-quality filter paper (68 g/m², ash 0.1 to 0.2%, more than 95% α-cellulose). Growth of cytophagas on mineral salts agar with cellulose is usually considerably stimulated by Ca^{2+}, Mn^{2+}, and $Fe^{2+/3+}$ (Bortels, 1956). While media with NO_3^- as the nitrogen source are often recommended in the literature, in my experience, media with NH_4^+ are far superior for the isolation of cytophagas and sporocytophagas, at least on agar media.

As an alternative, enrichment cultures may be started with strips of filter paper immersed in a mineral salts solution, e.g., Dubos medium or ST5 medium, in test tubes, so that part of the filter paper remains above the surface of the liquid. The tubes are then inoculated. After incubation for 1 to 3 weeks, glassy, translucent yellow to orange or red spots on the paper at the air-liquid interface indicate growth of cellulose-decomposing cytophagas and sporocytophagas. The yellow and orange spots usually give the flexirubin reaction when a drop of 10% KOH solution is added, but some (terrestrial) *Cytophaga* strains are flexirubin-negative. It appears that, in general, enrichment on plates gives better results because it allows the use of a heavier inoculum. However, an enrichment in liquid medium may be useful when habitats are investigated that are poor in cellulose degraders,

such as marine environments. For the latter, good results have been reported with KM7 mineral medium and incubation at 25°C (Kadota, 1956). As already mentioned, fresh samples should be used for isolating *Cytophaga* strains.

Dubos Mineral Medium (Dubos, 1928)

$NaNO_3$	0.05%
K_2HPO_4 (autoclaved separately)	0.1%
$MgSO_4 \cdot 7H_2O$	0.05%
KCl	0.05%
$FeSO_4 \cdot 7H_2O$	0.001%

The pH is adjusted to 7.2. The medium is autoclaved.

ST5 Mineral Medium (Stanier, 1942)

$(NH_4)_2SO_4$	0.1%
K_2HPO_4 (autoclaved separately)	0.1%
$MgSO_4 \cdot 7H_2O$	0.02%
$CaCl_2 \cdot 7H_2O$	0.01%
$FeCl_3$	0.002%

The pH is adjusted to 7.0 to 7.5. The medium is autoclaved. For enrichment cultures, 25 μg cycloheximide is added per ml from a filter-sterilized stock solution.

KM7 Mineral Medium (Kadota, 1956)

$NaNO_3$	0.05%
K_2HPO_4	0.1%
$MgSO_4 \cdot 7H_2O$	0.05%
$FeSO_4 \cdot 7H_2O$	0.01%

In natural seawater.

The pH is adjusted to 7.2. The medium is autoclaved. This medium was originally developed for a different purpose, which explains the inclusion of relatively small amounts of $MgSO_4$ in a seawater medium.

The purification of cellulose decomposers may be a tedious procedure that requires skill and considerable patience, and it almost always takes several weeks or months. The first subcultures are best started on filter paper placed on mineral salts agar. Now, however, small (about 10 × 15 mm) rectangular filter strips are usually used and inoculated independently from different sites of the crude culture. The filter paper pieces, three or four per plate, are kept well separated to prevent the passage of contaminants from one to the other. Of course, organisms such as flagellated bacteria, amebae, ciliates, and nematodes will spread quickly within the water-soaked filter pad. Before further purification is attempted, they should first be eliminated. To get rid of amebae, which are almost always abundant in cultures started from soil, the plate is exposed to the vapors of a 5% ammonia solution for 2 min (M. Aschner, personal communication). After another one to two minutes of incubation, the cytophagas are transferred to a fresh plate. If there are very many amebae, the procedure may have to be repeated after the cellulose decomposers have grown up. If nematodes are still there, the plate is frozen at −80°C for 2 days. The cellulose decomposers are transferred to a fresh plate as soon as possible after thawing. Next, contaminating bacteria have to be removed, which is the most difficult step. After the load of contaminants has been reduced by repeated transfers to filter paper on mineral salts agar, the cellulose decomposer may be transferred to cellulose overlay agar; we have often had good results with CEL1 agar.

CEL1 Agar

Top layer:

$(NH_4)_2SO_4$	0.1%
Cellulose powder	0.5%
Agar	1.0%

Cellulose powder MN300 from Macherey and Nagel (Düren, Germany) works well.

The pH is adjusted to 7.2. The medium is autoclaved and then poured as a thin layer on top of ST6 agar plates.

The cellulose decomposers penetrate the agar medium and spread within the cellulose layer, concommitantly producing a clear lysis zone. Most or all of the contaminants stay close to the inoculation site, so that after 1 to 3 weeks, a pure, or at least improved, inoculum can be obtained from the edge of the lysis zone.

Favorable results are sometimes obtained by inoculating a small rectangle of filter paper that has been placed on top of cellulose overlay agar, preferably close to one side of the plate. In this case, the cellulose decomposers grow profusely on the filter paper, and from there they spread within the cellulose agar, while the contaminants tend to remain in the macerating filter paper where they find higher nutrient concentrations.

We also find carboxymethyl cellulose media, like ST10 agar, useful for purification of cellulose decomposers. On this medium, too, they spread within the substrate; this can be recognized from a slowly increasing, shallow depression in the surface of the plate. Growth is usually very thin and can barely be seen, if at all; but bacterial cells are found under the microscope if slide mounts are made from the depressed area. Transfers are made from the edge of the depression zone after some time.

ST10 Agar

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$FeCl_3$	0.02%
K_2HPO_4 (autoclaved separately)	0.1%
Casitone (Difco)	0.2%

Carboxymethyl cellulose	1.5%
Agar	0.6%

Carboxymethyl cellulose Sigma no. C-5013, sodium salt, high viscosity, works well.

After autoclaving, standard trace elements (see Chapter 188) and, if used for contaminated strains, 25 μg cycloheximide per ml are added from filter-sterilized stock solutions.

Another technique for purification is to transfer the cellulose decomposers to a membrane filter (cellulose nitrate, 0.3 to 0.4 μm pore size) on cellulose overlay agar or, better, on a membrane of regenerated cellulose (e.g., no. 11604/50/N, pore size 0.8 μm, from Sartorius, Göttingen, Germany) on ST6 agar. The cytophagas will migrate through the membrane filter and produce colonies on the substrate below. If regenerated cellulose is used, these colonies appear particularly early and show a sharp margin. It may, however, still take from 1 to 3 weeks before colonies develop. They are often bright yellow and spread very slowly. With this technique, the time of removal of the top membrane is crucial, because other bacteria may soon grow through the membrane and contaminate the cellulose degraders again. Therefore, it is best to start several parallel cultures and to remove the top membrane at various different times, e.g., after incubation at 30°C overnight, for 1 day, and for 2 days.

With sporocytophagas, final purification is often possible by cautious heating of microcysts suspended in water. The heat resistance seems to vary substantially from strain to strain, and probably also depends on the maturation stage. For example, the thermal death point was reached after 10 min at 68°C with one strain of *Sp. myxococcoides*, while another strain survived 10 min at 70°C; a strain of *Sp. ellipsospora* was killed after 10 min at 58°C (Imshenetsky and Solntseva, 1936; Sijpesteijn and Fåhraeus, 1949). We found that occasionally a strain may even survive boiling for 10 min. Results are usually satisfactory in our laboratory if we incubate microcysts at 58°C and take samples after 10, 20, and 40 min. The heated samples may be streaked on CEL1 agar, on filter paper on CY agar, or on CA2, CA13, or HP18 agar.

CA2 Agar (Mullings and Parish, 1984)

Base agar:

Agar	1.5%

Stock solution A:

KNO_3	7.5 g
K_2HPO_4	7.5 g

Dissolved to give 100 ml.

Stock solution B:

$MgSO_4 \cdot 7H_2O$	1.5 g

Dissolved to give 100 ml.

Stock solution C:

$CaCl_2 \cdot 2H_2O$	0.27 g
$FeCl_3$	0.15 g

Dissolved to give 100 ml.

After autoclaving, the base agar is supplemented with: (a) 1% (v/v) of each of the three stock solutions: (b) 1% (w/v) of glucose (from an autoclaved 20% stock solution); and (c) standard trace elements (see, e.g., Chapter 188).

CA13 Agar

As for CA2 agar, but the KNO_3 in stock solution A is replaced by 0.5 g of $(NH_4)_2SO_4$.

HP18 Agar

Na glutamate	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. After autoclaving, 0.1% glucose (from an autoclaved stock solution) and standard trace elements are added.

Of course, plating of diluted cell suspensions would seem to be the method of choice for the purification of cellulose-degrading cytophagas. However, this can only be done if the organisms are already enriched to near purity since colonies composed of single cells are apparently not produced by these organisms, not even on glucose-containing media, such as those just mentioned, that allow massive growth of pure cultures. Whenever isolated colonies are obtained upon plating, these colonies probably always start from cell clusters, and these are normally contaminated when heavily contaminated cultures are used to prepare the suspension. Further, the cellulose degraders produce a lot of slime which makes it difficult to suspend the cells uniformly in a liquid. After plating on cellulose-overlay agar, colonies which are surrounded by a lysis zone appear only after weeks of incubation, and this gives contaminants ample time to develop and overgrow the cellulose degraders. Gliding and spreading bacteria become a particular nuisance under such conditions. It may be mentioned here that, when glucose is used in a medium, care has to be taken to sterilize the glucose separately, either by filtration or by autoclaving since cellulose-degrading cytophagas are extremely sensitive to toxic products arising when glucose is autoclaved together with other medium compounds (Stanier, 1942). Cellulose-degrading sporocytophagas and cytophagas have been known for many years (Hutchinson and Clayton, 1919; Winogradsky, 1929), but relatively few pure strains are available. They are very common in

soil and decaying plant material (for their occurrence, isolation, and cultivation, see Fåhraeus, 1947; Imschenezki, 1959; Imshenetski and Solntseva, 1936; Kadota, 1956; Krzemieniewska, 1930, 1933; Stanier, 1942; Stapp and Bortels, 1934; Veldkamp, 1965).

PECTIN DECOMPOSERS. Pectin-decomposing CLB can be obtained by plating samples, e.g., lake water, on pectin overlay agar like PEK1 agar or on PEK7 agar. Pectolytic organisms cause shallow depressions in the pectin gel or liquefaction; on PEK7 agar, the colonies are surrounded by clearing zones in a background of finely divided, dispersed pectin flakes or granules, which may be clearly seen, however, only under a dissecting microscope. If such plates are flooded with iodine solution, colonies of pectolytic organisms are surrounded by light yellow halos in a brown plate. The preparation of pectin media is somewhat tricky, and the results depend decisively on the type of pectin used. We found pectin from apple, 38% esterified (from Roth, Karlsruhe, Germany), useful.

PEK1 Agar (Güde, 1973)

Base agar:

Part A:

NH_4Cl	1 g
$CaCl_2 \cdot 2H_2O$	3 g
In 100 ml water.	

Part B:

K_2HPO_4	0.5 g
In 50 ml water.	

Part C:

$MgSO_4 \cdot 7H_2O$	0.2 g
Agar	15 g
Tris HCl buffer, 1 M, pH 8.0	100 ml
In 750 ml of water.	

After autoclaving the solutions are combined, standard trace elements (see Chapter 188) are added, and plates are poured.

Top layer:
12 g pectin is slowly dissolved in 300 ml water of 70°C, the pH is adjusted to 7.2, and the medium is autoclaved for exactly 10 min at 110°C. The solution is poured as a thin layer on base agar plates and will form a gel within 5 h. During autoclaving, the medium may become dark, but this does not interfere with its usefulness.

PEK7 Agar

Top agar:

Casitone (Difco)	0.2%
Pectin	0.5%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved and poured on CY agar plates.

Pectolytic CLB are very common in freshwater (Güde, 1973). They have also been isolated from soil samples after enrichment by percolation of a 1% pectin solution through the samples (Dorey, 1959; his *Fv. pectinovorum* is actually a CLB: Christensen, 1977b). The pectolytic CLB do not depend on pectin but may be stimulated by the presence of a carbohydrate like glucose. They can easily be purified by plating a diluted cell suspension on, e.g., CY agar + 0.3% glucose (= CYG2 agar) or on MYX agar.

MYX Agar

Na glutamate	0.5%
Yeast extract (Difco)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Glucose (autoclaved separately)	0.2%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

FISH PATHOGENS. CLB pathogenic for fish can usually be isolated and cultivated on relatively simple media. For freshwater strains, AO agar has been used with good results (e.g., Anacker and Ordal, 1955, 1959; Bullock, 1972; Pacha and Ordal, 1967; Snieszko and Bullock, 1976).

AO Agar (Anacker and Ordal, 1955)

Tryptone (Difco)	0.05%
Yeast extract (Difco)	0.05%
Beef extract	0.02%
Na acetate	0.02%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved. The agar concentration may be varied depending on the purpose for which the medium is used; a reduction to 0.9% is recommended for the first isolation from fish (for AOW agar), and to 0.4% for stock cultures (for AOS agar).

Infested material from gills, skin lesions, or from internal organs, such as kidney or spleen, is streaked on agar plates and incubated at 12 to 18°C or at 30°C depending on the origin of the fish. Initially, media containing diluted fish infusion were used for isolation (Ordal and Rucker, 1944), but this seems not to be required, at least not in all cases, because similar results have been obtained with beef extract (Bernardet, 1989). However, sometimes, the fish pathogens grow very slowly at first, and need an adaptation period before they can conveniently be handled (Ordal and Rucker, 194). This is not totally unusual, for it has been observed that a CLB that had been growing for a long time in a chemostat lost its ability to grow on plates, so that the plate count dropped to 20% of the viable cell count (Höfle, 1983). The

medium used for isolation is, of course, not exclusive for pathogenic CLB, or CLB at all, and many kinds of saprophytic bacteria will grow on it as well. This may become a problem especially if the fish has already been dead for some time, because it is quickly colonized by putrefying organisms. A study of the drug resistance of a collection of *Cy. columnaris* strains revealed that the organism is resistant to a number of antibiotics (Fijan and Voorhees, 1969), and by the addition of neomycin (5 μg/ml) + polymyxin B (10 units/ml) to AO agar, the isolation yields could be improved (Fijan, 1969). The pathogenic CLB can be recognized on the plate by their yellow to orange colonies, which give a positive flexirubin reaction, and, in the case of *Cy. columnaris*, by a very typical, rhizoid-colony morphology. Spreading of the colonies is not always well pronounced, especially with *Cy. psychrophila*; but this organism can easily be recognized, because it does not grow at 30°C and, in contrast to environmental CLB, does not utilize sugars.

For isolating CLB pathogenic for marine fish AOW agar prepared with artificial seawater (= MAOW agar) or, for estuarine sources, with one-third-strength artificial seawater (= BAOW agar) are useful. Also, a richer medium, Marine Agar (Difco), which is a peptone (0.5%)-yeast extract (0.1%) agar (1.5%) in artificial seawater, has been used with good results (Hikida et al., 1979; Campbell and Buswell, 1982). In another case, the pathogen proved more fastidious and could only be isolated and cultivated on an agar medium containing 5% of an enzymatic digest of fish muscle in addition to peptone (0.1%) and yeast extract (0.1%) in seawater (Anderson and Conroy, 1969). In this case it was also shown that the organism depended on a high salt concentration, and that a NaCl solution could not replace seawater. In fact, the fish—rainbow trout with severe lesions on the jaws and snout ("eroded mouth disease")—could be healed simply by transfer to fresh water. *Cy. columnaris*, on the other hand, is completely inhibited by 1% NaCl (Fijan and Voorhees, 1969; Pacha and Ordal, 1970).

THE GENUS *CAPNOCYTOPHAGA*. The capnocytophagas are normal inhabitants of the human oral cavity where they can be found in tooth pockets and in the dental plaque. They may also occur in large numbers in periodontal disorders and infected lesions in the mouth. The genus was established by Leadbetter et al. (1979), but the organisms are very probably identical with the fast-gliding, anaerobic, slender rods discovered 20 years earlier during a study of fusospirilloses of the human oral cavity, which were described under the name *Sphaerocytophaga* (Gräf, 1961). In fact, they were known even before that time, but as *Bacteroides* species. Although the capnocytophagas have a strictly fermentative metabolism, they are not particularly sensitive to oxygen and grow both in the presence and the absence of oxygen, provided an elevated level of CO_2 is supplied. The capnocytophagas are not fastidious at all and can easily be isolated and cultivated (Forlenza and Newman, 1983; Gräf, 1961; Leadbetter et al., 1979). Originally they were isolated on 10% sheep's blood agar. The samples were streaked onto the agar surface, and the cultures were incubated for 7 to 8 days at 37°C in Fortner plates, i.e., a co-culture with a facultative anaerobe. Spreading colonies were obtained, which showed a reddish hue and consisted of cells that were more or less yellow when scraped together (Gräf, 1961).

Leadbetter et al. (1979) recommended the following procedure: The sample material is quickly transferred to a screw-cap tube containing a modified Ringer's solution (NaCl, 0.9%; KCl, 0.042%; $CaCl_2 \cdot 2H_2$, 0.025%). Plaque material may be homogenized by a short burst of ultrasound (5 to 10 sec). Within 30 min after sampling, streaks are made on trypticase soy broth agar (TSB agar), which may be supplemented with 5% sheep's blood; the blood is, however, not essential. The cultures are incubated at 37°C in an atmosphere of $H_2 + CO_2 + N_2$ (GasPak, Baltimore Biological Laboratories = BBL). After 2 to 3 days, spreading colonies may be observed, but higher yields are obtained after 5 days (100% rather than 45%: Forlenza and Newman, 1983). There are three types of colonies—grey, pink, and yellow—but the cell masses of all three are yellow when scraped together. The shapes of the colonies depend critically on the ingredients used for preparing the medium: With stocks from other suppliers than BBL, nonspreading, small, compact colonies were obtained on the same type of medium (variations of this kind could, however, also be a result of using different batches of a medium component from the same supplier). The strains are purified by repeatedly streaking out material from swarm edges.

TSB Agar (Leadbetter et al., 1979)

Trypticase soy broth (BBL)	3%
Agar	3%

The pH is 7.3 (unadjusted). The medium is autoclaved.

Trypticase soy broth consists of:

Trypticase peptone	1.7%
Phytone peptone	0.3%
NaCl	0.5%
K_2HPO_4	0.25%

Glucose	0.25%

TSB agar may be supplemented with 5% sheep's blood (for TS-blood agar).

The capnocytophagas may also be first enriched by suspending sample material in trypticase soy broth without glucose in screw-cap tubes. After tightening the lids, the tubes are incubated at 37°C for 3 days. After that, large numbers of slender fusiform rods may be found in the liquid. Isolates are obtained by streaking the cell suspension on the media mentioned above.

It may be mentioned here that free-living CLB are also known that require CO_2 for fermentative growth on glucose—for example, the facultative anaerobe *Cy. succinicans* (Anderson and Ordal, 1961a, 1961b).

In addition to capnocytophagas, CLB that are not obligatory fermentative and that do not require CO_2 have also been found in dental plaque (London et al., 1982). The organisms could be isolated on blood agar media similar to those mentioned above, e.g., Columbia blood agar (BBL) or modified Schaedler agar with 5% defibrinated horse blood. The plates were incubated at 37°C in a GasPak atmosphere, but the bacteria can grow equally well in a normal atmosphere. The organisms were recognized by their spreading swarm colonies.

Purification

Purification of most members of the Cytophagales is relatively uncomplicated. It is usually sufficient to suspend, dilute, and plate samples from enrichment cultures by conventional methods. In some instances, e.g., with *Cy. columnaris*, the preparation of homogeneous suspensions may be difficult because the cells are embedded in a tenacious, sticky slime, but use of a small tissue homogenizer normally solves this problem. The plating medium should contain somewhat higher nutrient concentrations than the enrichment medium because high plating efficiency is desirable, and spreading growth is not required and should in fact be repressed. Some suitable media are CY agar, sometimes better with glucose (e.g., CYG2 agar); MYX agar; and, for marine strains, SAP2 agar. Often, pure strains are quickly obtained by repeatedly transferring material from the edges of spreading swarm colonies. These transfers should be made carefully, preferably by cutting out a little block of agar with the swarm edge using the sharp needle of a 1-ml disposable syringe. For this technique, media that favor gliding motility are, of course, preferable. The specific problems encountered with certain groups of the Cytophagales have already been discussed.

Cultivation

Most bacteria of the order Cytophagales can be cultivated on relatively simple media. VY/2 agar and CY agar have proved useful for all terrestrial and freshwater organisms except the cellulose decomposers. Cultures usually remain viable longer on VY/2 agar because growth is lighter and the pH is not changed as much as on CY agar. VY/2 agar is also useful for deciding whether an organism is a glider because it stimulates spreading growth. If heavier growth is desirable, CY agar may be enriched with glucose as, e.g., in CYG2 agar. Growth of some CLB is much stimulated by the presence of a carbohydrate. The cellulose decomposers grow very well on filter paper placed on CY agar. Other media suitable for their cultivation are listed above. If these gliding bacteria are cultivated on mineral salts-glucose media (CA2 and CA13 agar) they often grow only if a heavy inoculum is applied.

VY/2 Agar

Bakers' yeast (by fresh weight of commercial yeast cake)	0.5%
$CaCl_2 \cdot 2H_2O$	0.1%
Cyanocobalamin	0.5 μg/ml
Agar	1.5%

The cyanocobalamin is usually not required.

The pH is adjusted to 7.2. The medium is autoclaved. The yeast may be stored as an autoclaved stock suspension for several weeks. A uniform distribution of the yeast is obtained if the medium is melted before the yeast is added.

Many bacteria of the *Cytophaga* group produce heavy growth on HP6 agar, MYX agar, and similar media. Many will also grow well on mineral salts-glucose media like CA2 and CA13 agar. Special media that allow the detection of the ability of a strain to decompose certain macromolecules have already been mentioned. A medium useful for the demonstration of starch decomposition is STK2 agar.

HP6 Agar

Na glutamate	1%
Yeast extract (Difco)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Cyanocobalamin	0.5 μg/ml
Glucose (autoclaved separately)	0.5%
Agar	1.5%

The cyanocobalamin is usually not required.

The pH is adjusted to 7.2. The medium is autoclaved.

STK2 Agar

Base agar:

Casitone (Difco)	0.1%

Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2 The medium is autoclaved.

Top agar:
As base agar, but agar concentration increased to 1.5%. The medium is prepared with only about 85% of the total water volume. In the remaining water are dissolved, referring to the total volume of the top agar, the following:

Soluble starch	0.2%
K_2HPO_4	0.02%

The starch solution should be heated on a water bath before autoclaving in order to prevent clumping of the starch. The two solutions are combined after autoclaving, and the mixture is poured as a thin layer on plates of the base agar. Starch degradation can be discovered if, after a suitable incubation time, the culture plates are flooded with an iodine solution, e.g., Lugol's solution diluted 1:5.

The fish pathogens can be cultivated on AO agar but usually also grow well on CY, MYX, and HP6 agar. Most strains do not utilize carbohydrates at all. The capnocytophagas grow on TSB agar with or without sheep's blood.

The same types of media can be used for the marine Cytophagales, only prepared with natural or artificial seawater instead of distilled water. No case is known in which the latter would not do, but a simple NaCl solution is often not suitable (e.g., Anderson and Conroy, 1969). The tolerated salinity range differs depending on the organism and often depends on the origin of the strain (e.g., Lewin and Lounsbery, 1969; Reichardt et al., 1983). Marine cellulose decomposers may be cultivated on filter paper placed, e.g., on SW5 agar. Alternatively, the mineral salts-glucose media as described for the terrestrial organisms may be used, when prepared with seawater.

The type of peptone added to a medium is not as crucial in the case of the Cytophagales as it is for myxobacteria; nevertheless, very different results may be obtained with different preparations and even with different batches. An example has already been given for the capnocytophagas. In our experience, enzymatic digests of casein, e.g., casitone (Difco) or peptone from casein (Marcor, Merck, and Oxoid) are the most universally useful peptones. Soy peptones also often give excellent results. Addition of yeast extract may stimulate growth appreciably. Again, not all preparations are equally satisfactory; good results are obtained, e.g., with Difco yeast extract. Further, it should be kept in mind that quite a few bacteria of this group grow on inorganic nitrogen sources, and it is always worthwhile to test an isolate for that possibility

As a rule, members of the Cytophagales immediately produce homogeneous cell suspensions when inoculated into liquid media and shaken. Typically, the liquid shows a silky shimmer when rotated. Rarely, the bacteria grow in tiny granules or flakes, and then probably always are surrounded by thick capsules or slime layers. The medium sometimes becomes more or less viscous, especially when sugars are included, and harvesting the cells by centrifugation may then make difficulties. In one such case, the addition of 10% $(NH_4)_2SO_4$ (w/v) resulted in satisfactory separation (Verma and Martin, 1967).

Most Cytophagales grow well in liquid media that contain peptone, e.g., CAS liquid medium or FXA liquid medium, and for marine organisms, SP5 liquid medium. Addition of a sugar, such as in FXAG liquid medium, may stimulate growth considerably and may even be a prerequisite for cultivation. Glucose, galactose, mannose, saccharose, and maltose are often readily utilized. The sugar has two effects: it is a convenient carbon and energy source, and it is partly transformed into acids that delay the rise of pH of the medium that results from ammonia production. Shifts of pH may cause problems in shake cultures. Concentrations of buffers high enough to stabilize the pH reliably are often inhibitory to growth. With *Fx. filiformis* (former *Fx. elegans* Fx el), appreciable inhibition was observed at the following buffer concentrations (at a pH of about 7.0): citrate above 15 mM; phosphate, Tris HCl, and Tris-maleic acid-KOH above 20 mM; 3-morpholino-propane sulfonic acid (= MOPS) above 50 mM (E. Fautz, personal communication).

CAS Liquid Medium

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH is 6.8 and needs no adjustment if Difco casitone is used. The medium is autoclaved.

FXA Liquid Medium

Casitone (Difco)	1%
Yeast extract (Difco)	0.2%
$MgSO_4 \cdot 7H_2O$	0.1%

Other similar, enzymatically digested, casein peptones may also be used, e.g., Peptone from casein, tryptically digested (Merck, Darmstadt, Germany).
The pH is adjusted to 7.0. After autoclaving, 0.2% of separately autoclaved glucose may be added, for FXAG liquid medium.

SP5 Liquid Medium

Casitone (Difco)	0.9%
Yeast extract (Difco)	0.1%

In artificial seawater.

The pH is adjusted to 7.2. The medium is autoclaved.

The fish pathogens can be cultivated in the same media mentioned for their isolation, e.g., AO broth (AO agar without agar) (e.g., Bernardet and Kerouault, 1989; Bullock, 1972; Pacha, 1968). A supplement to AO broth of 5% fish peptone, prepared from brook trout, has been recommended and gave superior results with some isolates, although it was not strictly required; it may sometimes be useful with fresh isolates (Kincheloe, 1962). For marine fish pathogens, AO broth in seawater or TCY liquid medium may be used (e.g., Hikida et al., 1979).

TCY Liquid Medium (Hikida et al., 1979)

Tryptone (Difco)	0.1%
Casamino acids, technical (Difco)	0.1%
Yeast extract (Difco)	0.02%
NaCl	3.13%
KCl	0.07%
$MgCl_2 \cdot 2H_2O$	1.08%
$CaCl_2 \cdot 2H_2O$	0.1%

In distilled water.

The pH is adjusted to 7.0 to 7.2. The medium is autoclaved.

One study showed that growth of *Cy. columnaris* can be substantially improved by a fine-tuning of the medium formulation (Song et al., 1988). The optimal medium was SO broth, which was a modification of a medium used by Shieh (1980), from which glucose, pyruvate, and citrate have been omitted, because these compounds had no effect on growth. The medium was much superior to tryptone-yeast extract and tryptone-yeast infusion broth. The generation time was reduced to 150 min compared to 210 min in the next-best medium.

SO Liquid Medium (Song et al., 1988)

Peptone	0.5%
Yeast extract	0.05%
Na acetate	0.001%
$BaCl_2 \cdot H_2O$	0.001%
K_2HPO_4	0.01%
KH_2PO_4	0.005%
$MgSO_4 \cdot 7H_2O$	0.03%
$NaHCO_3$	0.005%
$CaCl_2 \cdot 2H_2O$	6.7 mg/liter
$FeSO_4 \cdot 7H_2O$	1.0 mg/liter

The capnocytophagas are obligatory fermenters and grow luxuriantly in trypticase soy broth (TSB agar without agar) supplemented with 1% glucose; the cultures are incubated under the exclusion of oxygen (Forlenza et al., 1981).

Many Cytophagales can also be cultivated in simple synthetic media, e.g., SY liquid medium. Stabilization of the pH is especially difficult in this case and is effectively achieved only in bioreactors.

SY Liquid Medium

KH_2PO_4	0.07%
$Na_2HPO_4 \cdot 2H_2O$	0.14%
$(NH_4)_2SO_4$	0.2%
$MgSO_4 \cdot 7H_2O$	0.02%
$FeSO_4$	5 mg/l
$MnSO_4$	5 mg/l

After autoclaving, 1% glucose is added from a separately autoclaved stock solution.

Cellulose decomposers grow well in liquid media with powdered cellulose, e.g., in CEL1 liquid medium or in Dubos liquid medium with 0.5% cellulose. We use, with good success, a peptone-mineral salts medium with cellulose powder (= M9 liquid medium). Also, CAS liquid medium with cellulose powder (0.5%) often allows good growth. Further, many strains of cellulose degraders may be cultivated in glucose-containing liquid media such as GLU liquid medium (Kath, 1990; Verma and Martin, 1967).

CEL1 Liquid Medium

ST5 liquid medium is supplemented with 0.1% powdered cellulose (e.g., MN300 for chromatographic purposes from Macherey and Nagel, Düren, Germany), autoclaved separately as a stock suspension.

M9 Liquid Medium

Base medium:	
NH_4Cl	0.1%
K_2HPO_4	0.075%
Casitone (Difco)	0.3%
Yeast extract (Difco)	0.09%
Supplement A:	
$MgSO_4 \cdot 7H_2O$	4.5%
Supplement B:	
$CaCl_2 \cdot 2H_2O$	0.2%
$FeCl_3 \cdot 6H_2O$	0.15%
$MnSO_4 \cdot H_2O$	0.15%
Supplement C:	
Cellulose powder	10%

After autoclaving all solutions, 1% (v/v) of supplements A and B, 5% (v/v) of supplement C, and filter-sterilized standard trace elements (see, e.g., Chapter 188) are added to the base medium.

GLU Liquid Medium (Kath, 1990)

The percentages indicated for each ingredient are with respect to the final volume of the medium.

Solution A:	
NH_4Cl	0.1%
K_2HPO_4	0.075%
Casamino acids (Difco)	0.3%
$Na\text{-}Fe^{III}\text{-}EDTA$	0.002%

HEPES 1.19%
In 90% of the total volume.
The pH is adjusted to 7.2.

Solution B:
$MgSO_4 \cdot 7H_2O$ 0.045%
$CaCl_2 \cdot 2H_2O$ 0.01%
Glucose 0.5%
In 10% of the total volume.

After autoclaving, solutions A and B are combined, and standard trace elements are added from a filter-sterilized stock solution (see, e.g., Chapter 188).

Most members of the Cytophagales can be grown without difficulties on a large scale in bioreactors. In ordinary batch cultures, typical yields obtained are between 10 and 15 g wet weight, or 2 to 4 g dry weight per liter on peptone media with sugar; the ratio of dry to wet weight is 0.20 to 0.25. Generation times are in the range of one to several hours. Thus, e.g., *Fx. filiformis* Fx el grows in peptone media at 30°C with a doubling time of 2 h and 15 min; in mineral salts-glucose medium (SY liquid medium) it grows with a doubling time of 6 h and 20 min (H. Fink, personal communication). *Tx. ocellatus* grows at 30°C with generation times of 1 h and 50 min in peptone liquid medium, 2 h in dilute peptone medium, and 3 h and 30 min in casamino acids-glucose medium.

Little is known about specific mineral and vitamin requirements by members of the Cytophagales. At least, they appear not to be particularly fastidious in that respect. In a study on trace element effects on cellulose-degrading *Sporocytophaga* growing in a mineral salts-cellulose medium, a stimulation of cellulose decomposition by Ca^{2+}, Fe^{2+}, Mn^{2+}, and sometimes Cu^{2+} was demonstrated (Bortels, 1956). Certain Zn salts (ZnO, ZnS, 0.1%) were found to encourage growth of a series of cytophagas and CLB; $ZnSO_4$ (0.1%) suppressed swarming and slime production on plates, and its use in isolation media was suggested (Mehra et al, 1967). In a comparative study of a large number of different marine Cytophagales, a dependence on thiamine and cyanocobalamin was found in a few instances (Lewin and Lounsbery, 1969).

Except for the capnocytophagas, the Cytophagales are strict aerobes. Those that are known to grow anaerobically are usually facultative anaerobes. Some are able to respire on nitrate. Not one of the tested strains could use fumarate as an electron acceptor (Callies and Mannheim, 1978). Several Cytophagales require carbon dioxide for fermentative metabolism, so that care should be taken that enough CO_2 is present in the atmosphere when strains are being tested for anaerobic growth (GasPak, candle jar, Fortner plates, carbonate in the medium). The only strictly fermentative Cytophagales known so far are the capnocytophagas, which are, however, not oxygen sensitive but do require an increased level of CO_2; if that is provided, they can grow even under aerobic conditions (Leadbetter et al., 1979). They need CO_2 because they depend on the activity of phosphoenolpyruvate carboxykinase for growth (Kapke et al., 1980). There seem also to be *Capnocytophaga* strains that grow at CO_2 levels found in air. The existence of strictly anaerobic Cytophagales is not yet excluded.

All known Cytophagales are restricted to pH values between 6 and 8. Their temperature range is wide, from about 0°C to more than 40°C. On plates, most strains will grow more or less at 30°C. In contrast, liquid cultures of many strains, particularly those isolated from aquatic environments, grow only, or grow much better, at lower temperatures (usually between 18 and 26°C).

Preservation

Agar cultures of many Cytophagales stay viable for months when stored at low temperatures (2 to 8°C). At room temperature or higher, plate cultures can usually be kept for 2 to 6 weeks. In general, organisms from aquatic environments are more sensitive than those from soil. Media that are rich in peptone or contain higher concentrations of a sugar are always less suitable for stock cultures, because they produce heavier growth and lead to unfavorable pH shifts. Good media for stock cultures are often VY/2, CYT, and SAP2 agar. For the fish pathogens, a reduction of the agar concentration in AO medium to 0.4% is advantageous. Cellulose decomposers are kept best on filter paper on top of CY or ST6 agar.

For long-term storage, essentially all standard methods for the preservation of bacteria can be applied to the Cytophagales. In our experience, the following methods give excellent results.

Drying in Skim Milk

From a young plate culture, a heavy cell suspension is prepared in about 0.7 ml of sterile skim milk. Three to five drops of this suspension are placed on a plug of skim milk predried by lyophilization in an ampule. The plug must not become solubilized but only wetted by the amount of added cell suspension. The loaded ampules are stored at 4 to 6°C until the whole set has been finished (not longer than one h), and are then dried in a desiccator over silica gel at a good vacuum for about 4 h at room tem-

perature. The desiccator is kept overnight under vacuum, then pumped again for 15 min, and filled with nitrogen gas (preferably by attaching it to a nitrogen-filled balloon). Then the ampules are sealed and stored at room temperature or at 4 to 6°C (we do not yet know whether there is a difference in survival times). So far, organisms have been revived by us after up to 10 years of storage at room temperature. Successful lyophilization is also reported for *Cy. columnaris* (Anacker and Ordal, 1959). Lyophilized cultures of *Cy. columnaris* and *Cy. psychrophila* which had been kindly supplied to us by Dr. R.E. Pacha (Ellensburg, Washington) could be reactivated without problems after 26 and 20 years, respectively.

Skim Milk Preparation (for Preservation)

40 g of powdered skim milk (e.g., Oxoid L31; must be free of antibiotics) are dissolved in 200 ml water and filtered through gauze. The solution is distributed into tubes (5 ml per tube) or ampules (1 ml per 5-ml ampule), and autoclaved at exactly 115°C for 15 min. May be stored in the cold for several weeks.

Storage at Ultra-Low Temperatures

From a dense liquid culture, e.g., in FXA or CAS liquid medium, 2-ml amounts are pipetted into screw-cap tubes and placed directly into a deep freeze at −70 to −80°C. Samples of marine organisms, e.g., in SP5 liquid medium, should be kept in an inclined position during freezing to prevent cracking of the tubes. Cellulose decomposers have been successfully frozen in CEL1 liquid medium.

Alternatively, a heavy loopful of cells from a plate culture is deposited in 1 ml of a peptone-containing liquid medium, like the ones mentioned above, and frozen in the same way. The peptone medium can also be used for cellulose decomposers. Fish pathogens can be frozen at −70°C as agar cultures in AO agar with 0.9% agar; they were found to remain viable for at least one year (Fijan and Voorhees, 1969). Of course, all cultures for preservation should be young, well-growing cultures in an optimal state.

Alternatively, cell suspensions in peptone liquid media may be stored frozen in liquid nitrogen. A special freezing program is not required. We routinely add 5% dimethyl sulfoxide (DMSO) to the suspension medium, although our experience suggests that this is not necessary. In a systematic study on cryopreservation of Cytophagales, mainly marine ones, good survival in liquid nitrogen was demonstrated when the cells were suspended in a medium containing 10% glycerol, while 10% DMSO proved less suitable. Also without additives, at least one cycle of freezing and thawing was usually well tolerated. Many strains remained viable even for some weeks at −22°C without additives, but eventually, after varying storage times, most strains died (Sanfilippo and Lewin, 1970).

For revival, the frozen tube or ampule is quickly thawed, best by placing it into cold water. Immediately after the medium has become liquid, the bacteria are transferred to a suitable growth medium. For reviving a culture, it is advisable to use several different agar and liquid media in parallel, because one or the other may be more appropriate depending on the organism. Also, we found that facultative anaerobes are occasionally better reactivated under anaerobic conditions; they sometimes refuse to start to grow in an aerobic atmosphere, even when they thrive ordinarily very well under such conditions. Thus far we have tested survival at −80°C for up to 15 years, and in liquid nitrogen for up to 10 years and have not yet observed any losses.

Storage in 50% Glycerol at −25°C

Using a young plate culture, a heavy cell suspension is prepared in 50 mM phosphate buffer, pH 7.2. Of this suspension, 1 ml is transferred to a screw-cap tube that contains 2 ml of 87% glycerol precooled to −25°C. The suspension is thoroughly mixed and stored at −25°C in an ordinary household deep freeze. Marine organisms may be suspended in SP5 liquid medium; 1 ml of the suspension is then transferred to 2 ml of precooled 87% glycerol. Alternatively, a heavy loopful of cells is suspended directly in precooled SP5 liquid medium + 87% glycerol (1:2, vol/vol).

To start an active culture, a loopful of the suspension is streaked on a suitable agar medium. The remaining suspension may be returned to the deep freeze, provided the temperature was kept low during handling. CLB preserved by this method may survive for at least several years (I. Hirsch, personal communication), but we have in some cases observed losses, particularly with marine strains, so this technique is advisable for long-term storage, especially when better alternatives are available.

Storage in 0.9% Saline or in Distilled Water

Starting from young plate cultures, cell suspensions are prepared in 0.9% saline or in distilled water. The cell density should not be very high; we usually prepare a suspension of about 10^7 to 10^8 cells/ml (a suspension just faintly turbid), and this stock suspension is then diluted fivefold. Then, 0.5-ml amounts of both suspensions

are transferred in parallel to 1-ml ampules, which are sealed under air and stored at room temperature (18 to 22°C) in the dark. Marine organisms may be suspended in artificial seawater. In our laboratory, a number of *Flexibacter* and CLB strains stored in saline for 7 years could be reactivated with ease and produced heavy growth within 2 days; it is likely that they would have survived for even longer periods. However, the organisms probably are not completely at rest in such suspensions and continue to grow, even if extremely slowly, so that over a long period variant strains may arise.

Characterization

Cell Morphology and Cytology

The cells of all Cytophagales without exception are rod-shaped (Fig. 1 and 2). The proportions and dimensions of the rods vary, however, over a wide range. The CLB have very short to moderately long rod cells; the short ones are often relatively fat, and the longer ones may be rather slender; they typically measure 0.5 to 1.0 × 2 to 8 μm; the cell ends are usually slightly tapered. The cells of *Capnocytophaga* resemble those of CLB with moderately long rods. *Taxeobacter* has relatively plump cylindrical rods with rounded ends. The rod cells of the cellulose decomposers (*Sporocytophaga, Cytophaga*) tend to be moderately long and very delicate, measuring 0.3 to 0.7 × 3 to 8 μm; *Cytophaga* cells are often spindle-shaped. *Flexibacter* and (*Microscilla*) have long thread cells which contain either very few or no cross-walls, and typically measure 0.4 to 0.8 × 10 to 50 μm. Many species readily form spheroplasts. Especially in cultures of cellulose-decomposing true cytophagas, large numbers of lemon-shaped intermediary forms can often be seen (Fig. 1f). This was a source of much confusion for the early investigators (who had no phase contrast microscopes), and fancy developmental cycles have been constructed on such observations (for a review, see Imschenezki, 1959). Inflated, spindle-shaped rods may still be motile and viable and may recover, but it is doubtful whether such stages are of any advantage for the organism, e.g., for a rearrangement of the genetic apparatus, as has been suggested. Lemon-shaped degeneration forms are also typical for *Taxeobacter*. Under starvation, a *Cy. johnsonae* strain was observed to produce coccoid cells which looked like spheroplasts, did not show a peptidoglycan layer, often had lost most of their cytoplasm, and were osmotically stable (Reichardt and Morita 1982). Nevertheless, they were found to be viable, and at least some of them could grow out again into rods. It was suggested that they represent survival forms. Spheroplastlike cells have also been interpreted as resting stages in several other Cytophagales (e.g., Gräf, 1961, 1962; Bauer, 1962), and generic names have even been proposed based on such observations ("*Sphaerocytophaga*," "*Sphaeromyxa*"). But the evidence for a function as resting forms is not convincing in any of those cases.

Several Cytophagales change their cell morphology in response to environmental conditions. Marine *Flexithrix dorotheae* is described to grow quasi-mycelially with long, sheathed filaments that release short, gliding fragments, which may again grow into filaments (Lewin, 1970). Unfortunately, the type strain, which is the only known strain of that organism, does not show this behavior any more; at least I have not been able to verify it in spite of many efforts.

The vegetative cells of *Sporocytophaga* may convert by shortening and fattening into small (diameter 1.2 to 1.4 μm), spherical, optically refractile microcysts. The microcysts are desiccation resistant; we have isolated strains from dry soil samples that had been stored for up to 9 years at room temperature. Their high heat tolerance, which allows them to survive at 60°C, in some cases even at 100°C for a short time, has already been mentioned.

Fx. filiformis (Fx el) and related species go through a spectacular shape change in the course of culture development (Fig. 2c to 2e). When inoculated into a liquid medium, e.g., CAS or MD1 liquid medium, the organism grows into long (15 to 50 μm and more), slender, flexible cells. These cells are not the usual filaments or trichomes, for they contain no cross-walls or septa, or only very few widely separated ones (10 to 30 μm); I therefore call them thread cells. The thread cells are extremely agile and can glide, bend, twist, and wriggle like little worms. When the culture ages, the cells become shorter and shorter and may finally end up a very short coccobacilli (this stage is not always reached). The shorter rods also become slightly fatter and darker, which clearly indicates that the shortening is not simply a fragmentation of the thread cells. Under certain conditions the organism may grow exclusively in the long or in the short form. One factor that determines the length of the cells is obviously population-density connected. The same cycle can also be observed in plate cultures, e.g., on VY/2 agar, on which fast-spreading swarms are produced. Here, agile thread cells are found at the edge, while shorter and shorter rods are found moving towards the center of the colony. Below a certain

length, the rods become nonmotile. The same developmental cycle has been described for *Chitinophaga*, only there the coccobacilli were interpreted as microcysts (Sangkhobol and Skerman, 1981); this appears, however, not to be correct. A study on the length control of *Flexibacter* strain FS-1 revealed that the long thread cells grew exponentially with a generation time of 90 min at 30°C. When the culture was shifted to 35°C they divided into three or four cells within the following 120 min. The culture continued to grow exponentially with about the same growth rate, but with shorter cells. When the culture was shifted back to 30°C, the shorter cells stopped dividing immediately but continued to grow, and the thread cells reappeared. When the thread cells divided, the constriction always occurred in the middle of the cell. The biochemical and genetic mechanisms that control all these fascinating morphogenetic processes are not at all understood and have not been thoroughly studied. In particular, *Fx. filiformis* should provide a beautiful model system for such investigations (Humphrey and Marshall, 1980; Poos et al., 1972; Reichenbach et al., 1974; Simon and White, 1971).

The fine structure of the cells of the Cytophagales is essentially that of typical Gram-negative bacteria, with a few remarkable peculiarities. The outer surface of the cells is usually corrugated or undulated and densely covered with cushionlike knobs and folds (e.g., Bovallius, 1979; Follett and Webley, 1965; Humphrey et al., 1979; Oyaizu et al., 1982; Strohl, 1979; van der Meulen et al., 1974). Often, vesicular and long, uneven, tubular extensions of the outer membrane and LPS can be seen (e.g., Follett and Webley, 1965; Holt et al., 1979a; Kuhrt and Pate, 1973; London et al., 1982; Martin et al., 1968; Pate and Ordal, 1967a; Pate et al., 1967; Simon and White, 1971). These strands may become as long as 0.5 μm and have been shown to contain LPS components, like 2-keto-3-deoxyoctonate (Humphrey et al., 1979). All Cytophagales excrete slime, sometimes in substantial quantities, and this slime can usually be distinguished as a dense network of fine fibril surrounding the cells (e.g., Bovallius, 1979; Humphrey et al., 1969; Martin et al., 1969; Pate and Ordal, 1967b; Ridgway and Lewin, 1973; Ridgway et al, 1975; Strohl and Tait, 1978; Verma and Martin, 1967). The microcysts of *Sp. myxococcoides* are encased in a massive, fibrillar capsule, about 180 nm thick (Holt and Leadbetter, 1967; the diameter of the microcysts as determined in this study was an astonishing 2 to 2.5 μm, which is much greater than is usually measured in the light microscope [1.2 to 1.4 μm]).

The cell envelope of the Cytophagales consists of a thin peptidoglycan layer and the usual outer membrane. In marine, filamentous *Fx. polymorphus* (clearly different from *Flexibacter* as defined here, and of uncertain taxonomic position), an unusual S-layer was discovered on top of the outer membrane (Ridgway, 1977; Ridgway and Lewin, 1973, 1983; Ridgway et al., 1975) The layer consists of densely packed, goblet-shaped subunits, which have a complicated structure and are perhaps rooted in the cytoplasmic membrane. Another very interesting structural detail has been detected in the cell envelope of certain CLB (Pate and Chang, 1979). Here, tiny rings were seen and could be isolated from cell lysates. The rings were about 20 nm wide and 10 nm thick, and were arranged in long chains that seem to form a large, regular, netlike superstructure. It was hypothesized that these rings might be homologous with the flagellar rotors, and that their rotation would somehow propel the cell. It may be added here that the mechanism of gliding motility has been studied for many years with several Cytophagales, but so far without a clear answer (e.g., Burchard, 1984; Chang et al., 1984; Duxbury et al., 1980; Glaser and Pate, 1973; Godwin et al., 1989; Lapidus and Berg, 1982; Pate, 1985; Speyer, 1953; Wolkin and Pate, 1984). What can be said is that there is some motility apparatus in the cell surface, because latex beads move along the surface of immobilized cells (Lapidus and Berg, 1982); that the excreted slime is essential for gliding because it acts as a Stefan adhesive allowing easy translocation but preventing efficient detachment of the cells from the substrate (Humphrey et al., 1979); that the cells rotate around their long axis during gliding (Godwin et al., 1989); and that the energy for gliding may not be provided by ATP, at least not exclusively (Pate and Chang, 1979; Ridgway, 1977). The speed of gliding may be on the order of 100 to 150 μm/min, with large deviations in both directions, depending both on the organism and on environmental conditions (e.g., Duxbury et al., 1980; Garnjobst, 1945; Lapidus and Berg, 1982; Speyer, 1953; Stanier, 1942).

Fine longitudinal fibrils, which were arranged in wide bands just below the outer membrane, have been discovered in *Cy. columnaris* (Pate and Ordal, 1967b). They were suggested to represent the machinery of gliding motility. The fibrils could indeed not be seen in nonmotile mutants (Glaser and Pate, 1973). In freeze-etched preparations, tiny beads of about the same diameter as the fibrils can be seen on the inner surface of the outer membrane (Burchard and Brown, 1973). When the cells are fixed with

glutaraldehyde before being fractured, those beads arrange themselves in long lines which resemble fibrils. Thus it seems possible that the fibrils seen in ultrathin sections are merely fixation artifacts.

Lysing cells of *Cy. columnaris* release unusual tubular structures that appear to derive by invagination from the cytoplasmic and mesosomal membranes (Pate et al., 1967). They are composed of lipid and protein, although the number of protein bands is much reduced in comparison with the cytoplasmic membrane (Kuhrt and Pate, 1973). Similar tubules are also known from other Gram-negative bacteria including *Sporocytophaga* (e.g., Holt and Leadbetter, 1967; Martin et al., 1968; Yamamoto, 1967); they are not identical with rhapidosomes as has occasionally been suggested. The latter were originally observed in *Saprospira* (see Chapter 200 for a detailed discussion); they were later found also in other bacteria, e.g., *Sp. myxococcoides* (Pate et al., 1967) and may be phage tails.

The cells of the Cytophagales divide in the usual way by formation of a septum, which is normally connected with a mesosome (e.g., Holt and Leadbetter, 1967; Poos et al., 1972; Ridgway et al., 1975).

Appendages like fimbriae and pili seem never to have been observed with Cytophagales. Pili were, however, isolated from *Fv. branchiophilum*, where they supposedly are important for the attachment of this fish pathogen to gill filaments (Heo et al., 1990).

In several *Capnocytophaga* strains, acid and alkaline phosphatases could be localized by cytochemical and immunochemical reactions in the periplasmic space; in fact the enzymes were associated with the outer membrane, probably the LPS, and about 12% of the activity was exposed on the outer cell surface. Most of the enzyme molecules were released from the cells when the cultures became older, a good part of them in a membrane-bound form (Poirer and Holt, 1983b, 1983c). While the bacteria normally cannot penetrate the periodontal tissue it seems conceivable that enzymes like the phosphatases may do so and thus are responsible for damage inflicted to the host by *Capnocytophaga.*

Chemical Composition

The peptidoglycan appears as a clearly distinguishable layer in ultrathin sections of all Cytophagales studied in this respect; it is between 2 and 5 nm thick, but increases to 9 nm in *Sporocytophaga* microcysts (e.g., Pate and Ordal, 1967a; Verma and Martin, 1967a). The murein sacculus has been isolated from *Cy. hutchinsonii* and *Sp. myxococcoides* and chemically analyzed (Verma, 1970; Verma and Martin, 1967a, 1967b). It had the composition of a typical Gram-negative peptidoglycan with L-Ala, D-Glu, *m*-DAP, D-Ala, and 70% direct cross-linking between *m*-DAP and D-Ala. Diaminopimelic acid (0.2 to 0.3% of the dry weight) was also observed in an early study on two flexibacters; the diamino acid came most probably from the cell wall (Holm-Hansen et al., 1965). The same organisms appear also to contain bound ornithine (0.08 to 0.7% of the dry weight); the origin of that amino acid is obscure (Holm-Hansen and Lewin, 1965; it could come from an ornithine-containing lipid, see below). Also, the lipopolysaccharide (LPS) of the Cytophagales seems to closely resemble that of the enterobacteria. The LPS of *Fx. filiformis* Fx el (= Fx ½) was found to contain mannose, galactose, glucose, rhamnose, ribose, glucosamine, galactosamine, and small quantities of xylose, arabinose, 2-keto-3-deoxyoctonate (KDO), and heptose (Rosenfelder et al., 1974). From 17 strains of CLB and one strain each of *Cy. aurantiaca* and *Sp. myxococcoides*, the LPS was extracted with phenol, and its sugar composition was subsequently analyzed (Sutherland and Smith, 1973). LPS yields were between 0.4 and 3.4% of the dry weight (in addition, substantial amounts of polysaccharide could be harvested from the culture supernatant by ultracentrifugation). The LPS of all strains contained a high proportion of ribose (in the absence of an appreciable ultraviolet (UV) absorption at 260 nm), mannose, and glucosamine; further, most LPS preparations yielded glucose, galactose, and galactosamine, and 7 out of 19 also rhamnose. The hexosamines remained after removal of lipid A by mild hydrolysis. Because of analytical problems, KDO and heptose could not be determined reliably; but KDO always appeared to be present, whereas heptose remained questionable and was there in very small amounts, if at all. The LPS of *Flexibacter* BH3 contained galactose, glucose, arabinose, rhamnose, glucosamine, deoxysugar, and KDO, but heptose could not be detected (Humphrey et al., 1979). An endotoxin, which was highly active immunologically as well as in the *Limulus* test, was isolated from a CLB; its main carbohydrate constituents (above 0.5% of the total) were rhamnose, fucose, mannose, galactose, glucose, glucosamine, galactosamine, and an astonishing 34% of (tentatively identified) heptose; KDO is not mentioned (Flaherty et al., 1984). The inner and outer membrane of *Cy. johnsonae* were separated and showed densities of 1.18 and 1.14 g/

cm^3, respectively; the outer membrane contained the sulfonolipids that will be discussed later, but little or no KDO (Godchaux and Leadbetter, 1988). Occasionally, members of the Cytophagales produce copious amounts of extracellular slime. In the case of *Cy. hutchinsonii* and *Sp. myxococcoides*, that slime was found to be an acidic heteropolysaccharide consisting of xylose, arabinose, mannose, glucose, and glucuronic acid; the slime of *Sporocytophaga* also contains galactose (Martin et al., 1968; Verma and Martin, 1967b). This slime seems to be broken down enzymatically in the later stages of the culture. *Flexibacter* BH3 produces an extracellular, water-soluble, glycoprotein slime with glucose, fucose, galactose, and some uronic acid in the carbohydrate part (Humphrey et al., 1979). The extracellular slime of *Cy. columnaris* was determined to consist of a homopolymer of α-(1-4)-linked D-galactosamine (Johnson and Chilton, 1966).

The fatty acid patterns of the Cytophagales consistently show two peculiarities (Collins et al., 1982; Fautz et al., 1979, 1981; Godchaux and Leadbetter, 1984; Kath, 1990; Liebert et al., 1984; Oyaizu and Komagata, 1981; Walker, 1969):

1. The dominant species are branched fatty acids, mainly 15:0 (15 to 45% of the total; in *Capnocytophaga* up to 77%: Collins et al., 1982). Branching is mostly of the iso type, but small amounts of anteiso fatty acids are usually also present. Only *Cy. hutchinsonii* contains larger quantities of anteiso fatty acids, almost exclusively 17:0 (26% of the total), but as the identification was tentative, this should be reinvestigated (Walker, 1969). It was also stated that *Capnocytophaga* and *Sporocytophaga* exclusively contain anteiso fatty acids (Holt et al., 1979a), but at least for *Capnocytophaga* this could not be corroborated (Collins et al., 1982). In one study, 1 to 3% of the total fatty acids from CLB have been identified with (delta 17)-cyclopropane fatty acids (Oyaizu and Komagata, 1981). Other major fatty acids are straight chain 16:1, 16:0, and 15:0, usually in that order. The double bond has been found to be in the *cis* configuration and in the C-11 to C-12 position (Kath, 1990; Oyaizu et al., 1982; Walker, 1969).
2. There are always substantial quantities (15 to 55% of the total fatty acids) of 2- and 3-hydroxy fatty acids (Collins et al., 1982; Fautz et al., 1979, 1981; Kath, 1990; Liebert et al., 1984; Oyaizu and Komagata, 1981; Oyaizu et al., 1982). In *Capnocytophaga*, only 3-hydroxy fatty acids could be identified (Collins et al., 1982). Only a small part of these hydroxy fatty acids seem to rise from LPS where, in addition, exclusively 3-hydroxy fatty acids are found (Rosenfelder et al., 1974).

Most of them rather appear to have their origin in novel sulfonolipids, the capnoids, which were originally discovered in *Capnocytophaga* but have since been isolated from many other Cytophagales and may indeed by a chemosystematic marker for that group (Godchaux and Leadbetter, 1980, 1983, 1984). The capnoids are essentially sulfonated sphingolipids, in which the hydroxyl on C-1 of the sphinganine base, capnine, is replaced by a sulfonic acid group. Free capnine was found only in *Capnocytophaga*; normally the amino group on C-2 bears an amide-bonded, long-chain, fatty acid as in true ceramides. The sulfonilipids may comprise as much as 20% of the cell's total lipids and are localized in the outer membrane (Godchaux and Leadbetter, 1988). It appears that there is a connection between sulfonolipids and gliding motility, for capnoid-negative mutants of *Cy. johnsonae* are no longer able to glide, but gliding may recover when sulfonolipid synthesis is restored (Abbanat et al., 1986). The biosynthesis of the capnines is presumably due to the reaction of cysteine or, more likely, of cysteic acid with a matching fatty acyl-CoA compound (Abbanat et al., 1985; White, 1984).

The fatty acid pattern of marine *Fx. polymorphus* is unique among the Cytophagales in that it consists of relatively low amounts of (mainly iso-) branched species and large quantities of polyunsaturated fatty acids, viz. 18% 20:5 (Johns and Perry, 1977). This, together with the ultrastructural details discussed above, suggests that this organism may not be correctly classified among the Cytophagales.

It is interesting to note that very similar lipid patterns to those just discussed have been demonstrated in nonmotile but phylogenetically related flavobacteria, i.e., a high proportion of branched and of 2- and 3-hydroxy fatty acids (e.g., Dees et al., 1979; Fautz et al., 1981; Moss and Dees, 1978; Oyaizu and Komagata, 1981; Yabuuchi et al., 1983; Yano et al., 1976) and the occurrence of capnoids (Godchaux and Leadbetter, 1983) and typical sphingophospholipids and ceramides (e.g., Asselineau and Pichinoty, 1983; Yabuuchi et al., 1983; Yano et al., 1983).

The complex lipids of the Cytophagales are still incompletely known. In all organisms that have been investigated (*Capnocytophaga*, *Cy. hutchinsonii*, *Sp. myxococcoides*) phosphatidylethanolamine was by far the major phos-

pholipid (Collins et al., 1982; Holt et al., 1979c; Iizuka et al., 1987; Walker, 1969). The phospholipid content of the capnocytophagas was between 30 and 36% of the total cellular lipids when estimated as acetone-soluble lipid. The organisms also contained an ornithine lipid, some phosphatidylserine, substantial amounts of a polyprenol, and 5% squalene; two laboratories report the absence of phosphatidylglycerol (Collins et al., 1982; Holt et al. 1979a) while in a third laboratory (Iizuka et al., 1987), this compound was detected along with phosphatidylinositol and cardiolipin. In *Cy. hutchinsonii*, 45% of the dominating 16:1 fatty acid was recovered from phosphatidylethanolamine; no other phospholipid could be demonstrated in this organism, but it contained substantial quantities of two unidentified glycolipids (Walker, 1969).

The respiratory quinones of the Cytophagales are exclusively menaquinones (Callies and Mannheim, 1978; Collins et al., 1982; Kleinig et al., 1974; Oyaizu and Komagata, 1981). Different species contain either MK-6 or MK-7, and the distribution of the two types may be of taxonomic significance. Thus, all cellulose decomposers contain MK-7 and differ in that respect neatly from most terrestrial CLB, which are presently classified with them in the same genus but contain MK-6 (M.D. Collins, personal communication). The respiratory quinone of *Capnocytophaga* is MK-6 with traces of MK-5 (Collins et al., 1982), that of *Flexibacter* is MK-7 (Kleinig et al., 1974). Again, the true flavobacteria are also menaquinone organisms (Callies and Mannheim, 1978; Oyaizu and Komagata, 1981).

Most Cytophagales synthesize pigments. Apart from an occasional strain that produces a dark, diffusing, probably melaninlike substance (e.g., "*Cy. krzemieniewskae*": Stanier, 1941; *Fv.* (*Cy.*) *uliginosum*: ZoBell and Upham, 1944), the pigments are always cell-bound. Chemically they are of two kinds, either carotenoids or flexirubin-type pigments. The two pigment types may occur in the same organism but then are typically localized in different places: the carotenoids in the cytoplasmic, and the flexirubins in the outer membrane (Irschik and Reichenbach, 1978).

It had been suggested for many years that the yellow and orange pigments that can be extracted from many Cytophagales might be carotenoids (e.g., Anderson and Ordal, 1961a; Fox and Lewin, 1963; Lewin and Lounsbery, 1969; Verma and Martin, 1967a). Unequivocal proof of zeaxanthin (4,4′-dihydroxy-β,β-carotene) could be provided for the yellow pigment of marine *Ft. dorotheae* (Aasen and Liaaen-Jensen, 1966c); the same pigment was demonstrated by chromatographic comparison in marine *Cy. lytica* (Lewin and Lounsbery, 1969), and it was later chemically identified also in a terrestrial CLB (*Cy. johnsonae*: Achenbach et al., 1978b). Two monocyclic ketocarotenoids, flexixanthin and deoxyflexixanthin, have been isolated from a flexibacter (probably *Fx. roseolus*: Lewin and Lounsbery, 1969); their chemical structures have been elucidated (Aasen and Liaaen-Jensen, 1966b). *Cy. diffluens* appears to contain the monocyclic dihydroxy carotenoid saproxanthin (Lewin and Lounsbery, 1969), which was originally isolated from *Saprospira grandis* and identified by chemical methods (Aasen and Liaaen Jensen, 1966a).

A novel pigment type, the flexirubins, which later turned out to be of considerable chemosystematic relevance, has been discovered in *Fx. filiformis* (formerly *Fx. elegans* Fx el: Achenbach et al., 1974, 1976; Reichenbach et al., 1974). The chromophore is an omega-phenyloctaenic acid which is connected via an ester bond to a resorcinol bearing two hydrocarbon chains (Fig. 4). This basic chemical structure may be modified by variation of the length and branching of the hydrocarbon chains on the resorcinol, and by the introduction of additional substituents on the omega-phenyl ring, specifically methyl and chlorine; actually, for all pigment species, chlorinated counterparts are found in every flexirubin-producing organism (for reviews of their chemistry and biosynthesis, see: Achenbach, 1987; Achenbach et al., 1978). In this way, a large variety of different flexirubin-type pigments arise, and one single strain may synthesize more than 25 different compounds (Achenbach et al., 1979) Still, certain structural types seem to be characteristic for certain taxa, e.g., a methyl in the *meta* position on the omega-phenyl ring seems to occur only in *Flexibacter*. Biosynthetically, the omega-phenyl ring with the first three carbon atoms of the chain derive from tyrosine, the rest of the chain from acetate, and the resorcinol ring with its hydrocarbon substituents from acetate and various starter molecules, like propionate or isovalerate, via an orsellinic acid homologue; only the methyl on the omega-phenyl comes from methionine; the linking of the two halves of the molecule is the last biosynthetic step (Achenbach et al., 1972, 1982, 1983). A total synthesis of flexirubin has also been performed (Achenbach and Witzke, 1977). Flexirubin-type pigments have been found so far only in the Cytophagales and in the true flavobacteria (Achenbach et al., 1981; Reichenbach et al., 1981; Weeks, 1981). However, not all Cytophagales contain flexirubin-type pigments, and even

closely related species, and perhaps even strains of the same species, may differ in that respect. Still, the presence of these pigments in a strain appears to be a reliable criterion that the isolate belongs to the Cytophagales and flavobacteria. The existence of flexirubin-type pigments in a strain can be demonstrated in three ways: 1) As already mentioned, the colonies show a reversible color shift when covered with a 20% KOH solution (see color plate I in *The Prokaryotes*, 1st edition). 2) This preliminary test can be confirmed by a simple thin-layer chromatography of an acetone extract of the bacteria, with an extract of a known flexirubin-producer as a reference; this test can be made even more reliable by recording the absorption spectra of the eluted spots and by performing the alkali reaction in the cuvette (Reichenbach et al., 1974). 3) Finally, as the only other bacterial pigments that give a similar color reaction appear to be aromatic carotenoids (Kohl et al., 1983), the pigments may be specifically labeled by feeding radioactive tyrosine (flexirubins) or mevalonic acid (carotenoids); the result is analyzed by autoradiography of the chromatograms (Fautz and Reichenbach, 1980). Incidentally, the color reaction of cellulose-decomposing cytophagas or sporocytophagas with alkali was already observed long ago, although its meaning was not understood at the time (Fåhraeus, 1947; Walker and Warren, 1938).

Occasionally, strains of CLB with a thin, filmlike growth show a striking greenish-reddish iridescence (see color plate I in *The Prokaryotes*, 1st edition). This is probably a physical color due to interference effects. Also, it has been suggested that the greenish color that is sometimes observed in cultures of Cytophagales may arise from the combination of a yellow cell mass and dark melaninlike pigments (Lewin and Lounsbery, 1969).

Pigment production by Cytophagales may be influenced by environmental conditions. Thus, *Cy. succinicans* is colorless when grown anaerobically, but yellow-orange under aerobic conditions (Anderson and Ordal, 1961a). Illumination may stimulate carotenoid synthesis; but the synthesis of the flexirubins is light-independent. In the latter case, however, the specific pigment content of the cells varied substantially with some other culture parameters; in particular, a high phosphate content and a low pH appear to reduce pigment synthesis (Reichenbach et al., 1974).

Little else is known about the chemical composition of the Cytophagales. The amino acid composition of the protein of a cellulose-decomposing cytophaga was analyzed and found to be rich in nutritionally valuable, essential amino acids (Chang and Thayer, 1975). The GC content of the DNA of the Cytophagales varies over a wide range from 28 to 65 mol% (e.g., Behrens, 1978; Kath, 1990; Mandel and Leadbetter, 1965; Mandel and Lewin, 1969; Oyaizu and Komagata, 1981). The base sequences of large chunks of the 16S rRNA of a series of *Cytophaga*, *Sporocytophaga*, and CLB strains have been determined (Kath, 1990). An unusual multicopy, single-stranded DNA-RNA species (msDNA) discovered in myxobacteria (see Chapter 188) was also found in *Fx. filiformis* (= *Fx. elegans* Fx el), but it was ruled out for *Cy. johnsonae* and *Tx. ocellatus* (Dhundale et al., 1985); it should be interesting to reinvestigate the isolated occurrence of msDNA in *Flexibacter* with the inclusion of other strains.

Phages and Bacteriocins

Phages have been reported for several CLB and appear not to be difficult to obtain (Anacker and Ordal, 1955; Kingsbury and Ordal, 1966; Pate et al., 1979; Richter and Pate, 1988; Stürzenhofecker, 1966; Valentine and Chapman, 1966). There is considerable morphological variability. Most of the phages bear a tail, which usually seems to be contractile. However, two temperate phages have been isolated from *Cy. johnsonae* strains that appear to have no tails; these phages also were sensitive to chloroform, and their plaque formation was inhibited by agar (Richter and Pate, 1988) In all cases that have been investigated, the phages contained double-stranded DNA. A phage of *Cy. columnaris* could not be propagated in the presence of streptomycin (70 μg/ml), probably because the antibiotic prevented the injection of the phage DNA into the host, which for its part was resistant to streptomycin (Kingsbury and Ordal, 1966). Much higher phage yields were often observed when $CaCl_2$ (1 to 4 mM) was present during infection. Interestingly, nonmotile mutants of *Cy. johnsonae* were completely resistant to all phages tested on them (Pate et al., 1988; Wolkin and Pate, 1986).

A bacteriocinlike activity was discovered in a strain of *Sp. myxococcoides* (Tchan and Giuntini, 1950). The strain inhibited other *Sp. myxococcoides* strains, but not *Cy. aurantiaca*; the activity could not be propagated, and no phage particles could be demonstrated under the electron microscope. Bacteriocin activity was found in many strains of the fish pathogen *Cy. columnaris* (Anacker and Ordal, 1959b). The target specificity of the bacteriocins produced by different *Cy. columnaris* strains varied, so that with the aid of seven selected bacteriocin preparations, 134 strains could be grouped into nine

sensitivity classes. No connection could be seen between a certain bacteriocin class and its distribution in nature. The same results were observed for serological classes of *Cy. columnaris* (Anacker and Ordal, 1959a). Bacteriocin activities were recorded in 20 out of 30 tested strains of *Cy. johnsonae* (Richter and Pate, 1988). The activities were destroyed by protease treatment and acted bactericidally on sensitive strains. With respect to their specificity, two types could be distinguished: 1) bacteriocins that acted on motile and nonmotile strains, and 2) ones that, like the phages discussed above, attacked only motile strains. With the latter, nonmotile mutants could be selected.

The occurrence in various members of the Cytophagales of rhapidosomes, which appear to be tails of defective phages, has already been mentioned.

Colony Morphology

The colonies of the Cytophagales typically are spreading swarms (Fig. 3). Spreading growth depends, however, on several environmental factors, so that organisms that are well able to move by gliding still may not produce swarms (e.g., Chang et al., 1984; Perry, 1973; Wolkin and Pate, 1984). Thus, e.g., 70% of yellow bacteria isolated from sewage plants showed gliding motility under the microscope, but only 25% also formed spreading colonies (Güde, 1980). It has been found in many cases that low nutrient concentrations favor swarming (e.g., Agbo and Moss, 1979; Bauer, 1962; Garnjobst, 1945; Wolkin and Pate, 1984). Therefore, if spreading is to be observed, agar media with a low peptone content (0.1% or less) should be used; also, VY/2 agar stimulates swarming in many cases. Other factors that may influence the spreading behavior are the kind of nutrients supplied, temperature, and humidity. No general rules can be given; however, often a relatively low temperature and a high humidity favor spreading.

The morphology of the swarm colonies varies very much, as is to be expected with such a large assembly of widely differing organisms. Often the swarms are almost unstructured, thin sheets; sometimes their surface is covered with flat mounds, tiny warts, or with veins; or it appears fibrous and feltlike; or the swarms form a network which may become confluent towards the center of the colony. While the swarm sheet is always somewhat slimy, the production of copious amounts of slime is relatively rare; it is observed, e.g., when the cellulose decomposers are grown on a glucose-containing agar (see also Strohl and Tait, 1978). The slime is usually soft, so that the cells can easily be scraped off the plate; but sometimes it becomes very tough, and the cell mass can hardly be removed from the agar surface, e.g., with *Cy. columnaris* (Garnjobst, 1945) and *Cy. uliginosa*. The organisms also often penetrate the agar, and some species even grow and spread preferentially within the plate, e.g., microaerophilic and agar-attacking organisms (e.g., Veldkamp, 1961). Colony variations have been reported for several species (Anderson and Ordal, 1961a; Bachmann, 1955; Oyaizu et al., 1982; Pacha, 1968; Stanier, 1942, 1947; Veldkamp, 1961). In one case, migrating microcolonies were observed (Strohl and Tail, 1978). The colonies of the cellulose decomposers on filter paper are slowly expanding, glassy, unstructured, slimy patches that are usually bright yellow to orange. Grey areas in the colonies of *Sporocytophaga* usually signal generous microcyst formation.

A sickening odor has been reported for *Cy. columnaris* on nutrient agar (Garnjobst, 1945). On peptone-containing media, and particularly with liquid cultures, a strong, cheesy smell is produced by many CLB. The cellulose degraders produce a pleasant sour-fruity odor when growing on glucose agar.

Physiology and Enzymology

With a few exceptions, the physiology and enzymology of the various members of the Cytophagales has not been thoroughly investigated, and virtually no information is available about most basic biochemical pathways. Further, many of the studies were published a long time ago, and a reevaluation of the data in the light of modern biochemical insights would be desirable. On the other hand, nothing discovered so far suggests that the metabolism of these bacteria would differ in some basic manner from the metabolism of other comparable organisms.

Most Cytophagales are strict aerobes, but there also are microaerophilic species, facultative anaerobes, and organisms with a strictly fermentative metabolism (Anderson and Ordal, 1961a, 1961b; Bachmann, 1955; Hirsch, 1980; Leadbetter et al., 1979; Stanier, 1947; Veldkamp, 1961). It appears that all Cytophagales that are capable of fermentative growth require elevated CO_2 levels (optimum 0.3 to 1% $NaHCO_3$: *Cy. fermentans*, *Cy. succinicans*, *Cy. salmonicolor*, *Capnocytophaga*). For strictly fermentative *Capnocytophaga* it has been shown that CO_2 is necessary because the organism depends on phosphoenolpyruvate carboxykinase (PEPCK) in order to synthesize ATP and the terminal electron acceptor, oxalacetate; the lat-

ter is reduced under regeneration of NAD to the level of succinate, which is then excreted as the major fermentation product. Obviously PEPCK replaces in that organism the more usual pyruvate kinase. The enzyme is regulated by the energy charge of the cell: low ATP levels stimulate, high ones inhibit PEPCK activity (Kapke et al., 1980). A condensation of CO_2 with phosphoenolpyruvate was also suggested for fermentatively growing *Cy. succinicans* (Anderson and Ordal, 1961b). The reaction was stimulated by GDP. A CO_2-independent fermentation of fructose-1,6-diphosphate could be performed in cell extracts supplemented with lactate dehydrogenase. The data could be well reconciled with the mechanism outlined for *Capnocytophaga*. As *Cy. succinicans* is a facultative anaerobe, it is likely to have alternative pathways starting from PEP. The fermenting organisms may utilize various sugars, mannitol, and polysaccharides such as agar or starch; however, as a rule, organic acids are not suitable fermentation substrates; one exception is *Cy. succinicans*, which grows anaerobically on pyruvate. Fermentation products are mainly succinate and acetate, usually also propionate and formate, and sometimes small quantities of lactate and ethanol. *Cy. salmonicolor* produces CO_2 and H_2 during fermentative growth (Veldkamp, 1961).

Nitrate respiration allows vigorous growth of *Cy. johnsonae* var. *denitrificans* (Stanier, 1947). More recently, a CLB was isolated that grew anaerobically with NO_3^-, NO_2^-, and N_2O as terminal electron acceptors (Adkins and Knowles, 1984, 1986) If small quantities of sulfide (0.4 μM) were available, this organism was able to reduce N_2O even in the presence of acetylene in concentrations (4 kPa) that normally inhibit N_2O reduction. This is also of interest because acetylene-inhibited N_2O reduction is generally accepted as a measure of denitrification in soils. However, other denitrifying CLB (*Cy. johnsonae* strains) did not show acetylene-insensitive N_2O reduction (Adkins and Knowles, 1986). The strains differed in their ability to reduce various nitrogen compounds. In one case, N_2O reduction turned out to be inducible by nitrite, but not by nitrate. Anaerobic growth under reduction of nitrite or N_2O has also been found among flavobacteria (Pichinoty et al., 1976). Growth with fumarate as the terminal electron acceptor was not possible with any of the Cytophagales and flavobacteria tested, but several of the organisms, e.g., *Cy. hutchinsonii* and *Cy. johnsonae*, could use fumarate for limited NAD regeneration under anaerobic conditions (Callies and Mannheim, 1978). As already mentioned, no strict anaerobes are known among the Cytophagales.

It appears that all Cytophagales, including the cellulose decomposers, grow on organic nitrogen compounds, e.g., peptones, as the sole nitrogen source. Many also use the same compounds for carbon and energy and grow vigorously on peptone media, even if, as a rule, carbohydrates are the preferred carbon and energy sources. Some organisms, however, require the addition of a carbohydrate, e.g., apparently all cellulose decomposers. On the other hand, there are also organisms that cannot utilize carbohydrates at all, e.g., *Cy. psychrophila* (Pacha, 1968) and many *Cy. columnaris* strains (e.g., Song et al., 1988a).

Many Cytophagales can be cultivated on inorganic nitrogen compounds. NH_4^+ is usually preferred to NO_3^-. The latter can sometimes not be utilized at all, thus by *Cy. fermentans* (Bachmann, 1955). The spectrum of utilizable carbon compounds is wide and varies with the individual organisms. Glucose is almost always accepted. One exception is the *Cy. diffluens* group: these bacteria require some other sugar like galactose or sucrose (Lewin and Lounsbery, 1969). Acid is often produced from carbohydrates even under aerobic conditions (e.g., Oyaizu and Komagata, 1981; van der Meulen et al., 1974). *Sp. myxococcoides* metabolizes glucose via the Embden-Meyerhof-Parnas pathway (Hanstveit and Goksøyr, 1974), as does *Cy. johnsonae* (Reichardt and Morita, 1982a).

Many of the Cytophagales are able to degrade biomacromolecules, particularly all kinds of polysaccharides, like agar, starch, cellulose, yeast cell-wall β-glucan, succinoglycan (Oyaizu et al., 1982), pectin, alginate, and heparin. As many of the responsible exoenzymes potentially are of some practical interest, these activities will be discussed under "Practical Aspects," this chapter.

DNA and RNA are efficiently degraded by many Cytophagales (e.g., Greaves et al., 1970; Mitchell et al., 1967). A particularly strong DNAse activity is observed with *Cy. columnaris*. It seems, however, that no organism is able to grow solely on nucleic acids Phosphatases are very common among the Cytophagales (e.g., Christensen, 1977a; Hirsch, 1980; Reichardt et al., 1983) An alkaline and an acid phosphatase of *Cp. ochracea* have been isolated and studied in detail (Poirier and Holt, 1983b). The enzymes are able to remove phosphate from phosphoseryl residues of phosvitin and may play a role in the dephosphorylation of phosphoproteins. CLB are able to grow on washing-powder polyphosphates as phosphate sources; the polyphosphates are well tolerated

up to 0.0025% and are rapidly hydrolyzed (Ruschke and Köhn, 1970). Lipolytic activities are also known from Cytophagales, e.g., cleavage of tributyrin and of Tweens (e.g., Christensen, 1977a; Hirsch, 1980; Jooste et al., 1985; Oyaizu et al., 1982; Reichardt et al., 1983), but the responsible enzymes seem never to have been characterized.

The patterns of antibiotic sensitivities have been determined for many members of the Cytophagales, although the data often are not really comparable because of differences in methods (e.g., Agbo and Moss, 1979; Arlet et al., 1987; Christensen, 1977a; Forlenza et al., 1981; Gräf and Morhard, 1966; Reichardt et al., 1983; van der Meulen et al., 1974; Warke and Dhala, 1968). It appears that many organisms are relatively resistant to penicillins, polymyxin B, aminoglycosides, and chloramphenicol. Kanamycin resistance has been used in the isolation of cellulose-decomposing *Cytophaga* and *Sporocytophaga* strains (2.5 to 10 mg kanamycin sulfate per liter); but it is not known whether these organisms are always resistant to that antibiotic (Rivière, 1961a). Capnocytophagas respond to several conventional antibiotics and are thus easy to control.

A genetics of the Cytophagales is still nonexistent.

Classification and Identification

As mentioned in the introduction, 16S rRNA studies have shown that the Cytophagales are a main branch, or phylum, of their own in the bacterial phylogenetic system (Paster et al., 1985). They are found there together with some other, phenotypically rather different bacteria; although our current knowledge suggests that some common characteristics may indicate connections between those groups, on this basis, probably, nobody would have dared earlier to propose the existence of a natural relationship among all those bacteria. Thus, e.g., *Capnocytophaga* resembles *Bacteroides* morphologically and metabolically to such a degree that it was formerly classified in this genus. Also, sphingolipids, in general rare in bacteria, are found in *Bacteroides* and in certain flavobacteria (but also in nonrelated myxobacteria). Further, the 16S rRNA tree of descent demonstrates unequivocally that the present genera of the Cytophagales are heterogeneous, and that we may even need new definitions for families and perhaps orders.

The order Cytophagales is defined here using conventional phenotypic characteristics so that new isolates can be classified relatively easily and reliably. As discussed in the introduction, only part of the group of phylogenetically related bacteria is included in the phenotypically defined order. As defined here, the order Cytophagales contains unicellular, Gram-negative, rod-shaped, gliding bacteria, that often exhibit a pronounced cellular shape change, or at least pleomorphism. Most species produce more or less brightly colored, yellow, orange, pink, or red colonies. The yellow and orange ones often give a positive flexirubin reaction. The respiratory quinones are exclusively menaquinones.

This definition presents us with two problems: First, a practical one—how to distinguish cytophagas from *Lysobacter*, which shares many of the above-mentioned characteristics. Differences in cell shape and pigmentation, as mentioned in the introduction, would quickly differentiate most, but unfortunately not all, Cytophagales from *Lysobacter*. In case of doubt, more subtle characteristics have to be examined. It seems that all lysobacters degrade chitin, while many Cytophagales do not. The GC content of *Lysobacter* DNA is high, between 65 to 70 mol%, values that are only reached by red *Taxeobacter* among the Cytophagales. The respiratory quinones of *Lysobacter* are ubiquinones (Q-8), while all Cytophagales appear to contain menaquinones exclusively (M.D. Collins, personal communication). Finally, no marine and no parasitic lysobacters have been found so far.

The second problem is how to integrate the flavobacteria into the order Cytophagales. The old genus *Flavobacterium* was plainly heterogeneous, but after exclusion of the high-GC-content species, the remaining, low-GC-content (30–45 mol%) species appear to be naturally related among themselves and with the Cytophagales. Those species of flavobacteria for which 16S rRNA catalogs exist are connected to the phylogenetic tree of the Cytophagales at various levels and are often found close to the gliding species. This suggests that the genus *Flavobacterium* is still heterogeneous, and that a gliding species may be more closely related to a nonglider than to another glider. The situation became even more confusing after several organisms that were originally described as nonmotile and consequently classified as *Flavobacterium* species were later discovered to glide; they would therefore have to be classified among the cytophagas. This is the case for the type species of *Flavobacterium*, *Fv. aquatile*, and for *Fv. pectinovorum*, *Fv. uliginosum*, and *Fv. heparinum*. The (nonmotile) flavobacteria also have, in common with the Cytophagales, menaquinones as the only respiratory quinones, and often flexirubin-type pigments. Therefore, most proba-

bly, gliding motility will lose its determining character in this taxonomic group, and eventually there may be order(s), families, and perhaps even genera that comprise motile and nonmotile species, just as there are in groups of flagellated bacteria. But before the new boundaries can be defined, more data, especially molecular and chemosystematic ones, are needed.

As set out above, the Cytophagales are restricted here to gliding organisms which can be differentiated into genera according to the following key:

Key to the Genera of the Cytophagales

1. Cellulose decomposers that grow on filter paper as the only carbon source; may utilize inorganic or organic N sources; cannot grow on peptone alone but require in addition a carbohydrate, like cellulose (filter paper) or a suitable sugar (e.g., glucose) 2

1′. Do not attack filter paper cellulose; usually grow well on peptones, but some are much stimulated by carbohydrate or depend on it for fermentative growth 3

2. Produce microcysts .... *Sporocytophaga*

2′. Do not produce microcysts, terrestrial .... *Cytophaga*

2″. Do not produce microcysts, marine .... *Cytophaga* (?)

3. Strictly fermentative; require CO_2 and carbohydrate for growth; inhabitants (mainly) of the oral cavity of man and mammals .... *Capnocytophaga*

3′. Strict aerobes or facultative anaerobes 4

4. Vegetative cells in young cultures are long (20 to 100 μm) thread cells 5

4′. Vegetative cells in young cultures are short to moderately long (2 to 15 μm) rods 6

5. Soil and freshwater bacteria; several species show a very conspicuous (cyclic) cellular shape change: in young cultures, long (20–30 μm), extremely agile thread cells; in older cultures, short immotile rods or coccobacilli; many strains contain flexirubins; GC content, 40 to 50 mol% .... *Flexibacter*

5′. Marine organisms; cellular shape change not observed .... *Microscilla*

5″. Marine organisms; very long (sometimes multicellular and nonmotile) filaments which may or may not have a sheath and release shorter, but often still rather long, gliding thread cells; colonies yellow due to zeaxanthin, no flexirubins; GC content, 37 mol% .... *Flexithrix dorotheae*

6. Short, stout rod cells with rounded ends, often arranged at the edges of the colonies in a palisadelike fashion; colonies more or less brick red; GC content, 55 to 65 mol% .... *Taxeobacter*

6′. Cell shape very variable: short to very short, but sometimes also moderately long (5 to 15 μm) rods, delicate or plump, with rounded or tapering ends; colonies often fast spreading, filmlike swarms, yellow to orange, marine organisms sometimes pink; many terrestrial isolates contain flexirubin-type pigments, marine isolates usually do not; in soil, freshwater, and marine habitats; some are fish pathogens; GC content, 30 to 40 mol% .... *Cytophaga*-like bacteria (CLB)

(6″.) Cells are relatively short, cylindrical rods with rounded ends, but often long thread cells or cell chains are also found in cultures; colonies (slowly) spreading, often rather slimy, pale grey to greenish yellow, brick red, or brown due to diffusing pigments; respiratory quinone is Q-8; GC content, 65 to 70 mol%: *these organisms do not belong to the Cytophagales* .... (*Lysobacter*)

The cellulose decomposers were historically the first cytophagas described, and thus taxonomically they represent the type of the whole group. For many years it has been suggested that these cellulose decomposers are rather specialized organisms that are not closely enough related to the other organisms of the group to be united with them in one genus. Experimental evidence for this hypothesis has been provided recently: Surveys of the respiratory quinones of gliding bacteria showed that many CLB contain MK-6: but all cellulose decomposers contain MK-7 (Oyaizu and Komagata, 1981; M.D. Collins, personal communication). Quantitative fatty acid analyses, DNA-DNA hybridization data, and especially comparisons of 16S rRNA base sequences suggest that the two type strains of the named species of the cellulose-decomposing cytophagas and of several new isolates are relatively closely related among themselves. Further, it could be shown that *Sporocytophaga* strains are equally closely related among themselves and, finally, that the latter are relatively closely related to the cellulose-decomposing cytophagas, but that other CLB, like *Cy. johnsonae* and *Cy. heparina*, are much farther off from both (Kath, 1990). The conclusion is that the genus *Cytophaga* should indeed be restricted to the cellulose decomposers. New genera will have to be defined for the other organisms hitherto classified in the genus *Cytophaga*, but this should not be done until after the boundaries between the various groups have been clearly established by molecular taxonomy. In the present situation it may be best to follow the practice used in the present review and to group these other organisms under the label "*Cytophaga*-like bacteria (CLB). *Sporocytophaga* appears to be a separate and equally natural genus, at least as far as cellulose decomposers are concerned. Sporocytophaga isolates can easily be recognized by the presence of microcysts; these are usually produced in enormous numbers in enrichment cultures, and their formation can also be reliably induced with pure strains that no longer produce them in ordinary plate cultures when the strain is grown in M9 liquid medium (Kath, 1990). *Sp. cauliformis* appears to be a misnomer (Gräf, 1962a): it seems neither to decompose cellulose nor to form microcysts and probably belongs to the large assembly of CLB.

Another source of confusion is the distinction between *Flexibacter* and *Cytophaga*. The definition of the genus *Flexibacter* given here is based on the original description by Soriano (1945, 1947), but it is in disagreement with that used in *Bergey's Manual*, eighth edition (Leadbetter, 1974) The definition of *Flexibacter* has recently been changed again in *Bergey's Manual of Systematic Bacteriology* (Reichenbach, 1990), where it is now placed in accordance with the ideas presented here. (A detailed explanation of the rather complex taxonomic situation may be found in the latter reference, but it will not be repeated here.) The organisms united in the present genus *Flexibacter* have long, highly flexible cells. The organisms also have in common a somewhat higher GC content of 40 to 50 mol% (Behrens, 1978; Mandel and Lewin, 1969) and they all seem to contain MK-7 as respiratory quinone (M.D. Collins, personal communication). The type species is *Fx. flexilis*, which shows rather sluggish movements and is flexirubin negative. Much more fascinating is *Fx. elegans* Soriano (1945), which for many years was regarded as the typical *Flexibacter*, and about which many details have been published, especially about strain Fx el (e.g., Achenbach et al., 1978; Behrens, 1978; Fautz et al., 1979, 1981; Hirsch, 1979; Paster et al., 1985; Poos et al., 1972; Rosenfelder et al., 1974; Reichenbach et al., 1974, 1981; Simon and White, 1971). In young cultures and at the edges of spreading swarms, the organism has long and extremely agile thread cells. These cells change their shape in the later stages of the culture, becoming shorter and shorter and finally becoming nonmotile (Fig. 2; Poos et al., 1972; Simon and White, 1971). Under certain conditions, the organism may grow exclusively in the short form, but the cells readily grow out into thread cells again if conditions are changed. Soriano (1945) did not mention any shape change, perhaps because he did not observe it, perhaps because he thought his cultures were contaminated, or perhaps because he regarded his organisms to consist of multicellular filaments and therefore judged fragmentation to be commonplace. But his description of *Fx. elegans*, and especially of the movements of the thread cells, leave no doubt that his and our organisms are at least closely related. It was later discovered that there existed in the literature an even earlier description that exactly fitted *Fx. elegans* as outlined above, shape change, color, and physiology included—that of *Myxococcus filiformis* by Solntseva (1940), whose only mistake was to misinterpret the short cells as myxospores. Unfortunately, the situation was further confounded by the description under the name of *Fx. elegans* of an organism that quite obviously was not identical with Soriano's species (Lewin, 1969; Lewin and Lounsbery, 1969) As the name *Fx. elegans* has been conserved with Lewin's stain as the type species, it has been proposed to change the name of the organisms discussed above into *Fx. filiformis* (Reichenbach, 1990). To complicate things even more, an organism has been described more recently under the name of *Chitinophaga*, without any reference to the publications cited above, which is clearly closely related or identical with *Fx. filiformis* (Sangkhobol and Skerman, 1981). In this case, microcysts have again been postulated, but the published pictures are not at all convincing, and when studying the type strain the present author has never observed anything even remotely resembling a microcyst (H. Reichenbach, unpublished observations). In the 16S rRNA phylogenetic tree, *Fx. filiformis* Fx el is found in a side branch far away from *Sporocytophaga* and the CLB (Paster et al., 1985). It remains to be established whether the genus *Flexibacter* in its present state is really homogeneous. The genus is restricted so far to soil and freshwater organisms; many, but not all, contain flexirubin pigments, which have in fact been discovered in strain Fx el. The marine counterpart of *Flexibacter* may be *Microscilla*; no cellular shape change is known for this genus (Lewin, 1969; Lewin and Lounsbery, 1969; Pringsheim, 1951) It has not been well studied, and the status of the genus and its relation to the other Cytophagales is unknown.

The CLB are unquestionably a very large and heterogeneous assembly of terrestrial and marine bacteria. They will probably have to be distributed over several new genera, as discussed above. In the absence of a sound taxonomy, it is not even remotely possible at the moment to estimate the number of existing species. From DNA-DNA hybridization data and other studies it may be deduced that there are many more genera than are named so far. Some efforts have been made to establish a reliable taxonomy for the fish pathogens, which would obviously be of great practical importance. DNA-DNA hybridization data showed that the fish pathogens *Cy. columnaris*, *Cy. psychrophila*, and *Cy. maritima* are all well-separated, homogeneous, genomic species, which show little relatedness among themselves or to the many environmental species included in the studies (Baxa et al., 1987; Bernardet and Grimont, 1989; Bernardet and Kerouault, 1989; Bernardet et al., 1990). There are, however, strong indications that these are not the only fish pathogens among the CLB, and that there are still other, hitherto undescribed species (Kent et al., 1988; Pyle and

Shotts, 1981). Further, the data seem to suggest that the fish pathogens are restricted to fish and cannot be isolated as free-living, environmental strains, although the latter possibility is difficult to rule out definitely. Information about an environmental reservoir of the fish pathogens would, of course, be of central importance for epidemiological considerations and control measures. Serological data speak also against a close relationship between fish-pathogenic and environmental CLB (Pacha and Ordal, 1970; Pacha and Porter, 1968). Serological tests have therefore been very useful for a quick diagnosis of the fish pathogens, which is important for practical reasons. Early studies showed that species-specific antigens exist in *Cy. columnaris* and *Cy. psychrophila* (Anacker and Ordal, 1959; Bullock, 1972; Pacha and Porter, 1968). *Cy. columnaris* has in addition at least seven type-specific antigens, which can be used to subdivide a collection of 325 strains into four serological groups; no link could be seen between those serological groups and levels of virulence (Anacker and Ordal, 1959; Pacha and Ordal, 1970). Fluorescence-labeled specific antibodies against *Cy. maritima* could be used to demonstrate the presence of the pathogen in various tissues (Baxa et al., 1988). Incidentally, the fish themselves develop antibodies against *Cy. columnaris*, and these seem to limit natural infection and can be applied to protection by vaccination (e.g., Becker and Fujihara, 1978; Liewes et al., 1982).

In another study, the isoenzyme patterns of 106 strains of spreading and nonspreading, yellow-pigmented bacteria from fish and other habitats were used to classify CLB. While one group coincided neatly with isolates that had been identified with *Cy. columnaris*, the other three groups were clearly heterogeneous, one of them even containing other *Cy. columnaris* isolates (Starliper et al., 1988). Thus, the results were inconclusive, and isoenzyme studies do not appear promising for taxonomic purposes.

The recently discovered genus *Taxeobacter* (H. Reichenbach, unpublished observations) has a special position among the soil Cytophagales. It is distinguished from the CLB by its cell morphology, the arrangement of the cells in spreading colonies (Figs. 1 and 3), and the brick red color of the latter. It is a common organism that can be cultivated without difficulties and has probably only been overlooked because it is not easily isolated by conventional techniques. By 16S rRNA cataloging, *Taxeobacter* (= Myx 2105), has been located in the *Fx. filiformis* side branch close to *Cy. heparina* (Paster et al., 1985).

As already mentioned, *Capnocytophaga* has been known for many years under different names. It is a fermenter requiring an atmosphere with 5% CO_2, at least for isolation, and produces mainly acetate and succinate from glucose. Initially only known from the human oral cavity, related species have since been found also in animals, e.g., in dogs (Brenner et al., 1989) and in the rice rat (Shklair and Ralls, 1988). The genetic homogeneity of the three human species, and the identity of one of them with *Bacteroides ochraceus* (type strain) has been established by DNA-DNA hybridization (Williams and Hammond, 1979; Williams et al., 1979).

Practical Aspects

The Cytophagales are of considerable practical interest. Their importance becomes even more impressive, if we take also into consideration the many isolates classified as *Flavobacterium* in the literature, which would be justified because those strains may often have been CLB with unrecognized gliding motility; and even if they were true flavobacteria, they would be closely related organisms. A general review of the practical aspects of gliding bacteria including the Cytophagales has been published (Reichenbach, 1988).

Bacteria belonging to this large complex of species are found virtually everywhere in nature, at least in aerobic and microaerobic environments. They definitely play a major role in the turnover of matter. Their activities are, of course, not always beneficial for humans. Some undesired effects with respect to the dairy industry (see also Cousin, 1982; Guamis et al., 1987) and the rotting of cellulose fabrics have already been mentioned. Other examples of this less pleasant side are: the participation of pectolytic CLB in the spoilage of vegetables (Liao and Wells, 1986; Lund, 1969) and of proteolytic CLB in the putrefaction of fish, although in the latter case, gliding bacteria may be associated with freshly caught fish and are gradually replaced by other bacteria during deterioration (Cho et al., 1984; Gennari and Tomaselli, 1988; Liston, 1960; Shewan, 1971). Also in nature the actions of CLB are not always beneficial. Thus, e.g., CLB have been found tunneling in the cell walls of seagrass leaves, apparently killing the leaves in the process (Porter et al., 1989). A case of symbiosis was discovered in calcareous sponges of the genus *Clathrina*; the bacterium may be sponge-specific and has been associated with the sponge for a long time (Burlando et al., 1988). There may yet be many more examples

of similar symbioses to be discovered. One such case may be the yellowish-brown bacterium living in the mycetomes of the granary weevil *Sitophilus granarius* (Bhatnager and Musgrave, 1970).

In a different context, the destruction of organic molecules may become a positive asset. The occurrence of large populations of CLB in sewage plants has already been discussed (see also Bauer, 1962). Cellulolytic *Cytophaga* and *Sporocytophaga* seem to play a role during composting of cattle manure (Godden and Penninckx, 1984). Many articles describe the decomposition by flavobacteria of recalcitrant chemicals such as pesticides, and, as just explained, some of these could really have been CLB. Thus, flavobacteria have been found to attack chlorobenzoic acid (Baggik 1985), pentachlorophenol (Brown et al., 1986; Crawford and Mohn, 1985), parathion (Mulbry et al., 1986), nylon oligomers (Negoro and Okada, 1982), biphenyl and phenanthrene (Stucki and Alexander, 1987), and aliphatic diols (Willetts, 1983), to give just a few examples. The digestion of hardwood mesquite (*Prosopis* sp.) with a cellulose-decomposing *Cytophaga* strain has been studied with the aim of improving the feed quality of the plant material for cattle (Chang and Thayer, 1975). It was shown that the *Cytophaga* protein is particularly rich in essential amino acids, but feeding experiments with mice gave unsatisfactory results.

The production by members of the Cytophagales of special enzymes for technical application could be another field of practical interest. Not too much is known about such enzymes, but a number of potentially useful hydrolase and lyases has indeed been discovered and more or less characterized. The following examples may illustrate this. The *Cytophaga* and *Sporocytophaga* species are very active cellulose decomposers and have been studied since the beginning of the century (e.g., Berg et al., 1972; Fåhraeus, 1947; Hutchinson and Clayton, 1919; Imshenetski and Solntseva, 1936; Krzemieniewska, 1930, 1933; Rivière, 1961; Sijpesteijn and Fåhraeus, 1949; Stanier, 1942; Winogradsky, 1929). Initially it was believed that enzymatic attack required close contact between cell and fiber, but later it was found that in the culture supernatant of *Sp. myxococcoides* there were also enzymes that could solubilize cellulose, at lest to a certain degree (Kauri and Kushner, 1985; Osmundsvåg and Goksøyr, 1975; Vance et al., 1980). With other organisms, however, cell-free cellulases could not be demonstrated (Chang and Thayer, 1977). Also, transglycosylations to β-1-3 and β-1-6 oligosaccharides (Charpentier, 1965), and a conversion of β-D-glucose into α-D-glucose by the activity of an exoglucanase (Charpentier and Robic, 1974) have been demonstrated. Relatively little is known about enzymes themselves, and a reinvestigation using modern methods would be desirable.

Another group of enzyme producers known for some time are the pectolytic CLB (e.g., Donderski, 1982; Dorey, 1959; Güde, 1973). The responsible enzyme is a randomly cleaving polygalacturonate lyase, which catalyzes a trans-elimination reaction; a pectin methyl esterase could not be found (Kurowski and Dunleavy, 1976; Sundarraj and Bhat, 1971). Only one single enzyme was found in *Cy. johnsonae*, and this enzyme was the smallest one (35 kDa) of all pectate lyases characterized (Liao, 1989). The pectolytic activity of *Cy. johnsonae* made water-stored spruce logs more permeable for preservatives and was therefore considered to be of practical relevance (Kurowski and Dunleavy, 1976; Ward and Fogarty, 1974).

Although chitin degradation is often observed among CLB and flexibacters, relatively little is known about the enzymes (Donderski, 1984; Reichardt et al., 1983; Stanier, 1947; Sundarraj and Bhat, 1972) The enzymes of *Cy. johnsonae*, a chitinase and a chitobiase, may be excreted or cell-bound. Deacetylation seems to be the first degradation step. The chitinolytic strain of *Cy. johnsonae* studied by Veldkamp (1955) was either a *Lysobacter*, judging from the strain deposited at NCIB (no. 8501), or a *Flexibacter*, as may be concluded from the published description of the organism.

Several enzymes from CLB that degrade polysaccharides derived from marine algae have been characterized, mainly agarases (Duckworth and Turvey, 1969a, 1969b, 1969c; van der Meulen and Harder, 1975, 1976), but also a porphyranase (Turvey and Christison, 167), and a large (100 kDa) extracellular carrageenase (Sarwar et al. 1987).

Many Cytophagales efficiently hydrolyze starch (e.g., Christensen, 1977a), but the enzymes never seem to have been studied. In two cases, special enzymes have been found in CLB because they had been screened for them for an application in structural studies. A strain was found and identified with *Cy. johnsonae* that produced endo-β-glucanases, which could then be used to study the composition of yeast cell walls (Bacon et al., 1970; Webley et al., 1967). The discovery of a strain that attacked heparin (Payza and Korn, 1956a, 1956b) proved a decisive contribution to the elucidation of the chemical structure of this complex heteropolysaccharide (e.g., Dietrich, 1969). The organism was first classified as *Flavobacterium he-*

parinum but later recognized to be a CLB (Christensen, 1980). Enzyme production has to be induced by the addition of heparin, and yields are not particularly good. Later, another (tentatively classified) *Flavobacterium* strain was isolated that produced heparinase constitutively and at a 10-fold higher level (Joubert and Pitout, 1985). The enzyme may be of considerable practical interest for the deheparinization of blood.

Many Cytophagales excrete strong proteinases. A few of these enzymes have been further characterized because of their unusual specificities. In a screening, strains were discovered that solubilized autoclaved feathers and wool and could grow on these substrates as the only C and N sources; they did not attack the native material (Christison and Martin, 1971; Martin and So, 1969). The organisms resembled *Cy. johnsonae* in their characteristics but were never clearly classified. The keratinolytic enzyme appears to be associated with acidic polysaccharides on the surface of the cells. *Capnocytophagas* show strong aminopeptidase activities (e.g., Nakamura and Slots, 1982). In a screening for arylaminopeptidases among oral bacteria, several different activities at high levels were discovered in capnocytophagas, including monopeptide-, dipeptide-, and tripeptide-cleaving enzymes, some of which were only seen in capnocytophagas, e.g., enzymes attacking ala-, leu-, his-, lys-, and met-β-naphthylamines (Suido et al., 1986). Such proteolytic enzymes could contribute to the occasional pathogenicity of the organisms. Also the fish-pathogenic CLB show very strong proteolytic activities, which may be responsible for at least part of their infectivity. In an effort to prepare compounds with immunoadjuvant activity from cell walls of *Staphylococcus epidermis*, an interesting endopeptidase was isolated from the culture supernatant of the gliding bacterium *Cytophaga* B-30 (Kawata et al., 1984). The identity of the organism is not unequivocally established, and the description does not rule out the possibility that it was really a lysobacter. The enzyme released long-chain polysaccharide peptides from *Staphylococcus*, but little or nothing from *Streptococcus* and *Micrococcus* peptidoglycan. In cells and in the culture supernatant of *Cytophaga* NCMB 1314, an agent was discovered, presumably an enzyme, that solubilized active cholinesterase from fish muscle (plaice, *Pleuronectes platessa*). Again, the identity of the organism is not completely clear. Release of this "S-factor" into the medium was stimulated by cultivation under magnesium limitation (Bovallius, 1978, 1979; Lundin, 1968; Lundin and Bovallius, 1966).

Substantial phospholipase A_2 activity has been seen in *Capnocytophaga* (*Cp.*) *ochracea* strains; it has been suggested that this enzyme is a factor contributing to the pathogenic potential of the organism (Sandholm et al., 1988).

Interesting immunological effects may be produced with certain cell components of the Cytophagales. The allergenic activity of *Cytophaga allerginae* endotoxin, leading to humidifier fever, a lung disorder, has already been mentioned; the chemical composition of the endotoxin has been determined (Flaherty et al., 1984; Liebert et al., 1984). The purified endotoxin proved to be a novel mitogen that induced peripheral blood lymphocytes in vitro to synthesize IgG and IgA; as the immunoglobin induction is not inhibited by cyclosporin A, it seems to be T-cell independent (Alevy and Compas, 1987). Another potent mitogen called gliding bacteria adjuvant (GBA) was recovered in relatively large quantities (140 to 400 mg/l) from the culture supernatant of the *Cytophaga* GB-2. The psychrotrophic bacterium was first isolated from contaminated fetal calf serum. GBA was free of endotoxin and protein and perhaps consisted of a complex slime polysaccharide. It stimulated mouse B lymphocyte proliferation in vitro, the production of immunoglobulins, and the release of colony-stimulating factor and interleukin 1 by macrophages (Shiigi et al., 1977; Usinger et al., 1985). Purified exopolysaccharide from *Capnocytophaga* cultures activated the human complement system in vitro (maximum effect at 28 μg/ml plasma); this activation may be a factor leading to tissue destruction in periodontal lesions (Bolton and Dyer, 1986). A large (155-kDa), lectinlike protein was isolated from the outer membrane of *Cp. gingivalis* (Kagermeier and London, 1986). The lectin appears to be specific for neuraminic acid, *N*-acetylgalactosamine, and *N*-acetylglucosamine, and it is probably responsible for coaggregation with other bacteria, like *Actinomyces israelii*, in the formation of dental plaque. Similar adhesins with specificities for rhamnose and fucose were found on *Cp. ochracea* (Weiss et al., 1987). A lactose-specific, lectinlike receptor was demonstrated on *Cp. sputigena* and *Cp. gingivalis* (Saito et al., 1988).

Some members of the Cytophagales have been found to produce very interesting secondary metabolites. In a screening for antibiotic activities, about 20% of the 270 tested strains showed inhibitory effects (Reichenbach et al., 1984). Several β-lactams were isolated from *Flexibacter* strains, including new monobactams with oligopeptide side chains (Cooper et al., 1983; Sing et al., 1983) and monobactams with formylamino- and glucuronic acid substi-

tuents, the formacidins (Hida et al., 1985; Katayama et al., 1985). Monobactams with a dehydroasparagine residue were obtained from *Cy. johnsonae* (Kato et al., 1987a, 1987b), and deacetoxycephalosporin C and 7-formylamidocephalosporins from a *Flavobacterium* (Shoji et al., 1984; Singh et al., 1982, 1984). *Cy. uliginosa* (formerly *Fv. uliginosum*) contributed marinactan, a heteropolysaccharide with marked antitumor activity in mice (Umezwawa et al., 1983).

Finally, there are some important medical and veterinary aspects of the Cytophagales: Flexibacteria are able to pass through membrane filters of 0.1-μm pore size used for sterilizing seawater; the contaminants could be eliminated only by pasteurization (Little et al., 1987). Immunological effects of cell components and products of diverse Cytophagales and resulting health problems have already been reviewed. A further example are the mitogenic and immunomodulatory effects exerted by cell wall fractions from a *Capnocytophaga* strain which had been isolated from a patient with juvenile periodontitis; the effects were also given by fractions that were free of LPS and peptidoglycan (Murayama et al., 1982). It is not known to what extent or whether *Capnocytophaga* contributes to periodontal disorders. Cytopathogenic effects were observed for "*Sphaerocytophaga*" (Gräf, 1962b, 1962c). These bacteria were present in large numbers in acute and chronic inflammations in the human oral cavity. In cell cultures (calf kidney cells), they caused cell lysis, and they destroyed human leukocytes in vitro. When inoculated subcutaneously into guinea pigs, they produced inflammations and ulcerations, but were not pathogenic for mice and rabbits when applied intraperitoneally and intravenously, respectively. It was found that neutrophils from patients with large *Capnocytophaga* populations in dental infections showed abnormal behavior, and that such behavior could be induced in normal neutrophils when they were exposed to sonic extracts of *Capnocytophaga* (Shurin et al., 1979). Sonic extracts of *Cp. sputigena* showed moderate toxicity for human gingival fibrablasts as indicated by inhibition of cell proliferation and thymidine incorporation (Stevens and Hammond, 1988). Heat-killed *Cp. gingivalis* cells elicited strong endotoxin reactions in the *Limulus* and the Shwartzman test (e.g., Fumarola et al., 1981). As capnocytophagas are usually found in large numbers in cases of severe destructive periodontitis, especially in juvenile periodontitis, and as they produce similar symptoms when inoculated into healthy gnotobiotic rats, they may indeed not be completely harmless, even if they are always present in the normal buccal flora (Forlenza and Newman, 1983). Perhaps they also play a certain role in the "piggyback" transport of nonmotile bacteria into periodontal pockets. While the situation appears complex and somewhat controversial with periodontal pathogenicity, the case is clear when general infections occur (see also Hawkey et al., 1984). Newly described *Cp. canimorsus* and *Cp. cynodegmi* have been considered to be responsible for septicemia and localized wound infections in humans after dog bites; the organisms seem occasionally also to be transmitted by cats (Brenner et al., 1989). Capnocytophagas respond well to antibiotics, like various β-lactams, quinolones, chloramphenicol, and tetracycline (see also Arlet et al., 1987).

As already discussed in the section on "Habitats," the fish-pathogenic CLB are showing a steadily increasing economic impact on fish cultivation and, to a lesser extent, also on wildlife, in fresh water as well as in seawater. *Cy. columnaris*, *Cy. psychrophila*, *Cy. maritima*, and *Fv. branchiophilum* appear to be the major pathogens and have been reported worldwide, but other species are probably also involved (see also Amin et al., 1988; Farkas and Oláh, 1984; Kuo et al., 1980, 1981; Kusuda and Kimura, 1982; Ostland et al., 1989; Spangenberg, 1975). The outbreaks of disease may follow a seasonal pattern (e.g., Kuo et al., 1981). This is easily understandable, for the fish, as well as the pathogen, usually have well-defined temperature optima; thus, for example, *Cy. columnaris* is a typical warm-water, *Cy. psychrophila* a cold-water pathogen (e.g., Snieszko, 1974). Losses due to infections by CLB can be severe and sometimes approach 100% within a few days. Individual strains of the same species may differ substantially in their virulence. It seems that the pathogens become a problem mainly when the fish are kept under suboptimal conditions. The bacteria are sensitive to certain antibiotics, e.g., chloramphenicol, tetracyclines, and erythromycin, but better suited for practical application are chemotherapeutics like nifurpirinol or Mefarol. As pointed out already, control of the disease may also be effected by vaccination or transfer of the fish to water with a higher or lower temperature or salinity, depending on the specific case. Numerous studies on the various aspects of fish diseases caused by CLB have been published in the last 40 years, and some references to specific topics are: *preconditioning by environmental factors*: Chen et al., 1982; Chowdhury and Wakabayashi, 1989a, 1989b; Hanson and Grizzle, 1985; Snieszko, 1974; *experimental infection*: Baxa et al., 1987b, Chow-

dury and Wakabayashi, 1989a; Kuo et al., 1987b; *histopathology*: Pacha and Ordal, 1967; and *control measures*: Amin et al., 1988; Deufel, 1974; Liewes et al., 1982; Ostland et al., 1989; Snieszko, 1953, summarizes the older literature.

Finally, it seems safe to predict that, beyond the examples given earlier, more diseases and disorders of aquatic animals other than fish will be discovered that are connected to CLB.

CHAPTER 200

The Genus *Saprospira*

HANS REICHENBACH

Gram-negative gliding bacteria that form helical, multicellular filaments are grouped in the genus *Saprospira* (Fig. 1). All known species live in aquatic environments. They are moderately common but relatively difficult to isolate, and therefore have not been studied very well, although some of them can be cultivated without problems. Relatively little has been added to our knowledge of *Saprospira* since the first edition of *The Prokaryotes* (Reichenbach and Dworkin, 1981).

The genus *Saprospira* was defined by Gross (1911). He described two marine species, *S. grandis* and *S. nana,* of which only the former has since been isolated by other investigators. The two organisms differed considerably in their dimensions, as shown in Table 1, which lists some characteristics of the known strains of the genus.

It seems, however, that at least three other investigators had observed saprospiras before Gross. Kolkwitz (1909) described a freshwater saprospira under the name of *Spirulina albida.* He obviously believed his organism to be an apochlorotic blue-green "alga" (cyanobacterium).

In 1875, van Tiegham (1880) observed a delicate white scum that resembled *Beggiatoa* covering the mud in the water course of an old mill. Under the microscope, he discovered that the organism consisted of long, fine, helical filaments that were so tightly wound up that the coils touched. The helices moved by rotation around their long axis. The long filaments were also actively bending. He called this organism *Spirulina alba,* thereby deliberately emphasizing its close affinity to the blue-green algae of the same genus. Although his description is rather scant, it seems almost certain that he was dealing with a *Saprospira* species.

In the same year, Warming (1875) observed a very large helical organism in marine debris from the Danish coast and named it *Spirochaeta gigantea.* From his careful description, one can deduce that this organism, too, may have been a *Saprospira* species.

Not much was published in the five decades following the definition of the genus. In addition, until the middle of the 20th century, *Saprospira* was regularly regarded as belonging to the spirochetes, which caused considerable confusion. Gross (1912) himself stressed the similarity between *Cristispira,* which was also first defined by him, and *Saprospira.* To him and most other investigators at the time, the latter was essentially a spirochete without a crista or an axial filament. Unfortunately, in stained preparations, both organisms also showed a multichambered aspect, which was in fact a staining artifact but obscured the difference in organization of the two bacteria. Dobell (1912) described a new freshwater species, *Saprospira flexuosa.* From the careful description given by Dobell, one may deduce that his organism really was a *Saprospira,* perhaps *S. albida* as suggested by Lewin (1962), although this point cannot be decided because we do not know how many different freshwater saprospiras exist. During a study on helical bacteria in the digestive tract of oysters, Dimitroff (1926) observed several types of organisms which he regarded as saprospiras. One he identified with *S. grandis,* the others he described as new species, *S. lepta* and *S. puncta.* His account of the movements of his isolate of *S. grandis* leaves considerable doubt whether the bacterium was really *Saprospira.* On the other hand, he observed true cristispiras under the microscope and distinguished their very fast movements quite clearly from those of *Saprospira.* If one takes into account the fact that before the days of the phase contrast microscope, it was not so easy to observe living bacteria, it is easier to understand this uncertainty. It might be worthwhile to investigate again for the presence of saprospiras in shellfish. The two new species could never be observed by Dimitroff in the living state so their motility behavior is not known. They both had long, tapering ends with a sharp point, which is not known for any *Saprospira* species. The giant, gliding "spirochete" observed by Soriano in an enrichment culture and very briefly mentioned by him in the legend to a rather suggestive draw-

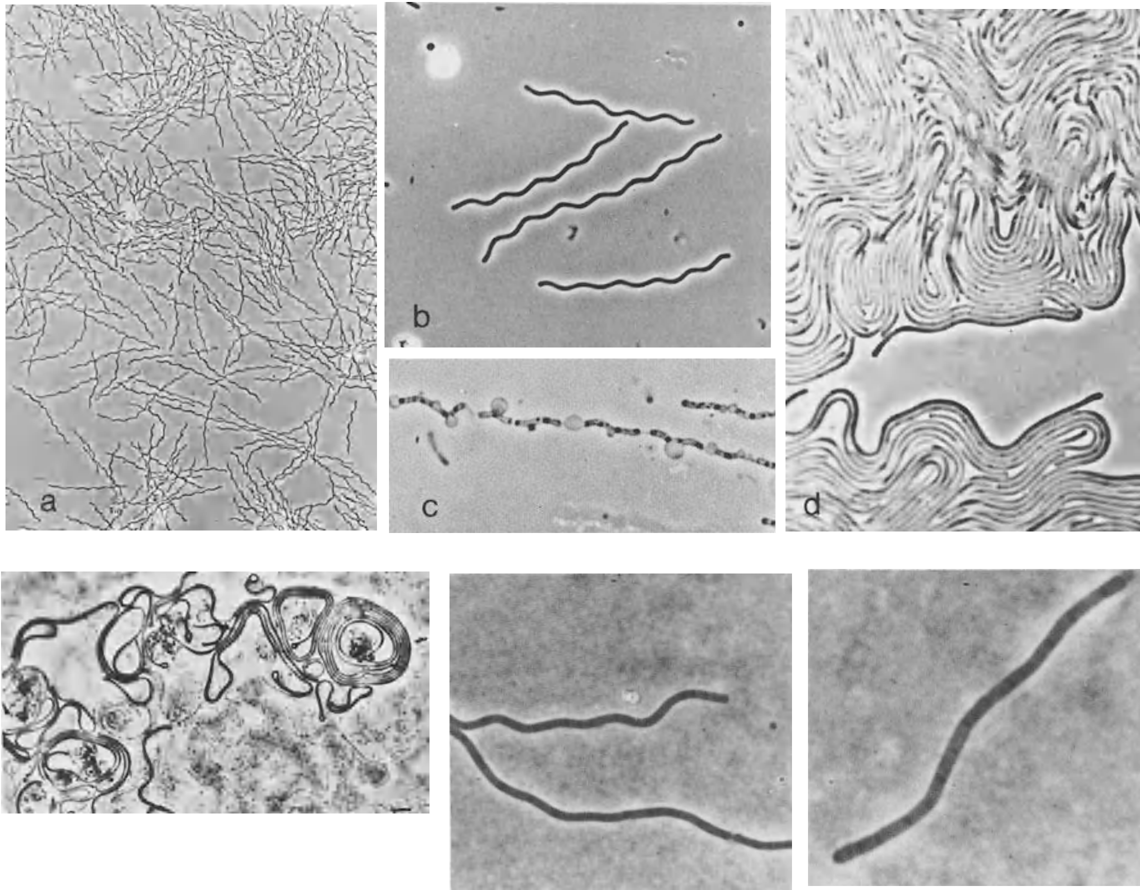

Fig. 1. Phase contrast photomicrographs of *Saprospira grandis.* (a) Helical filaments from a 1-day-old liquid culture, survey picture; × 180. (b) Filaments at higher magnification; × 500. (c) Decaying filament showing the individual cells; × 900. (d) Growing in the narrow space between agar and cover glass in a chamber culture, the filaments have lost most of their helical shape and concomitantly their ability to glide; × 920. (Lower left) Nonhelical filaments in a chamber culture with large, optically refractile, terminal bulbs; × 470. (Lower center and lower right) At very high magnification (× 1000 and × 1200; Zeiss Axiomat) the cross-walls in the filaments are visible. The lower filament shows a constriction near one end, perhaps one possible way of filament fragmentation.

ing (Soriano, 1945), was probably a (freshwater) saprospira. Dyar (1947) described the isolation and cultivation of a freshwater "spirochete." This organism resembled *Saprospira* in many respects, and indeed was later identified with *S. albida* by Pringsheim (1963). Skuja (1948) described the new species, *Achroonema spiroideum,* from Swedish lakes. The organism was later equated with *S. albida* (Lewin, 1962), but the very lax coils typical for *Achroonema spiroideum* leave some doubts whether this assignment is correct.

Many details about the morphology and physiology of the saprospiras were elucidated between 1960 and 1970 through the research of Lewin and his collaborators, who also defined several new species and emended the taxonomic position of the genus (Lewin, 1962, 1965a, 1965b, 1969, 1972; Lewin and Lounsbery, 1969; Lewin and Mandel, 1970). The phylogenetic relationship of *Saprospira grandis* was recently established by 16S rRNA oligonucleotide cataloging: The organism belongs to the *Bacteroides-Flavobacterium-Cytophaga* phylum (Paster et al., 1985). A relationship with the cyanobacterium *Spirulina* has specifically been ruled out (Reichenbach et al., 1986).

A short review of the genus *Saprospira* has recently been published (Reichenbach, 1989). A movie showing the movements and the development of the swarm colonies of *Saprospira* is also available (Reichenbach et al., 1975/1976; Reichenbach, 1980).

Habitats

The saprospiras appear to live exclusively in aquatic environments. *S. grandis* and other marine species have been isolated from sand and

Table 1. Characteristics of the *Saprospira* strains.

Strain	Morphological characteristic (μm)[a]					GC content (mol%)	Habitat
	Length of filament	Diameter of filament	Width of helix	Pitch of helix	Length of cell		
S. grandis, Gross 1911	6–100	0.8		6–6.5	1.5–2.2		Marine
S. grandis, Lewin 1962	10–500	0.8–1.2	1.5–2	4–10	1–2.5	46–48	Marine
S. grandis, Dimitroff 1926[b]	50–90	1.2–1.4[c]		20–28			Oyster, marine
S. grandis, Reichenbach 1980	15–450	0.8–0.9	1.4–1.8	5–6.5	2.7–5.5	47	Marine
S. nana, Gross 1911	36	0.5		2.3–3	1.5–3		Marine
S. gigantea, Warming 1875	About 400	1.5–3	5–9	25–40			Marine
S. toviformis, Lewin and Mandel 1970	10–500	0.8	1.5	4–9	1–2.5	38	Marine
S. lepta, Dimitroff 1926[b,d]	54–92	0.5	1.6–4.8	5–13			Oyster, marine
S. puncta, Dimitroff 1926[b,d]	60–100	0.9–1.2		4–8			Oyster, marine
S. albida, Kolkwitz 1909		1	4–5				Fresh water
S. albida, Dyar 1947	About 400		2	3–6.5			Fresh water
S. albida, Lewin 1965b	10–500	0.8–1.2	1.5–2	3–7	2–3	40–43	Fresh water
S. albida, Ashton and Roberts 1987	10–450	0.8–0.9	1.4–1.6	2.9–4.9	2.1–2.7		Fresh water
S. flexuosa, Dobell 1912[e]	3–50	0.8	2	3			Fresh water
S. spiroidea, Skuja 1948[f]	10–250	0.3–0.5	2.8–5.7	9–25	3–15		Fresh water
S. flammula, Lewin 1965b	10–500	1.0	1.5	3–4	2–3	48	Fresh water
S. thermalis, Lewin 1965a	10–500	1.0	1.5–2.5	7–17	2–5	35–37	Fresh water

[a]In the older literature, measurements were often taken from fixed and stained specimens which may have been considerably distorted.
[b]From the description by Dimitroff it cannot be decided with confidence whether his organisms were true saprospiras.
[c]It is not clear whether Dimitroff was talking about the width of the filament or the width of the helix.
[d]With tapering ends.
[e]Probably actually *S. albida.*
[f]*Achroonema spiroideum* was equated with *S. albida,* but it forms a very lax helix, and, in this respect, it resembles *S. thermalis* more closely than *S. albida.*

mud, and collected at the sea coast at many different locations all over the world (Gross, 1911; Lewin and Lounsbery, 1969; Lewin and Mandel, 1970). One strain of *S. grandis* has been obtained from a rotting crab carapace (Reichenbach, 1980). As discussed above, several species may possibly be found within oysters (Dimitroff, 1926). Saprospiras are common also in fresh water (Lewin, 1965b). They seem to prefer eutrophic conditions and are often associated with algae. Saprospiras have been obtained from the mud in rivers and lakes (Kolwitz, 1909; Pringsheim, 1963), from planktonic algae and cyanobacteria, as well as from the upper layers of surface waters, in which the filaments may be free-floating (Dobell, 1912; Skuja, 1948; Brunel, 1949; Ashton and Robarts, 1987), from decaying organic matter in a sulfur spring (Dyar, 1947), from a bog (Jarosch, 1967), and from sewage plants, including activated sludge (Kolkwitz, 1909; Cyrus and Sladká, 1970; Sladká and Ottová, 1973). *S. thermalis* was first isolated from a hot spring in Iceland, but the organism is not thermophilic and in fact not even thermotolerant, for its maximum temperature is 35–37°C (Lewin, 1965a). Only one strain of *S. albida* was ever isolated from soil. The sample came from Canada, but unfortunately nothing was said about the water conditions of that soil (Lewin, 1965b).

Interesting details about the interaction of a saprospira species with the cyanobacterium *Microcystis aeruginosa* in a South African reservoir have been published (Ashton and Robarts, 1987). Usually *Saprospira* is found in the surface layers of the lake at a very low density of less than 10 filaments per liter, but during *Microcystis* blooms, its density increases to more than 10,000 filaments per liter, and the saprospiras colonize and lyse the floating colonies of the cyanobacterium. Curiously, the *Saprospira* seems selectively to attack a toxic variant of *M. aeruginosa,* which is dominant at the site for most of the year. It has been suggested that saprospiras could be useful to control this undesired organism.

Isolation

No specific enrichment methods are known for saprospiras. Gross (1911) described a collection technique that makes use of the tendency of *Saprospira* to attach itself to a substrate surface. He filled a large petri dish with a sample of marine sand, covered it with sea water, placed coverslips on the water surface, and left them floating overnight. Most of the saprospiras stuck to the glass surface and could be removed from the crude culture.

To isolate saprospiras, samples are taken from appropriate habitats (see above) and placed as well-separated streaks or spots onto the surface of dry agar plates. To prevent excessive growth of contaminants, the media should contain nutrients in low concentrations only. For marine samples, MS1, SW2, or SP6 agar can be used. It appears that for saprospiras, natural and artificial seawater are equivalent, so that the following media could be prepared with either one.

MS1 Agar

> Agar 1.5%
> Natural seawater
>
> The pH is not adjusted. The medium is autoclaved.

SW2 Agar

Agar	1.5%
NH_4Cl	0.1%
Na acetate	0.002%
Artificial seawater (see below)	

The pH is adjusted to 7.2. The medium is autoclaved.

Artificial Seawater (Dawson et al., 1972)

> The following recipe has been used by us with good results: NaCl, 24.7 g; KCl, 0.7 g; $MgSO_4{\cdot}7H_2O$, 6.3 g; $MgCl_2{\cdot}6H_2O$, 4.6 g; $CaCl_2$ (anhydrous), 1.0 g; $NaHCO_3$, 0.2 g. Bring to 1 liter with water. To avoid precipitation, $CaCl_2$ and $NaHCO_3$ are autoclaved as separate stock solutions.

SP6 Agar

Casitone (Difco)	0.03%
Yeast extract (Difco)	0.01%
Agar	1.5%
Artificial seawater (see above)	

The pH is adjusted to 7.2. The medium is autoclaved.

The freshwater saprospiras are often more fastidious, and most investigators were only able to maintain their isolates for longer periods in mixed cultures, e.g., in fouling soil suspensions such as soil enriched with proteinaceous material in water (Pringsheim, 1963). Repeatedly, it has been found that small quantities of H_2S are stimulatory, although the organisms do not really depend on it (Dobell, 1912; Dyar, 1947). Perhaps the good results with Pringsheim's technique were also due to the production of H_2S from the added protein. Dyar (1947) seems to have been the first to succeed in isolating and cultivating a strain of *S. albida.* She used a leaf-infusion agar with a few drops of blood for isolation.

Several freshwater saprospiras were isolated by Lewin using LEW1 agar (Lewin 1965a, 1965b).

LEW1 Agar (Lewin, 1965b)

$Ca(NO_3)_2{\cdot}4H_2O$	0.05%
$MgSO_4{\cdot}7H_2O$	0.01%
K_2HPO_4	0.01%
Tryptone (Difco)	0.01%
Agar	1%

Yeast extract (Difco) can also be used in place of tryptone.

The crude cultures are incubated at 30°C, room temperature, or in the refrigerator, depending on the starting material. For freshwater strains, 23–27°C is recommended (Lewin, 1965a). Although marine *S. grandis* has a temperature optimum around 30°C, it is useful to keep crude and enrichment cultures at 6°C, since the organism still grows and spreads reasonably well at that temperature, while the growth of contaminants is considerably reduced (H. Reichenbach, unpublished observations). The crude cultures are examined from time to time under a dissecting microscope. Oblique illumination should be applied to make delicate, spreading colonies also visible. Already after 3 to 4 days, or, at lower temperatures, after a longer interval of up to 2 to 3 weeks, spreading colonies with long, rootlike tongues (Fig. 2) or with irregular, flamelike edges may be found. This is the typical appearance of colonies of

gliding bacteria. *Saprospira* colonies often also show a very regular striped pattern (Dyar, 1947; Reichenbach et al., 1975/76; Reichenbach, 1980), which is seen with other screw-shaped bacteria, e.g., *Methanospirillum hungatii* (Ferry et al., 1974). A microscopic control should show the typical *Saprospira* filaments (Fig. 1) and their characteristic movements (Reichenbach et al., 1975/76). Further purification is achieved by making transfers from the spreading edges of the swarm colonies; it is best to cut out a piece of the colony using the sharp point of a 1-ml disposable syringe. The material is streaked on the same medium as before, or, as soon as the colonies appear sufficiently pure, also on a richer medium e.g., SAP2 agar for marine, and LEW2 and LEW3 agar for freshwater strains.

SAP2 Agar

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Agar	1.5%
Artificial seawater (see above)	

The pH is adjusted to 7.2. The medium is autoclaved.

LEW2 and LEW3 Agar (Lewin, 1965a).

The recipe is the same as for LEW1 agar, but the tryptone concentration is raised to 0.03% and 0.3%, respectively.

Finally, diluted filament suspensions may be plated on the richer versions of the above-mentioned media. The most troublesome contaminants are other gliding bacteria and, in marine samples, agar decomposers. Both groups should be eliminated at the very beginning of the enrichment process.

Cultivation

All *Saprospira* strains that have been studied so far are strictly aerobic organotrophs and seem to prefer amino acids as carbon, nitrogen, and energy sources, often without an alternative. Many marine strains grow well on relatively simple media, such as SAP1 or SAP2 agar.

SAP1 Agar (Lewin, 1962)

Tryptone (Difco)	0.5%
Yeast extract (Difco)	0.5%
Agar	1.5%
Artificial seawater (see above)	

The pH is adjusted to 7.2. The medium is autoclaved.

The marine saprospiras can be cultivated without difficulties and with good yields in liquid media, such as SP5 liquid medium or SAP1 liquid medium (as for SAP1 agar, but without agar). They usually form homogeneous suspensions in shake cultures.

SP5 Liquid Medium

Casitone (Difco)	0.9%
Yeast extract (Difco)	0.1%
Artificial seawater (see above)	

The pH is adjusted to 7.2. The medium is autoclaved.

An almost fully defined medium is reported for *S. grandis* (Lewin, 1972). It is composed of nine essential amino acids, mineral salts, and an unknown growth factor present in yeast nucleic acid hydrolysate. The marine saprospiras almost always require at least half-strength sea water, but *S. toviformis* and a few *S. grandis* strains also grow at freshwater salt concentrations (Lewin and Lounsbery, 1969).

Among the freshwater saprospiras, *S. thermalis* is the least fastidious one and can be grown on relatively simple media, e.g., LEW3 agar (see above) and in LEW4 liquid medium. A synthetic medium also has been developed (Lewin, 1965a).

LEW4 Liquid Medium (Lewin, 1965a)

Casamino acids (Difco)	0.1%
Sodium glutamate	0.1%
Glucose (sterilized separately)	0.1%
Tris (hydroxymethyl) aminomethane	0.1%
$MgSO_4 \cdot 7H_2O$	0.01%
KNO_3	0.01%
KNO_3	0.01%
$CaCl_2 \cdot 2H_2O$	0.01%
Sodium glycerophosphate	0.01%
Thiamine	1 mg/liter
Cobalamine	1 μg/liter
Fe	0.5 mg/liter
Zn	0.3 mg/liter
B, Co, Cu, Mn, Mo	0.1 mg/liter each

The pH is adjusted to 7.5. The medium is autoclaved.

Good growth was also obtained in a medium containing the mineral salts (and glycerophosphate) of LEW4 liquid medium plus tryptone (Difco) 0.02% and glucose 0.02%. If the tryptone is replaced by casamino acids, the addition of the vitamins became necessary (as in LEW4 liquid medium). The casamino acids in turn can be replaced by 0.2% sodium glutamate and three essential amino acids, i.e., leucine (50 mg/liter), isoleucine (50 mg/l), and valine (100 mg/liter). Growth was substantially faster when tyrosine (100 mg/liter) or phenylalanine (250 mg/liter) were also added.

The freshwater saprospiras of the *S. albida* type are more difficult to cultivate. Dyar (1947)

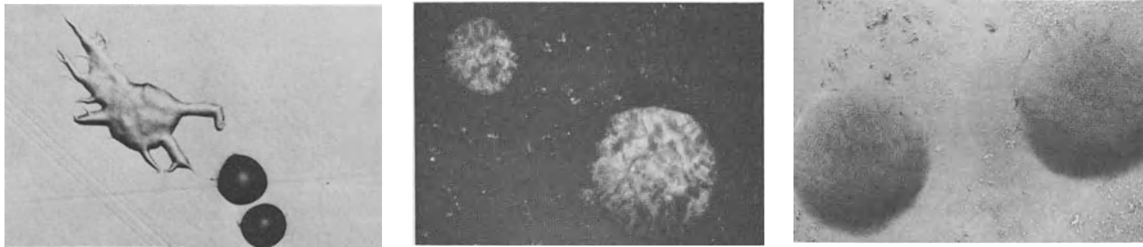

Fig. 2. Colonial morphology of *Saprospira grandis*. (Left) Colony on peptone-seawater agar together with two colonies of a nongliding organism. The *Saprospira* colony is rather tough and remains relatively compact; it spreads mainly along the grooves scratched into the agar surface by the inoculation loop. Leitz Aristophot; × 7.2. (Middle) Compact colonies on SP2 agar, in dark field; × 33. (Right) Colonies under oblique illumination; × 33. In both cases, the appearance of the colonies suggests some orderly arrangement of the filaments; in bright field, a pattern of fine, parallel, concentric stripes can be seen; Zeiss Axiomat.

could grow pure cultures on blood agar containing 5–10% erythrocytes and 1–1.5% agar. The organism did not grow if blood serum or heat-sterilized blood was used, which seems to indicate that it required either a heat-labile growth factor or enzyme in erythrocytes. Lewin (1965b) recommended a semisolid medium, LEW5 agar, for those strains, but even then they grow rather slowly.

LEW5 Agar (Lewin, 1965b)

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Gelatin (Difco)	0.1%
Glucose (sterilized separately)	0.1%
Tris buffer	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
KNO_3	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
NaCl	0.1%
Sodium glycerophosphate	0.01%
Fe	0.5 mg/liter
Zn	0.3 mg/liter
B, Co, Cu, Mn, Mo	0.1 mg/liter each
Agar	0.25%

The pH is adjusted to 7.5. The medium is autoclaved.

Unlike the other freshwater saprospiras, *S. flammula* is stimulated by 0.3% NaCl. It does not grow on casamino acids alone, but can be cultivated on a medium containing 0.5% tryptone, 0.3% NaCl and 0.25% agar (Lewin, 1965b).

Most saprospiras grow well at 30°C. Many strains even grow at 40°C (Lewin and Lounsbery, 1969). The temperature optimum is near 25°C for (marine) *S. toviformis* (Lewin and Mandel, 1970), 26°C for (freshwater) *S. albida* (the range is still 15–34°C; Dyar, 1947), and about 37°C for (marine) *S. grandis* (Lewin, 1962). *S. grandis* survives 46°C for 30 min (Lewin, 1972). This high temperature optimum of *S. grandis* is somewhat surprising, for the organism usually is found in a relatively cold environment. Thus, strain Sa gl was isolated at Roscoff, Brittany, where the Atlantic Ocean rarely reaches 17–18°C and is much colder most of the year. This strain also grows rather well at 6°C, and thus has a very wide temperature range.

The optimal pH is around neutral, and the range in which growth is possible is 6.5 to 7.5 and occasionally slightly beyond. The doubling time of *S. grandis* is 2 to 3 h at 30°C in SAP1 liquid medium (Lewin, 1962, 1972), that of *S. thermalis* 6 to 7 h at 30°C (Lewin, 1965a). A yield of about 250 mg dry cell mass per liter has been found with *S. thermalis* (Lewin, 1965a). With *S. grandis* in SP5 liquid medium at 30°, after 24 h of cultivation we obtained 12.5 g bacteria per liter by wet weight, corresponding to 2.5 to 3 g dry weight. Aasen and Liaaen-Jensen (1966a) harvested 400 g wet cells, giving 51.5 g freeze-dried bacteria, from 200 liters of culture broth after 20 h at 30°C.

Preservation

Cultures of *S. grandis* strain Sa gl on SAP2 agar remain viable for 2 to 3 weeks at room temperature (21°C). Lysis within 3 days at 30°C, and within a few weeks at 25°C, on all tested liquid and agar media, has been reported for other strains (Lewin, 1962). Dyar (1947) found that her *S. albida* survived on blood agar for about one month but died after a short time in the refrigerator.

Filaments of *S. grandis* strain Sa gl can be suspended in SP5 liquid medium and frozen at −80°C or in liquid nitrogen without any further precautions. We were able to revive both cultures without difficulty after 2.5 years, the longest period tested so far. They will certainly survive for a much longer time. We had no success

with drying in skim milk (H. Reichenbach, unpublished observations).

Sanfilippo and Lewin (1970) tested several freezing techniques with 27 strains of five *Saprospira* species. The longest survival times they found for cultures frozen at −22°C was 2 to 3 weeks (only marine species). In media containing 10% glycerol, all marine strains survived in liquid nitrogen for 1 year, the longest period tested. Of the freshwater species, only some strains of *S. thermalis* could be preserved in this way. Dimethyl sulfoxide (DMSO, 10%) proved toxic for all saprospiras: all strains were killed within 24 h at room temperature.

Characterization

The saprospiras form helical, multicellular, unbranched filaments (see Fig. 1) that move by gliding when in contact with a substrate surface. The length of the filaments is not fixed and varies considerably, even within one culture. The filaments tend to be longer in liquid media than on agar plates. *S. grandis* strain Sa gl, e.g., measures 15–130 μm when grown on a plate, and 20–450 μm when grown in a liquid medium of the same composition. Similar figures have been reported for other strains and species (see Table 1). The diameter of the filaments is relatively constant and usually around 1 μm.

The filaments are composed of cylindrical cells that are 1–5 μm long and closely attached to one another. No constrictions are visible at the surface of the filaments at the sites of the septa. The cells at the ends of the filaments are rounded, but otherwise do not seem different from the rest. (As mentioned above, two dubious species with pointed filaments have been described from oysters; Dimitroff, 1926). The length of the cells within one filament is variable, which suggests that the cells divide along the whole filament and independently from one another. With a good microscope and applying phase or interference contrast, the cross-walls can be seen in the living filament. Also, darkfield microscopy shows the septa clearly (Dyar, 1947; Jarosch, 1967). The cell boundaries become more apparent when the filaments begin to disintegrate (see Fig. 1c). Drying of the filaments to the slide may be sufficient to induce fragmentation (Dyar, 1947). Further, the multicellular nature of the screws can be seen after staining, e.g., with an I-KI solution (Skuja, 1948) or with Heidenhain's hematoxylin (Gross, 1911). Other staining methods often used in the older literature, e.g., with safranine, borax carmine, or methylene blue, also produced chambered filaments in *Saprospira*, but this may sometimes have been an artifact due to shrinkage of the protoplast, for true spirochetes also showed such a chambered appearance (Dobell, 1912; Dimitroff, 1926). Another identified artifact was an "axial filament" in heavily stained mounts of *S. albida* (Dyar, 1947). Of course, the septa are easily recognizable in thin sections under the electron microscope (Lewin, 1962). Also, in the election microscope, a typical Gram-negative cell wall with a thin peptidoglycan layer and an outer membrane can be seen. As usual, the septa consist only of the two cytoplasmic membranes and the peptidoglycan layer. The filaments multiply by breaking in two, apparently sometimes at the sites of necridia, i.e., dead cells (Gross, 1911; see also Chapter 209 on *Herpetosiphon*). It seems that reproduction by simultaneous fragmentation into many short, one- or few-celled pieces can also take place (Gross, 1911, 1912; Dobell, 1912; Lewin, 1962, 1965b). The short pieces move only very slowly if at all, but with growing length their movements speed up again (Dobell, 1912; Skuja, 1948).

The helix of *Saprospira* usually is relatively loose (Fig. 1). Its pitch is 3–10 μm, and its width is 1.5–2.5 μm. Some species show especially lax helices, e.g., *S. thermalis* and *S. (Achroonema) spiroideum.* But pitch and width are not constant features of a strain and can vary somewhat even within one culture. With the freshwater species, the helices appear usually to be coiled sinistrally (Lewin, 1965b), while the marine strains are coiled dextrally (Lewin and Mandel, 1970). The screw shape of the filaments may completely disappear during cultivation, in which case the organism would be difficult to recognize as a *Saprospira* (Dyar, 1947; Lewin, 1965b). Thus, the very long filaments seen in liquid cultures generally form only rudimentary and irregular helices. Also after improper fixation (e.g., with picric acid) the filaments tend to straighten out (Gross, 1911). In chamber cultures when restricted to the narrow space between the agar surface and the cover glass, *S. grandis* grows in the shape of very long, meandering filaments that are completely straight and, interestingly, also nonmotile (Fig. 1d; Reichenbach et al., 1975/1976; Reichenbach, 1980).

In such chamber cultures of *S. grandis,* filaments can sometimes be seen with the end cells inflated into spherical, optically refractile bulbs of 1.4–3 μm diameter (Fig. 2; Reichenbach, 1980). Those bulbs are probably a degeneration phenomenon but should not be confused with the spheroplasts that are found in old cultures all along the filament (Dyar, 1947), or can be produced by adding a 5 to 10% NaCl solution

("blisters"; Dobell, 1912). Filaments of *S. grandis* from liquid cultures appear to be very sensitive to changes in environmental conditions. Simply mounting them on a slide is sufficient to induce a decay of the filament and the formation of spherical protrusions at the surface of the cells (Fig. 1c).

Inside the cells of *S. albida* many highly refractive granules can be seen, sometimes extending from one side of the cell to the other (Dobell, 1912; Dyar, 1947). Dyar distinguishes two types: 1) volutin granules, i.e., polyphosphate, which show metachromatic staining with methylene blue and dissolve in (hot) water or in 0.02% $NaHCO_3$ solution; and 2) lipid globules, which stain with Sudan black B. The latter could well consist of poly-β-hydroxybutyrate. The inclusions are also seen under the electron microscope (Dyar, 1947). They appear to be relatively rare in *S. grandis* (Lewin, 1962; Lewin and Kiethe, 1965).

Gross (1911) mentioned that, in aging cultures of *S. grandis,* series of cells with increased stainability could occasionally be seen within filaments. Such cells later became spherical and surrounded themselves with a heavy wall. He suggested that those cells were spores, although he could not observe any further development. This observation has not yet been corroborated by other investigators.

A DNA phage of *S. grandis* with an icosahedral head, a contractile tail sheath, and rigid tail spines has been isolated and characterized (Lewin et al., 1964). Peculiar rod-shaped particles with long, wicklike tails, found in lysing cultures of *S. grandis* (Lewin, 1963; Lewin and Kiethe, 1965; Reichle and Lewin, 1968) and of the freshwater species *S. albida* and *S. flammula* (Lewin, 1965b) have been described as "rhapsidosomes." The preparations showed no infectivity whatsoever. Initially it was thought that the particles consisted of a ribonucleoprotein containing a highly 2′-*O*-methylated RNA (Correll and Lewin, 1964; Correll, 1968). This, however, turned out to be an analytical error, for the particles are composed exclusively of protein (Delk and Dekker, 1969, 1972; Price and Rottman, 1970). Very similar particles were later found in a myxobacterium and identified as the tails of a defective phage (Reichenbach, 1967). The *Saprospira* particles very probably have the same origin (Delk and Dekker, 1972). In fact, defective phage tails are rather common in bacteria, and many examples are known today. Unfortunately, the term rhapidosome was later also used for rod-shaped particles of a totally different morphology and nature, leading to unnecessary confusion (e.g., Pate et al., 1967; Yamamoto, 1967; Baechler and Berk, 1972).

In autolysed cultures of *S. thermalis,* but not of any other *Saprospira,* cell-wall fragments with a periodic hexagonal substructure are seen under the electron microscope, obviously remnants of a surface layer (Lewin, 1965b).

The helical filaments of *Saprospira* move by gliding when in contact with a suitable substrate surface, e.g., an agar or glass surface. The speed of *S. grandis* at room temperature (25°C) is 50–120 μm/min, and the movement is thus very obvious (Lewin, 1962). A speed of 120–180 μm/min has been determined for *S. thermalis* (Lewin, 1965b), one of 600 μm/min for *S. spiroidea* (Skuja, 1948), and one of only 14 μm/min for *S. flexuosa* (Dobell, 1912). The gliding screws rotate around their long axis, and are also able to bend actively. Bending is particularly conspicuous when the filaments are suspended in a liquid. The helices move equally well in both directions and may quickly and frequently reverse the sense of their movement. As already mentioned, loss of the helical arrangement of the cells leads to a loss of translocation. The locomotory machinery still seems to be operative, however, since tiny particles stuck to the surface of the filaments can be seen to migrate back and forth over a limited distance, presumably the length of a cell (Reichenbach et al., 1975/1976). Obviously, the proper spatial arrangement of the cells in the helix is a prerequisite for their efficient cooperation during movement (Reichenbach, 1980). As with all other gliding bacteria, the mechanism of locomotion is not understood in *Saprospira.* A movement of Indian ink particles on a helical path along the surface of filaments of *S. albida* has been explained by the movement of a helical slime belt that could also be responsible for the translocation of the filaments (Jarosch, 1967), but what moves the slime, is still an open question. A sticky surface is, no doubt, essential for gliding motility, and the surface of *Saprospira* is indeed very sticky (Gross, 1911). Slimy material has been isolated from viscous, nonlysing liquid cultures of *S. thermalis* (27 mg/liter), and various sugars have been provisionally identified in the hydrolysate (glucose, xylose, rhamnose, traces of galactose and mannose; Lewin, 1965a).

The colonies of *S. grandis* on rich agar media are compact with entire edges and of a rather tough consistency (Fig. 2). On dilute media, however, the colonies spread, albeit often slowly and to a much lesser extent than the swarms of many other gliding bacteria. Long, unbranched, rhizoidal tongues may radiate from the edges of those colonies (Fig. 2). In other cases, the swarms are thin and filmlike (e.g., *S. grandis* on SP6 agar). The spreading colonies and, less

so, also the compact ones, show a surprising and very regular pattern of narrow stripes (Fig. 3). The striations are particularly impressive under dark-field illumination. As already mentioned, the phenomenon was first described for *Saprospira* by Dyar (1947) and is also known for other, unrelated, helical bacteria. It may be explained by an exact alignment of the screws (Fig. 3d). The optical pattern seems to arise from differences in light scattering in the rising and falling gyres of the helices, perhaps in combination with an interference effect. Colonies of *S. grandis* Sa gl show a periodicity of the stripes of 7.6 to 8.6 μm, while the pitch of the helices in suspension is 4.9 to 6.5 μm. Apparently, the helices are slightly distorted on the plate.

Relatively little is known about the chemical composition of *Saprospira.* The respiratory chain contains menaquinone MK-7 exclusively (M. D. Collins, personal communication). While initial studies seemed to indicate an *o*-type cytochrome as the terminal oxidase (Webster and Hackett, 1966), it was later found that *S. grandis* has four functional cytochromes, one of which has an unusual maximum at 603 nm (77°K) in the difference spectrum, and that an a,a_3-type cytochrome is most probably the oxidase (Dietrich and Biggins, 1971). NADH-oxidation by *Saprospira* particles is insensitive to antimycin A, rotenone, and amytal, but it is inhibited by cyanide and HOQNO.

The GC content of the DNA of the various species is 35–48 mol% (see Table 1).

The saprospiras are colored in shades of yellow, orange, pink, and red. The pigments are cell-bound. Initial studies provided a preliminary characterization of the pigment patterns by thin-layer chromatography, and of the pigment type by absorption spectra of chromatographic fractions (Fox and Lewin, 1963; Lewin and Lounsbery, 1969). It soon became apparent that the pigments were probably carotenoids, but so far only one, the new xanthophyll saproxanthin (a modified 3,1′-dihydroxy-γ-carotene) from *S. grandis,* has been chemically characterized (Aasen and Liaaen-Jensen, 1966a). The pigment content was 0.02% of the freeze-dried cells. From *S. thermalis,* a single carot-

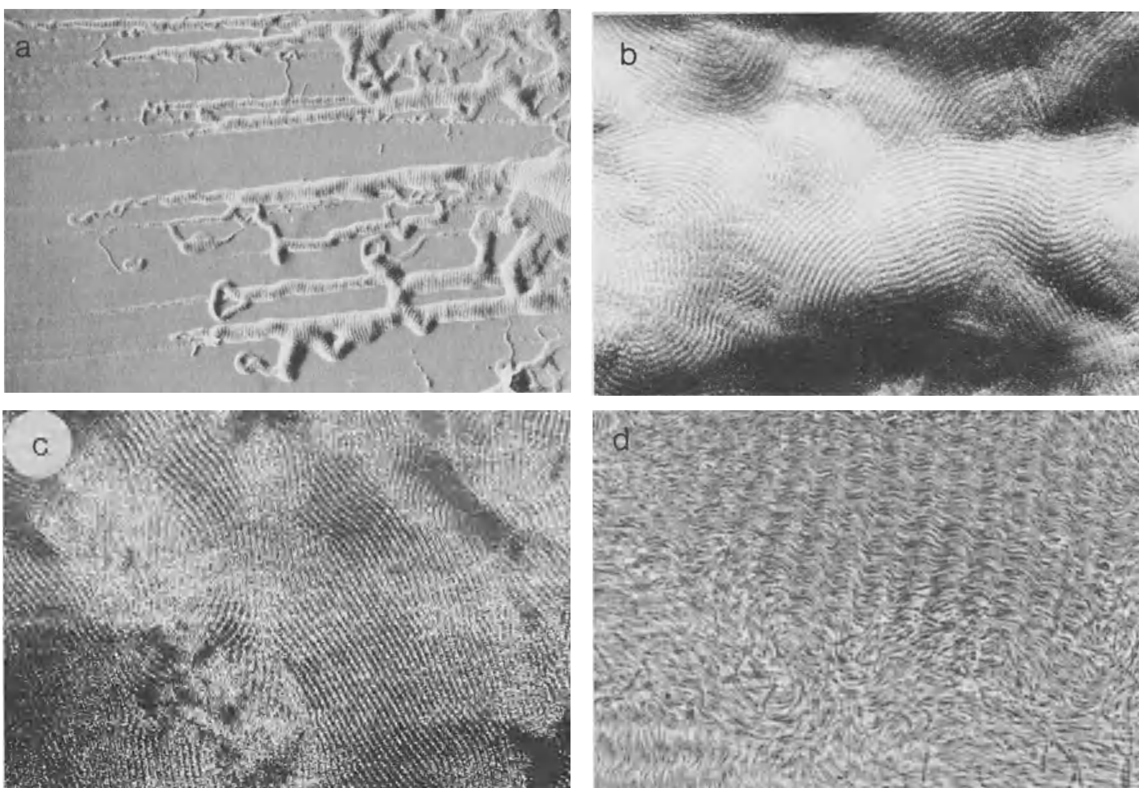

Fig. 3. Striated colonies of *Saprospira grandis.* (a) Colony spreading along grooves in the agar surface; the stripes run almost perpendicular to the direction of the spreading movement; Zeiss Standard Microscope, with oblique illumination; × 60. (b) Surface of a colony under oblique illumination; the filaments are just recognizable as a very delicate striation perpendicular to the stripes; Zeiss Axiomat; × 120. (c) Under dark-field illumination, the pattern of stripes becomes even more distinct; Zeiss Axiomat; × 120. (d) At high magnification it can be seen that in the striated areas the filaments lie strictly parallel, with the screws "in phase"; Zeiss Axiomat; × 580.

enoid, apparently a keto-carotenoid, was obtained, but because of very low yields (0.002% of the dry weight) its chemical structure could not be determined (Aasen and Liaaen-Jensen, 1966b). The early investigators described *S. albida* as completely unpigmented (however, they may have thought mainly of chlorophylls), but when a sufficiently high cell density is obtained, the organism shows a pale yellow tint (Fox and Lewin, 1963). Carotenoid synthesis by *S. thermalis* is stimulated by light, by suboptimal concentrations of cobalamine or tyrosine, and by subinhibitory concentrations of thiamine or sodium thiosulfate (Lewin, 1965a).

As already mentioned, *S. grandis* depends entirely on amino acids for growth (Lewin, 1972). It can be cultivated on various peptones, such as tryptone, casitone, phytone, or yeast extract. It can also be grown on casamino acids, but only if the medium is supplemented with tryptophan, asparagine, and a small quantity of yeast nucleic acid hydrolyzate (the growth factor supplied by the latter could not be identified). In that case, the casamino acids could be replaced by a mixture of essential amino acids, i.e., arginine, histidine, isoleucine, leucine, valine, methionine, phenylalanine, threonine, and perhaps lysine. Curiously, asparagine cannot be substituted by aspartate or glutamine. In nature, *S. grandis* may provide itself with the required amino acids by the degradation of proteinaceous matter. Gelatin liquefaction, the clotting and digestion of milk casein, and the decomposition of bacterial cells by *S. grandis* have been reported. In accordance with the metabolic restrictions outlined above, polysaccharides like starch, alginate, carboxymethyl cellulose, and agar are not hydrolyzed (Lewin and Lounsbery, 1969). Strain Sa gl also does not attack chitin and yeast cells. Marine *S. toviformis* differs from *S. grandis* in that it grows on casamino acids alone and does not require asparagine. Also, it is stimulated by lactate and acetate and depolymerizes carboxymethyl cellulose. It, too, does not utilize any of the tested sugars (Lewin and Lounsbery, 1969).

S. thermalis, the only freshwater species studied in some detail, utilizes glucose but none of the other tested sugars, sugar alcohols, ethanol, or acetate (Lewin, 1965a); Lewin and Lounsbery, 1969). This organism also hydrolyzes starch. *S. thermalis* grows well in a mineral salts/glucose medium with tryptone. The latter can be replaced by either 1) yeast extract; 2) casamino acids plus the vitamins cobalamine and thiamine; or 3) glutamate plus the essential amino acids valine, leucine, and isoleucine and the vitamins. Much better growth is obtained if phenylalanine or tyrosine are also added to the synthetic medium. The main nitrogen source in the latter medium, glutamate, can be substituted by asparagine, methionine, or threonine, to a certain extent also by NH_4^+ or urea, but not by NO_3. *S. thermalis* too is proteolytic. The organism appears to operate a citric acid cycle (Lewin, 1965a). A fructose-bisphosphate aldolase has been purified 240-fold from *S. thermalis* (Willard and Gibbs, 1968). It is a type II aldolase, as is characteristic for bacteria, requiring cysteine, Zn^{2+}, and K^+ for maximum activity.

All saprospiras are catalase negative and produce ammonia from amino acids, none reduces nitrate to nitrite. Only *S. thermalis* produces H_2S and minor amounts of indole.

Taxonomy

An extensive study on the taxonomy of flexibacteria, including several types of saprospiras, was performed in the late 1960s (Lewin, 1969; Lewin and Lounsbery, 1969). The study was based mainly on a set of about 70 morphological and physiological features, but the GC content of the strains was also determined (Mandel and Lewin, 1969; in case of a discrepancy between data in the literature, the GC values given in Table 1 were taken from this study). The data were processed in two different ways: by an Adansonian analysis (Colwell, 1969) and by a recurrent group analysis (Fager, 1969). While in both schemes, the strains of *S. grandis, S. thermalis,* and *S. toviformis* turn out as coherent and clearly separated groups, the connections between those groups, and between them and other flexibacteria, differ substantially. Considering the limitations of such a phenotypic classification it may, however, be too early to conclude that the various saprospiras are not closely enough related to be included in one genus.

The phylogenetic relationship of *S. grandis* with the cytophagas and flavobacteria has already been mentioned. The branching point is, however, relatively low, and the connection to the other members of the group is consequently weak.

At present, only one species of *Saprospira* is accepted, *S. grandis* (Reichenbach, 1989). Although there are no conclusive arguments to prove it, at least some of the various organisms classified as saprospiras in the past (Table 1) may indeed represent other *Saprospira* species. Apparently, a similar situation exists with *Saprospira* as with *Beggiatoa,* for which strains or species of widely different dimensions have also been reported. Unfortunately, with the excep-

tion of *S. grandis*, no other *Saprospira* seems to be currently available for comparison in a public culture collection, so that all planned studies will have to start with new isolates.

Applications

Apart from the remote possibility discussed earlier for using saprospiras for the control of freshwater cyanobacteria, no other practical interest in the saprospiras is obvious at the moment.

The Genus *Haliscomenobacter*

EPPE GERKE MULDER and MARIA H. DEINEMA

In the 1st edition of *The Prokaryotes,* the genus *Haliscomenobacter* was considered together with bacteria of the genera *Sphaerotilus* and *Leptothrix,* but *Haliscomenobacter* is not closely related to these other Gram-negative sheathed bactera.

Habitats

Strains of *Haliscomenobacter hydrossis,* the only species of the genus *Haliscomenobacter* isolated so far, are nearly always present in activated sludge flocs, sometimes in large amounts. The conditions for such an abundant development, which gives rise to bulking sludge, are not understood.

Straight, thin, needle-shaped, sheath-forming chains of cells protruding from the sludge flocs (Fig. 1) may interfere with clumping and compacting of the solids.

Isolation

The following procedure (van Veen, 1973) can successfully be used to isolate *Haliscomenobacter* sp. from bulking activated sludge.

I Medium (g/liter of distilled water)

Glucose	0.15
$(NH_4)_2SO_4$	0.5
$Ca(NO_3)_2$	0.01
K_2HPO_4	0.05
$MgSO_4 \cdot 7H_2O$	0.05
KCl	0.05
$CaCO_3$	0.1
Vitamin B_{12}	10^{-5}
Thiamine	4×10^{-4}
Agar (Oxoid)	10

S.C.Y. Medium (g/liter of distilled water)

Sucrose	1.0
Casitone (Difco)	0.75
Yeast extract (Difco)	0.25
Trypticase soy broth without dextrose (BBL)	0.25
Vitamin B_{12}	10^{-5}
Thiamine	4×10^{-4}
Agar (Oxoid)	10

The vitamins are sterilized separately by filtration.

A sample of 0.10–0.50 ml of sludge with a relatively large amount of *Haliscomenobacter* threads is pipetted into tubes containing 10 ml sterile tap water. The tubes are stirred for several minutes with a tube mixer and the flocs allowed to settle. The settling time depends on the characteristics of the sludge and especially on the degree of bulking. This treatment of the sludge is repeated until sufficient filamentous organisms are observed microscopically in the upper layers of the supernatant. During moderate agitation and rotating movements of the dilute floc suspensions, fragments of threads are severed from the protruding filaments. The low total numbers of organisms and the favorable ratio between filamentous and other bacteria in the upper liquid layers permit a direct inoculation of the plates without further dilution of the suspension. The time of agitation of the flocs in the tubes appears to be related to the mechanical properties of the stirrer and to the nature and number of filamentous organisms present in activated sludge.

Very small droplets containing sufficient numbers of filamentous bacteria are transferred to the previously dried surfaces of 30 to 40 agar plates containing I medium. The cells are regularly spread over the whole surface of the agar plates by rubbing firmly with a sterile glass rod. The plates are incubated for 3 to 4 weeks at a temperature between 17 and 20°C.

The small colonies that develop from filamentous bacteria are often difficult to detect with a stereomicroscope, but recognition of the poorly contrasting, filamentous microcolonies on the agar is facilitated by low-magnification (150×) phase-contrast microscopy. Isolation is performed by transferring bacterial cells to S.C.Y. medium using sterile capillary tubes.

Preservation of Cultures

Stock cultures of *Haliscomenobacter hydrossis* can be maintained in the following way. Three milliliters of sterile tap water are pipetted onto the surface of the S.C.Y. agar slopes. The inoculated tubes are incubated at 20–25°C until turbid growth has developed in the liquid layer

---

This paper is taken from the 1st edition of *The Prokaryotes.*

on the agar. The cells remain viable during 3 months' storage at 4°C.

Identification

The main characteristics of *Haliscomenobacter* spp. are presented in Table 1. Pinkish, smooth, or slightly filamentous colonies about 1–3 mm in diameter are formed on S.C.Y. medium. The cells are nearly always enclosed by a narrow, hardly visible, hyaline sheath (Fig. 2). A holdfast, as may be present in *Sphaerotilus natans,* has never been detected. The sheaths do not attach to glass walls of culture flasks; occasionally single cells are liberated from the sheaths in fast-growing, aerated cultures. Flagella have not been detected by electron microscope examinations, and motility in liquid or hanging-drop cultures has never been observed. Glucose, glucosamine, lactose, sucrose, and starch have been found to be excellent carbon and energy sources. The cells grow very well with $(NH_4)_2SO_4$, KNO_3, glutamate, or casamino acids as the nitrogen source. Both vitamin B_{12} and thiamine are required for growth. Maximum growth was generally obtained after an incubation period of 4–6 days on a rotary shaker at 25°C (Krul, 1977; van Veen et al., 1973).

Instead of poly-β-hydroxybutyrate (present in *Sphaerotilus* and *Leptothrix* spp.), polysaccharide globules are present in cells from media with a high C/N ratio (Fig. 3) (Deinema et al., 1977). Strains of *Haliscomenobacter* isolated so far belong to one species, *H. hydrossis* (Crombach et al., 1974; Eikelboom, 1975; van Veen et al., 1973).

The GC content of the DNA of *H. hydrossis* strains was found to be 49.0 ± 0.7 mol% (Crombach et al., 1974). This value, together with the other properties of this sheathed bacterium (Table 1), confirms the theory that except for the presence of a sheath, bacteria of the genus *Haliscomenobacter* are entirely different from those belonging to the genera *Sphaerotilus* and *Leptothrix.*

Three strains of *Haliscomenobacter hydrossis* have been deposited with the American Type Culture Collection (ATCC 27775–7) in Rockville, Maryland, and with the Deutsche Sammlung für Mikroorganismen (DSM 1100) in Göttingen.

CHAPTER 202

The Genus *Chlamydia*

PATRICIA I. FIELDS and ROBERT C. BARNES

Introduction

Members of the genus *Chlamydia* are obligate intracellular prokaryotes whose unique life style has earned them their own order, family, and genus within the kingdom Prokaryotae. The chlamydiae have a unique biphasic developmental cycle that alternates between a spore-like, infectious, metabolically inactive particle, the elementary body (EB), and a noninfectious, metabolically active, replicative form, the reticulate body (RB). The chlamydial outer envelop shares some features with the envelops of Gram-negative organisms but it lacks peptidoglycan, a major structural component of bacterial cell walls. The chlamydiae seem to be completely dependent on their host for high-energy metabolities. However, they are capable of synthesizing their own macromolecules.

The three recognized species of the genus *Chlamydia* cause a wide range of human and animal diseases. *C. trachomatis* is primarily a human pathogen and the causative agent of ocular, genital, and respiratory diseases. *C. trachomatis* causes the most frequent sexually transmitted disease in the industrialized world. Complications of chlamydial infections, and infections in newborns of infected mothers, are a serious health concern. *C. psittaci* is primarily an animal pathogen. Some strains can cause serious respiratory infections in humans as a result of contact with birds. The third, recently described, *C. pneumoniae,* has been shown to cause acute respiratory disease in humans.

Chlamydiae were first observed in 1907 by Halberstaedter and von Prowazek who noted inclusions of the trachoma biovar in conjunctival scrapings (Halberstaedter and von Prowazek, 1909). The organism received worldwide attention in 1929 as the causative agent of a pandemic of psittacosis, an acute pneumonia that resulted from contact with infected parrots. Similar organisms were also identified in association with urethritis and lymphogranuloma venereum infections (LGV). The developmental cycle was first described by Bedson and Bland (1932). Because of the unusual nature of these organisms, early investigators considered this agent first a protozoan (Halberstaedter and von Prowazek, 1909) and then a virus (Miyagawa et al., 1935a). Chlamydiae were considered viruses through much of their early history; they were not generally accepted as bacteria until the 1960s (Moulder, 1964; Storz and Page, 1971).

A major problem in the study of chlamydiae has been the difficulties involved in culturing the organism. The organisms were first cultured in vitro by Miyagawa et al. (1935b) 30 years after they were initially described. Miyagawa et al. cultured LGV isolates in the chorioallantoic membrane of embryogenated hens eggs; this technique was never widely used. It was not until Rake developed a method for in vitro culture of LGV in the yolk sac of embryogenated hens eggs (Rake et al., 1940) and T'ang applied it to the culture of the trachoma strains (T'ang et al., 1957) that chlamydiae were routinely cultured away from the infected host. However, culture in eggs is a tedious procedure, and thus not generally useful, particularly for diagnostic purposes. Two major advancements have facilitated the study of chlamydiae; these were the development of a method for the cultivation of chlamydiae in cell culture (Gordon and Quan, 1965) and the development of recombinant DNA technology. Now, chlamydial DNA can be isolated, introduced into a host organism that is easily manipulated in vitro, and studied, obviating the need to culture chlamydiae for many experiments.

Biology

Taxonomy

Chlamydiae are the only members of the order Chlamydiales, family Chlamydiaceae, genus *Chlamydia* (Storz and Page, 1971; Moulder et al., 1984). There are three recognized species: *C. trachomatis, C. psittaci,* and *C. pneumoniae*

(Moulder et al., 1984; Grayston et al., 1989). Because of the high degree of genetic and biologic diversity within these species, particularly *C. psittaci,* additional species may be designated as our understanding of chlamydiae increases (Table 1).

C. trachomatis is the best characterized of the three species; it has been divided into three biovars based on the nature of disease each group causes. The mouse biovar contains a single nonhuman *C. trachomatis* serotype, MoPn, the causative agent of mouse pneumonitis. The oculogenital or trachoma biovar consists of 12 serotypes (A, B, Ba, C, D, E, F, G, H, I, J, and K) that cause trachoma, conjunctivitis, and genital infections. The third biovar consists of three serotypes (L_1, L_2, and L_3) that are the causative agents of LGV. *C. psittaci* strains are far more diverse. They have a wide range of hosts, including birds, mammals, and reptiles, and are antigenically diverse, factors which so far have precluded any generally accepted scheme for typing. *C. pneumoniae* strains were originally grouped with *C. psittaci.* Although *C. pneumoniae* shares some characteristics with *C. psittaci* studies of DNA similarity show it to be as unrelated to *C. psittaci* as it is to *C. trachomatis* (Table 1). Because a limited number of *C. pneumoniae* isolates have been identified and characterized so far, no statements can be made regarding the potential diversity of this species.

Although there was controversy early in their history as to the nature of chlamydiae, these organisms are clearly bacteria. Chlamydiae have a cell envelope similar to that of Gram-negative bacteria and they have prokaryotic ribosomes; they replicate by binary fission; and they are sensitive to many antibiotics that affect bacteria, including rifampicin, chloramphenicol, erythromycin, and tetracycline. Unlike viruses, chlamydiae contain both DNA and RNA. Like viruses, they depend on the host cell for energy; however, viruses are also dependent on the host for biosynthetic functions. Although chlamydiae require precursors from the host cell, they synthesize their own DNA, RNA, and protein.

Several features differentiate the three species of chlamydiae (Table 1). The EBs of *C. trachomatis* and *C. psittaci* are spherical while *C. pneumoniae* EBs are pear-shaped and, unlike *C. trachomatis* and *C. psittaci,* contain a periplasmic space (Fig. 1) . Inclusions, the phagocytic vacuoles that are the intracellular habitat for these organisms, formed by *C. trachomatis* contain glycogen of bacterial origin whereas *C. psittaci* and *C. pneumoniae* inclusions do not. Also, multiple inclusions may be observed in cells infected with *C. psittaci* whereas cells infected with *C. trachomatis* contain only one inclusion even when grown at high multiplicities of infection, suggesting that phagosomes containing this organism fuse (Fig. 2). *C. trachomatis* is sensitive to sulfadiazine, indicating that it is capable of folate biosynthesis; *C. psittaci* and *C. pneumoniae* are resistant to sulfadiazine. The preferred host and spectrum of diseases also varies with strain (Table 2).

The high degree of structural and genetic heterogeneity among the chlamydiae contrasts with the many functional similarities that are unique to these organisms. This observation raises questions concerning the evolution of these organisms. Convergent evolution is suggested by the very low level of DNA relatedness among the three species (Kingsbury and Weiss, 1968; Cox et al., 1988). Divergent evolution predicts that conserved functions such as enzymes in-

Table 1. Characteristics of the chlamydiae.

Property	Species

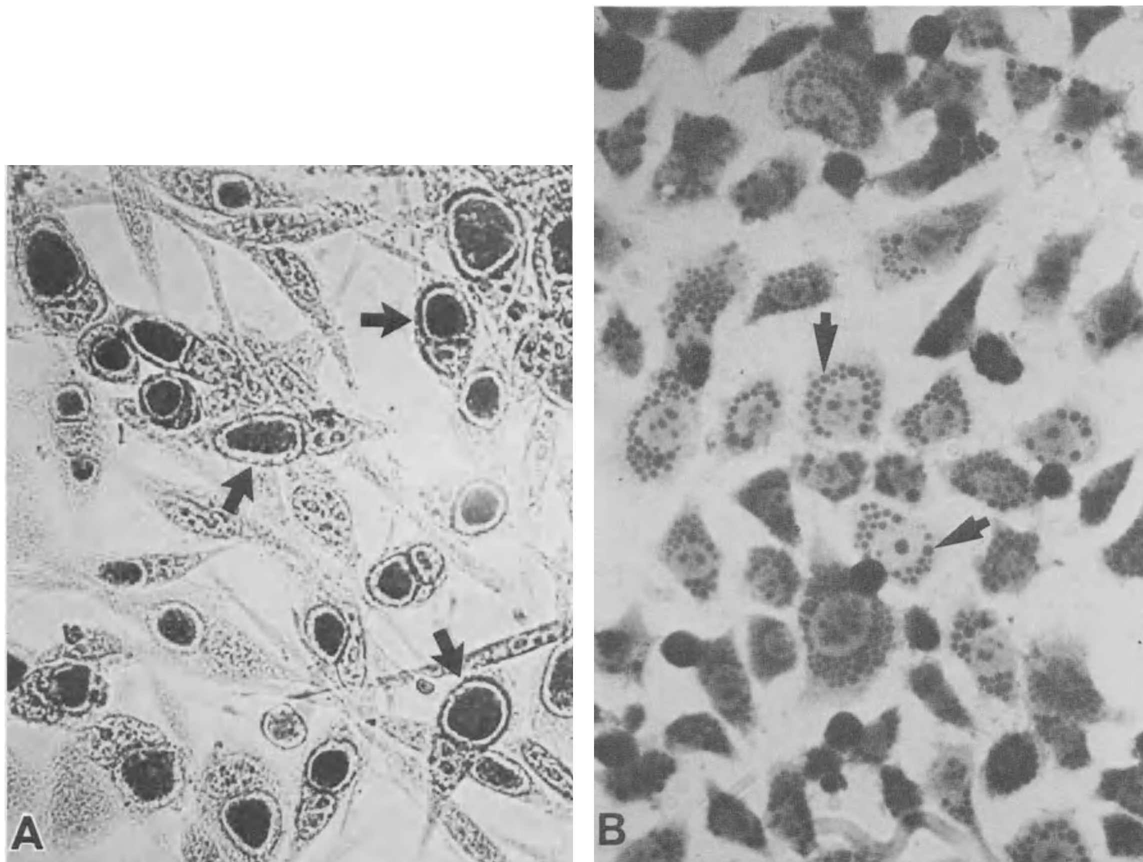

Fig. 2. Light microscopy of *C. trachomatis* and *C. psittaci* inclusions. (A) Single *C. trachomatis* inclusions (arrows) within McCoy cells stained with Jones iodine. (B) Multiple *C. psittaci* inclusions (arrows) within L-929 cells stained with Giemsa. Taken from Hodinka et al., 1988; ASM Publications.

Table 2. Human diseases caused by chlamydiae.

Disease	Causative agent	Serotype	Syndrome
Trachoma	*C. trachomatis*	A,B,B_a,C	Progressive conjunctivitis that may lead to scarring of the cornea and blindness
Inclusion conjunctivitis	*C. trachomatis*	D-K	Self-limiting conjunctivitis transmitted by contact with conjunctivia or genitalia
Urethritis, cervicitis, related infections	*C. trachomatis*	D-K	Inflammation of urethra or cervix, may spread to adjacent organs, conjunctivitis and pneumonia are common infections of newborns exposed to an infected birth canal
Lymphogranuloma venereum	*C. trachomatis*	L_1,L_2,L_3	A sexually transmitted infection that spreads from genitalia to reticuloendothelial system, producing inflammation and suppuration of regional lymph nodes
Ornithosis, psittacosis	*C. psittaci*	Undefined	Acute respiratory infection or pneumonia, bird-to-human transmission
Respiratory infections	*C. pneumoniae*	Unknown	Includes pneumonia, bronchitis, sinusitis, pharyngitis; human-to-human transmission

volved in lipopolysaccharide (LPS) biosynthesis should be similar. A limited amount of data compare DNA sequences from *C. psittaci* and *C. trachomatis.* The genes for the major outer membrane protein (MOMP) from *C. psittaci* and *C. trachomatis* show 60–70% DNA sequence homology (Zhang et al., 1989). The 16S rRNA genes from *C. trachomatis* and *C. psittaci* share 95% DNA sequence homology (Weisburg et al., 1986). These reports contrast with the reported value of 10% overall DNA sequence homology for the two species. The conservation of DNA sequences supports the hypothesis that these species evolved divergently; however, further comparisons of the genetic organization of the three species is required before any definitive conclusions may be made.

Developmental Cycle

One of the unique aspects of chlamydial biology is the biphasic developmental cycle. Chlamydiae exist as two distinct life forms, each of which is adapted to specific environments in a manner not unlike spore formation in *Bacillus* spp. The EB is small (200–300 nm) extracellular, and spore-like. It is infectious but metabolically inactive, and possesses a rigid outer cell wall that may provide protection against environmental stresses. The EB attaches to the host cell, possibly via a receptor/adhesin interaction. Attachment is followed by penetration into a membrane-bound vesicle where the EB differentiates into the larger (700–1000 nm) RB. RBs are noninfectious and relatively fragile but capable of synthesizing macromolecules and replicating by binary fission. After multiple rounds of replication the RBs differentiate into EBs. Throughout the intracellular portion of the developmental cycle, the organisms remain within the phagocytic vacuole, the inclusion, and can be seen as a distinct entity in the cytoplasm of the host cell (Fig. 3). *C. psittaci* infected host cells lyse late in infection and release EBs that can infect other cells. *C. trachomatis* infected cells do not always lyse and must be physically disrupted to release infectious EBs.

Cell Membrane

The cell membrane of chlamydiae exhibits features of Gram-negative organisms, including an inner and outer membrane and LPS. Although peptidoglycan, a major component of most bacterial cell walls, appears to be absent in chlamydiae (Garrett et al., 1974), these organisms have features that are usually attributable to peptidoglycan. For example, chlamydiae are somewhat susceptible to penicillin, an antibiotic that interferes with peptidoglycan synthesis. In the presence of penicillin, EBs differentiate into RBs and replicate; but, the RBs are larger than normal, are irregularly shaped, and cannot differentiate back into EBs (Matsumoto and Manire, 1970; Kramer and Gordon, 1971). In addition, *C. trachomatis* possesses penicillin-binding proteins which are enzymes involved in peptidoglycan biosynthesis in other bacteria (Barbour et al., 1982). The role of these proteins in chlamydiae remains to be determined.

The bacterial cell wall serves to protect the cell from environmental stress. In chlamydiae, rigidity of the EB outer membrane is thought to result from crosslinking of proteins in the outer membrane (Newhall and Jones, 1983; Hackstadt et al., 1985; Hatch et al., 1986a). This crosslinking is lost as the EB differentiates into the more osmotically fragile RB. Thus, the crosslinking of outer membrane proteins may serve the same role as peptidoglycan in other

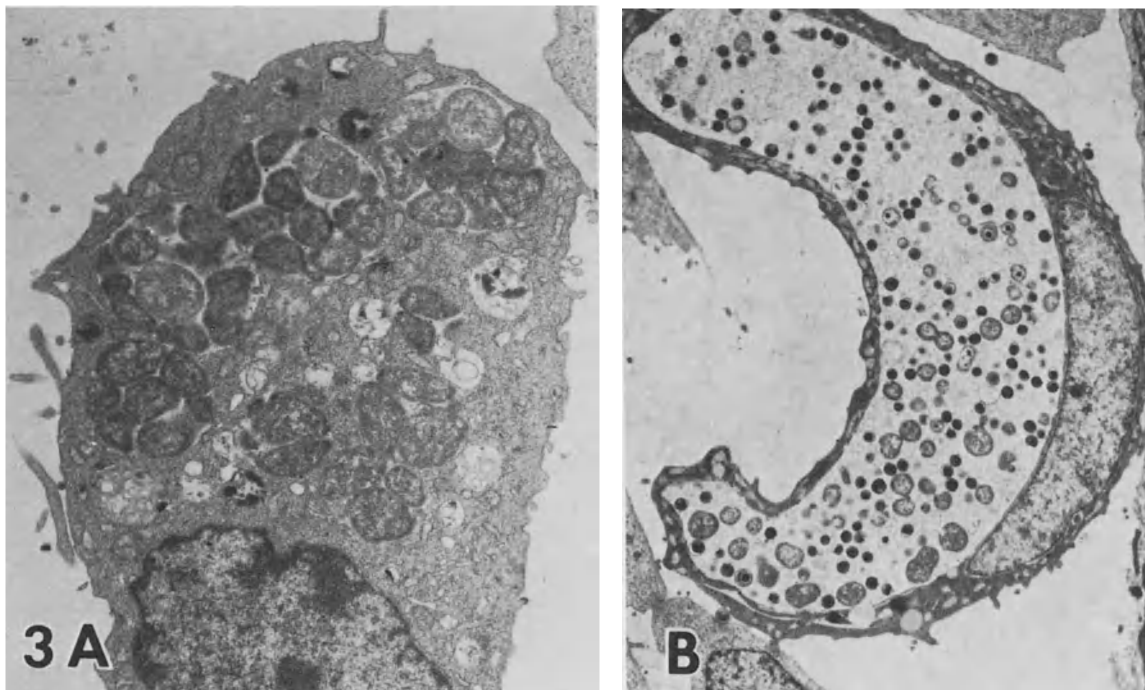

Fig. 3. Electron micrograph of *C. trachomatis* and *C. psittaci* inclusions. (A) *C. trachomatis*. (B) *C. psittaci*. RBs are seen within a membrane bound vesicle in the host cell cytoplasm. Taken from Wyrick and Richmond, 1989; American Veterinary Medical Association Publications.

bacteria; i.e., the formation of a rigid barrier between the cell and its environment.

MAJOR OUTER MEMBRANE PROTEIN (MOMP). The major constituent of the outer membrane and the best-characterized protein in *C. trachomatis* is MOMP. MOMP accounts for approximately 60% of the dry weight of the outer membrane (Caldwell et al., 1981). It has a monomeric molecular weight of approximately 40 kDa; however, it exists in the membrane as a multimeric, transmembrane complex (Chang et al., 1982). Evidence of disulfide-mediated cross-linking between MOMP molecules has been found in the EB but not the RB (Newhall and Jones, 1983). It has been suggested that MOMP functions as a porin in vivo based on in vitro evidence that MOMP confers polar permeability to liposomes (Bavoil et al., 1984).

C. trachomatis has been divided into 15 serotypes based on the reactivity of different strains with monoclonal antibodies (Grayston and Wang, 1975). Much of the heterogeneity seen among the serotypes can be attributed to antigenic differences in MOMP (Stephens et al., 1982). MOMP contains genus-, species-, subspecies-, and serotype-specific epitopes, indicating that there may be conserved and variable regions of this protein (Stephens et al., 1982; Zhang et al., 1987a). DNA-sequence analysis and epitope mapping have supported this hypothesis (Stephens et al., 1987; Baehr et al., 1988). Most DNA-sequence variability among MOMP genes is confined to four domains. Monoclonal antibodies that react with serotype-specific epitopes recognize variable sequences whereas the genus- and species-specific epitopes are encoded by the constant sequences. The DNA sequence of MOMP genes from two strains of *C. psittaci* has also been determined. When compared to *C. trachomatis* MOMP, *C. psittaci* MOMP shows a 60–70% conservation of DNA sequence, and has analogous conserved and variable domains (Zhang et al., 1989). The high interspecies relatedness of MOMP is interesting, given that these species have an overall DNA relatedness of $\leqslant 10\%$.

The temporal expression of the MOMP gene of *C. trachomatis* serotype L2 has been studied (Stephens et al., 1988a). Two mRNA species corresponding to the MOMP gene have been identified. One mRNA is expressed constitutively; the production of the second begins approximately 16 h after infection when RBs are dividing rapidly and presumably need large quantities of MOMP. Analysis of the DNA sequence upstream from the MOMP gene supports this finding; two putative promoters have been identified.

CYSTEINE-RICH OMPs. Cysteine-rich proteins make up a major portion of the outer membrane of *C. trachomatis* strains. Three such proteins have been identified in LGV strains; these have molecular weights of approximately 62, 59, and 12 kDa (Batteiger et al., 1985). The 62-kDa protein is absent in the trachoma strains (serotypes A–K; Batteiger et al., 1985). These proteins are found predominantly in the EB; they are not synthesized until late in the developmental cycle, when RBs are differentiating into EBs (Hatch et al., 1986a; Sardinia et al., 1988). This, combined with the fact that they are highly crosslinked, suggests that they function in the structural integrity of the EB. Like MOMP, there appears to be some serotype heterogeneity in the cysteine-rich outer membrane proteins (Zhang et al., 1987b); this heterogeneity has not been well characterized.

Molecular cloning has revealed that the 62 and 59 kDa cysteine-rich outer membrane proteins are products of a single gene, designated *omp2* (Allen and Stephens, 1989). The different molecular weights are a result of cleavage of the signal peptide at two different sites, resulting in peptides of 507 and 525 amino acids. This is the first description of two-site posttranslational processing of a signal sequence in prokaryotes. The physiologic role of this differential cleavage remains to be determined.

LPS. Chlamydial LPS has not been completely defined chemically; however, immunological studies show that it resembles the short LPS chains of rough *Salmonella* Re mutants (Nurminen et al., 1985). LPS from *Chlamydia* spp. and *Salmonella* LPS share at least two epitopes (Brade, L. et al., 1985). In addition, chlamydial LPS possesses a chlamydia-specific epitope, KDOp (2→8) KDOp (2→4) KDO (Brade, H. et al., 1987), that has been used extensively as a tool for the identification of these organisms. LPS is often referred to as the genus-specific antigen because it was first identified as an immunoreactive moiety common to all chlamydial species and subsequently identified as LPS. A gene encoding an enzyme, presumably a glycosyl transferase, required for the biosynthesis of this epitope has been cloned (Nano and Caldwell, 1985). This epitope is expressed on LPS in *Salmonella* Re strains bearing the cloned gene (Brade, L. et al., 1987).

Genome

Chlamydiae have one of the smallest genomes among the bacteria; estimates of its size range from 5–10 $\times$ 10^5 base pairs (Kingsbury, 1969; Sarov and Becker, 1969; Frutos et al., 1989). This is approximately the size of *Mycoplasma* spp. genomes and one quarter of the *Escherichia coli* genome. The GC content of the chlamydial genome is 40–45 mol% (Kingsbury and Weiss, 1968; Gerloff et al., 1970; Cox et al., 1988). Hybridization studies indicate that the three species of chlamydiae are equally distantly related, each sharing less than 10% DNA-sequence homology with each of the other species (Cox et al., 1988).

Most strains of *C. trachomatis* and *C. psittaci* possess a 7–7.5 kb plasmid of unknown function (Lovett et al., 1980). *C. pneumoniae* strains examined to date do not contain a plasmid (Campbell et al., 1987). The complete nucleotide sequence of the plasmid from several *C. trachomatis* serotypes has been determined (Sriprakash and Macavoy, 1987; Comanducci et al., 1988; Hatt et al., 1988; Black et al., 1989); the sequence of the plasmid is highly conserved among these serotypes. Based on DNA-hybridization experiments, limited DNA-sequence homology exists between the *C. trachomatis* and *C. psittaci* plasmids (Joseph et al., 1986). Eight open-reading frames have been identified on the *C. trachomatis* plasmid; however, this information has not led to any direct insight into plasmid function.

Like other prokaryotic organisms, the chlamydial chromosome appears to be organized in nucleoids. The EB chromosome is highly condensed, perhaps similar to the nucleoid of endospores (Costerton et al., 1976; Popov et al., 1978). In electron micrographs, it is visible as an electron-dense region. The genome in the RB is dispersed, similar to other metabolically active bacteria. DNA-binding proteins that are specific for the EB have been described (Wagar and Stephens, 1988), suggesting that these proteins may serve to hold EB DNA in a specific configuration.

Metabolism

Studies of chlamydial metabolism are complicated by the fact that the chlamydiae are obligate intracellular parasites; biochemical processes of interest must be distinguished from those of the host. The absence of a particular function in uninfected host cells or an altered function in infected cells compared to uninfected cells is helpful; however, the possibility exists that chlamydial infection has altered host metabolism rather than initiated its own. Additionally, since chlamydiae exist as two different forms, the possibility that EB preparations are contaminated with RBs or vice versa must be eliminated in studies of one form or the other.

The metabolic deficiencies that make chlamydiae completely dependent on a host cell for growth are not clear. There is no evidence that chlamydiae make ATP, an observation consistent with Moulder's hypothesis that they are energy parasites (Moulder, 1962). They have their own ribosomes and RNA polymerase (Sarov and Becker, 1971) and synthesize RNA, DNA, and proteins in the absence of host DNA and protein synthesis (Alexander, 1968; Alexander, 1969). These functions are susceptible to bacterial inhibitors such as chloramphenicol and rifampicin (Tribby et al., 1973). Thus, chlamydiae appear to be able to synthesize their own macromolecules; however, the extent of their dependence on the host for the precursors of these macromolecules is unknown.

Host-protein synthesis is not required for chlamydial growth, as evidenced by the fact that they replicate in cycloheximide-treated host cells (Alexander, 1968; Ripa and Mardh, 1977). In fact, chlamydiae grow better when host metabolism is inhibited. Nor is host cell metabolism specifically inhibited by chlamydiae after infection. At low multiplicities of infection, where chlamydial growth has little adverse effect on the host, infected cells continue to divide (Horoschak and Moulder, 1978).

ENERGY METABOLISM. Chlamydiae appear to lack the ability to synthesize high-energy molecules and do not produce cytochromes and other molecules required for aerobic respiration. Enzyme activities associated with energy-producing pathways such as glycolysis (Ormsbee and Weiss, 1963; Weiss et al., 1964; Weiss, 1965), the pentose phosphate pathway (Moulder et al., 1965), and the tricarboxcylic acid cycle (Weiss, 1967) have been found; however, the significance of the presence of only portions of these pathways in chlamydiae is not known. It has been suggested that they acquire ATP from the host via an ATP/ADP exchange mechanism. Host-free *C. psittaci* RBs take up radiolabelled ATP; this activity can be competitively inhibited with ADP (Hatch et al., 1982). Increased numbers of host mitochondria have been observed surrounding chlamydial inclusions (Matsumoto, 1981), suggesting that they may parasitize mitochondrial products.

DNA AND RNA SYNTHESIS. Host-free RBs are capable of both DNA and RNA synthesis if provided with the appropriate precursors and an energy source (Tamura, 1967; Hatch et al., 1986b). In addition, permeabilized EBs may also synthesize RNA (Sarov and Becker, 1971). RNA synthesis in EBs was found to be inhibited by rifampicin, an inhibitor of bacterial RNA polymerase, and actinomycin D, indicating that it is dependent on double-stranded DNA for activity. Unfortunately, this finding could not be reproduced in another study (Hatch, 1988).

It seems clear that chlamydiae draw on host nucleotide pools for RNA synthesis (Hatch, 1975); however, the source of precursors for chlamydial DNA synthesis is uncertain. *C. psittaci* incorporates host guanine nucleotides into RNA and DNA (Ceballos and Hatch, 1979), but does not use thymidine or deoxycytosine of host origin (Tribby and Moulder, 1966). The reason for this is unknown. It has been suggested that chlamydiae synthesize thymidine nucleotides from deoxyuridine monophosphate (dUMP) (Tribby and Moulder, 1966; Hatch, 1976).

PROTEIN SYNTHESIS. The presence of ribosomes in both EBs and RBs, the sensitivity of chlamydiae to antibiotics that inhibit bacterial protein synthesis, and the synthesis of chlamydial proteins in the presence of drugs that inhibit host protein synthesis, all indicate that chlamydiae synthesize their own proteins. In addition, purified RBs have been shown to synthesize a limited amount of protein in vitro; and the proteins synthesized correspond to those produced at the stage of development from which the RBs were harvested (Hatch et al., 1985; Plaunt and Hatch, 1988). However, it is unclear whether chlamydial or host amino acid pools are incorporated into bacterial protein. The fact that host-free RBs are only stimulated by, not dependent on, added amino acids indicates that RBs have intracellular pools of amino acids. However, researchers have been unable to prolong in vitro protein synthesis for more than a few hours (Hatch et al., 1985). This may be due to an inability to replenish depleted amino acid pools by de novo synthesis or a requirement for an unknown host function.

Chlamydial growth in cell culture can be inhibited by the omission of some amino acids but not others from the growth medium (Karayiannis and Hobson, 1981; Allan and Pearce, 1983). Also, amino acid requirements may be strain dependent. However, it is unknown whether the requirement for a particular amino acid is due to the inability of that strain to make the amino acid or to an inadequate pool of the amino acid within the host cell.

There is evidence that chlamydiae synthesize specific amino acids. *C. psittaci* can grow in L cells in the absence of added arginine, lysine, and histidine, all of which are required for L cell growth (Bader and Morgan, 1958). In addition, radiolabelled precursors of arginine are incorporated into chlamydial but not host protein during growth of both *C. psittaci* and *C.*

trachomatis in L cells, indicating that these organisms posses some enzymes of the arginine biosynthetic pathway (Treuhaft and Moulder, 1968).

GLYCOGEN DEPOSITION. A curious aspect of *C. trachomatis* metabolism is the accumulation of glycogen within its inclusion; *C. psittaci* and *C. pneumoniae* do not accumulate glycogen. Although this difference has served as a useful tool in differentiating the species (*C. trachomatis* inclusions are stained with iodine due to the presence of glycogen; *C. psittaci* and *C. pneumoniae* inclusions are not), the physiological basis for the difference is unknown. HeLa cells infected with *C. trachomatis* have a glycogen synthetase activity not found in uninfected cells, suggesting that the glycogen is produced via a chlamydiae specific pathway (Jenkin and Fan, 1971). The enzyme requires ADP glucose, a substrate normally associated with bacterial glycogen synthetases, which distinguishes it from the host cell glycogen synthetase.

Gene Expression

Analysis of gene expression has begun for only a limited number of chlamydial genes. *ompA,* the gene encoding MOMP, is expressed from two promoters in serotype L2 (Stephens et al., 1988a). The DNA sequence upstream from MOMP coding sequences resembles typical bacterial promoters in that they contain identifiable -10 and -35 regions; however, the sequence is only minimally related to *E. coli* consensus promoter sequences. The two promoters are differentially regulated since one is transcribed throughout the developmental cycle whereas transcription from the other begins approximately 16 h after infection when demand for MOMP increases. The chlamydial rRNA genes are also transcribed from two promoters, both of which are expressed throughout development (Engel and Ganem, 1987). A 70-kDa protein is expressed from a single promoter (Sardinia et al., 1988). Comparison of these three promoter sequences indicates that, in addition to being distinct from *E. coli* promoters, there is no developing consensus sequence for chlamydial promoters (Sardinia et al., 1988).

Most clones of chlamydial genes in *E. coli* use vector-supplied promoters for expression of the cloned gene product. This observation has led to the conclusion that chlamydial promoters do not function optimally in *E. coli.* In addition, chlamydial genes that are expressed from their own promoters in *E. coli* tend to be variably transcribed (Sardinia et al., 1988), indicating that *E. coli* RNA polymerase is inefficiently recognizing chlamydial transcription signals. Thus, currently available data suggests that there are some basic differences between gene expression in *Chlamydia* spp. and *E. coli;* however, the physiological basis for these differences remains to be determined.

Ecophysiology: Interaction with the Host Cell

The ecological niche of the chlamydiae is in association with a human or animal host. With the exceptions of mouse pneumonitis and guinea pig inclusion conjunctivitis, there are no animal models for the study of chlamydial disease; thus, studies of chlamydiae in their natural habitat are limited. Most experimentation with chlamydiae has been performed in defined cell lines in vitro. Although the development of in vitro culture systems led to an explosion of research on chlamydiae, the relevance of this information to the understanding of the mechanism of infection remains to be shown.

Cellular Tropism

The oculogenital strains of *C. trachomatis* infect human columnar and squamocolumnar epithelial cells in vivo. These include cells of the conjunctiva, urethra, and cervix. The LGV strains of *C. trachomatis* and *C. psittaci,* which are generally associated with more invasive disease, migrate to the reticuloendothelial system where they reside in macrophages. With the exception of the MoPn strain, *C. trachomatis* infects only cells of human origin. The host and tissue specificities for *C. psittaci* are much broader than those of *C. trachomatis; C. psittaci* strains infect a wide range of organisms including mammals and birds, with tissue specificities that include most major organs of its hosts. Little is known about the host range of *C. pneumoniae.* At present, the only host identified for *C. pneumoniae* is humans.

Host Cell Entry

The obligate requirement for host cells for growth suggests that chlamydiae have efficient mechanisms for attachment to and entry of host cells. Our knowledge of internalization of chlamydiae is taken from in vitro infection experiments. All chlamydiae readily enter nonphagocytic cells that are otherwise impermeable to bacteria, which suggests that they take an active role in the entry of host cells. Live or ultraviolet (UV)-inactivated chlamydiae are readily taken up by nonphagocytic cells, whereas heat-killed

chlamydiae, *E. coli,* and latex beads are not (Byrne and Moulder, 1978), suggesting that a heat-labile moiety is required for uptake. Evidence suggests that chlamydiae can be taken up by different mechanisms depending on the cell system and culture conditions used. Receptor-mediated and nonreceptor-mediated endocytosis and phagocytosis-like mechanisms have been described (Söderlund and Kihlström, 1983; Ward and Murray, 1984; Hodinka and Wyrick, 1986; Hodinka et al., 1988). A recent report shows that the uptake of *C. trachomatis* by polarized epithelial cells is via receptor mediated endocytosis. Furthermore, the mechanism of uptake could be changed by varying culture conditions. When the epithelial cells were grown under nonpolarizing conditions, *C. trachomatis* was not taken up into clatherin-coated pits (Wyrick et al., 1989). Taken together, these findings suggest that chlamydia can enter host cells by multiple mechanisms depending upon the environment in which the EB finds itself.

Evidence for a receptor-mediated endocytic mechanism for uptake of chlamydiae suggests the existence of a specific receptor on the host cell surface and an adhesin on the chlamydial surface. Evidence for a host cell receptor for chlamydiae is circumstantial; however, at least two *C. trachomatis* surface molecules bind specifically to HeLa cell extracts, suggesting that these molecules may be involved in attachment (Hackstadt, 1986; Wenman and Meuser, 1986). Similarly, one such molecule has been identified for *C. psittaci* (Hackstadt, 1986).

Intracellular Survival and Growth

The ability of an organism to survive or replicate within a host cell is a trait limited to pathogenic microbes which have evolved specific mechanisms to evade normal host defense. These pathogens either enter nonphagocytic cells that are incapable of inactivating the intracellular bacteria or evade or inhibit the microbiocidal activities of professional phagocytic cells. The chlamydiae can to varying degrees do both, depending on the strain. *C. psittaci* and, to a lesser extent, the LGV strains of *C. trachomatis* survive and replicate in professional phagocytes, paralleling their invasiveness in vivo; *C. trachomatis* oculogenital strains do not (Kuo, 1978; Eissenberg and Wyrick, 1981). All chlamydiae replicate in epithelial cells. The ability of chlamydia to replicate in host cells has been shown to correlate with the inhibition of fusion between lysosomes and phagosomes that contain chlamydiae, a commonly employed mechanism for intracellular survival among intracellular parasites. In macrophages, lysosomes do not fuse with phagosomes containing *C. psittaci* or LGV strains of *C. trachomatis;* and, these strains replicate. Lysosomes fuse with phagosomes containing the oculogenital strains of *C. trachomatis* and they are inactivated (Yong et al., 1987). PMNs readily kill the chlamydiae in vitro; and, killing is accompanied by fusion of phagosomes with lysosomes (Hammerschlag et al., 1985; Yong et al., 1986). Thus, the inability of chlamydiae to interfere with phagolysosome fusion in PMNs may be the reason they are susceptible to killing by these cells.

The mechanism(s) employed by chlamydiae to inhibit phagolysosome fusion is unknown; however, inhibition of fusion can be prevented by pretreatment of *C. psittaci* with antibody, suggesting that a surface-exposed moiety is involved in this mechanism (Friis, 1972; Wyrick et al., 1978). Also, lysosomes fuse with phagosomes that contain heat-killed *C. psittaci* but not UV-inactivated organisms (Wyrick et al., 1978; Eissenberg et al., 1983), suggesting that the molecule involved is heat labile. Isolated cell membranes from *C. psittaci* EBs inhibit fusion (Levy and Moulder, 1982), whereas purified RBs do not (Brownridge and Wyrick, 1979). This result suggests a functional difference between EBs and RBs in inhibition of phagolysosomal fusion.

Host Response

Studies of the host response to *C. trachomatis* are difficult to interpret because, with the exception of the mouse pneumonitis strain, the only natural host for this organism is the human. As a result, a wide range of animal systems have been used to study chlamydial infection. Conflicting results from the different animal models compounds problems in the assessment of the human immune response to chlamydiae. However, generalizations can be made.

INFLAMMATION. Inflammation at the site of chlamydial infection results in the infiltration of first PMNs then mononuclear phagocytes, cells whose primary function is to phagocytize and kill invading organisms. *C. trachomatis* may inhibit or fail to stimulate specific portions of the respiratory burst in the PMN (Tosi and Hammerschlag, 1988; Tauber et al., 1989). Myeloperoxidase-deficient PMNs are as microbiocidal as normal PMNs (Yong et al., 1986), suggesting that some aspects of oxygen-dependent killing by PMNs are not required to inactivate *C. trachomatis.* Lymphoid follicle formation at the site of infection is common in infections with the oculogenital strains of *C. tra-*

chomatis, whereas granulomatous lesions, most common in lymph nodes, are characteristic of LGV infections.

Inflammation may contribute to the pathologic outcome of some chlamydial infections. Lymphoid follicle formation on the conjunctiva contributes to the mechanical irritation and scarring that ultimately leads to blindness in trachoma. Tubal infertility may be caused by inflammation and scarring that results from repeated or prolonged infection of the fallopian tubes in *C. trachomatis* infection.

IMMUNE RESPONSE. Both humoral and cell-mediated immune responses are stimulated by a chlamydial infection. The relative contributions of each part of the immune system in controlling chlamydial infection is unclear; a complete understanding of the immune response may require the development of better immunologic model systems.

In human infection, seral and mucosal antibodies are produced. In vitro, antibody can neutralize chlamydial infectivity. A similar role for antibody in vivo has not been established; however, secretory immunoglobulin A (IgA) is often produced at the site of mucosal infection and may modulate chlamydial propagation (Brunham et al., 1983). Because chlamydiae are capable of surviving within host cells, cell-mediated immunity may be required for clearing a chlamydial infection. In animal models, passive transfer of *C. trachomatis*- immune T cells can protect a naive mouse against challenge with virulent *C. trachomatis* (Williams, D. M. et al., 1984a; Brunham et al., 1985). Also, mice depleted of B cells are as proficient as control mice at clearing *C. trachomatis* infection suggesting that the T-cell response alone is capable of controlling an infection (Williams, D. M. et al., 1987; Ramsey et al., 1988). Conversely, antibodies administered locally, but not systemically, protected naive mice from challenge with *C. trachomatis* (Williams, D. M. et al., 1984b). Infections in guinea pigs with *C. psittaci* required both humoral and cell-mediated immunity for clearance (Rank et al., 1979, 1989). Together, these results suggest that humoral immunity may play a role in limiting bacterial replication rather than eradicating an infection. Clearing an infection may require cell-mediated immunity; antibody may be important for controlling more invasive infections.

Vaccines

The development of immunity to chlamydiae is complex. In some instances, a single infection or vaccination may produce only short-term immunity, while previous exposure to chlamydiae results in a more severe second infection in others. For example, reinfection plays an important role in the pathogenesis of trachoma, where scarring of the cornea, the major contributing factor to blindness resulting from trachoma, is caused by a hypersensitivity response to reinfection. This may also be the case in tubal infertility, where repeated infection may cause scarring and blockage of the fallopian tubes.

The adverse consequences of delayed hypersensitivity reactions of the host to chlamydiae may hamper the development of whole cell vaccines. In monkeys immunized with whole cells, live organisms or Triton X-100 extracts stimulate a hypersensitivity response whereas formalin-killed or UV-irradiated organisms do not (Taylor et al., 1987). This response suggests that a sensitizing antigen is present within chlamydial cells that must be released either by cell growth or the solublization of EBs. Most of the sensitizing effect of the Triton X-100 extract can be attributed to a 57-kDa protein (Morrison et al., 1989). Thus, a subunit vaccine deficient in the sensitizing molecule that also stimulates protective immunity without stimulating hypersensitivity can be envisioned. Alternatively, antigens that elicit T cell responses could be identified and recombinant or synthetic polypeptides vaccines derived from these antigens. A third approach to vaccine development is the construction of a chlamydial strain deficient in the sensitizing antigen(s) that could be used as a live, attenuated vaccine. Unfortunately, the molecular genetic tools required for the alteration of specific genes are not yet available for chlamydiae.

Diseases

Human Diseases

C. trachomatis and *C. pneumoniae* are primarily human pathogens; *C. psittaci* is primarily an animal pathogen that can be transmitted to humans though contact with infected animals. The most common chlamydial infections affect the eyes, genitalia, and respiratory tract (Table 2). Chlamydial infections are of serious public health concern worldwide. Genital chlamydial infections are the most frequent sexually transmitted disease in developed countries, causing about twice as many urethral infections as *Neisseria gonorrhoeae.* Trachoma is a major cause of preventable blindness in developing countries.

GENITAL INFECTIONS. Genital infection with strains of the oculogenital biovar of *C. trachomatis* account for the majority of chlamydial

infections in North America and western Europe. These infections are caused by *C. trachomatis* serotypes D through K. In men, chlamydia usually causes urethritis; in women, cervical infections are most common, with urethral and rectal involvement occurring in some cases. Cervical and urethral infections may be accompanied by a mucopurulent discharge; however, frequently, these infections are asymptomatic. A major problem in controlling chlamydial infections is that up to one-third of infected men and three-fourths of infected women may be asymptomatic. Women with cervical infection may carry chlamydia without prominent clinical symptoms for more than 1 year; the maximum duration of such carriage is unknown, but may be years. The large reservoir of asymptomatically infected individuals with prolonged carriage and presumed infectivity is responsible for the high prevalence of *C. trachomatis* in sexually active populations.

The diagnosis and treatment of genital chlamydial infections is particularly important because the complications from these infections can be severe. In women, endometritis, salpingitis, and perihepatitis are common sequelae of *C. trachomatis* infection. These infections of the upper female reproductive tract are usually asymptomatic, but may be accompanied by severe lower abdominal pain and tubal inflammation, a syndrome called pelvic inflammatory disease (PID). As many as 300,000 PID infections occur each year in the United States; many PID patients require hospitalization. Both subclinical and overt PID can lead to scarring and dysfunction of the fallopian tubes; chronic chlamydial infections are the most common preventable causes of ectopic pregnancy and tubal infertility.

In men, untreated chlamydial infections may develop into epididymitis. Infection of the epididymis results in acute, painful inflammation of the testicular apparatus which may require hospitalization. Although it is presumed that chlamydial infection may result in male infertility, conclusive studies of this possible complication have not been performed.

Rarely, men or women infected with *C. trachomatis* may develop Reiter's syndrome. This syndrome is a rheumatic disorder of unknown etiology, which consists of chronic inflammation of joints, skin, blood vessels, and mucosal surfaces. Reiter's syndrome is classified as a "reactive arthropathy," and may be seen in increased frequency in individuals of the HLA B27 haplotype following infection with *Chlamydia, Shigella, Yersinia,* and other bacterial species. This suggests that Reiter's syndrome results from some autoimmune phenomena, but this remains to be determined.

NEONATAL INFECTIONS. As many as 60–70% of infants born to mothers with urogenital chlamydial infections acquire some form of chlamydial infection as they pass through the birth canal; 25–50% develop conjunctivitis while 10–20% get pneumonia. Infections are not limited to these sites; localizations to the nasopharnx, rectum, vagina, and ears also occur.

Prophylactic treatment of the newborn's conjunctivae, usually with silver nitrate, is used to prevent neonatal gonococcal conjunctivitis. In spite of this prophylaxis, chlamydial conjunctivitis is seen in a substantial proportion of infected neonates. In addition, ocular prophylaxis does not eliminate chlamydia in the respiratory tract. Thus, the best method to prevent neonatal chlamydial infection is to identify and treat infected mothers prior to delivery.

LYMPHOGRANULOMA VENEREUM INFECTIONS (LGV). LGV is a sexually transmitted disease rarely seen in the western world, but common in tropical areas. It is caused by the more invasive *C. trachomatis* serotypes, L_1, L_2, and L_3. The disease is manifested by a systemic spread of the chlamydial organisms, with production of fever, myalgias, and signs of meningeal irritation. In men, swelling of the inguinal or femoral lymph nodes resulting in buboes is common.

OCULAR INFECTIONS. Trachoma is caused by *C. trachomatis* infection of the squamocolumnar epithelial cells of the conjunctivae. *C. trachomatis* serotypes A, B, Ba, and C are most often associated with this infection. Trachoma is endemic in most developing countries. Most individuals with trachoma become infected in childhood; they develop acute conjunctivitis that progresses to chronic follicular keratoconjunctivitis and pannus (neovascular) formation. Repeated exposures lead to a scarring of the conjunctiva that distorts the eyelid, causing abrasion of the cornea every time the eye is closed. Over time, the irritation causes corneal destruction and eventually blindness.

Uncomplicated conjunctivitis is frequently seen in sexually active adults with genital infections. Inoculation of the eye with infected genital secretions is presumed to be the route of inoculation for this infection. The conjunctivitis is generally self-limited, and does not lead to visual impairment, which may require repeated episodes of active infection as with trachoma.

ORNITHOSIS/PSITTACOSIS. Although humans are not a natural host for *C. psittaci,* human infection can occur after exposure to infected animals, particularly birds. Strains of *C. psittaci* vary greatly in their virulence for humans, with some avian strains being particularly capable of causing human disease. Most *C. psittaci* infections are caused by occupational exposures of poultry or pet-store workers. Because *C. psittaci* infections of humans may come from both psittacine and nonpsittacine birds such as turkeys, the term "ornithosis" is now used naming pneumonic illness caused by avian strains of *C. psittaci.* Symptoms range from mild respiratory infections to severe pneumonia that can be fatal.

C. PNEUMONIAE INFECTIONS. Atypical *C. psittaci* isolates from humans that were not of avian origin were first identified in studies of trachoma (Dwyer et al., 1972; Grayston, 1967). Subsequently, serological studies showed that respiratory infections may be due to similar atypical chlamydial strains (Saikku et al., 1985). A prospective study of university students with acute respiratory disease identified eight more atypical chlamydiae and gave the group the strain designation "TWAR" (Grayston et al., 1986). Characterization of these isolates indicated that they were sufficiently distinct from *C. psittaci* and *C. trachomatis* to warrant a new species, designated *C. pneumoniae* (Grayston et al., 1989). The full spectrum of *C. pneumoniae* disease is not yet known; however, the organism appears to be capable of causing a range of respiratory syndromes. The original isolation of *C. pneumoniae* from trachoma patients is thought to be the serendipitous recovery of respiratory pathogens. No animal reservoir or vector has been described, suggesting human-to-human transmission.

DIAGNOSIS AND TREATMENT. The incidence of chlamydial disease has apparently been increasing for several years; however, a contributing factor to this is the development of simpler tests for the detection of chlamydiae, with the result that infections of unknown etiology in the past are now being diagnosed as chlamydiae. Traditionally, isolation of the organism in cell culture was the only method for detection of chlamydiae. Culture of chlamydiae is technically difficult and requires about 2 days before inclusions can be identified, limiting the usefulness of this technique as a diagnostic test before treatment. Nonculture methods for the detection of chlamydiae have recently become commercially available. These tests allow the much more timely diagnosis of chlamydiae; however, the sensitivity and specificity of the testing are still under debate.

Serologic test are not generally applicable to the diagnosis of chlamydial infections. There is a fairly high frequency of antibody titer to chlamydiae in the general population. In addition, chlamydial infections are not always accompanied by significant increases in anti-chlamydial antibody titer. Significant changes in antibody titer are seen with the systemic infections LGV and ornithosis; a fourfold increase is antibody titer between acute and convalescent sera is considered diagnostic for these diseases. A high anti-chlamydial immunoglobulin M (IgM) titer is often seen in infant pneumonia; therefore, IgM serology may be useful in diagnosing this infection.

Tetracycline or doxycycline are the drugs of choice in treating most chlamydial infections. When tetracycline therapy may not be appropriate, erythromycin is substituted. Topical antibiotic ointments are effective in treating conjunctivitis; however, they do not prevent second site infections. In the case of newborns where multiple site infections are possible, systemically administered antibiotics are more appropriate.

Animal Diseases

C. psittaci includes many different strains that infect a wide variety of animal species resulting in many disease syndromes. The most common *C. psittaci* isolates are of avian and mammalian origin. Avian chlamydioses are of particular interest because of the possibility of transmission to humans. Infections in birds primarily involve the gastrointestinal tract, resulting in organisms being excreted in the feces; however, conjunctivitis and respiratory symptoms are not uncommon. Chlamydial diseases affecting farm animals are of economic importance; they include gastroenteritis, mastitis, and spontaneous abortions. *C. psittaci* can also infect synovial tissues of lambs, resulting in ovine arthritis. Feline pneumonia and conjunctivitis are also common.

Isolation

Animals and Embryogenated Eggs

Until the 1970s, culture of chlamydiae in laboratory animals (Storz, 1971) or embryonated hen's eggs (T'ang et al., 1957; Rake et al., 1940) were the only means available for the propagation of the organism. However, such methods are expensive, tedious, and time consuming. Because of its relative ease and sensitivity, cul-

tivation of chlamydia in defined cell lines has now replaced animal and egg culture for most applications (Gordon et al., 1969); but, animal and egg culture are still used for specific needs. The pathogenicity of chlamydial strains in animal models is useful in differentiating species and determining host range for *C. psittaci* isolates. No reliable substitute has been found for egg-grown chlamydia as a source of antigen for use in complement fixation (CF) assays. In addition, growth in eggs still proves useful for cultivation of fastidious isolates.

Cell Culture

A variety of cell lines have been used for the propagation of chlamydiae in vitro. Most common are L-cells for *C. psittaci,* HeLa and McCoy cells for *C. trachomatis,* and HeLa229 cells for *C. pneumoniae. C. psittaci* and the LGV strains of *C. trachomatis* readily infect a wide range of cell lines, while the oculogenital strains of *C. trachomatis* and *C. pneumoniae* are restricted in host range and infectivity in vitro. The reasons for this difference are unknown; however, it has been suggested that it may be due to a difference in net negative charge on the bacterial surface. The host cell surface is negatively charged; a strongly negatively charged bacterium may be repelled from the host-cell surface under normal circumstances.

Several techniques have been developed to enhance chlamydial infectivity and growth in vitro. Centrifugation of host-cell monolayers after adding the inoculum enhances recovery of non-LGV strains of *C. trachomatis* and *C. pneumoniae;* the reason for this effect is not understood. Although it is logical to think that centrifugation brings the organisms into closer proximity to the host-cell surface, the centrifugal force applied is not great enough to pellet the bacteria onto the host cell. Alternatively, this effect may be due to an alteration of the host-cell membrane. Treatments that inhibit host-cell metabolism increase recovery of chlamydiae, suggesting that they may have to compete with the host for metabolic pools in growing cells. Cycloheximide, a drug that inhibits cukaryotic protein synthesis, is commonly used because it is added at the time of infection. Gamma radiation and treatment with cytochalasin B or iododeoxyuridine (IUDR) have also been used to inhibit host-cell metabolism; however, these inhibitors have the disadvantage of requiring the pretreatment of host cells several days before infection. Treatment of host-cell monolayers with diethylaminoethyl-dextran (DEAE-dextran) enhances the number of inclusion-forming units (IFUs) obtainable with oculogenital strains of *C. trachomatis* and *C. pneumoniae,* perhaps by the modification of charge on the host-cell membrane; but, this appears to have a substantial effect only in the absence of centrifugation.

A General Method for the Culture of *Chlamydia* in Defined Cell Lines

1) Monolayers of an appropriate host cell, such as McCoy, HeLa229, or L-cells, are prepared in flat-bottom vials that can be centrifuged (15×45 mm shell vials are commonly used for this purpose). Growth of the host cells on glass coverslips in the vials will facilitate the subsequent removal and staining of the monolayers. Eagle's minimal essential medium supplemented with 10% heat-inactivated fetal calf serum, 2 mM glutamine, 60 mM glucose, 0.1 mM nonessential amino acids, and 10 mM HEPES buffer is commonly used for chlamydial culture. Care should be taken that the cell-culture medium used does not include antibiotics that are inhibitory to chlamydial growth.

2) The confluent monolayers are inoculated by removing the medium and replacing it with 0.1 ml of a clinical specimen or an inoculum of a pure culture diluted in 2SP (0.2 M sucrose, 20 mM potassium phosphate buffer, pH 7.5) or SPG (0.2 M sucrose; 10 mM potassium phosphate buffer, pH 7.5; 5 mM glutamic acid). Clinical specimens should be sonicated or vortexed with glass beads to disrupt any infected cells before adding to monolayers.

3) The vials are centrifuged at 2,500–3,000 × g at 35°C for 1 h. This step is omitted when culturing *C. psittaci* and LGV strains of *C. trachomatis.*

4) The inoculum is removed and replaced with 1.0 ml of chlamydial growth medium containing 0.5–2 μg cycloheximide/ml. Individual lots of cycloheximide should be tested to determine the concentration that is optimally stimulatory for chlamydial growth without being toxic for the host cells. Removal of the inoculum is particularly important when culturing clinical specimens, where inhibitors of chlamydia or host cells may be present.

5) Infected monolayers are incubated at 35°C, in an atmosphere supplemented with 5.0% CO_2 for 48–72 h.

6) Inclusions can be detected by a variety of staining techniques. Alternatively, chlamydial EBs can be recovered by disruption of the host cells by sonication and passed onto new monolayers or purified by differential centrifugation. Commonly, a low-speed centrifugation (approximately 1,000 × g for 5–10 min) is used to remove host-cell debris, followed by a high-speed centrifugation (30,000× g for 30 min) to pellet EBs. EBs can be further purified by sucrose or renografin density gradient centrifugation.

This general procedure can be modified for a variety of culture conditions:

1) Microtiter plates can be used in place of shell vials. Microtiter plates (96, 48, or 24 well) are particularly appropriate for the large-scale screening of clinical specimens (Hayashi and Sheth, 1982; Lees et al., 1988); however, this method may not be as sensitive as that with

shell vials when 96-well microtiter plates are used (Mallinson et al., 1981; Kiviat et al., 1985). Six-well microtiter plates are also useful for the bulk propagation of strains that require centrifugation for optimal infectivity. Microtiter plates should be centrifuged at 1,500× g rather than 3,000× g because the plates may crack under higher g forces.

2) Cell-culture flasks can also be used in place of shell vials for the bulk propagation of chlamydial strains. Monolayers that will be used for the growth of oculogenital strains of *C. trachomatis* should be treated with DEAE-dextran (30 μg/ml in 2SP or SPG) for 30 min before infection when centrifugation is not possible. The DEAE-dextran is removed and replaced with the inoculum after treatment. The volume of the inoculum should be adjusted to the flask size; approximately one ml is appropriate for a 150 cm^2 cell-culture flask. The flasks are incubated at 35°C for 1 h; they should be gently rocked or periodically agitated by hand to keep the inoculum evenly spread over the monolayer and to prevent it from drying during the infection period. The inoculum is then removed and replaced with chlamydial growth medium; and, incubation proceeds as described above. *C. psittaci* and the LGV strains of *C. trachomatis* are particularly suited for culture in flasks because centrifugation is not necessary for optimal infectivity.

3) For clinical specimens, blind passage of cultures that appear devoid of chlamydial inclusions by disrupting the host cells and inoculating a second monolayer may increase recovery of clinical isolates. This technique has been shown to be particularly useful when culturing *C. trachomatis* in 96-well microtiter plates (Jones et al., 1989; Schachter and Martin, 1987).

Identification

Isolation

Because the formation of intracellular inclusions is unique to the chlamydiae, the visual identification of inclusions is the only requirement for positive identification of the organism. To a trained eye, *C. trachomatis* inclusions are easily visible in unstained, infected cells using an ordinary light microscope. *C. psittaci* and *C. pneumoniae* inclusions are not. This difference has not been explained, though it may be due to the presence of glycogen in *C. trachomatis* inclusions. Thus, monolayers are usually stained to confirm the presence of inclusions. This is particularly important for clinical specimens, where numbers of infected cells may be low. Direct or indirect fluorescent antibody stains specific for chlamydia are the most sensitive and commercially available; however, they are relatively expensive and require a fluorescence microscope for visualization of the inclusions. Alternative stains are: 1) Iodine, which stains the glycogen in inclusions, and thus is only applicable for *C. trachomatis* identification. Timing is important in iodine staining because glycogen levels are maximal at 40–72 h postinfection. This is particularly true for the LGV strains that begin to deplete the glycogen stores at about 60 h postinfection. 2) Giemsa stains may also be used. Both inclusions and cellular organelles are stained; thus, Giemsa-stained cells may be difficult to interpret unless the cells are visualized by dark field microscopy where only the inclusion is brightly illuminated.

Nonculture Techniques

Because of the specialized equipment and techniques that are required for the culture of chlamydiae, the expertise for cultivation of this organism is available in only a limited number of clinical and research laboratories. Recently, a number of techniques have been developed that detect chlamydial proteins, carbohydrates, or nucleic acids, thus obviating the need to culture the organism to identify it. These techniques are particularly suitable for clinical laboratories where diagnosis of infection only requires the identification of chlamydiae in a clinical specimen. An obvious drawback of these techniques is that the clinical isolate is not available for further study.

IMMUNOFLUORESCENT STAINING. The fluorescent antibody stains described above for the detection of inclusions can also be used to detect EBs in clinical specimens. Commercially available stains are usually direct stains in which a fluorescent molecule, usually fluorescine isothiocyanate (FITC), is conjugated directly to an antibody that recognizes chlamydial protein or LPS. This method is sensitive and simple; however, a skilled microscopist must interpret the slides.

ENZYME-IMMUNOASSAYS (EIA). EIAs detect chlamydial antigen in a solubilized specimen and can take any of several formats. Generally, the sample is denatured, chlamydial antigens are bound to a matrix or chlamydiae-specific antibody, then incubated with an enzyme-conjugated monoclonal antibody specific for the bound chlamydial antigen. The adsorbed mon-

oclonal antibody can then be detected in several different ways, usually in a colorimetric assay that can be detected spectophotometerically.

NUCLEIC ACID-BASED ASSAYS. The use of specific DNA or RNA sequences to detect a wide range of microbes including those of the genus *Chlamydia* is a new and rapidly expanding technology. Currently, nucleic acid detection takes one of two formats. A nucleic acid probe homologous to a chlamydiae-specific DNA or RNA sequence is linked to an assayable enzyme, a chemiluminescent molecule, or a radioisotope. The probe is then hybridized to denatured target DNA, nonhybridized probe is removed, and the labelled probe is detected by standard methods. Alternatively, new methodologies that employ specific DNA primers to direct the synthesis of DNA to specific sequences allow the amplification of specific DNA sequences in vitro using the polymerase chain reaction (PCR). Published reports of the application of this later technique to chlamydiae are limited at this time; however, the usefulness of this approach to the study of chlamydiae is obvious. PCR technology has potential application both for the detection of chlamydiae in clinical samples and as a research tool where a difficult-to-obtain DNA sequence can be amplified in vitro for further experimentation.

Strain Typing

Fifteen serotypes of *C. trachomatis* have been delineated based on antigenic heterogeneity found predominantly in MOMP (Wang, S.-P. and Grayston, 1971; Wang, S. P. et al., 1985). Monoclonal antibodies have been isolated that react with genus, species, group, and serotype-specific epitopes on MOMP (Ma et al., 1987; Baehr et al., 1988; Stephens et al., 1988b) and other antigens (Caldwell et al., 1975; Hourihan et al., 1980; Zhang et al., 1987b). A strain of *C. trachomatis* can be characterized with respect to its reactivity with a panel of monoclonal antibodies and assigned to specific serogroups. Conversely, the exposure of an individual to a particular serotype(s) of *C. trachomatis* can be assessed by the reactivity of their sera with EBs from the 15 serotypes. This assay, termed microimmunofluorescence (MIF; Wang et al., 1975), has been used for epidemiologic studies but is generally not suitable for clinical applications due to the tedious nature of the assay.

The Order Planctomycetales and the Genera *Planctomyces, Pirellula, Gemmata,* and *Isosphaera*

J. T. STALEY, J. A. FUERST, S. GIOVANNONI, and H. SCHLESNER

Introduction

The order Planctomycetales comprises a remarkable group of budding bacteria. They and their nearest relatives, the chlamydiae (Weisburg et al., 1986) (see Chapter 202), are the only known cell-wall containing eubacteria that lack peptidoglycan. Furthermore, the planctomycetes are morphologically distinctive because of their budding division, their spherical to ovoid cells with crateriform pits (Figs. 1 and 2), and the nonprosthecate appendages (stalks) produced by some members of the group (Fig. 3). In some species the stalks, which are multifibrillar bundles or fascicles (Fig. 2), are too thin to be discerned by light microscopy. Multicellular aggregates or rosettes are formed by some species that produce polar holdfasts (Fig. 3). One genus, *Isosphaera,* is a multicellular filamentous bacterium that moves by gliding. Other motile members of the group produce flagella. Knowledge of the order is limited due to the relatively few species that have been obtained in pure culture and characterized.

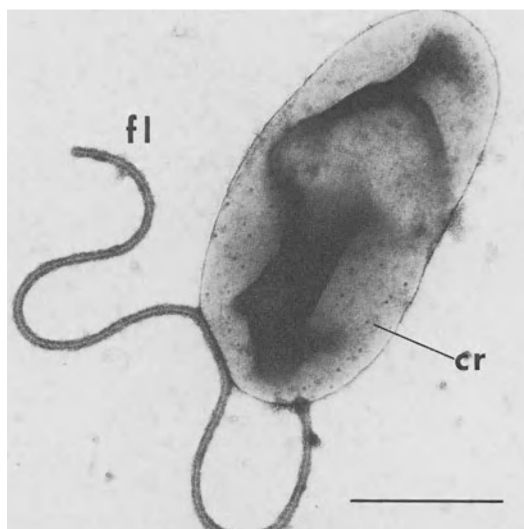

Fig. 1. An electron micrograph of a motile cell of *Pirellula marina* showing flagellum (fl) and numerous circular surface structures referred to as crateriform structures (cr). More distinctive crateriform structures are evidenced on some species (see Fig. 2 below). Bar = 1.0 μm. (Courtesy of Heinz Schlesner.)

The planctomycetes have a typical and unique ribosomal RNA composition. An analysis of their 16S rRNA by oligonucleotide cataloging and sequence analyses places this order as a deep branch within the eubacteria (Stackebrandt et al., 1984) and/or as a group that is undergoing rapid evolution (Woese, 1987). Thus, the planctomycetes differ markedly from the heterotrophic budding and prosthecate bacteria that fall in the alpha group of the purple bacteria. A dendrogram (Fig. 4) of some species has been constructed based upon the 16S rRNA oligonucleotide composition (Stackebrandt et al., 1986a). More recent studies of their 5S rRNA (Bomar et al., 1988) indicate that its length is significantly shorter than that of most eubacteria, ranging from 109–111 nucleotides rather than the "minimal" length of 118 bases of eubacteria and archaebacteria (Erdmann and Wolters, 1986). In addition, position 66 lacks an insertion, and numerous transversions were noted in the secondary structure, features previously unknown for other eubacteria. The evolutionary tree constructed from 5S rRNA data is shown in Figure 5. Another report further indicates that, in contrast to typical eubacteria, the two 16S regions of the ribosomal RNA operon of *Pirellula marina* on the chromosome are separated from the two interlinked 23S-5S rRNA regions by 8.5 and 4.4 kb (Liesack and Stackebrandt, 1989).

Members of the genera *Planctomyces* and *Pirellula* (the latter formerly called *Pirella*) have characteristic eubacterial ester-linked polar lipids rather than the ether-linked lipids of the archaebacteria (Kerger et al., 1988). However, their lipids differ from those of other eubacteria in having large amounts of palmitic, oleic, and palmitoleic acids typically associated with microeukaryotes.

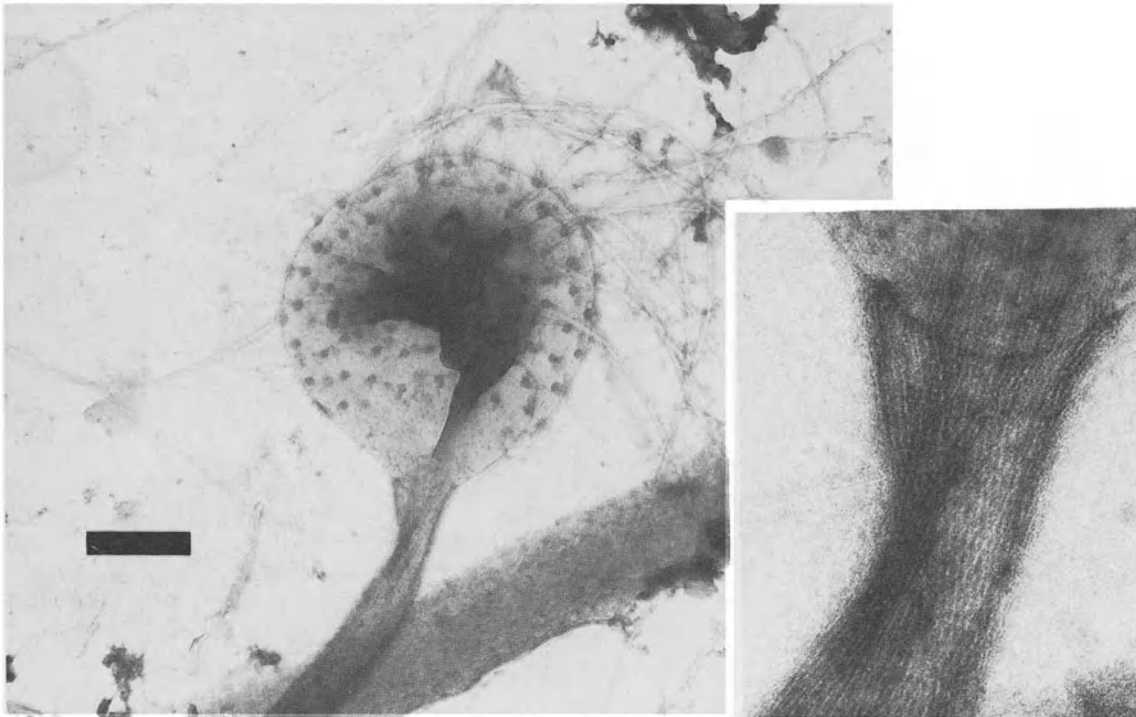

Fig. 2. An electron micrograph of a whole cell of *Planctomyces bekefii* showing many crateriform structures. The inset is an enlargement of the stalk-cell junction, showing the fibrillar nature of the stalk. Sample was collected from University Lake, St. Lucia, Australia, and stained with 1% uranyl acetate in 0.4% sucrose. Bar = 0.5 μm. (Courtesy of John A. Fuerst.)

Because of their unique position within the eubacteria, a new order, Planctomycetales, has been proposed to accommodate members of this group (Schlesner and Stackebrandt, 1986). The order is named for the species *Planctomyces bekefii,* which was first described early in the century by Gimesi (1924), who observed this rosette-forming microorganism in a pond in Hungary. He regarded it as a planktonic fungus, thereby explaining the root "myces" in the genus name. Organisms of this group were also reported by Henrici and Johnson (1935) who observed them in lakes in the northern United States. Neither Gimesi (1924) or Henrici and Johnson (1935) obtained pure cultures. Subsequently several other planktonic, rosette-forming colonial species, including *P. crassus, P. stranskae, P. gracilis,* and *P. guttaeformis* were named but not isolated (see Starr and Schmidt, 1989)

The first reports of pure cultures of this group were published in the 1970s (Staley, 1973a; Bauld and Staley, 1976; Schmidt, 1978). The organisms grew as slow-growing heterotrophs on dilute organic media. Even yet, however, many of the large rosette forms have not been isolated, including the type species of the genus, *Planctomyces bekefii.* All species are aquatic, occurring in freshwater lakes, marine habitats, and salt ponds.

In addition to the unicellular and rosette-forming colonial forms, the order contains filamentous organisms. The filamentous types were initially thought to be cyanobacteria and were named *Isocystis pallida* (Woronichin, 1927). However, strains that have been isolated do not contain chlorophyll *a* or other photosynthetic pigments (Giovannoni et al., 1987b). Isolated strains that were obtained from neutral and alkaline hot springs at temperatures between 35 and 55°C were placed in a new genus as *Isosphaera pallida.*

Table 1 can be used to distinguish the genera of the order Planctomycetales.

Planctomyces

Since the first report of *Planctomyces bekefii,* by Gimesi (1924), limnologists and bacteriologists have periodically reported similar organisms and ascribed several new species and generic names to these bacteria. Isolates of *Planctomyces* spp. were not obtained until the

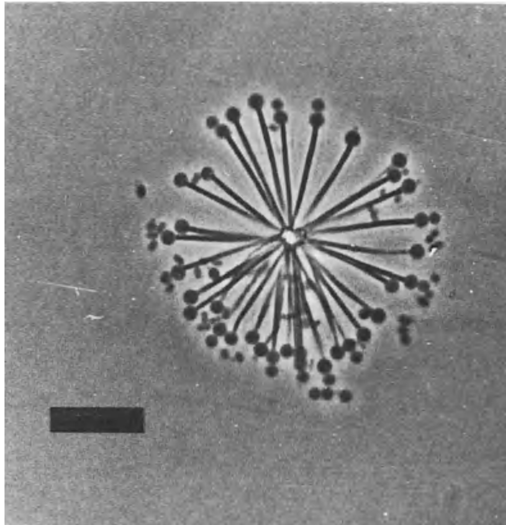

Fig. 3. A phase photomicrograph of a rosette of *Planctomyces bekefii* from University Lake, St. Lucia, Australia. The rosette consists of many spherical cells joined together at the distal tips of their stalks. Bar = 10.0 μm.

late 1970s (Bauld and Staley, 1976; Hirsch et al., 1977; Schmidt, 1978). Even today, *P. bekefii, P. guttaeformis,* and *P. stranskae,* as well as several other unrecognized species, remain unisolated although they are common residents of freshwater habitats.

Habitats

These bacteria occur in freshwater, marine, and saline habitats. Unicellular forms are frequently found attached to other organisms in the environment (Fig. 6). They attach by a holdfast structure located at the tip of the stalk. Species with the most striking morphology, such as *Planctomyces bekefii,* occur in the plankton of freshwater lakes as microcolonies of free-floating rosettes (Fig. 7). It is not known how they can specifically associate with one another to form these rosettes in the natural habitat. The colonial forms do not appear to occur in soft-water habitats, (low osmotic pressure) perhaps because of the peculiar nature of their cell envelop structure. They are most common during the summer and early fall, particularly in eutrophic lakes. For example, in North America they are found in eutrophic lakes in the Midwest (Wintergreen Lake near Kalamazoo, Michigan) and Southeast (University Lake near Chapel Hill, North Carolina, as well as most other lakes of the Carolina and Virginia Piedmont) (J. Staley, unpublished observations). These colonial forms have also been reported to occur in eutrophic ponds in Arizona (Starr and Schmidt, 1984). In contrast, rosette-forming species have not been reported in the mesotrophic to eutrophic soft-water lakes of the Pacific Northwest such as Lake Washington in Seattle, where unicellular forms are found (J. Staley, unpublished observations) (see Fig. 6).

Planctomyces spp. have been enumerated in a variety of Australian freshwater habitats using Most-Probable-Number (MPN) techniques with a dilute peptone broth medium (0.01%). They were found in habitats of all trophic states and their proportion to total viable heterotrophs by this procedure (about 0.025%) was essentially the same, regardless of the trophic state of the habitat (Staley et al., 1980). Thus, higher concentrations were found in eutrophic habitats that contained correspondingly higher concentrations of heterotrophic bacteria than did the less nutrient-rich habitats.

Isolation Procedures

SAMPLE COLLECTION. Water samples (200 ml or more) should be collected aseptically from the environment. If enrichments are to be prepared

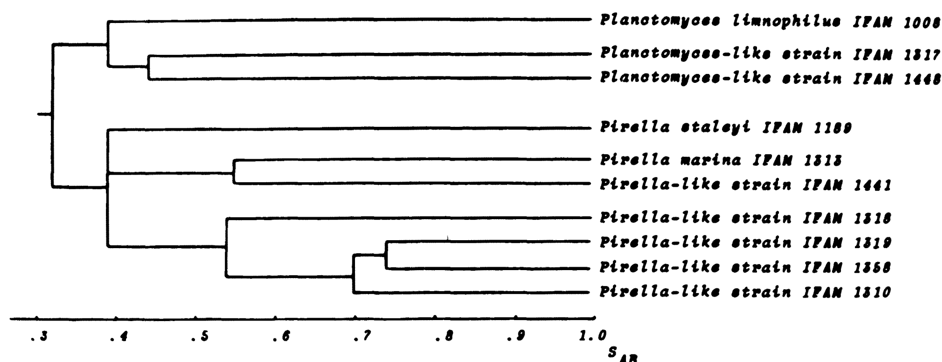

Fig. 4. A dendrogram of similarity coefficients of selected members of the Planctomycetales based on sequence analysis of 16S rRNA oligonucleotides. Note that the genus *Pirella* is now called *Pirellula.* (Courtesy of E. Stackebrandt et al., 1986.)

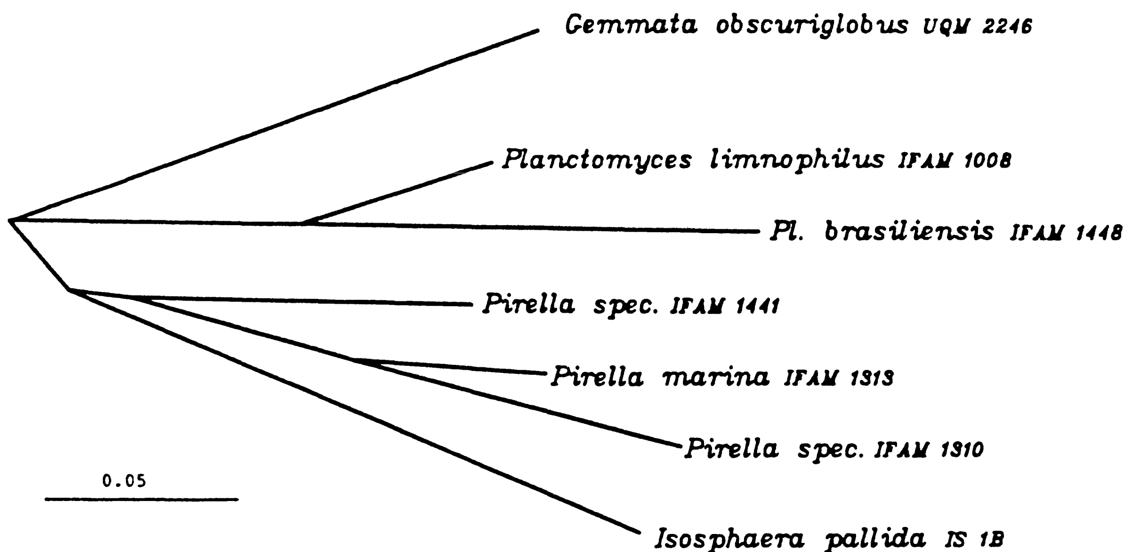

Fig. 5. The evolutionary tree of various members of the Planctomycetales based on 5S rRNA sequences. Scale bar denotes an evolutionary distance of 0.05 D. (Courtesy of D. Bomar et al., 1988.)

Table 1. Characteristics differentiating the genera of the order Planctomycetales.

Genus	Cell arrangement	Stalk	Flagellar type	Crateriform structure	GC content (mol%)
Pirellula	Rosettes in pure culture	−[b]	Single, polar	Reproductive pole	54–57
Gemmata	Single cells	−[a]	Polar bundle	Over entire cell surface	64
Planctomyces	Single cells or rosettes	+	Single, polar	Over entire surface or reproductive pole	50–58
Isosphaera	Filamentous	−	− (gliding)	Over entire surface	62

[a]+, property present; −, property absent.
[b]A rudimentary "stalk" has been reported in ATCC strain 27377 (Starr et al., 1983).

at the day of sampling, samples can be kept at the collection temperature. For periods longer than 12–24 h, it is advisable to refrigerate. In situ temperature and salinity should be known since these parameters will determine the appropriate conditions for enrichment and isolation.

DIRECT ISOLATION AND ENRICHMENT METHODS. Because these organisms occur in low numbers in most natural environments, they usually have to be enriched. Although they are very distinctive morphologically, they have few physiological features that can be used for the development of enrichment and isolation procedures. The addition of penicillin G (1,000–2,000 U/ml) or other antibiotics that inhibit peptidoglycan synthesis, may be used with some success (Schmidt and Starr, 1981), at least at the time of plating, since all isolated strains lack peptidoglycan.

In some cases, it may be possible to isolate strains from natural samples by direct streaking of the sample onto an appropriate agar medium. For example, Hirsch et al. (1977) describe a water agar plating procedure used successfully for the isolation of *Planctomyces limnophilus.* Likewise, *P. brasiliensis* was isolated directly from a salt pit sample from Brazil (Schlesner, 1989) by streaking on a saline medium, M 13 (described in *"Pirellula"*).

A variety of techniques have been applied for the enrichment of *Planctomyces* when numbers from the environment are low. A common procedure is to use the dilute peptone enrichment procedure described for *Prosthecomicrobium* and *Ancalomicrobium* see (Chapter 103). Peptone (Bauld and Staley, 1976) is added to a freshly collected natural sample to a final concentration of 0.01% (or peptone and yeast extract at 0.005% each) and the enrichment incubated at room temperature (or the temperature of the environment from which it was collected). Schmidt (1978) used somewhat lower concentrations of peptone ranging from 0.002 to 0.005% in her enrichments.

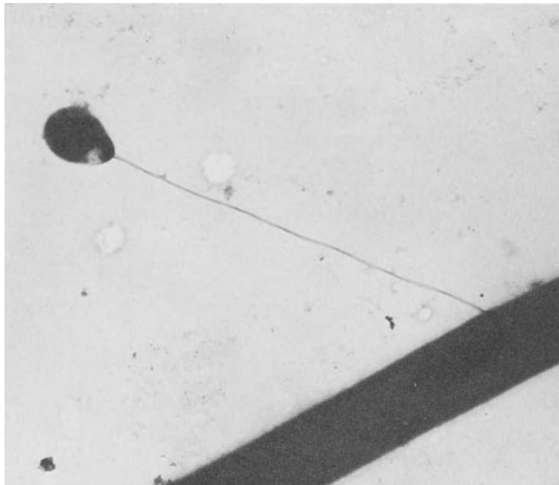

Fig. 6. A lone *Planctomyces* cell attached by its stalk to a sheathed cyanobacterial filament in a sample collected from Lake Washington. Presumably the flexible stalk acts as a tether, allowing the cell to be moved by water currents while the holdfast anchors the cell to the filament. Cell diameter is about 1 μm. Electron micrograph.

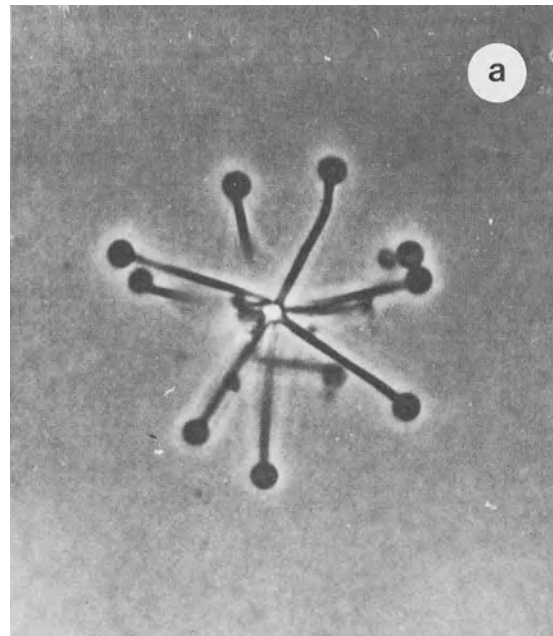

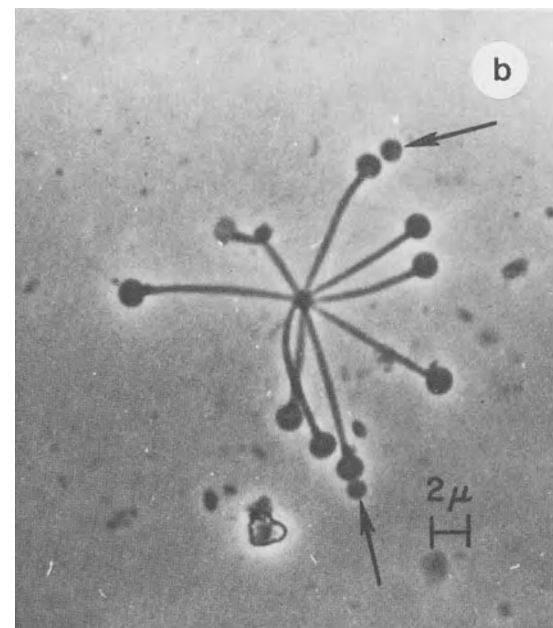

Fig. 7. Phase photomicrographs of a rosette-forming species of *Planctomyces* from University Lake, Chapel Hill, North Carolina. (A) Note the encrustation in the central holdfast region of the rosette due to deposition of iron and/or manganese oxides. (B) Arrows point to buds. Bar = 2.0 μm.

Hirsch and Müller (1986) have described other procedures that have been used successfully in the enrichment of *Planctomyces* spp. 1) In addition to using media with low nutrient concentrations, they have incubated water samples directly with no nutrient addition either in the light or dark for periods of 4 to 16 weeks. 2) Another procedure entails hanging sterile glass slides into fresh or stored water samples and incubating in the light at 20°C. This is reminiscent of the original Henrici procedure in which submerged slides were used to detect periphytic bacteria in lakes (Henrici and Johnson, 1935). When interesting forms appear, material is scraped from the slide with a sterile scalpel and streaked onto an isolation medium. 3) In a different procedure, sterile glass coverslips, some coated with 2% water agar, were inserted vertically into a sterile water agar layer (2 cm deep) in petri dishes, to which was added sufficient sample water to cover the coverslips. Coverslips were examined periodically by phase microscopy for the attachment of budding bacteria. When coverslips contained organisms of interest, replicate ones were removed and material streaked for isolation (Hirsch et al., 1977).

ISOLATION PROCEDURES. Enrichments are examined periodically by phase microscopy to identify types characteristic of the genus: spherical to ovoid cells, oftentimes large (i.e., >1.0 μm in diameter), that attach to detritus or other cells (especially sheathed organisms) and that produce polar to subpolar buds and stalks. The stalks may not be sufficiently thick to be seen by phase microscopy, so to identify these it is advisable to examine samples from prospective enrichments with the transmission electron microscope, by preparing negative stains of enrichment culture material (Fig. 8). Positive en-

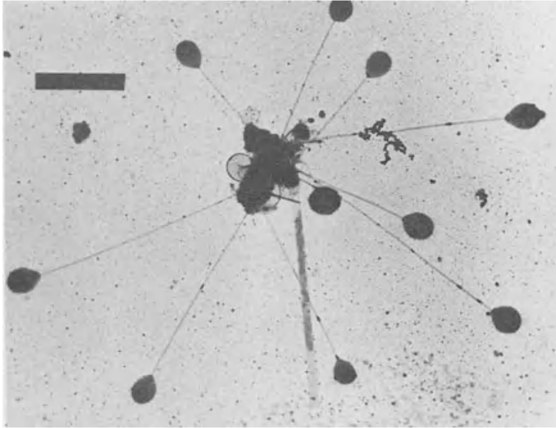

Fig. 8. An unidentified rosette-forming species of *Planctomyces* from a 0.01% peptone enrichment culture of water collected from the Mississippi River in Minneapolis. Bar = 5.0 μm.

richment samples are streaked or dilutions spread (spread 0.1 ml samples from 10^{-2} to 10^{-4} dilutions) on agar media. Media that have been used successfully for this include PYGV medium or PYG medium (same as PYGV, but without vitamins; Staley, 1968).

PYGV medium:

Peptone	0.025%
Yeast extract	0.025%
Glucose	0.025%
Hutner's salts solution (see Chapter 103)	20 ml/l
Vitamin solution (see *Pirellula*)	10 ml/l
Agar	1.5%

For freshwater strains, add distilled water; for marine strains, aged seawater or artificial seawater solution at half- or full-strength should be added (see section on *"Pirellula"*); for strains from other saline or brackish sources, an appropriate salt solution mimicking that of the environment should be used. The pH is adjusted to 7.0 before autoclaving.

Schmidt and Starr (1981) recommend using one of three other media for streaking from enrichment culture material. One medium contains 0.02% peptone, 0.01% yeast extract, 0.1% filter-sterilized glucose or galactose, 10 ml of Hutner's mineral base (Cohen-Bazire et al., 1957), 5 mM $MgSO_4 \cdot 7\ H_2O$ and 1.0 or 1.5% agar. Their second medium contains 0.04% peptone, 0.02% yeast extract, 5 or 10 mM magnesium sulfate, and 1.0 or 1.5% agar made up in either tap water or distilled water to which 10 ml of the Hutner's salts solution is added. The pH of this medium can be adjusted above 7.0 for alkaline samples using 0.005 M Trizma Buffer (Sigma Chemical Co.). Usually a pH of 7.8 or 8.0 is used. Their final medium contains 0.2% peptone, 0.1% yeast extract, 10 ml/l Hutner's salts solution, and 5 mM magnesium sulfate, with 1.0 or 1.5% agar made up with distilled or tap water. Autolysis of osmotically unstable strains can occur in this latter medium.

Colonies of *Planctomyces* spp. develop slowly. Cultures from primary plates need to be incubated for at least one week, and often more than a month is required before they fully develop. One of the most striking characteristics of the colonies is that they continue to develop after most other colony types have stopped growing and are beginning to recede. Typical colonies of the *Planctomyces* types as well as *Pirellula* persist and form impressive mounds about a month after streaking when incubating at room temperature. Colonies may be pigmented (light rose, bright red, or yellow to ochre) or they may be unpigmented.

Repeated restreaking may be necessary to purify some strains. Indeed, some strains cannot be readily isolated even after several restreaking attempts, but some of these can be maintained in monoxenic culture with another heterotrophic bacterium (J. Staley, unpublished observations).

Identification

Because the planctomyces are such distinctive organisms, it is normally a simple matter to determine whether an isolate belongs to this group by microscopic examination alone. If the stalks are sufficiently large, they may be discerned by phase microscopy. However, in the species currently available in pure culture, this is not possible because the stalks are too fine. Thus, the most direct means to verify their identity is by transmission electron microscopy (see Figs. 6 and 8). Whole cell preparations that are negatively stained should show the typical spherical to ovoid cell types with polar stalks. Stalks are the primary characteristic used to distinguish *Planctomyces* from *Gemmata* and *Pirellula.* Although stalks have been infrequently reported from these latter two genera, they are quite rare and often nondistinctive. In contrast, stalks are very common in *Planctomyces* spp. Indeed, in a typical growing preparation of *Planctomyces* spp., all mature, budding cells would be expected to bear a stalk.

Classification of species in the genus has been based largely upon morphological attributes, especially for types that have not yet been isolated. Schmidt and Starr (1977; 1978) and Starr and Schmidt (1989) classified this genus into five morphotypes, I–V. Cells of morphotype I

are spherical, joined together in rosettes, as represented by *Planctomyces bekefii* (Figs. 7 and 9). Cells of morphotype III are ellipsoidal and are represented by the isolated species, *P. maris, P. limnophilus*, and *P. brasiliensis*. Cells of morphotype V are bulbiform-shaped and form rosettes (Figs. 10 and 11). *Planctomyces guttaeformis* and *P. stranskae* are members of this group. No species names have been proposed for morphotypes II and IV, cells of which are ovoid. However, one member of morphotype IV is now classified as *Pirellula staleyi*.

Pure cultures are available of three species, all of morphotype III, including *Planctomyces maris* (Fig. 12), *P. limnophilus*, and *P. brasiliensis*. The stalks on these species are so fine they cannot be discerned by observation with the phase contrast microscope. When observed by the electron microscope, the stalk can be seen to contain a number of fine fibrils bundled together to form a fascicle that emanates at one pole of the ellipsoidal cells. This stalk develops at the pole near the site of the subpolar flagellum. These species are differentiated by 16S rRNA oligonucleotide catalog, salt requirements for growth, and various other morphological and physiological characteristics (Table 2).

All culture isolates have dimorphic life cycles. Reproduction occurs by budding, in which the cell envelope of the daughter bud is formed de novo (Staley, 1973a; Tekniepe et al., 1981). Daughter cells are motile by a polar to subpolar flagellum. Though they lack stalks initially, these are formed as part of their maturation process in a fashion that is analogous to that of *Caulobacter* (although the stalks of *Planctomyces* spp. are not prosthecae).

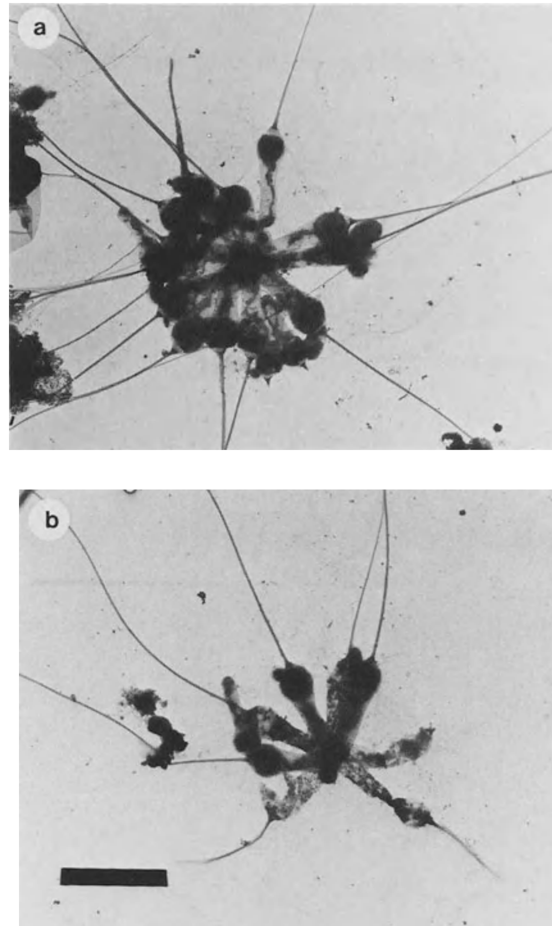

Fig. 10. Rosettes of *Planctomyces guttaeformis*. (A) Note the bulbiform cells that are joined together at their narrow poles. Also note the long spike appendage extending away from the bulbous reproductive pole of mature cells in the rosette. (B) Another rosette from same locale containing budding cells at different stages of development. Buds begin as spherical protuberances but then become bulbiform. Several cells in this rosette are lysed. From University Lake, Chapel Hill, North Carolina. Bar = 5.0 μm.

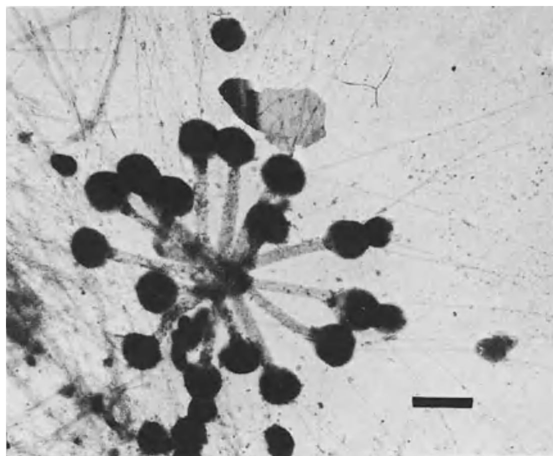

Fig. 9. An electron micrograph of an organism that resembles *Planctomyces bekefii*. Though this organism is similar to *P. bekefii*, note that its cells have two to four or more very long prominent filiform appendages extending outward from each cell of the rosette near the reproductive pole rather than several shorter ones characteristic of *P. bekefii* (see Fig. 2). This type of *Planctomyces* is common in lakes in the southeastern USA. From University Lake, Chapel Hill, North Carolina. Bar = 2.0 μm.

All three of these species are heterotrophic organisms that grow aerobically. Various mono- and dissacharides are used, including glucose, galactose, cellobiose, maltose, and N-acetylglucosamine. *P. maris* and *P. brasiliensis* also use glucuronic acid. Ammonium salts can be used as the sole nitrogen source by *P. maris* and *P. limnophilus*. Vitamins are not required by any of the isolates.

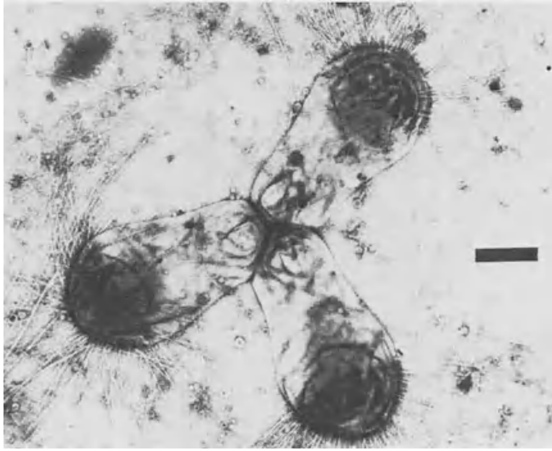

Fig. 11. *Planctomyces stranskae* collected from Kiwanis Park in Tempe, Arizona. Cells of this species do not develop terminal spikes. Bar = 1.0 μm. (Courtesy of Jean Schmidt.)

The characteristics of the other unisolated but currently recognized species are given in Table 3. All of these species produce large, conspicuous rosettes in the natural freshwater habitats in which they occur. Each cell of *Planctomyces bekefii* produces a distinctive thick stalk that terminates in a holdfast. The stalk is a tubular structure comprising many fibrils (Schmidt and Starr, 1980). The holdfasts enable cells to join together in the natural habitat to form rosettes (Figs. 7 and 9). Some colonial forms such as *P. bekefii* can develop stalk encrustations (Fig. 13) containing iron and/or manganese oxides (Schmidt et al., 1981).

The most characteristic feature of *P. guttaeformis* and *P. stranskae* is their bulbiform cells (Starr and Schmidt, 1984), which are joined together at their narrow poles to form rosettes (Figs. 10 and 11). In addition, *P. guttaeformis* produces a long terminal spike from its large pole, a feature lacking in *P. stranskae.*

Pirellula

Habitats

Pirellula spp. and morphologically similar bacteria have been observed in and isolated from a variety of aquatic environments: freshwater (Staley, 1973; Tekniepe et al., 1981; Schlesner, 1989); brackish water (Gebers et al., 1985; Kauolbel-Boelke et al., 1985; Schlesner, 1986);

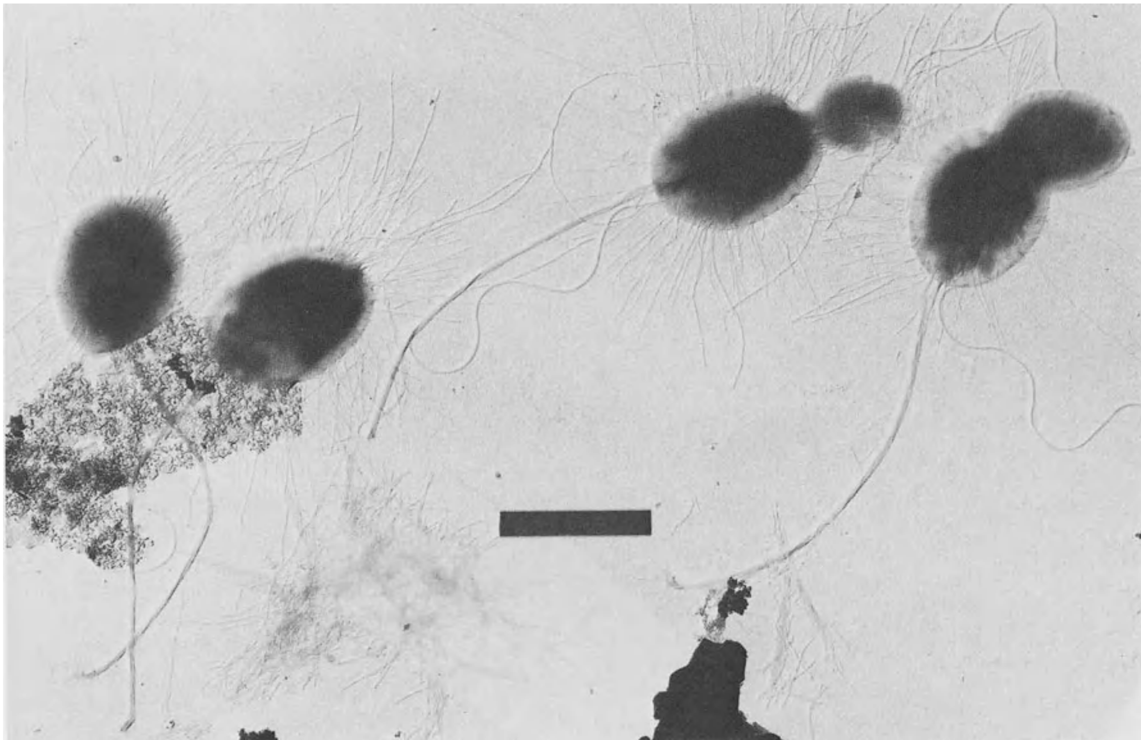

Fig. 12. Shadowed electron micrograph of cells of *Planctomyces maris.* Note the polar to subpolar buds, fibrillar stalks, subpolar flagella, and peritrichous fimbriae. Bar = 1.0 μm.

Table 2. Differentiation among isolated species of *Planctomyces*.

Character	*P. maris*	*P. limnophilus*	*P. brasiliensis*
Cell shape; maximum cell diameter	Ovoid, 1.5 μm	Ovoid, 1.5 μm	Spheroid, 1.8 μm
Source	Marine	Freshwater	Salt pit
Colony pigmentation	Colorless to light rose	Red	Yellow

NaCl growth range (mM)	100–>300	ND[a]	100–170
Temperature growth range	6–38°C	17–39°C	ND
GC content (mol%)	51	53	55–58
Genome size (× 10^9 daltons)	3.62	2.67	2.81

[a]ND, not determined.

Table 3. Differentiation among recognized species of *Planctomyces* that have not yet been isolated in pure culture.

Characteristic	*P. bekefii*	*P. stranskae*	*P. guttaeformis*
Cell shape	Spherical	Bulbiform	Bulbiform
Stalk	Tubular	Absent	Absent
Other cell appendages	Fimbriae and larger spikes[a]	Fimbriae only	Fimbriae and a single long tapering spike

[a]At least two variants (species?) exist. One type has several shorter spikes (see Fig. 2) whereas another type has fewer, very long spikes (see Fig. 3).

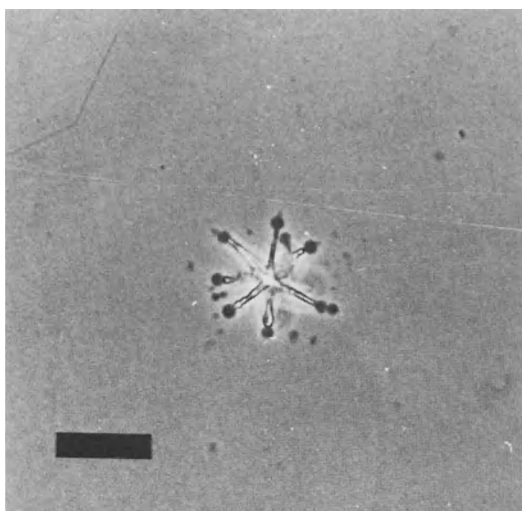

Fig. 13. A phase photomicrograph of a small rosette-forming species of *Planctomyces* from University Lake, St. Lucia, Australia, showing heavy deposition of iron and or manganese oxides on the stalks. Bar = 10 μm.

hypersaline water of a salt pit (Gebers et al., 1985); hot springs of Tiberias in Israel (Kahan, 1961); groundwater (P. Hirsch, personal communication); alkaline water from ponds in a lime pit near Lägerdorf (Schleswig-Holstein, Germany; Schlesner, 1989); lakes rich in Na_2SO_4, Na_2CO_3, and $NaHCO_3$ ("Lacken") in Burgenland, Austria; wastewater aeration lagoons of a sugar factory; marine and brackish water basins in an aquarium (Institut für Meereskunde, Universität Kiel); water basins in a greenhouse in the botany garden of the University of Kiel; and even in the pitcher trap of the insectivorous plant *Nepenthes* sp. (Schlesner, 1989).

In spite of the widespread distribution, *Pirellula*-like bacteria are only occasionally observed in water samples. After storage at room temperature (a few days to some weeks), however, such organisms are often found in high numbers, especially on the bottom or at the wall of the vessel. Obviously, the organisms live attached to surfaces and only the swarmer cells are free in the water column. When the population is very dense, however, *Pirellula*-like organisms may be found in high numbers in the free water.

Isolation

Various methods have successfully been applied for the enrichment of *Pirellula* spp.:

1. Storage of samples in the laboratory.
2. Addition of small amounts (0.005–0.01%) of peptone, yeast extract, or glucose to the water sample.
3. Addition of 0.1% chitin to the sample.
4. Addition of 0.1% KNO_3 and anaerobic incubation.

Isolation procedures take advantage of resistance to antibiotics that affect the biosynthesis of peptidoglycan and, furthermore, the ability to utilize N-acetylglucosamine as sole carbon and nitrogen source. The salinity of the

medium should not differ much from that of the natural environment, since many strains show a rather narrow salinity tolerance (H. Schlesner, unpublished observation). The following media have successfully been applied for isolation of strains of *Pirellula* spp.:

Medium M 1 + A

Solution 1:

$CaCO_3$	5.0 g
$Na_2HPO_4 \cdot 2H_2O$	0.1 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Hutner's basal salts (see below)	20 ml
Gellan gum Gelrite[a]	9.0 g
Vitamin solution No. 6	10 ml
Distilled water	920 ml

Adjust pH to 9.0; autoclave 121°C for 20 min.

[a]Kelco Inc., San Diego, California, USA.

Solution 2:

N-acetylglucosamine	2.0 g
Ampicillin sodium salt	0.2 g
Distilled water	50 ml

Adjust to pH 9.0, filter sterilize, and add to solution 1.

Hutner's basal salts (Cohen-Bazire et al., 1957)

Nitrilotriacetate (NTA)	10.00 g
$MgSO_4 \cdot 7H_2O$	29.70 g
$CaCl_2 \cdot 2H_2O$	3.34 g
$NaMoO_4 \cdot 2H_2O$	12.67 mg
$FeSO_4 \cdot 7H_2O$	99 mg
Metal salt solution "44" (see below)	50 ml
Double-distilled water	900 ml

The NTA is first dissolved by neutralization with KOH. The other salts are then added. Adjust pH to 7.2 with KOH or H_2SO_4. Adjust volume to 1,000 ml with double distilled water. Store cold (5°C) and clean. The solution is clear.

Metal salts solution "44"

Ethylene diamino tetraacetate (EDTA)	250.0 mg
$ZnSO_4 \cdot 7H_2O$	1,095.0 mg
$FeSO_4 \cdot 7H_2O$	500.0 mg
$MnSO_4 \cdot H_2O$	154.0 mg
$CuSO_4 \cdot 5H_2O$	39.2 mg
$CoCl_2 \cdot 6H_2O$	20.3 mg
$Na_2B_4O_7 \cdot 10H_2O$	17.7 mg
Double-distilled water	1 liter

To retard precipitation add a few drops of H_2SO_4 before making to volume. Store cold (5°C).

Vitamin solution No. 6 (Staley, 1968)

Biotin	4.0 mg
Pyridoxine hydrochloride	20.0 mg
Thiamin hydrochloride	10.0 mg
Ca pantothenate	10.0 mg
p-Aminobenzoic acid	10.0 mg
Folic acid	4.0 mg
Riboflavin	10.0 mg
Nicotinamide or nicotinic acid	10.0 mg
Vitamin B_{12}	0.2 mg
Double-distilled water	1 liter

Stirring of the mixture improves dissolution. Sterilize by filtration only. Store dark and cold (5°C).

Medium M 30 + A

Solution 1:

Hutner's basal salts	20 ml
Artificial seawater	125 ml
Buffer 0.1 M Tris/HCl, pH 7.5	50 ml
Agar	18 g
Distilled water	760 ml

Autoclave at 121°C for 20 min.

Solution 2:

N-acetylglucosamine	2.0 g
$Na_2HPO_4 \cdot H_2O$	0.1 g
Ampicillin sodium salt	0.2 g
Vitamin solution No. 6	10 ml
Distilled water	40 ml

Add filter-sterilized to solution 1.

Artificial seawater (Lyman and Fleming, 1940)

NaCl	23.477 g
$MgCl_2$	4.981 g
Na_2SO_4	3.917 g
$CaCl_2$	1.102 g
KCl	0.664 g
$NaHCO_3$	0.192 g
KBr	0.096 g
H_3BO_3	0.026 g
$SrCl_2$	0.024 g
NaF	0.003 g

Medium 31 + A

Solution 1:

$CaCl_2 \cdot 2H_2O$	0.1 g
$MgCl_2 \cdot 6H_2O$	0.1 g
Hutner's basal salts	20 ml
Buffer 0.1 M Tris/HCl, pH 7.5	50 ml
Agar	18.0 g
Distilled water	880 ml

Adjust pH to 7.5, autoclave at 121°C for 20 min

Solution 2:

N-acetylglucosamine	2.0 g
$Na_2HPO4 \cdot 2\ H_2O$	0.1 g
Ampicillin sodium salt	0.2 g
Vitamin solution No. 6	10 ml
Distilled water	40 ml

Adjust pH to 7.5, filter-sterilize, and add to solution 1.

To minimize growth of fungi, 0.2 g/l cycloheximide may be added to solution 2 of each respective medium.

For culturing or long-term storage of pure cultures, the above media should be enriched by adding 0.25 g of peptone and 0.25 g of yeast extract to solution 1. Good results are also obtained with medium M 13.

Medium M 13 (Schlesner, 1986)

Peptone	0.2 g
Yeast extract	0.2 g

Glucose	0.2 g
Hutner's basal salts	20 ml
Vitamin solution No. 6	10 ml
Buffer 0.1 M tris/HCl, pH 7.5	50 ml
Artificial seawater	250 ml
Distilled water	670 ml

Identification

Pirellula spp. are easily recognized by their morphology. The cells are ovoid, sometimes elliptical, or nearly spherical. They are polarly organized. From the smaller cell pole, holdfast substance is excreted which allows the cells to attach to surfaces or to each other and form rosettes (Fig. 14). Buds develop at the broader pole as a minor mirror image of the mother cell (Fig.15). Immunoferritin labeling experiments have shown that at least the surface components of the new buds are synthesized de novo (Tekniepe et al., 1982). The buds are motile by a single flagellum, polarly to subpolarly inserted, which is about 20 nm thick (Schlesner, 1986) and which inserts at the proximate (the later reproductive) pole (see Fig. 1).

Crateriform structures are scattered over the whole cell surface of the buds in the early developmental stage, while in adult cells their distribution is restricted to the reproductive pole only. Adult cells also have fimbriae, originating from the crateriform structures.

Another type of surface structure, described as "stacked disks" (Schmidt and Starr, 1979), is shown in thin sections through the reproductive cell pole (Liesack et al., 1986).

Colonies are red, pink, or colorless. Pigmentation seems to be of taxonomic significance, as homology groups derived from DNA/DNA hybridization experiments with 54 strains contained either pigmented or unpigmented strains (Bartels and H. Schlesner, unpublished observations).

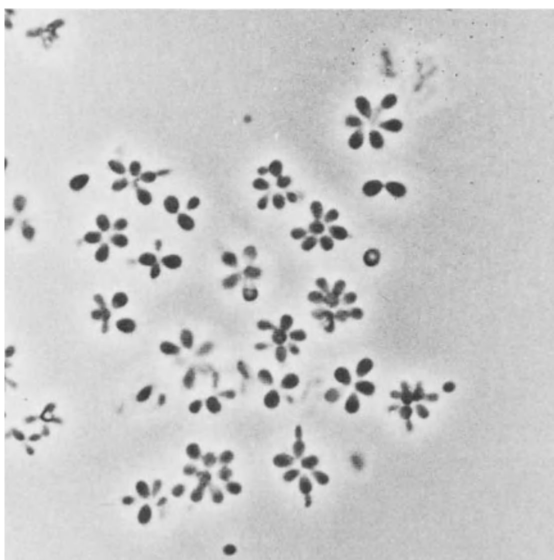

Fig. 14. Phase photomicrograph illustrating rosette formation by *Pirellula marina.*

The phylogenetic position of seven strains of *Pirellula* spp. (including *P. staleyi* and *P. marina*), analyzed by 16S rRNA cataloging showed a great phylogenetic diversity among these strains (Stackebrandt et al., 1986). These findings are supported by analysis of 5S rRNA (Bomar et al., 1988).

Despite their phylogenetic diversity, the strains investigated are phenotypically very similar. As carbon sources, mainly sugars and sugar derivatives are utilized; N-acetylglucosamine serves as both carbon and nitrogen source. Sugar alcohols may or may not be utilized. Some strains are able to reduce nitrate anaerobically. All strains tested so far hydrolyze gelatin; casein, DNA, or starch are hydrolyzed by some strains, but cellulose is not hydrolyzed at all. Additional methods will have to be applied to find more discriminating taxonomic characteristics.

Two species are described. The type species is from freshwater: *Pirellula staleyi* (Schlesner and Hirsch, 1987), syn. *Pirella staleyi* (Schlesner and Hirsch, 1984), syn. *Planctomyces staleyi* (Starr et al., 1983), syn. *Pasteuria ramosa* (Staley, 1973). The other species is marine: *Pirellula marina* syn. *Pirella marina* (Schlesner, 1986).

Gemmata

The genus *Gemmata* is at present represented by one species, *Gemmata obscuriglobus.* The single strain (UQM 2246) representing the single species was isolated from a single source, the surface waters of Maroon Dam, during a study of the microflora of freshwaters in southeast Queensland, Australia (Franzmann and Skerman, 1984). The discoverers of the strain recognized the similarities of this coccoid budding bacterium to a strain of great significance in the history of Planctomycetales systematics, strain ATCC 27377, which at one time was proposed as the neotype of *Pasteuria ramosa,* but later transferred to the genus *Planctomyces* (Starr et al., 1983) and to the genus *Pirella* (Schlesner and Hirsch, 1984), a genus name later rejected in favor of *Pirellula* (Schlesner and Hirsch, 1987; see above "Pirellula" for a detailed account of these changes). Franzmann and Skerman (1984) distinguished *Gemmata obscuriglobus* UQM 2246 from ATCC 27377 by DNA base content, number of flagella on

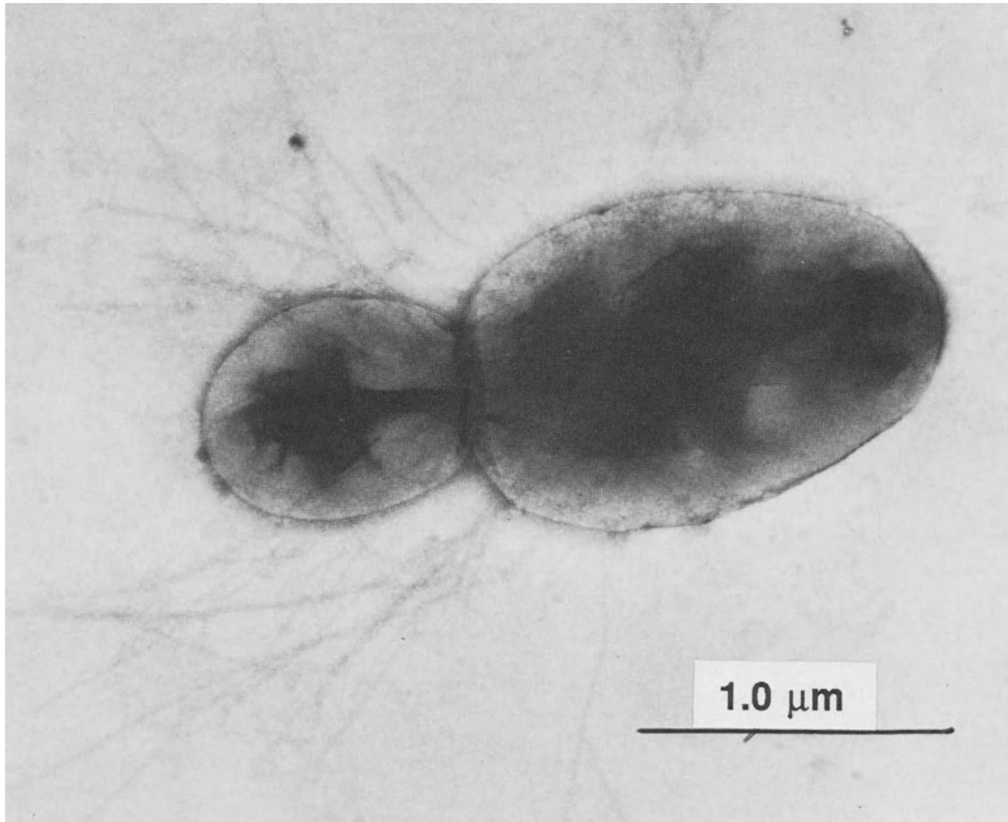

Fig. 15. An electron micrograph of *Pirellula marina* showing a single polar bud. Bar = 1.0 μm.

swarmer cells, lack of a discrete holdfast, and the possession of a phase-dark inclusion in *Gemmata* postulated to contain DNA, in addition to several other phenotypic characters outlined in Table 4. Later molecular systematics investigation of the 16S rRNA and 5S rRNA of *G. obscuriglobus* confirmed its status as a distinct genus and as a member of the phylogenetically distinct eubacterial order Planctomycetales (Stackebrandt et al., 1986; Bomar et al., 1988). *Gemmata* occupies a distinct position within the Planctomycetales phylogenetically, since not only does its 16S rRNA possess its own unique set of signature oligonucleotides among the eubacteria (Table 5), but both 16S rRNA and 5S rRNA sequence similarities with other Planctomycetales genera indicate that the root of the evolutionary tree derived for members of the order lies close to the point at which the ancestor of *G. obscuriglobus* branched off. Thus, this species is the deepest branching organism within the order Planctomycetales (Stackebrandt et al., 1986b; Bomar et al., 1988; see Figs. 4 and 5).

Isolation

The only existing strain of *Gemmata obscuriglobus,* UQM 2246, was isolated from the surface waters of the littoral zone of a freshwater dam in subtropical Queensland, Australia. Micromanipulation using the equipment and methods of Skerman (1968) as applied by Franzmann (1983) was employed in the isolation. This method employs a micromanipulator consisting of a glass microtool attached to a magnet, which is in turn carried on a metal slide that is part of a lens "collar" screwed onto the microscope objective mounting. A Leitz 32× Phaco phase objective is used on a phase contrast microscope (preferably an Olympus CHA microscope equipped with a Reichert Phase contrast condenser or any system compatible with a Leitz 32× Phaco objective). The microtool is focused by moving the lens collar up and down on the objective mounting; once focused, it can be used to transfer cells on an agar surface across the surface and away from other cells by trapping cells in the water film around the microtool and moving the mechanical stage con-

Table 4. Characteristics of *Gemmata obscuriglobus* UQM 2246 and strain ATCC 27377.

Character	UQM 2246[a]	ATCC 27377[b]

trols, the agar plate being mounted on the stage. The whole assembly can be placed in a UV-sterilizable Perspex chamber or in a plastic bag with eyepiece holes, to facilitate aseptic handling of plates. 9 cm plastic petri dishes containing 10 ml of lakewater agar (filtered lakewater solidified with 1.5% Noble agar for optical clarity; see below for formula) are inoculated by running an approximately 0.5 ml drop of sample water down the center of a plate which is surface-dried in advance. Storage of samples before inoculation should be avoided. Inoculated plates are allowed to remain horizontal until free moisture is absorbed. Plates are examined after 8 h incubation at 28°C or until microcolony formation is apparent. Cells from microcolonies displaying cell morphology and size consistent with *Gemmata* are manipulated away from the central inoculum line to a position on the surface of the same plate, well separated from the inoculation line. Position of a single cell can be marked using a microtool and an agar block circumscribing that area excised with a sterile scalpel and transferred to a fresh lakewater agar plate or to a fresh lakewater peptone yeast extract agar plate (see formula below). Purity can be checked microscopically at each stage of the isolation. Strains can be maintained on soil extract agar supplemented with 0.1% glucose or on casitone yeast extract agar:

Lakewater Noble Agar (Franzmann and Skerman, 1981)

Filter water from a eutrophic lake or pond through a 2 μm membrane filter and add Bacto Noble agar to 1.5%. Sterilize by autoclaving at 121°C for 20 min.

Lakewater Peptone Yeast Extract Agar (Franzmann and Skerman, 1981)

Bacto peptone	0.1 g
Bacto yeast extract	0.1 g
Bacto agar	15 g

2 μm-membrane-filtered eutrophic lake water 1 liter
Sterilize by autoclaving at 121°C for 20 min.

Casitone Yeast Extract Agar

Bacto casitone	5 g
Bacto yeast extract	3 g
$MgSO_4 \cdot 7H_2O$	2 g
Bacto agar	15 g
Distilled water	1 liter

The pH is adjusted to 7.2, the agar is added and the medium sterilized by autoclaving at 121°C for 20 min.

Soil Extract Agar with 0.1% Glucose

Soil	1000 g
Distilled water	1 liter

From Stackebrandt et al. (1986b).
[a]Where n equals the number of organisms included.

Mix soil with water and autoclave at 121°C for 20 min. Add 10 g $CaCO_3$ and mix. Decant and filter liquid. Autoclave filtrate at 121°C for 20 min. and store as stock solution. Add agar to 1.5% to stock solution and autoclave at 121°C for 20 min. After autoclaving, add filter-sterilized glucose aseptically to the agar medium to give a final concentration of 0.1%.

AXENIC CULTURE MAINTENANCE. *Gemmata* has been successfully stored by lyophilization and under liquid nitrogen; it has been revived after liquid nitrogen storage for eight years. Also, when reviving stored ampoules from liquid nitrogen, soil extract agar supplemented with 0.1% glucose is superior to lake water agar.

Identification

Gemmata obscuriglobus is a budding, nonprosthecate aerobic organism with spherical to avoid cells. Initial appearances from negative-stain transmission electron microscopy and phase contrast light microscopy (Fig. 16) suggest a spherical or ovoid shape. However, scanning electron microscopy of cells prepared by critical point drying reveals that a "puckered" area roughly square in shape is often present on one side of the cell surface, deforming the spherical shape (Fig. 17). Such puckered areas are consistent with the crescent form often seen in thin-sectioned cells (Fig. 18). This feature is unique among the Planctomycetales and may be unique among the bacteria as a whole.

Consistent with the position of the genus within the order Planctomycetales, cells observed by negative staining possess crateriform structures—circular areas on the cell that accumulate negative stain (Fig. 19). These are distributed all over the cell surface, similar to the distribution found in the genus *Planctomyces,* but unlike that in *Pirellula* species (Schlesner and Hirsch, 1984). Such crateriform structures have also been observed in metal-shadowed cell walls of *Gemmata obscuriglobus* (Stackebrandt et al., 1986b). The cell walls of *G. obscuriglobus,* like those of other Planctomycetales, lack pep-

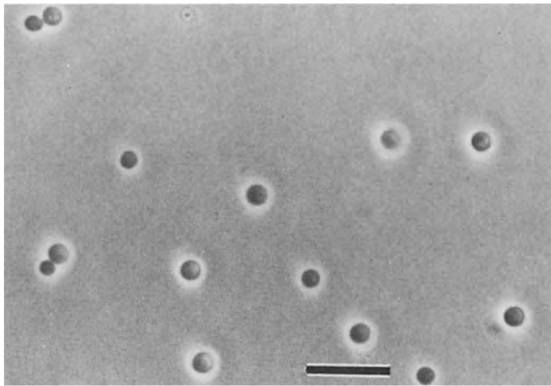

Fig. 16. Phase contrast photomicrograph of cells of *Gemmata obscuriglobus* UQM 2246. Budding is displayed in addition to the superficially spherical cell shape. Bar = 10 μm.

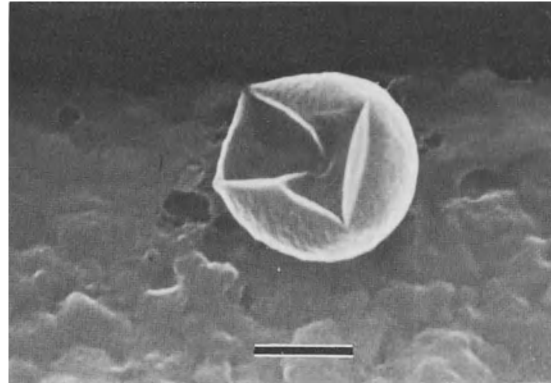

Fig. 17. Scanning electron micrograph of *Gemmata obscuriglobus* UQM 2246, showing the "pucker" in the otherwise spherical cell surface. Cell surface appears continuous inside the "pucker." Cells were prepared by dehydration in ethanol, critical-point drying from amyl acetate, and sputter-coating with gold. Bar = 1 μm.

tidoglycan and diaminopimelic acid, and are also similar to other members of the order in the predominately proteinaceous composition of the wall (Stackebrandt et al., 1986b). In thin sections, the cell wall has the typical appearance expected for the peptidoglycan-less walls of Planctomycetales (Fig. 20) with inner and outer electron-dense layers separated by an electron-transparent layer, the inner layer being more electron-dense, as found for morphotype IV planctomycete ultrastructure by Tekniepe et al. (1981). *Gemmata* thus shares budding reproduction, crateriform structures, and cell-wall composition with other genera of the Planctomycetales, and this relationship is confirmed by the high number of Planctomycetales-specific signature oligonucleotides present in the 16S rRNA oligonucleotide catalog of the genus (Stackebrandt et al., 1986b), and by the presence of the unique Planctomycetales-specific "short" 5S rRNA with lack of insertion at position 66 and numerous characteristic base-pair inversions (Bomar et al., 1988).

In the initial study of *G. obscuriglobus,* Franzmann (1983) noted that in some thin-sectioned cells nuclear material was packaged in a discrete body within the cell, and that this might be correlated with the appearance of phase-dark inclusions in light microscopy preparations. Intracellular membrane material is commonly seen in thin sections, and although in some cases an appearance of membrane involvement with nuclear packages suggests that they may be membrane-bound structures (Fig. 18), this may be artifactual and further studies are required to resolve the nature of the nuclear packages. Such packages often consist of an appearance of fibrillar material within a shell of electron-dense amorphous material separating the material from the rest of the cell (Fig. 18). Several such packages can occur within a single cell.

A stalk structure was not observed in the original examination of the genus, but more recent observations indicate that a multifibrillar stalk-like bundle can sometimes arise from groups of cells (Fig. 21). This bundle is coherent enough to resemble a *Planctomyces* stalk, but further work is required to delineate its significance.

As shown in Table 4, differentiation of *Gemmata obscuriglobus* from the morphologically similar ATCC 27377 is based on the higher GC content of *Gemmata,* occurrence of phase-dark inclusions, flagellation, oxidase test, utilization of fructose and pyruvate, temperature range for growth, and colony color. The GC content for ATCC 27377 has been subject of several determinations, with slightly variable results; thus, Starr et al. (1983) reported a high value of 59.0 ± 0 mol% by buoyant density and Schlesner has noted a lowest value of 56.4 ± 0.4 mol% by thermal denaturation (Schlesner and Hirsch, 1984), while for their comparison, Franzmann and Skerman (1981) used the figure of 57.1 mol% found by Staley (1973) by thermal denaturation. In all cases, however, the GC content of *G. obscuriglobus* is significantly higher. Although stalklike structures are not prevalent in *Gemmata,* and thus confusion with *Planctomyces* is not likely, they are sometimes seen, so that this character does not seem ideal for inclusion in differential keys for the Planctomycetales.

Isosphaera

Isosphaera pallida is an aerobic, heterotrophic budding bacterium that is unusual because it is motile by gliding and is also phototactic. With

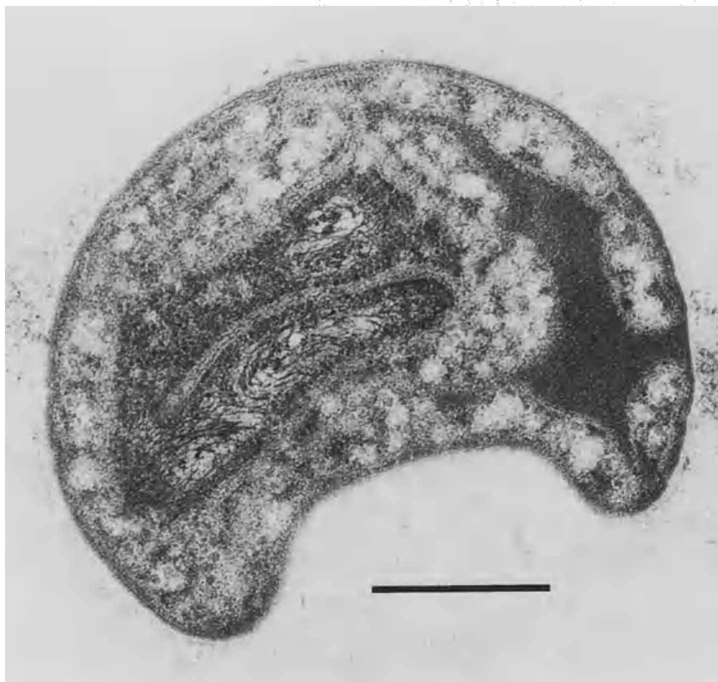

Fig. 18. Electron micrograph of thin section of *Gemmata obscuriglobus* UQM 2246, displaying crescent-cell profile and the package of fibrous nuclear material enclosed within a membrane, folding of which has resulted in a double-membrane profile in the center of the nucleoid. An amorphous electron-dense body with irregular outline but without condensed nuclear fibers is also present in the cell. Cells were fixed with glutaraldehyde and osmium tetroxide. Bar = 0.5 μm.

other members of the Planctomycetales, *Isosphaera* shares characteristics that are of potential evolutionary significance—the presence of proteinaceous cell walls and phospholipids containing beta-hydroxylated fatty acids (Kerger et al., 1984; Stackebrandt et al., 1984; Giovannoni et al., 1987).

Molecular phylogenetic comparisons of 5S rRNA have shown that *I. pallida* is a member of the order Planctomycetales (Bomar et al., 1988), but only distantly related to members of the genera *Gemmata, Pirellula,* and *Planctomyces.* Analyses of 16S rRNA have confirmed the results obtained with the 5S molecule.

Isosphaera pallida, the only recognized species of the genus *Isosphaera,* inspired a debate in the taxonomic literature long before it was first isolated in pure culture in 1979 (Giovannoni et al., 1987b). The organism attracted attention because of its conspicuous habitat and morphology. It commonly occurs in North American and European hot springs at temperatures from 35 to 55°C. The distinctive chains of spherical, budding cells formed by *Isosphaera* (Fig. 22) are readily distinguishable from morphologically similar organisms, such as cyanobacteria of the genus *Pseudanabaena.* However, because of this similarity, *Isosphaera pallida* was originally described by Woronichin (1927) as a cyanobacterium, *Isocystis pallida,* based only on observations of collected field specimens. This early case of mistaken identity was understandable, considering that *I. pallida* is invariably found in the euphotic zone of hot springs in association with cyanobacteria.

Geitler (1955) obtained the first enrichment cultures of an organism resembling *Isosphaera.* These were taken from a water-filled depression in a rotting spruce stump. He concluded that his isolate was a yeast, and assigned it to a novel genus and species, *Torulopsidosira filamentosa.* After examining collected specimens of *Isocystis pallida,* he assigned it also to the genus *Torulopsidosira* (Geitler, 1963). This decision was based on the two observations. The fact that the organisms divided by budding suggested that they were yeasts, since Geitler was dubious that budding occurred in bacteria. Secondly, cytological staining indicated that the nuclear material was sequestered within a small region of the cell—indicating a structure similar to a eukaryotic nucleus. Although it is now clear that *Isosphaera* is a prokaryote, modern staining techniques (e.g., 4′,6-diamidino-2-phenylindole) confirm Geitler's early observation (1963) that the nuclear material is located in a distinct region of the cell.

The micrographs of *Torulopsidosira filamentosa* provided by Geitler show an organism strongly resembling *Isosphaera pallida* in size, shape, and the distinctive formation of intercalary buds within filaments. This suggests that species similar to *Isosphaera* may occur in habitats outside of hot springs. Indeed, in the original definition of the cyanobacterial genus *Isocystis* by Borzi, eight species were named, not

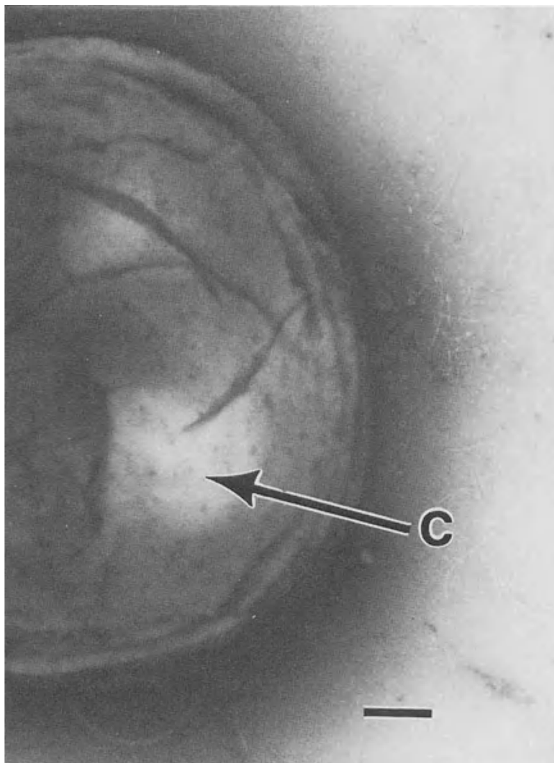

Fig. 19. Electron micrograph of a portion of a negatively stained cell of *Gemmata obscuriglobus* UQM 2246, displaying crateriform structures (C), which are electron-dense pits distributed uniformly over the cell surface. The arrow points to one example of such a structure; many others are visible on the cell surface displayed. Fimbriae are visible outside the cell perimeter. Negatively stained with 1% uranyl acetate supplemented with 0.4% sucrose. Bar = 0.2 μm.

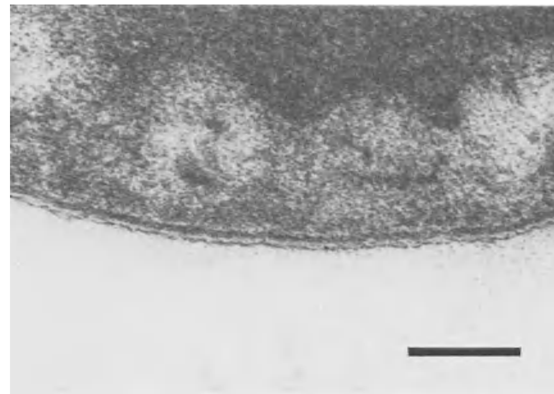

Fig. 20. Electron micrograph of a thin section of *Gemmata obscuriglobus* UQM 2246, displaying cell wall structure. The cell wall consists of an outer electron-dense layer and an inner electron-dense layer separated by an electron-transparent layer. The inner layer is more electron-dense than the outer layer. Cells were fixed with glutaraldehyde and osmium tetroxide. Bar = 100 nm.

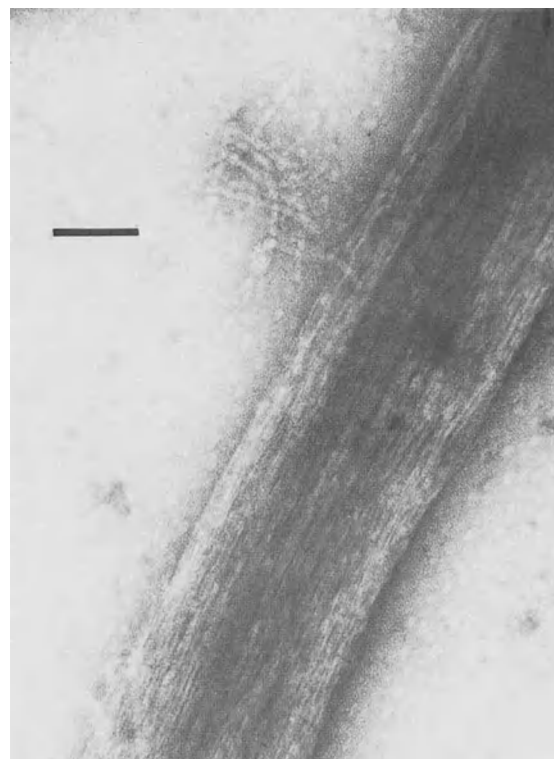

Fig. 21. Electron micrograph of multifibrillar stalklike structure originating from a cluster of cells of *Gemmata obscuriglobus* UQM 2246. Negatively stained with 1% uranyl acetate supplemented with 0.4% sucrose. Bar = 100 nm.

including *I. pallida.* One of these, *I. salina* was described from saline springs and mineral waters. We obtained mixed enrichment cultures of cyanobacteria and *Isosphaera* from a saline hot spring in Utah, U.S.A. (13% NaCl). Attempts to obtain pure cultures failed, even when the *Isosphaera* medium was supplemented with 0.2 M NaCl.

The conclusions of Geitler were later disputed by Anagnostidis and Rathsack-Kunzenbach (1967), who were familiar with *Isocystis pallida* from hot spring collections in Greece. Their extensive description and discussion indicated that *Isocystis pallida* from their cultures and *Isosphaera pallida* are the same. They detected a weak red fluorescence in their cultures, which they attributed to cyanobacterial pigments. We have been unable to confirm this fluorescence with North American collections or cultured material.

Following the first isolation, it immediately became apparent that *Isosphaera* was neither a yeast nor a cyanobacterium, but instead, an aerobic, heterotrophic bacterium. It is a salmon color in culture due to the presence of carot-

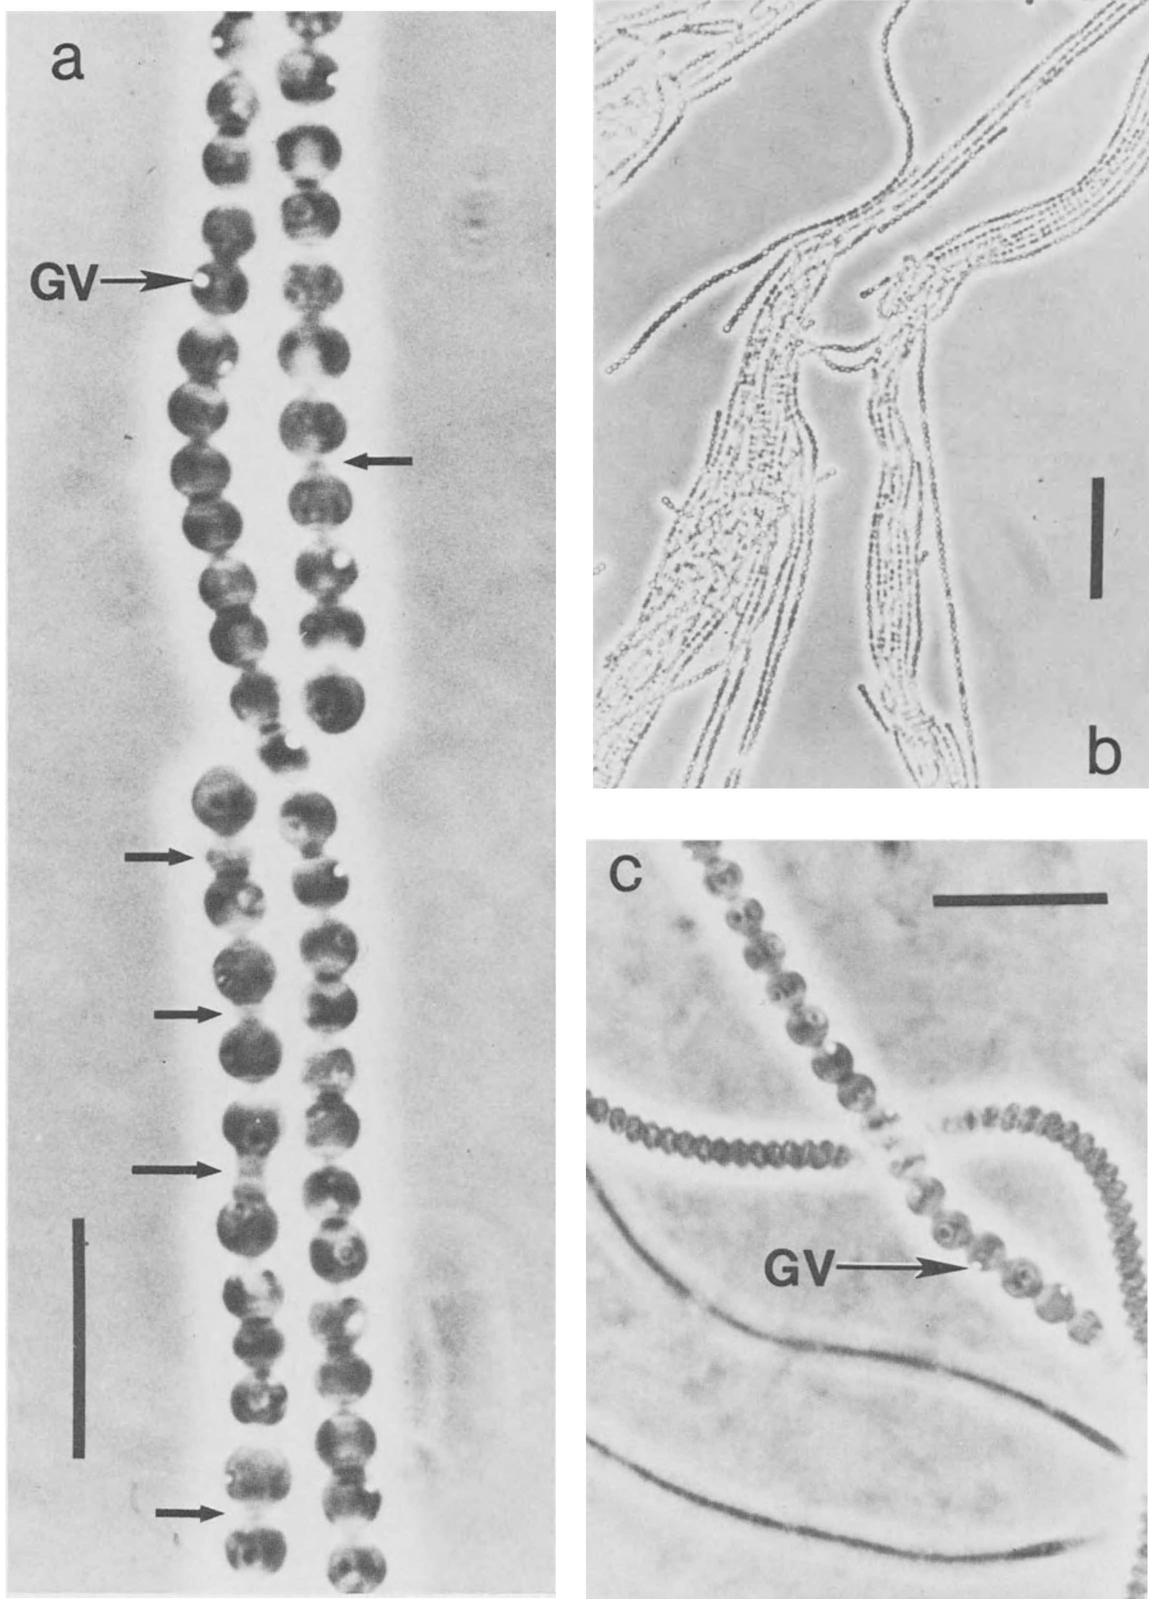

Fig. 22. Phase contrast micrographs of *Isosphaera pallida.* (a) Exponential phase culture (strain IS1). Bar = 10 μm. (b) Exponential phase culture, (strain IS1). Bar = 50 μm. (c) *Isosphaera* from a natural population, Mammoth Hot Springs, Yellowstone National Park, U.S.A., showing *Isosphaera pallida* and *Spirulina.* Bar = 10 μm. Arrows indicate buds. GV, gas vacuoles. Note that the frequency of buds in the exponentially growing culture (b) is low, suggesting that the process of bud development is relatively short compared to the cell cycle.

enoids, but absorbance spectra reveal no maxima corresponding to chlorophylls or phycobiliproteins.

Freshly isolated strains produce gas vacuoles containing gas vesicles with typical conical ultrastructure (Fig. 23). The gas vacuoles are small and usually occur singly in cells.

Colonies of *Isosphaera* are motile. Motility occurs most readily on Gelrite surfaces, though migration is observable to a lesser degree on agar, particularly if it has excess surface moisture. When suspensions of concentrated cells are dropped on plates, they form multiple aggregates of variable size (called comets). These move randomly at about an equal rate in darkness or in uniform light. In the presence of a directional light source, the aggregates are phototactic.

Ultrastructural observations have revealed that the cell surface is uniformly and densely covered with pili. However, there is no evidence for flagella. The mechanism of motility remains unknown. As with other Planctomycetes, surface crateriform structures are present. In *I. pallida* they appear to be uniformly distributed over the cell. Electron-transparent "holes" of similar size and density are found in the isolated SDS insoluble cell wall fraction.

A number of unusual cytoplasmic structures can be present (Fig. 23). Polyhedral structures, similar in appearance to carboxysomes, are often seen. However, there is no evidence for autotrophic metabolism. Also seen are paracrystalline inclusions, and "wall bodies." No functions are associated with these structures.

The first axenic cultures of *Isosphaera pallida* (strain IS1B) were obtained from hot springs located on the Warm Springs Indian Reservation, Oregon, U.S.A. Subsequently, five additional strains were isolated from hot springs in Yellowstone National Park, U.S.A., and Big Spring, Thermopolis, Wyoming, U.S.A.

I. pallida is found either as a component of microbial mats, or planktonically, in which case it may be suspended in the water column by gas vacuoles. The co-occurrence of *I. pallida* with cyanobacteria may be a coincidence. *I. pallida* is an obligate aerobe, and like cyanobacteria, requires neutral or alkaline conditions for growth.

Isolation

I. pallida can be isolated on plates of medium IM incubated in an atmosphere of 5% CO_2/95% air. Medium IM is a dilute mineral medium containing no added carbon sources, and 50 mM bicarbonate. The pH of the medium (7.9) is determined by the bicarbonate/CO_2 buffering system.

Medium IM

Solution A:

$CaCl_2 \cdot 2H_2O$	0.32 g
$MgSO_4 \cdot 7H_2O$	0.4 g
KCl	0.5 g
NaCl	1.0 g
$(NH_4)_2SO_4$	0.5 g
KH_2PO_4	0.3 g
$FeCl_3$	0.292 mg
Trace element solution SL-7[a]	10 ml
Vitamin B_{12}	5 μg
Water	1 liter

Adjust solution to pH 7.6 with NaOH, remove precipitate by filtration through Whatman No. 1 filter paper, store at 4°C.

Solution B:

$NaHCO_3$	42.0 g
Water	1 liter

Autoclave, then bubble vigorously with sterile CO_2 for 1 h.

Final medium:

Solution A	250 ml
H_2O	650 ml

After autoclaving add 100 ml sterile solution B.

[a]Pfennig and Trüper (1981).

In the dark, or in the light with 3-(3,4-dichlorophenyl)-1,1-dimethyl urea, an inhibitor of photosystem II, present, medium IM is selective for *Isosphaera.* Plates of medium IM streaked with microbial mat material from a hot spring and incubated in the dark at 45°C usually develop small (1–2 mm) colonies of *Isosphaera* after two weeks. The colonies are firm to the touch of an inoculating loop. In part, the basis for the selectivity of medium IM seems to be the absence of added carbon other than the contaminating organic compounds present in Bacto-agar. However, *Isosphaera* is not agarolytic.

Cultivation

Isosphaera can be routinely cultivated in liquid batch culture on medium IMC sparged with 5% CO_2/95% air.

Medium IMC

Medium IM containing: 0.025% D-glucose, 0.025% casamino acids, 0.5 ml/1 vitamin solution (added after autoclaving). Vitamin solution contains: nicotinic acid, 2 mg/ml; thiamine HCl, 1 mg/ml; *p*-aminobenzoic acid, 0.2 mg/ml; biotin, 0.02 mg/ml.

The minimum doubling time observed (18 hours) occurs at 42°C, but substantial growth is seen at temperatures from 37 to 55°C. A high concentration of CO_2 is probably not required for growth.

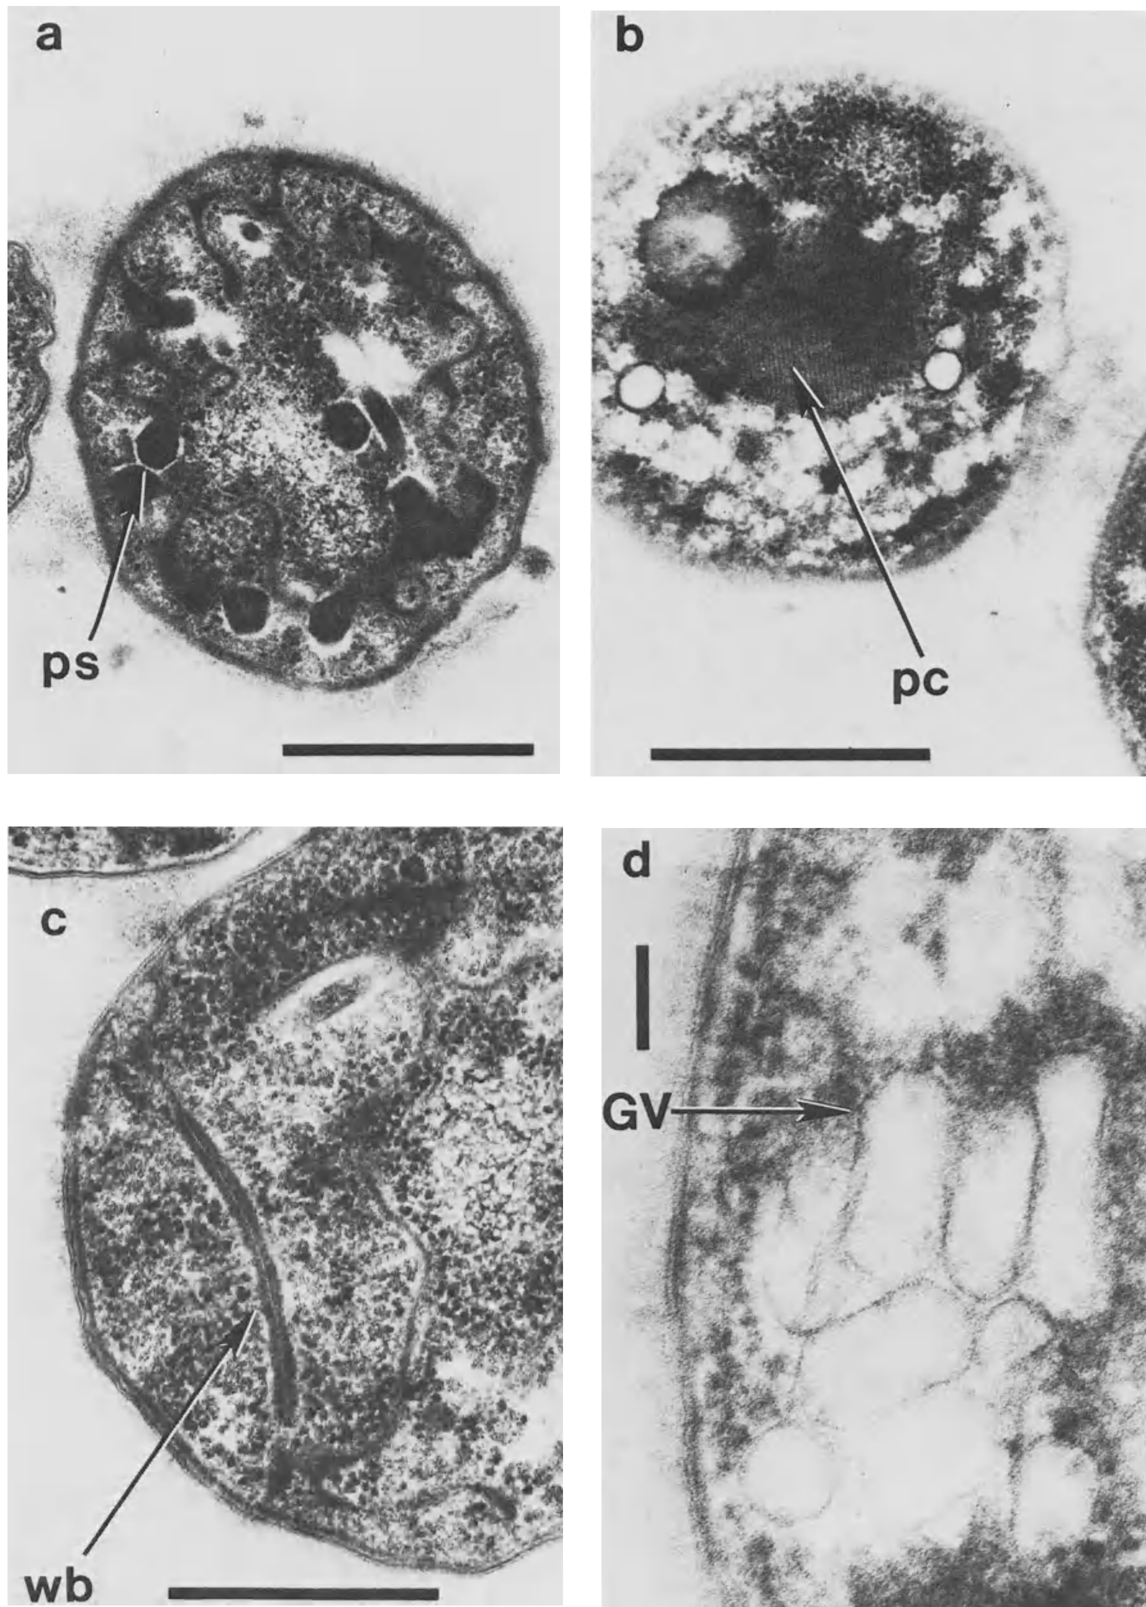

Fig. 23. Thin-sections showing cytoplasmic inclusions of *Isosphaera pallida*. (a) Polyhedral structures (ps). Bar = 1 μm. (b) Paracrystalline inclusion (pc). Bar = 1 μm. (c) Wall body (wb). Bar = 1 μm. (d) Gas vesicles (GV). Bar = 0.1 μm.

Although visible growth occurs on Bacto-agar without organic supplements, the addition of carbon sources at low concentration enhances growth on plates. Only a few compounds, including glucose, ribose, and lactate, are utilized as sole sources of carbon for growth. Growth is more robust in the presence of casamino acids, suggesting that they are assimilated, but are not utilizable as sole carbon sources. D-glucose concentrations of 0.025% are routinely employed because higher concentrations (0.05% D-glucose) inhibit growth. Ribose, which serves as a sole source of carbon for growth in three of four strains investigated, is also inhibitory at concentrations above 0.25%.

The optimal growth temperature of strain IS1B is 42°C. Growth of this strain occurs at temperatures up to 55°C, and as low as 37°C. The reports of Geitler (1955, 1963) suggest that mesophilic strains of *Isosphaera* may inhabit environments other than hot springs, but these have not yet been cultured.

Identification

Isosphaera pallida cells are spherical and typically vary in size from 2.0 to 2.5 μm, although some cells are larger in stationary phase cultures. In wild-type strains the cells are arranged in unbranched filaments of indefinite length. Repeated subcloning results in selection for short chain mutants, such as the type strain, IS1B (S. Giovannoni, unpublished observations).

CHAPTER 204

The Family Deinococcaceae

ROBERT G. E. MURRAY

The members of the family Deinococcaceae have the remarkable distinction of providing the most radiation resistant of vegetative cells. The Greek root of the generic name, *deinos,* can be translated as both wondrous and strange, which is appropriate because strains have been derived from cells surviving as much as 5 Mrad (50 kGy) of gamma radiation. Despite this strongly selective property, these organisms are not often isolated. Despite some biochemical distinctions, they are not often recognized if isolated incidentally and without knowledge of radiation resistance because of an undistinguished physiology and unreactivity on the commonly used substrates. They masquerade as simple aerobic chemoorganotrophic bacteria; yet they have unusual features, which must be recognized for determination but are not in the routine of most bacteriologists.

The original isolation of an extremely radiation resistant, Gram-positive, tetrad-forming coccus that produced pink to reddish colonies was from cans of meat subjected to supposedly sterilizing doses of radiation in the megarad range. This led to a description of *"Micrococcus radiodurans"* by Anderson et al. (1956). Their original R_1 strain remains the type strain of the species which is now known as *Deinococcus radiodurans* in the family Deinococcaceae (Brooks and Murray, 1981). A number of strains have been isolated since that time and nearly all of them have been obtained with selective assistance by treating the source sample with ultraviolet (UV) or γ-radiation at a dose (1–2 Mrad = 10–20 kGy) that allows few if any other survivors. In this way, radiation-resistant red-pigmented "micrococci" were isolated from diverse sources: Strains from haddock tissue (Davis et al., 1963) subsequently named *D. radiopugnans;* an identifiable species from "Bombay duck" (a dried fish product, *"Micrococcus radiophilus,"* Lewis, 1973) subsequently named *D. radiophilus;* and a species from the feces of *Lama glama* originally named *"M. radioproteolyticus"* (Kobatake et al., 1973) and subsequently named *D. proteolyticus* by Brooks and Murray (1981), who also assigned the new nomenclature because these organisms are not included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). Unfortunately, Brooks and Murray (1981) included *Deinococcus erythromyxa* (UWO #1045) as a *species incertae sedis* in this study. They and others (Murray and Brooks, 1986; Embley et al., 1987) have subsequently recognized that this was an error because neither the low-radiation resistance nor the chemotaxonomic characters fit either the genus or the family; this culture should be recognized as belonging to the genus *Micrococcus.*

One could argue that most of the extant strains are not "wild type" because they were radiation resistant. However, the isolates from unirradiated sources (e.g., Anderson's U_1 and the Sark strains) have shown an exactly similar extreme resistance to that of the R_1 strain of *D. radiodurans,* which shows virtually no drop in viable count at a dose less than 5 kGy, and, thereafter, a dose for 10% survival (D_{10}) of about 1.5–3 kGy. Because *D. radiodurans* is mutable, albeit with difficulty, by using nitrosoguanidine, and the radiation resistance can be lost (Moseley, 1967); because there are few places on earth with such a large flux of radiation; and because the organisms have been grown from diverse high- and low-radiation sources, we must consider the resistance is incidental to some unknown function important to these organisms. Another utilitarian property that seems to be shared in the family is an extreme capability for surviving desiccation when dried onto non-reactive surfaces (Sanders and Maxcy, 1979b). Because these organisms have been isolated from room dust and air, from textiles as well as from radiated medical instruments (Christensen and Kristensen, 1981; Kristensen and Christensen, 1981), it must be assumed that dessication resistance applies in nature.

The *Deinococcus* strains have a remarkable superficial similarity to *M. roseus* and *M. agilis,* which are red-pigmented species that also suffer from an excess of negative characters in their description but are not radiation resistant. As-

signment of these red-pigmented, Gram-positive cocci to the genus *Micrococcus* (Hill, 1959) was not maintained (Baird-Parker, 1974) because the cell wall and fatty acid composition was inconsistent with that genus. Yet, for some time, *"Micrococcus radiodurans"* was held as *incertae sedis* alongside the red micrococci.

Several biochemical and structural features shared by the species of *Deinococcus* have been identified. These included a lack of the teichoic acids usual in the walls of Gram-positive bacteria and a peptidoglycan type of L-Orn-Gly_{2-3} (Work and Griffiths, 1968; Schleifer and Kandler, 1972); cell membranes without phosphatidyl glycerol and containing phosphoglycolipids and glycolipids unlike the normal membrane phospholipids (Rebeyrotte et al., 1979; Thompson et al., 1980; Counsell and Murray, 1986); loosely bound cellular lipids that were *iso*- and straight chain saturated and mono-unsaturated fatty acids and unlike those of Gram-positive bacteria (Girard, 1971; Brooks et al., 1980; Embley et al., 1987); a complex wall profile in electron microscopy of sections, including an outer membrane (Brooks et al., 1980). These data made it evident that *D. radiodurans* and related species were distinctively different from the red micrococci (Table 1). In fact, on structural and biochemical grounds they are Gram-negative bacteria whose thick peptidoglycan layer in the complex cell wall prevents decolorization (Fig. 1).

The uniqueness of the members of the genus *Deinococcus* was further emphasized by 16S rRNA cataloging which showed (Stackebrandt and Woese, 1979; Brooks et al., 1980) that the radiation-resistant species were related but were very distant from *Micrococcus* and most other eubacterial species. Subsequent sequence analysis and comparison of 16S rRNAs has shown that *Deinococcus* species represent a lineage at least as old if not older than the rest of the 10 phylogenetic lineages of eubacteria (Woese et al., 1985; Woese, 1987). Unique signatures, formed by site-specific nucleotides in the rRNA sequence or specific oligonucleotide sequences in the catalogs, now allow the testing of putative relatives to the Deinococcaceae. A Gram-negative bacillus (Fig. 2) has been so recognized and is assigned to a new genus as *Deinobacter grandis* (Oyaizu et al., 1987). It has a cell wall profile and the biochemical features resembling those of *Deinococcus* species. This organism is as closely related to the *Deinococcus* species as they are to each other (S_{AB}, from 16S rRNA cataloging of 0.55).

The family Deinococcaceae, as now defined, appears to form a stable grouping in both phenotypic and phylogenetic terms and consists of the genera *Deinococcus* and *Deinobacter.* We must suppose that this ancient lineage of cells must have given rise to various related clones at different stages of evolution; they are not obvious and will not be easily recognized even with powerful chemotaxonomic and sequence markers. The first of these are *Thermus* species, which have been identified as distant relatives (Hensel et al., 1986; Weisburg et al., 1989) on the basis of rRNA sequence analysis (S_{AB} 0.22–0.29). They are of the same peptidoglycan and menaquinone type, but the presence of branch chain fatty acids and phosphatidyl glycerol plus its derivatives as membrane components exclude this genus from the family as now defined (Murray, 1986a).

The radiation biology of *D. radiodurans* has been studied intensively and reviewed by Moseley (1983) who, with his co-workers, has shown that this species is naturally transformable using spontaneous or chemically induced mutations (Tigari and Moseley, 1980). All the *Deinococcus* species possess their own plasmids

Table 1. Major distinctions between *Deinococcus* and *Micrococcus*.[a]

Characteristic	*Deinococcus* species	Red *Micrococcus* species
Proteolysis (casein or gelatin)	Yes, usually	No
Cell wall structure in electron micrographs of sections	Complex, layered, thick, and with outer membrane	Thick, homogeneous, and single layered
Survive high doses of UV (about 600 J/m^2) and γ- (about 10 kGy) radiation	Yes, usually	No
Di-amino acid in peptidoglycan	L-Ornithine	L-Lysine
Predominant fatty acids	Straight chain mono-unsaturated	Saturated, branched chain
Presence of phosphatidyl glycerol (PG) or di-PG among membrane phospholipids[b]	No	Yes
Possess lipoteichoic acids	No	Yes

[a]Data from Brooks et al. (1980). Adapted from Murray (1986).
[b]From Counsell and Murray (1986).

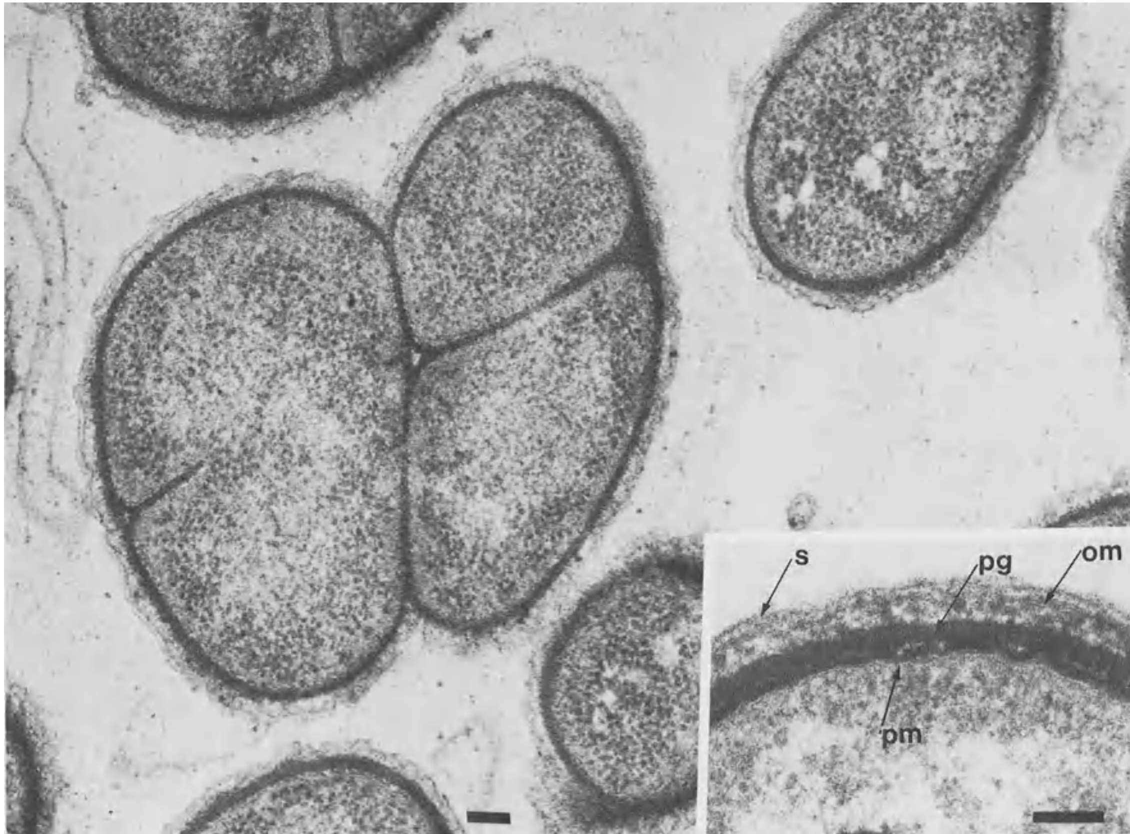

Fig. 1. Section of *D. radiodurans* with inset at high magnification, stained to show the cell wall profile and demonstrating tetrad formation. This species has a protein S-layer (S) outside of the outer membrane (OM), which is well separated from the thick peptidoglycan layer (PG) of the cell wall. The plasma membrane (PM) is heavily stained. Bars = 0.1 μm.

(Mackay et al., 1985; Smith et al., 1988) although they have seemed resistant to accepting plasmids from unrelated organisms.

Habitats

The natural habitat for these organisms is not known because all of the extant species are chemoorganotrophic, require complex media for growth, and have been isolated from a diversity of sites. Their own proteases might allow useful generation of amino acids that are certainly used as are a few sugars. It seems likely that companion microbes would be required in most habitats to process their organic requirements, which may include vitamins, hemin, and methionine, as well as ferric iron (Raj et al., 1960; Shapiro et al., 1977), among other growth factors. It is not surprising that when *Deinococcus* strains have been sought intensively they have been grown from materials, surfaces, and dust contaminated by humans and animals as well as soil, and from soil contaminated by animals, and vice versa (Krabbenhoft et al., 1965; Sanders and Maxcy, 1979a, 1979b; Kristensen and Christensen, 1981; Christensen and Kristensen, 1981; Murray, 1986b), from feces of animals (as quoted above for *D. proteolyticus* and for *D. grandis*), from meat (Grant and Patterson, 1989), and from sewage (Ito et al., 1983). As a result, these strictly aerobic organisms are likely to come from rich organic environments such as soils; a less likely permanent habitat, despite some isolations, is the anaerobic niche provided by feces or intestinal contents. From the beginning, there have been isolations from foods, especially meats at varied stages of processing or packaging, but without evidence of danger to health (Welch and Maxcy, 1979). Some opinions (Ito et al., 1983; Christensen and Kristensen, 1981) incline more to human and animal origins, but the large amount of work on medical bacteriology without recognizable isolations does not give this much support. Certainly the properties of desiccation and radiation (including UV) resistance would allow persistence in dust and lead to aerial contamination at a low

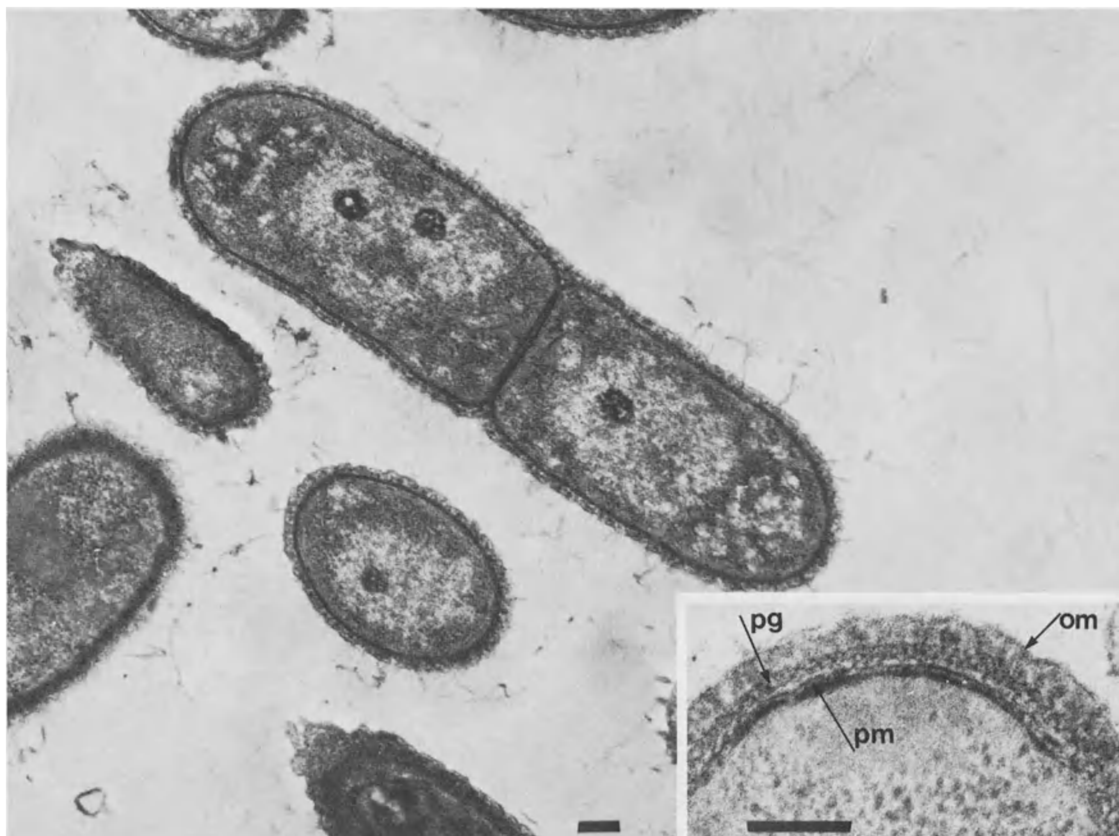

Fig. 2. Section of *Deinobacter grandis* (the fish strain) showing a divided rod and the cell wall profile (inset with abbreviations as in Fig. 1). The OM is hard but possible to resolve as a double-track, as is often the case in this family. The cells show a diffuse nucleoid and low-scattering cytoplasmic inclusions, commonly seen in other family members. The "looped" appearance of the wall is also a common feature. Bars = 0.1 μm.

level in many sites including "clean rooms" (where radiation is extensively used). Dispersal from an as yet unknown habitat subject to desiccation and worldwide distribution in small numbers by turbulence and wind could occur (Murray, 1986b), which would give wide possibilities to explore.

Certainly slower growth than other copiotrophs makes them poor competitors. Wherever they have been found, they seem to occur at low frequency. Few estimates exist of the actual proportions of these bacteria to the total population when isolated direct and without radiation selection. Christensen and Kristensen (1981) stated that the number was one in "several thousand" colony-forming units. There is also an inexplicable patchiness in isolations around positive sites (Krabbenhoft et al., 1965). This has been reinforced by recent experience (I. Masters, personal communication) with a set of isolations from wet (or very damp) soils at an English lakeside but not from nearby dry soils or from the animal excreta thereon. In one study, Ito (1977) grew *D. radiodurans* only from sawdust used for mushroom culture and *D. proteolyticus* from sewage sludges and animal feeds. It is evident that there is still a lot to learn about the biology of the family Deinococcaceae.

Despite extreme radiation resistance and isolation of organisms resembling *D. radiodurans* from shielding liquid pools for radiation sources (Kristensen, 1974), there is no evidence that a major habitat and center of distribution is in a site with a high-radiation flux.

Summary Description of the Family Deinococcaceae (Brooks and Murray, 1981, 356)

Either spherical cells dividing alternatively in two planes showing pairs and tetrads, or rods dividing in one plane to show paired cells. Nonmotile and without differentiated resting forms. Septa may be formed from two sides of the cell

and close as curtains rather than like an iris diaphragm. Gram negative in fine structure but may stain Gram positive. Cell wall profiles show a thick peptidoglycan component, an outer membrane spaced away from the peptidoglycan, and sometimes an external paracrystalline protein S-layer. Most are pigmented pink or orange red to brick red.

Aerobic, catalase positive, mesophilic, chemoorganotrophs with a respiratory metabolism. Although most strains show optimum growth rate at 25–30°C, the temperature limits for growth of some strains may be as high as 42°C and for others as low as 4°C. May require vitamins and accessory growth factors. Generally inactive toward sugars and those that are metabolized cause little if any acid production. Most strains show protease activity, utilize and may require specific amino acids.

Cellular lipids are mainly mono-unsaturated straight chain fatty acids, few with branched chains, and no hydroxy fatty acids (presumably lipopolysaccharide-less). A number of unusual polar lipids with phosphoglycolipids predominating, and absence of phosphatidyl glycerol and derivatives.

Menaquinone type is MK-8 as major and MK-7 as occasional minor component. Peptidoglycan type is L-Orn-Gly_{2-3}.

Most strains are resistant to γ-radiation, UV radiation, and desiccation.

GC content of the DNA ranges from 60–70 mol% (measured from the T_m). Ribosomal RNA signatures allow recognition of relatives.

The type genus is *Deinococcus* Brooks and Murray, 1981, 354. The other genus is *Deinobacter* Oyaizu et al. 1987, 66, which has only been distinguished from *Deinococcus* by being rod-shaped and staining Gram negative.

Isolation

Media

The majority of studies of Deinococcaceae have used either tryptone-glucose-yeast extract or peptone-yeast extract media for both isolation and maintenance. The former derives from that used by Anderson et al. (1956). Raj et al. (1960) performed early nutritional studies, which were supported by the biochemical analyses of Work and Griffiths (1968). They added methionine to their media because it was essential in a chemically defined medium but it seems to be inessential in complex media. They also observed that glucose was readily utilized. Consequently, the following is the most useful basal medium:

TGYM Medium

Tryptone	5.0 g
Yeast extract	3.0 g
Glucose	1.0 g
DL-Methionine	1.0 g
Water (15 g agar, is required	1 liter
Adjust pH to 7.0.	

This may also be used as TGY medium by omitting the methionine. For some purposes, a chemically defined medium may be useful and the simplest is that provided by Raj et al. (1960) for *D. radiodurans:*

Chemically Defined Medium

Ammonium phosphate (dibasic)		50 mg
L-Methionine		1 mg
L-Glutamic acid		50 mg
Biotin		1 μg
Pyridoxine		20 μg
Niacin		25 μg
Thiamin hydrochloride		50 μg
Glucose		500 mg
Salt solution A	0.5 ml	
KH_2PO_4	25 g	
K_2HPO_4	25 g	
Distilled water	250 ml	
Salt solution B	0.5 ml	
$MgSO_4d7H_2O$	10 g	
$FeSO_4 \cdot 7H_2O$	0.5 g	
$MnSO_4 \cdot 4H_2O$	0.5 g	
Distilled water	250 ml	

Make up to 100 ml final volume with distilled water. Adjust pH to 6.8 with NaOH.

Whether or not this defined medium is adequate for all strains or for other species in the genus is not known. A large number of other additives contribute to growth in some smaller degree and these have been assessed and listed by Shapiro et al. (1977). A minimal medium does not seem to have been sought.

For determining characters such as sugar utilization, Brooks et al. (1980) used two standard peptone-based media and obtained no acid production from glucose and sucrose, or a few weak reactions (30°C for 3 weeks) at best, except from *D. proteolyticus.* However, Ito et al. (1983) added 0.1% yeast extract to determinative peptone media and observed acid production from both glucose and sucrose by *D. radiodurans* and *D. proteolyticus* while *D. radiophilus* produced acid from glucose only.

It was evident from the work of Shapiro et al. (1977) that Fe^{3+} was essential for good growth and could be provided by ferric ammonium sulfate (about 50 mg/l). Also of interest is a definite effect of trace amounts of Mn^{2+} (10 μmol) in quenching the formation of thymine dimers, leading to some increase in radiation resistance

(Leibowitz et al., 1976). Some factor of this kind may be responsible for the observations of differences in radiation resistance according to the medium of growth (Krabbenhoft et al., 1967), which might involve differing trace metals, or an increase in resistance after an initial dose of radiation (Tan and Maxcy, 1986). We have also observed that pigmentation is increased by traces of Mn^{2+} (R. G. E. Murray, unpublished observations).

Isolation Methods

Although it is possible to occasionally isolate deinococci by direct plating, isolation is made difficult by low frequency in positive samples. The majority of isolations have taken advantage of the extreme radiation resistance by exposing natural samples, usually suspended in a small volume (2–10 ml) of water or buffer, with or without aeration, to 1–2 Mrad (10–20 kGy) in a ^{60}Co irradiation unit (e.g., Anderson et al., 1956; Kristensen and Christensen, 1981; Ito et al., 1983). At those doses almost but not all spores are killed, but, if the suspension is made in a medium allowing germination, irradiation after allowing a short period of growth reduces the number of surviving spore-formers. A high proportion of the survivors grown after such treatments appear to be deinococci. However, there are other highly radiation-resistant organisms that may be encountered, such as the *Acinetobacter* strains described along with deinococci from chickens (Thornley, 1963; Thornley and Glauert, 1968; Welch and Maxcy, 1979) and from radiation-sterilized cotton tampons (Nishimura et al., 1981).

Selective cultivation and enumeration of radiation-resistant, nonsporeforming bacteria has been attained by Dickson and Maxcy (1985) from a mixture of pasteurized soil (to provide spores) and cultured suspensions of four radiation-resistant bacteria (one of which was *D. radiodurans*) suspended in skim milk or meat serum. They got 50% to complete recovery of the nonsporeforming, radiation-resistant bacteria and little interference from surviving *Bacillus* species, using three 3 kGy doses of γ-radiation preceded and separated by 1 h incubation at 32°C.

The proportion of aerobic organisms collected by slit-sampler from clean laboratories and work areas capable of surviving a γ-radiation dose (1.8–2.4 Mrad or 18–24 kGy) sufficient to reduce the total population one millionfold was estimated by Christensen and Kristensen (1981). Some 20,000 colonies were assessed and 117 of them survived to 10^{-6} (D-6); 35 of these were sporeforming rods (D-6 = 1.8–3.2 Mrad), 50 were cocci of which 10 of the less resistant were nonpigmented (D-6 = 1.8–6.0 Mrad); 32 were nonsporeforming rods, and none were fungi. Some 60% of the strains were pigmented (yellow through orange to red) and the strains resistant to the highest radiation level were salmon pink. The majority of the very resistant cocci resembled *Deinococcus* species (a few have been characterized since then as *D. radiodurans*) and three of the very resistant rods (D-6 = 4.5 Mrad) were, in retrospect, *Deinobacter*-like. A few of the rods isolated in the above study and in a separate set of isolations from textiles and clothing (Kristensen and Christensen, 1981) were tentatively identified as *Nocardia* species. Thus, the proportion of Deinococcaceae in the total from dust populations in relatively clean work rooms, where the organisms must be already selected by desiccation and sometimes UV radiation, is small and about 0.2%.

Selection can also be attained by exposure of a sample in a thin film to UV light. This has been done with soil from an English lakeside (B. E. Moseley and I. Masters, personal communication) using the supernatant of a slurry exposed in a petri dish to 600, 900, and 1200 Jm^{-2} followed by plating 0.1 ml amounts on TGY medium; a number of strains of *Deinococcus* species were obtained.

A procedure for isolation of radiation-resistant bacteria without exposure to radiation (Sanders and Maxcy, 1979b) depends on the extreme resistance to desiccation shown by the vegetative cells of their *Moraxella-Acinetobacter* isolates and "pink micrococci" (including a test strain of *D. radiodurans*) that they studied. They dried the organisms on stainless steel plates (we have done the same on glass coverslips) and survival is almost complete for a year. After 6 years (R. B. Maxcy, personal communication), there is about 10% survival. The procedure of Sanders and Maxcy (1979b) was to suspend the organisms from the specimen in neutral phosphate buffer (they also isolated cultures from nature by shaking 1 g of cattle hair in 99 ml of buffer), storing overnight before smearing 0.01-ml samples on stainless steel plates for storage at 33% relative humidity over saturated magnesium chloride at 25°C for 14 days to 5 months. The smear was then rehydrated for plating and, after growth, radiation resistance was assessed by replica plating. It was noted that the desiccated bacteria recovered slowly, requiring 4–5 days to form visible colonies when sporeformers provide a major problem of overgrowth. A better procedure would include an appropriate growth medium for sus-

pension, a short incubation to germinate the spores, followed by desiccation.

Identification

When the isolation has been made by chance, without using radiation as a selective agent which would be likely to direct attention to this group, one or more of the other traits of the Deinococcaceae outlined above will make one suspect the diagnosis and lead to further characterization. The morphological clues are likely to come first in trying to identify large rods or cocci forming pink to red colonies. Given some degree of suspicion, a rough test for radiation resistance using ordinary eubacteria for reference is helpful (Murray and Brooks, 1986). Because the Gram reaction can be misleading, the wall profile should be defined by electron microscopy as well as the pattern of septum formation and cell division. The most useful chemotaxonomic character is the peptidoglycan type, the pattern of phosphoglycolipids, and the lack of phosphatidyl glycerol and derivatives. Finally, given a high index of suspicion, the culture could be submitted to a laboratory undertaking sequence analysis of rRNA.

THE STRUCTURE OF THE CELL WALL. Cell wall profiles observed in sections by electron microscopy (Fig. 1a, 1b, and 2) show an unusual total thickness of, perhaps, 50–60 nm. A densely staining inner layer, some 14–20 nm thick, is the peptidoglycan component, which alone forms the septa and in some species shows as a fenestrated or "holey" layer (Work and Griffiths, 1968; Fig. 3). The fenestrations are best seen when sections are stained with lead alone rather than the usual lead and uranyl acetate (Thompson and Murray, 1982) and represent areas of different reactivity. The external portion of the wall is a loose, looped, outer structure, which can be resolved with some difficulty as an outer membrane (Brooks et al., 1980; Sleytr and Glauert, 1982). *D. radiodurans* has a remarkably stable, regularly structured S-layer on the outer surface of the outer membrane that is hexagonally arrayed (Baumeister et al., 1982). Often there is relatively little stainable material visible between these major layers but the form is much the same, though the thickness varies for the strains that have been examined. The *Deinococcus* species are mostly tetrad formers, and when they divide alternately in two planes the cell wall septum for the second division usually is initiated before the first septation is complete. Most remarkable (Murray et al., 1983) is the form of the septum, which closes from opposite sides of the cell (Fig. 4a) as a pair of curtains rather than the iris-diaphragm that is usual in most bacteria. *Deinobacter,* on the other hand, has a thinner peptidoglycan layer (about 10 nm), allowing the cells to be Gram negative, and is a rod form with division in only one plane. The septum also completes as a closing pair of curtains (Fig. 4b; R. G. E. Murray, unpublished observations).

Isolation of the peptidoglycan and amino acid analysis of the peptide portion provides indication of the diamino acid and linkage structure, which is unusual enough in Gram-negatives to be helpful: L-Orn-Gly_{2-3} (Schleifer and Kandler, 1972).

Radiation resistance is such an extreme character in the case of the Deinococcaceae (Moseley, 1983) that rather simple testing procedures would be enough to be indicative and the generation of survival curves could be left to later work (Murray and Brooks, 1986). Most isolates have shown 90% survival or better at a dose of 5 kGy in a ^{60}Co-irradiator or at a dose of UV light (254 nm) of 500 Jm^{-2}. These are doses that give survivals at the level of 10^{-4}–10^{-6} or less for most other bacteria. The form of survival curves (Fig. 5) is remarkable for the extent of the shoulder (2–5 kGy of γ-radiation and 300–600 Jm^{-2} of UV radiation) and the subsequent decline in survivors (gives D_{10} values in the range of 1.0–3.5 kGy for γ-radiation and of about. 150 Jm^{-2} for UV radiation) is in sharp contrast to those of most sensitive bacteria.

Phospholipid analysis has shown that representative strains of the species of *Deinococcus* and *Deinobacter* have a most unusual diversity in the number and chromatographic behavior of the polar lipids, which are dominated by glycolipids and phosphoglycolipids (Rebeyrotte et al., 1979; Counsell and Murray, 1986; Embley et al., 1987). A negative but useful character shared by all true members of the family is the absence of phosphatidyl glycerol and diphosphatidyl glycerol or their derivatives, which, together with the complexity (8–14 spots) of the polar lipid pattern, gives a distinctive appearance in both one- (Counsell and Murray, 1986) and two-dimensional (Embley et al., 1987) thin-layer chromatograms.

Fatty acid analysis has shown (Embley et al., 1987; Oyaizu et al., 1987) that the Deinococcaceae show a remarkable range of mono-unsaturated and straight chain fatty acids as major components, few if any branched chains in minimal proportions, and they are unusual for having significant amounts of different isomers of individual fatty acids. Furthermore, both *Deinobacter grandis* (Oyaizu et al., 1987) and *Deinococcus radiodurans* (R. G. E. Murray, unpub-

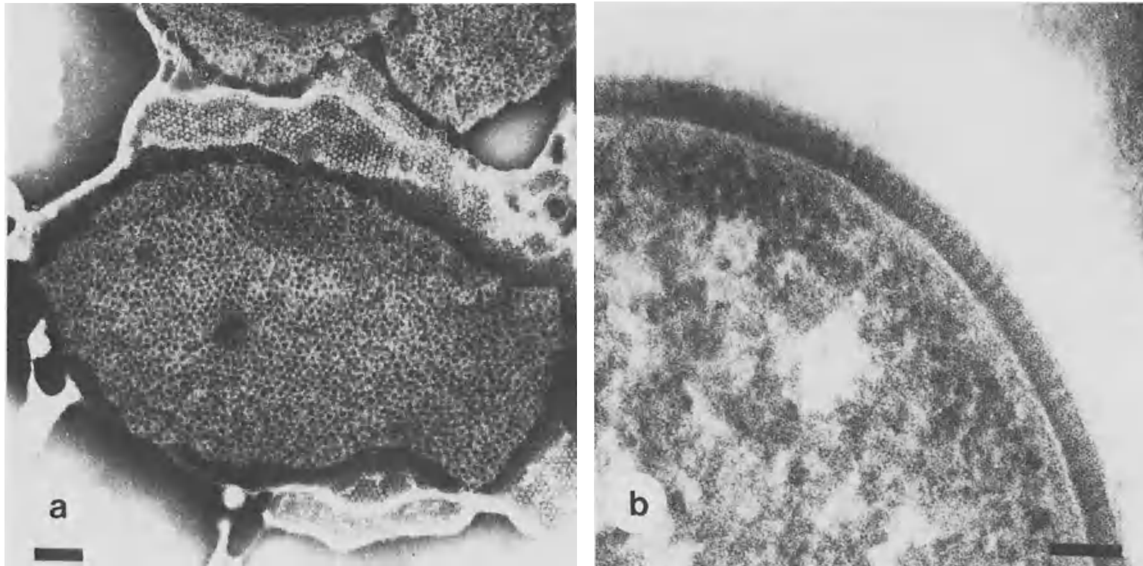

Fig. 3. (a) Negatively stained (Na phosphotungstate) fraction of cell wall of *D. radiodurans* showing a piece of the hexagonally arranged array of units in the S-layer and a piece of the peptidoglycan layer showing the appearance of fenestrations. (b) A section of *D. radiodurans* stained with lead acetate to show fenestrations in the peptidoglycan (see Thompson and Murray, 1982). Bars = 0.1 μm.

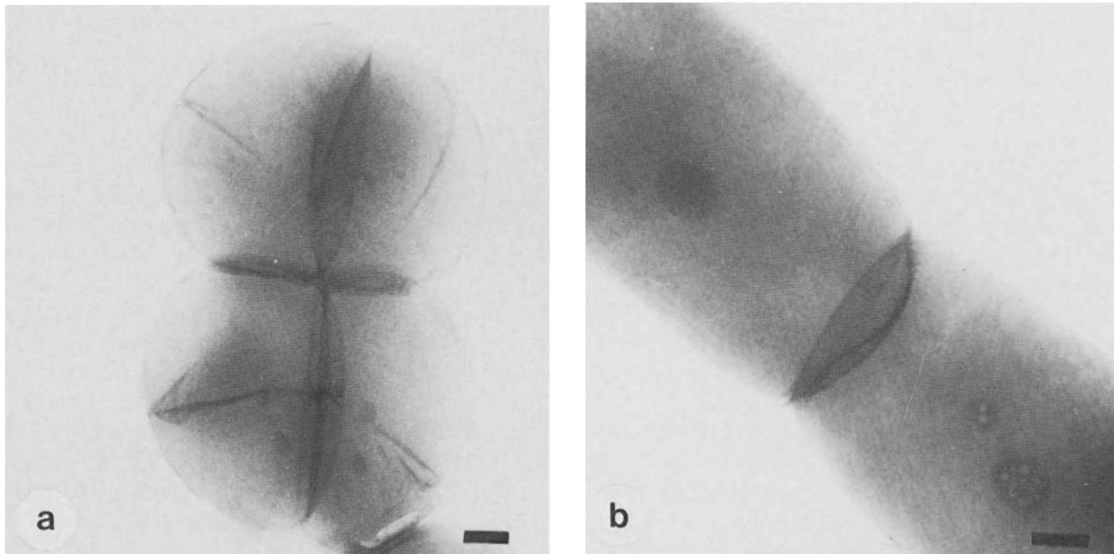

Fig. 4. (a) A dividing tetrad of *D. radiodurans* stained with uranyl acetate after blocking most staining sites with $CoCl_2$ to show the septal curtains. Bars = 0.1 μm.

lished observations) lack hydroxy fatty acids, from which we assume that these Gram-negative walls lack lipopolysaccharide.

Chemotaxonomic characters give clear direction to the definition and circumscription of the family but give rise to doubts about the validity of some strains assigned to the extant species because of heterogeneity shown by fatty acid and polar lipid analyses (Embley et al., 1987).

Nucleic acid sequence and homology analyses provide an important taxonomic resource. A strain from each of three species of *Deinococcus* (*D. radiodurans, D. radiopugnans,* and *D. radiophilus*) and one strain of *Deinobacter grandis*

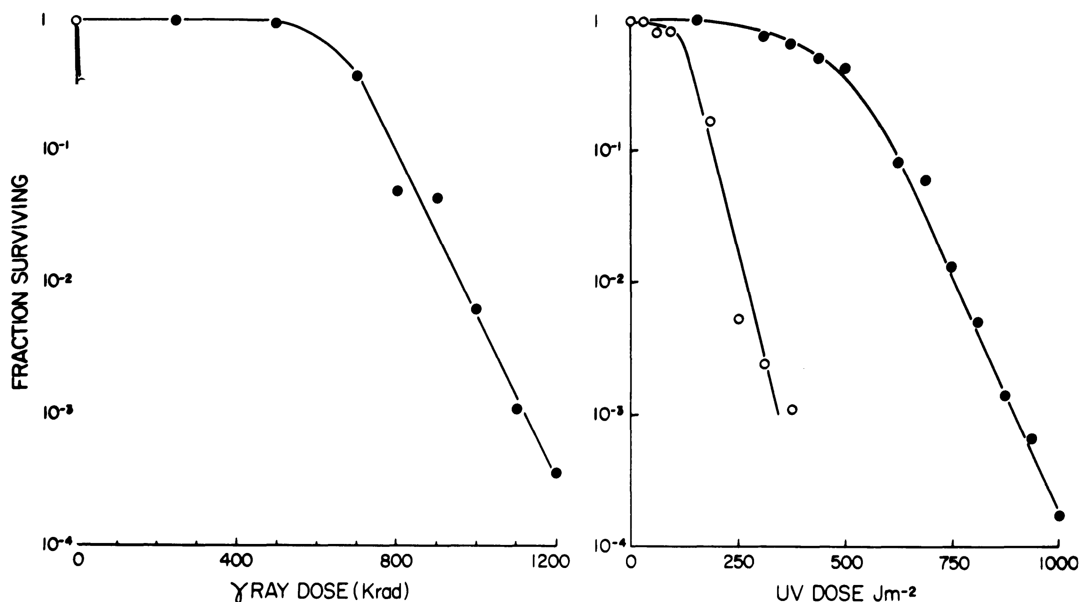

Fig. 5. Survival curves to γ- and UV radiation of *D. radiodurans* (closed circles), showing extreme resistance, and survival of a pink *Micrococcus* strain (open circles) (actually the strain misnamed *D. erythromyxa*, which does not have the chemotaxonomic characters of a *Deinococcus* sp.), showing radiation sensitivity. Note the "shoulders" demonstrating almost complete survival to a rather high dose. (Data kindly provided by Dr. B. E. B. Moseley. Note: 500 Krad = 5 kGy.)

have been compared in respect of catalogs of the 16S RNA oligonucleotides generated with T_1 ribonuclease. There is no doubt of their all being related at a S_{AB} 0.58–0.68 (Oyaizu et al., 1987) and these bacteria are related very distantly to all other eubacteria at a level of S_{AB} 0.22–0.25. Thus, the extant members appear to form a stable phylogenetic group, related to each other, and separated into the two genera by no characters of importance other than morphological division pattern. Oyaizu et al. (1987) consider that until more strains of the species of each group can be studied there is good reason to maintain the genera while recognizing a close relationship. In the meantime, RNA sequencing and the recognition of rRNA signatures (Woese et al., 1985) will remain a powerful technique for recognizing relatives, both close and distant, even in the face of having no concept of where an unknown might be classified. As already stated, this has happened in the case of *D. grandis;* this technique has also allowed recognition of *Thermus aquaticus* and *T. ruber* as distant relatives of the Deinococcaceae. (They also share high GC (59–65 mol%), L-Orn-Gly_2 peptidoglycan, but not polar lipid patterns.) Undoubtedly, other relatives at various levels will be found in the future with such powerful and directive techniques. DNA-DNA reassociation is unlikely to be helpful at the generic level, although not yet attempted between *Deinococcus* and *Deinobacter,* because the homology between the *Deinococcus* species is of a very low order (Brooks et al., 1980).

Identification of Species

There are four described species of *Deinococcus* and one of *Deinobacter.* These can be distinguished on phenotypic grounds as shown in Table 2, and we can say definitely that the type strains of each of the *Deinococcus* species show no significant DNA-DNA homology and must be considered genetically separate species (Brooks et al., 1980; Brooks and Murray, 1981). However, the reliability of characterization using a limited palette of characters may be illusory and will need more careful monitoring by analysis and comparison of the chemotaxonomic and genetic approaches. Embley et al. (1987) provide clear evidence that the representatives of *D. radiodurans, D. proteolyticus,* and *D. radiophilus* (essentially the only species in which more than two strains were available to compare) showed marked differences among the available strains in terms of principal fatty acids and the patterns of polar lipids. A strain reputedly *D. radiophilus* showed the distinctive polar lipid pattern of *D. radiopugnans.* Furthermore, Embley et al. (1987) showed that the R_1 and Sark strains of *D. radiodurans* have considerable heterogeneity in those respects, which may not be unexpected because they were also known to exhibit a 70% difference in DNA-

Table 2. Phenotypic distinctions among *Deinococcus* and *Deinobacter* species.[a]

Character	*Deinococcus*				*Deinobacter*[c]
	D. radiodurans	*D. radiophilus*	*D. proteolyticus*	*D. radiopugnans*	*D. grandis*
GC content (mol%) (T_m)	67	62	65	70	69
Cell shape	Coccal	Coccal	Coccal	Coccal	Rods
Gram reaction	+	+	+	+	−
Lysis by lysozyme[b]	−	+	−	ND	ND
Oxidase reaction	+	+	+	+	−
Fenestrated peptidoglycan in Pb-stained sections	+	−	−	+	+[d]
Growth in 5% NaCl	− (80%)	+	−	−	−
Growth in 3% NaCl media[b]	−	+	+	−	−[d]
Nitrate reduction	− (80%)	−	−	+	+
Acid from glucose in a standard peptone medium	−	−	+	−	−
Acid from glucose in medium + yeast extract[b]	+	+	+	−[d]	−[d]
Acid from sucrose in medium + yeast extract[b]	+	−	+	ND	−[d]
ONPG (β-galactosidase)	−	−	−	+	+[d]
Esculin hydrolysis	−	−	+	−	+

+, property present; −, property absent; ND, no data.

DNA reassociation (Brooks et al., 1980). Counsell (1986) has observed that the protein profiles obtained with polyacrylamide gel electrophoresis on 24 strains of *D. radiodurans* showed five or more distinct patterns. Thus, we can expect that a more definitive taxonomic study of *Deinococcus* will undoubtedly lead to further species or subspecies.

These inconsistencies underline the taxonomic hazards involved in working from small numbers of strains, with few positive determinative characters, and with no accurate estimate of the reliability of the characters in use. Difficulties arise, as shown in Table 2, from the choice of media for determining reactions to substrates. The inclusion of yeast extract makes a big difference to reactions in peptone media with sugars (Ito et al., 1983) even if slow growth can occur with utilizable sugars in peptone medium. Possibly anomalous reactions occur because of acid neutralization by-products of dissimilation of amino acids.

Toward the future

Systematic efforts to obtain more strains of *Deinococcus* and *Deinobacter* as well as to find and classify relatives that may belong outside of the present circumscription of the Deinococcaceae, will be important to future understanding. As now constituted, the family has two genera that are so alike in everything but shape and Gram reaction that they could well be fused. There should be a wider range of relatives to be found in nature, if the phylogenetic indications are not misleading, because an ancient lineage of bacteria must have spawned persistent variants during evolution. Furthermore, an expanded effort at retrieval should bring with it an understanding of habitat, which has escaped us up to now because of the diversity of sources (Table 3). To persist in nature for eons, these organisms must have a favorable habitat somewhere.

The identification of *Thermus* species as distant relatives tells us that other distant relatives may have differing selections of the chemotaxonomic characters. Their descriptions might not include radiation resistance because this is already known to be mutable, as pointed out above. Anomalous characters are already a major part of the picture when *Deinococcus* species are recognized as Gram-positive/Gram-negative bacteria; there may be more surprises involving, for instance, more unusual phospholipids (Anderson and Hansen, 1985) and exceptions to the apparent lack of phosphatidyl glycerol and derivatives.

Although these remarkably radiation-resistant bacteria have been used to assess the effectiveness of radiation sterilization, much less at-

Table 3. Sources of Cultures of Deinococcaceae.

Deinococcus species	
D. radiodurans	Irradiated canned meat, cattle hairs and skin, and creek water in Oregon (Anderson et al., 1956). Air contaminant in Canada (Murray and Robinow, 1958). House dust, used towels and underwear, from air in "clean room" laboratories in Denmark, and from radiation facilities (Christensen and Kristensen, 1981; Kristensen and Christensen, 1981). Sawdust culture media for mushrooms in Japan (Ito, 1979). From suture material in Sweden (Osterberg, 1974). Most strains were isolated after high-dose irradiation.
D. radiophilus	Irradiated "Bombay Duck" (*Harpodon nehereus*) in India (Lewis, 1973).
D. proteolyticus	Irradiated feces of *Lama glama* (Kobatake et al., 1973). Irradiated sewage sludge cake, and from animal feeds in Japan (Ito et al., 1983).
D. radiopugnans	From haddock tissue in Massachusetts (Davis et al., 1963). From weathered granite in Antarctica (Counsell and Murray, 1986).
Deinobacter grandis	From the feces of *Elephas maximus* in a zoological garden, from the intestines and skin of a fresh-water fish (*Cyprinus carpio*), and from the skin of an eel (*Anguilla japonica*) in Japan (Oyaizu et al., 1987). From a sample of pork in England (Grant and Patterson, 1988).

Adapted from Murray (1986).

tention has been paid to them as models for the understanding of the resistance mechanisms. Capability for the effective repair of damage to DNA has been assessed and some genetical studies have been accomplished (Moseley, 1983) but much less attention has been paid to the survival of structure and function of the plasma membrane of the Deinococcaceae. The possibility exists that it is not just the high concentration of carotenoids (a feature of all the radiation-resistant bacteria, like the Halobacteriaceae) that play a role, but that the unique polar lipids could also have protective properties including the regulation of ion leakage and a function as antioxidants (Anderson and Hansen, 1985).

The Deinococcaceae provide all sorts of challenges to microbiologists, radiation biologists, biochemists and, indeed, to those interested in general biology, taxonomy, and ecology. Yet, they are familiar to only a few on whom their properties of radiation resistance impinge. There is every reason to encourage a wider awareness and interest.

Acknowledgments

The author is grateful to B. W. Brooks, T. J. Counsell, P. Lancy, Jr., and B. G. Thompson, whose participation in the laboratory helped to generate understanding of this group of bacteria, and to M. Hall and D. Moyles for technical assistance and electron microscopy. Long-term discussions have been invaluable with B. E. B. Moseley concerning biological attributes and with E. Stackebrandt and C. R. Woese concerning phylogeny. The research of the author's laboratory has been supported generously by The Medical Research Council of Canada.

The Genus *Thermus* and Related Microorganisms

R. A. D. WILLIAMS and MILTON S. DA COSTA

Bacteria of the genus *Thermus* have been isolated from many natural and artificial thermal environments throughout the world. The first strains of the type species *Thermus aquaticus* were isolated from neutral and alkaline hot springs in Yellowstone National Park, USA (Brock and Freeze, 1969). Since then, strains have also been isolated from Yellowstone Park (Munster et al., 1986), and from other terrestrial hot springs in Iceland (Cometta et al., 1982b; Hudson et al., 1987a; Kristjansson and Alfredsson, 1983; Pask-Hughes and Williams, 1977), New Zealand (Hudson et al., 1986, 1987b), and Continental Portugal and the Azores Islands (Prado et al., 1988; Santos et al., 1989). In Japan, early isolates were named *"Flavobacterium thermophilum"* (Oshima and Imahori, 1971), and then renamed *"Thermus thermophilus"* (Oshima and Imahori, 1974). Other isolates have been given invalid species names (Saiki et al., 1972; Taguchi et al., 1982). In addition to terrestrial thermal environments, strains of *Thermus* have also been isolated from shallow marine thermal vents off Iceland (Kristjansson et al., 1986).

The isolation of *Thermus* strains from artificial and from natural environments was simultaneous (Brock and Freeze, 1969). They appear to be widespread in neutral, hot aqueous artificial environments, including hot tap water (Brock and Freeze, 1969; Pask-Hughes and Williams, 1975; Stramer and Starzyk, 1981), domestic and industrial hot water systems (Brock and Boylen, 1973), and thermally polluted streams (Brock and Yoder, 1971; Degryse et al., 1978; Ramaley and Bitzinger, 1975; Ramaley and Hixson, 1970). *Thermus* is not usually reported in cold water without obvious thermal inputs, but Stramer and Starzyk (1981) report a low count in rivers and lakes.

Red-pigmented strains of *Thermus ruber,* which have a temperature optimum of 60°C, have been isolated from hot springs in the Kamchatka Peninsula, USSR (Loginova and Egorova, 1975), Iceland (Sharp and Williams, 1988), the island of Sao Miguel in the Azores (R. A. D. Williams and G. Holtom, unpublished observations), and from an aerated fermenter fed with yeast wastes (Hensel et al., 1986). The taxonomic position of *Thermus* relative to other genera remains uncertain, but an oligonucleotide catalog of 16S rRNA has indicated a remote but distinct relationship between *T. aquaticus* and *T. ruber* and *Deinococcus* (Hensel et al., 1986). The sequence of 16S rRNA shows that *"T. thermophilus"* falls in the cluster of the green nonsulfur bacteria along with *Thermomicrobium roseum, Chloroflexus aurantiacus,* and *Herpetosiphon aurantiacus* (Hartmann et al., 1989).

Isolation and Preservation

Thermus Medium (Medium D for *Thermus,* Brock, 1978, 1981)

Basal salts medium D (Castenholtz, 1969) with 0.1–0.3% tryptone and 0.1% yeast extract is generally used for the culture of *Thermus* spp. The salts medium has the following composition (mg per liter of water):

Nitrilotriacetic acid (NTA)	100
$CaSO_4 \cdot 2H_2O$	60
$MgSO_4 \cdot 7H_2O$	100
NaCl	8
KNO_3	103
$NaNO_3$	689
Na_2HPO_4	111
$FeCl_3$	0.28
$MnSO_4 \cdot H_2O$	2.2
$ZnSO_4 \cdot 7H_2O$	0.5
H_3BO_3	0.5
$CuSO_4$	0.016
$Na_2MoO_4 \cdot 2H_2O$	0.025
$CoCl_2 \cdot 6H_2O$	0.046

The pH is adjusted to 8.2 with NaOH.

The salts medium is made from three stock solutions: 1) the macroelements containing NTA and the salts through Na_2HPO_4 are dissolved in water at 10× the final concentration, 2) the $FeCl_3$ is made up at 100×, and 3) the other trace salts are dissolved separately and then combined at 100× final concentration in water with 0.5 ml H_2SO_4. All three solutions can be stored at 4°C or frozen. To make the final basal salts mixture for

Thermus medium, 1/10 volume of the macroelements, 1/100 volume of the $FeCl_3$ solution, 1/100 volume of the trace salts are added to water, the pH is adjusted to 7.6, and the medium sterilized by autoclaving at 121°C for 15 min. Tryptone and yeast extract may be sterilized separately from, or together with, the basal salts medium.

Isolation Procedures

A low concentration of organic constituents in the medium and an incubation temperature of 70–75°C (to inhibit the growth of bacillus species) were stressed by Brock (1978) as important factors for the isolation of *T. aquaticus.*

Thermus strains are easily isolated by inoculating samples of water, biofilms, mats of biomass or mud into *Thermus* medium and incubating for 1–3 days at 55–65°C for *T. ruber,* or at 70–75°C for yellow to colorless strains. Sample volumes of 0.5–1.0 ml are generally sufficient, but the medium can be made up at 2× concentration to accommodate large inocula. Turbid cultures are streaked on the same medium solidified with 2–3% agar. Plates are sealed, or placed in containers to reduce evaporation, and incubated aerobically for several days at the appropriate temperature. Streaking samples directly onto solidified *Thermus* medium has also been successful (Hudson et al., 1986). Large sample volumes have been concentrated by centrifugation or membrane filtration, and then directly plated (Stramer and Starzyk, 1981). *Thermus* medium has also been used for enumerating *Thermus* cells in water specimens by the most-probable-number method (Brock and Boylen, 1973; Stramer and Starzyk, 1981).

The isolation of the red-pigmented strains at their optimum of 55–65°C often gives cultures overgrown with aerobic sporeforming bacteria. Nevertheless, red colonies can be detected on plates of solidified *Thermus* medium, and isolated by replating.

Other dilute media are sometimes used for the isolation and growth of *Thermus* strains. The basal mineral medium 162 (Degryse et al., 1978) together with 0.25% tryptone, 0.25% yeast extract, and 3% agar was used for the isolation of *Thermus* from samples concentrated by filtration (Kristjansson and Alfredsson, 1983; Kristjansson et al., 1986). Many strains will grow on 0.4% yeast extract, 0.8% polypeptone, and 0.3% NaCl (Oshima and Imahori, 1971), but this is not true of *T. aquaticus.* This medium gives a higher growth yield for strains like *"T. thermophilus"* than more dilute media.

Occasional contamination by thermophilic spore-formers (which occur in some samples of media components) can be overcome by increasing the autoclaving time, or using 131°C. A combination of 0.015% sodium azide and 0.01% lysozyme in *Thermus* agar suppresses the growth of many strains of *B. stearothermophilus,* with little effect on *Thermus* strains (N. D. H. Raven and R. A. D. Williams, unpublished observations). Others have found their strains to grow poorly on such plates, and have instead used gramicidin D at 20μg/ml in plates to suppress sporeformers (H. Nagayama, personal communication).

Preservation of Strains

Most strains of *Thermus* can be stored frozen in *Thermus* medium containing 10–15% glycerol at −80°C, or in liquid nitrogen, for years without loss of viability. Lyophilized strains in *Thermus* medium have been maintained in freeze-dried ampules for 18 years. Strains grown densely on plates of *Thermus* medium survive for about 1 month at 4°C.

Ecology

The original isolations of *T. aquaticus* were from water and algal mats of alkaline hot springs in Yellowstone Park at temperatures of 53–86°C, and pH values between 8 and 9 (Brock and Freeze, 1969). In the same area, 65 sites with temperatures of 30–90°C and pH values from 1.2–10.5 were sampled for strains of *Thermus* (Munster et al., 1986). Isolates were only obtained from sources between 55 and 80°C and pH 6.0–10.5. In Iceland, 55 hot springs from 32–90°C, and pH from 2.1–10.1 were sampled (Kristjansson and Alfredsson, 1983), and *Thermus* spp. were isolated from sites with temperatures ranging from 55–85°C and pH values higher than 6.5. The occasional isolation of strains from a site at 95°C, was felt to be due to transient bacteria washed in from cooler algal mats. Although the temperatures of thermal springs can be quite stable, the effect of rain or snow may be drastic in shallow exposed channels. In Iceland, we have noted that the temperature in shallow pools may drop by as much as 20°C during strong gusts of wind. Such effects may lead to the isolation of *Thermus* from sites with temperatures at which the bacteria cannot grow.

In New Zealand, *Thermus* strains have been isolated from thermal sites as acidic as pH 3.9 (Hudson et al., 1986), but these cells may have originated from more alkaline regions.

Thermus-like strains from shallow submarine hot springs off Iceland (Kristjansson et al., 1986) were generally more halotolerant than

their terrestrial counterparts, but otherwise were similar. The sites yielding these marine isolates contained thin sediment layers where fresh thermal water was mixed with cold sea water. When isolations from the same sites were performed in media with 2–3% NaCl, *Thermus* strains were inhibited and replaced by red-pigmented isolates, later named *Rhodothermus marinus* (Alfredsson et al., 1988). The relationship of this genus to *Thermus* remains to be determined.

The bacteria of the genus *Thermus* are obligate heterotrophs and grow on small amounts of organic materials in the water or derived from photosynthetic or chemolithotrophic organisms growing in biomass accumulations with *Thermus* strains. More studies are needed to clarify the sources of nutrients in natural environments, as well as their uptake and utilization.

Properties of Strains

Morphology and Cellular Composition

The bacteria of the genus *Thermus* stain as Gram negative despite their phylogenetic relationship to the Gram-positive genus *Deinococcus* (Hensel et al., 1986).

Upon initial isolation, many strains form long filaments, but after repeated transfers in laboratory media, most grow as pleomorphic rod-shaped cells and short filaments (Brock, 1978).

Electron microscopy demonstrates that the cell envelope is composed of a thin dense layer, presumably representing the peptidoglycan, surrounded by a highly corrugated outer layer which is closely connected to the peptidoglycan layer only at the indentations (Brock and Edwards, 1970; Hensel et al., 1986; Pask-Hughes and Williams, 1978; Williams, 1975). Unusual morphological structures, such as "rotund bodies" are sometimes seen (Brock and Freeze, 1969; Golovacheva, 1977), and these appear to be of two types. The "aggregation" type of structure consists of several cells bound together by the external layer of the cell envelope. This layer encloses several cells and a large intercellular space (Brock and Edwards, 1970; Kraepelin and Gravenstein, 1980; Becker and Starzyk, 1984). A "vesicular" type of rotund body is seen as developing from an extended bleb on the surface of a single cell (Kraepelin and Gravenstein, 1980). In contrast to other strains, *Thermus filiformis* has a stable filamentous morphology and does not form rod-shaped cells in culture. It possesses an extra coat surrounding the corrugated layer, which runs uninterrupted over zones of septum formation (Hudson et al., 1987b).

All strains examined have peptidoglycan containing ornithine (Pask-Hughes and Williams, 1978; Merkel et al., 1978), a relatively rare peptidoglycan type not found in other Gram-negative bacteria, but which is present in bacteria of the Gram-positive genus *Deinococcus* that are remotely related by 16S rRNA to *Thermus* (Hensel et al., 1986). Ketodeoxyoctulosonate and heptose were not detected in preparations from *Thermus* made by methods for the isolation of lipopolysaccharide (Pask-Hughes and Williams, 1978). A major component of the cell wall of *"T. thermophilus"* HB-8 has been shown to be a calcium-protein complex (Berenguer et al., 1988).

Most strains, including *T. filiformis,* have yellow, orange, or red carotenoids, but some strains are colorless. The isolates from natural habitats exposed to sunlight are generally pigmented, while those from artificial thermal environments lacking illumination are frequently nonpigmented. Only 13% of the *Thermus* strains isolated by Brock and Boylen (1973) and 30% of the strains isolated by Stramer and Starzyk (1981) from domestic and commercial hot-water tanks were colored. Pigmentation, at least in some strains, may be an unstable characteristic. Cometta et al. (1982a) reported the frequent isolation of colorless mutants from *T. aquaticus* YT-1 grown in continuous culture. By contrast, the pigment of strain YS-45 varied directly with the degree of illumination in chemostat cultures (Cossar and R. J. Sharp, unpublished observations), but was never completely lost, and colorless mutants were not detected.

Menaquinone 8 (MK-8) is the predominant quinone detected in all *Thermus* strains examined (Collins and Jones, 1981; Hensel et al., 1986; Williams, 1989), together with minor quantities of MK-7 and MK-9.

The polar fraction of the lipids of several yellow-pigmented and colorless strains comprise a major glycolipid which is a diglycosyl-(*N*-acylglycosaminyl)-glucosyl-diacylglycerol in which the hexose and hexosamine vary from strain to strain (Oshima, 1978; Pask-Hughes and Shaw, 1982; Prado et al., 1988), and a major phospholipid that contains glucosamine. Branched fatty acyl chains (*iso*-C15 and *iso*-C17) comprise the major aliphatic moieties of the polar lipids of *Thermus* spp. (Hensel et al., 1986; Oshima, 1978; Pask-Hughes and Shaw, 1982; Prado et al., 1988).

Physiology and Metabolism

The yellow and nonpigmented strains have an optimum growth temperature, in *Thermus* medium, of 70–75°C. The minimum is about 37–45°C and the maximum about 79°C, although a few strains (such as *"T. thermophilus"* HB-8) grow at temperatures up to about 85°C. The red-pigmented strains related to *T. ruber* have lower growth temperatures with optimum about 60°C, minimum between 35–40°C and maximum close to 70°C (Loginova et al., 1984; Sharp and Williams, 1988). The pH optimum for high-temperature *Thermus* strains is between 7.5 and 8.0, but some strains will grow at pH 5.1 and many grow at pH 9.5 (Hudson et al., 1986, 1987a; Munster et al., 1986).

Metabolic studies of *T. aquaticus* YT1 and four Icelandic strains indicate a complete tricarboxylic acid cycle, together with isocitrate lyase and malate synthase, providing a glyoxylate bypass as well (Pask-Hughes and Williams, 1977). Similar results were reported for the Belgian isolate Z05 (Degryse and Glansdorff, 1976). All of the enzymes of glycolysis have not been systematically measured, but a significant number have been purified and characterized, albeit from several strains, and it seems safe to assume that the Embden-Meyerhof pathway is present. The electron transport chain of *"T. thermophilus"* comprises NADH dehydrogenase, menaquinone, and cytochromes *b, c,* aa_3 and *o* (McKay et al., 1982). These authors found the molar growth yield for glucose to be low relative to comparable mesophiles, and suggest that this is due to a high permeability of the membrane to protons.

Strains of the genus *Thermus* utilize carbohydrates, amino acids, carboxylic acids, peptides, and several other proteinaceous substrates for growth. Most studies have found a nutritional diversity among *Thermus* strains (Alfredsson et al., 1985; Pask-Hughes and Williams, 1977; Santos et al., 1989) which have been reported to correlate with the geographical source of the isolates (Hudson et al., 1989). However, strains with different physiological properties, which have been shown to be different genospecies, coexist in geothermal areas in the USA (Munster et al., 1986) and Europe (Santos et al., 1989). Studies that have involved similar media and test conditions are in broad agreement about the properties of key strains. Where significant discrepancies with particular tests have been found, this may be due to the use of different test procedures. *Thermus* strains may be inhibited by even low concentrations of organic substrates. For this reason, single carbon source utilization is tested with 2–4 g/l of the substrate. Incomplete substrate utilization and growth inhibition have been reported for a number of strains, but no explanation for this phenomenon has been proposed (Sonnleitner et al., 1982).

Many "high-temperature" strains use acetate, pyruvate, proline, and glutamate (Alfredsson et al., 1985; Hudson et al., 1989), while the red-pigmented strains are generally unable to grow on acetate and pyruvate (Sharp and Williams, 1988). On the other hand, polyols are used by many red-pigmented strains but serve as single carbon sources for a minority of the high-temperature strains.

Several monosaccharides are used as single carbon sources by strains of *Thermus,* but pentoses are not usually metabolized at all (Alfredsson et al., 1985; Hudson et al., 1986, 1987a; Munster et al., 1986). Disaccharides, but not necessarily their constituent monosaccharides, may be used. Thus, most strains from Iceland used sucrose and maltose, while only two used glucose and none grew on fructose (Alfredsson et al., 1985).

Proteins such as elastin, fibrin, and casein are hydrolyzed by many isolates, but some strains are incapable of hydrolyzing each substrate (Munster et al., 1986; Hudson et al., 1989; Santos et al, 1989).

Several strains will grow in basal salts medium with ammonium as nitrogen source and an appropriate carbon source. Many strains, nevertheless, require vitamins for growth on minimal medium with single carbon sources (Alfredsson et al., 1985; Sharp and Williams, 1988). Nitrate is not reduced by *T. aquaticus, T. filiformis,* nor most of the red-pigmented strains examined, but serves as a terminal electron acceptor for many high-temperature strains, several of which also reduce nitrite (Brock, 1978; Munster et al., 1986; Hudson et al., 1987b). Moreover, many high-temperature strains grow anaerobically in the presence, but not in the absence, of nitrate. No *Thermus* strain has been shown to be capable of fermentation.

Identification

Most high-temperature strains form yellow or pale to colorless colonies. The low-temperature strains related to *T. ruber* are red pigmented. All strains are Gram negative, and with the exception of *T. filiformis,* form pleomorphic rod-shaped cells and short filaments. "Rotund bodies" present in liquid cultures can be seen by phase-contrast microscopy.

All strains are cytochrome oxidase-positive, nonmotile in liquid cultures, and do not form flagellae. Endospores are not seen in cultures on any medium, including starch agar. Sensitivity to β-lactam antibiotics is reported for all strains of this genus.

The presence of MK-8 as the predominant quinone (Collins and Jones, 1981) and ornithine-containing peptidoglycan are diagnostic characteristics of the members of the genus *Thermus* examined to date (Pask-Hughes and Williams, 1978; Hensel et al., 1986; Sharp and Williams, 1988). The presence of predominantly iso- and anteiso branched fatty acids can be used as a confirmatory characteristic (Hensel et al., 1986; Pask-Hughes and Shaw, 1982, Prado et al., 1988). The mean GC content of the DNA of the strains examined varies between is 57–65 mol%, but analyses of most strains give results above 60 mol%.

Three species of the genus *Thermus* are validly described at present, and there appear to be at least four others that should be recognized (Table 1).

1. *T. aquaticus,* the type species of the genus, has been shown by DNA homology (Williams, 1989) to have a number of representatives (which come from the same site as the type strain) among the numerical taxonomy groups 1a and 1b of Munster et al. (1986). The numerical taxonomy study of Hudson et al. (1989) also shows the type strain YT1 clustered with other Yellowstone isolates.
2. *T. ruber* strains, which are easily distinguished by their red pigment and lower growth temperature optimum, have been isolated from worldwide sources. The DNA-DNA homology is high within the species, but low with yellow and colorless strains (Sharp and Williams, 1988).
3. *T. filiformis,* apparently a single strain which has a stable filamentous morphology and an extra outer cell wall layer. There seem to be no other characteristics that distinguish it clearly from other yellow strains.
4. *"T. thermophilus"* was validly described (Oshima and Imahori, 1974), but subsequently not included in the *Approved Lists of Bacterial Species* (Skerman et al., 1980). The type strain HB8 has a high DNA-DNA homology with *"T. flavus"* AT-62, *"T. caldophilus"* GK24, and *Thermus* strain B (Wil-

liams, 1989) and there is no doubt that *"T. thermophilus"* comprises a distinct genospecies.

5. A taxon tentatively named *"T. brockii"* was identified by DNA-DNA homology (Williams, 1989) among strains of numerical taxonomy cluster 2 of Munster et al. (1986). Phenotypic characters that allow it to be distinguished from *T. aquaticus* are: the former produces pale-yellow spreading colonies on *Thermus* agar, and commonly grows on fructose and galactose, while the latter forms deep-yellow nonspreading colonies and generally degrades starch, gelatin, and casein. The name *"T. brockianus"* seems likely to be preferred for this taxon, to avoid confusion with *Thermoanaerobium brockii* (Zeikus et al., 1979).
6. A genospecies detected by DNA-DNA homology (Williams, 1989) corresponds to the numerical taxonomy clusters A,B,C, and D of Santos et al. (1989).
7. A genospecies detected by DNA-DNA homology (Williams, 1989) corresponds to the numerical taxonomy clusters E and F of Santos et al. (1989).

Biotechnological Applications of *Thermus*

Restriction and Modification Enzymes

Strains of the genus *Thermus* are sources of several restriction endonucleases that are both thermostable and active at higher temperatures than most other such enzymes (Table 2). Some are isoschizomers, or at least have the same recognition sequences as known enzymes from other microorganisms (Roberts, 1989). Others are important because they are unique in hydrolyzing certain sequences; in particular Taq I is widely used in molecular biology. The corresponding modification enzyme, M.Taq I, which methylates the A residue in the Taq I recognition sequence, has found a minor use in producing large DNA fragments. This depends on the fact that Dpn I will only cut a sequence derived from two adjacent Taq I sites in which both A residues are methylated (McClelland et al., 1984).

DNA Polymerase

The DNA-dependent DNA polymerase of *T. aquaticus* YT1 has optimal activity at 80°C (Chien et al., 1976; Kaledin et al., 1986). It lacks a proofreading 3′to 5′ exonuclease activity and produces base substitution errors at a frequency of 1:9000 (Tindall and Kunkel, 1988). The amplification of selected segments of DNA by the polymerase chain reaction (PCR) involves repeated cycles of: 1) priming with pairs of synthetic oligonucleotides; 2) DNA synthesis; and 3) heat-denaturation to allow the next priming. Originally conceived utilizing thermolabile DNA polymerase (Saiki et al., 1985), the PCR technique has been greatly improved by the use of the *T. aquaticus* enzyme, which survives the heat-denaturation step, and therefore does not need replenishing at each cycle (Saiki et al., 1988). The error rate is not a problem as misincorporated bases are randomly distributed throughout the sequences, and form a fraction of a percent at any one site. Single-stranded DNA can be produced by modification of PCR (asymmetric PCR) and used directly for sequence determination (Gyllensten and Ehrlich, 1988). The *T. aquaticus* DNA polymerase has also been used for the sequencing reactions at 70°C and produced electrophoretic ladders with uniform bands of more than 1000 bases per gel (Innis et al., 1988).

Proteinases

Caldolysin, a neutral serine proteinase from New Zealand isolate T351 (Cowan and Daniel, 1982a; Cowan et al., 1987) which is calcium dependent (Khoo et al., 1984) has been immobilized for use in continuous-flow proteolysis (Cowan and Daniel, 1982b). This enzyme, together with a proteinase from an unidentified strain of *Thermus,* were as thermostable as the bacillus proteinase thermolysin, but less resistant to organic solvents (Owusu and Cowan, 1989). A thermophilic alkaline proteinase (aqualysin I) was isolated from strain YT1 (Matsuzawa et al., 1983). The sequence of amino acids deduced from the DNA sequence of the cloned gene (Kwon et al., 1988) showed a high homology to proteinase K and the subtilisins. Aminopeptidase T, which requires cobalt II ions for activity, has also been purified from strain YT1 (Minagawa et al., 1988). It is optimally active at 75–80°C, is of low specificity, and is more thermostable than the *B. stearothermophilus* aminopeptidase. The amino terminal sequence indicates that it is structurally unlike other proteinases discovered to date.

Carbohydrases

Thermus strain YT1 (Ulrich et al., 1972) and New Zealand isolate 4–1A (Cowan et al., 1984) have been used as sources of β-galactosidase. Both enzymes are thiol dependent and have narrow pH optima at 5.0 (YT1) and 6.0 (4–1A), but were different in molecular weights and metal ion activation. The enzyme from strain 4–1A was immobilized, but its value in lactose processing is likely to be limited by its susceptibility to product inhibition.

Thermus strain Z1 produces a thermostable β-glucosidase (Takase and Horikoshi, 1988, 1989), which also has activity against other β-glycosides including β-galactosides. This enzyme has a broad pH optimum from 4.5–6.5 and is also stable within this range. Its optimum activity is above 80°C, but it is more stable at 70–75°C. The ability to hydrolyze cellobiose to completion may render this enzyme useful for cellulose degradation in conjunction with cellulases that are inhibited by cellobiose.

Pullulanase, which hydrolyzes α1:6 links in starch, has been purified from *T. aquaticus* YT1 (Plant et al., 1986). The enzyme has a broad pH profile and a high thermal stability suitable for the debranching process in the saccharification of starch. Strain AMD33 also produces pullulanase which is both activated and stabilized by calcium ions, and also has α-amylase activity (Nakamura et al., 1989). It has been cloned and expressed in *Escherichia coli* (Sashihara et al., 1988) with a view to use in starch processing. Strain AMD33 was described as *Thermus,* and has ornithine in its peptidoglycan, but has a GC content of only 55 mol% and a growth optimum of 65°C. Its taxonomic position is yet to be determined.

CHAPTER 206

The Family Chloroflexaceae

BEVERLY K. PIERSON and RICHARD W. CASTENHOLZ

The discovery of the photosynthetic flexibacteria was made by Pierson and Castenholz (1971), and *Chloroflexus aurantiacus* was the first genus and species described (Pierson and Castenholz, 1974a). The Chloroflexaceae was proposed as a family (Trüper, 1976) with affinities to the Chlorobiaceae. The similarities with the green sulfur bacteria were signified by grouping both families under the suborder Chlorobiineae. The family was defined as follows: filamentous, phototrophic bacteria with gliding motility, Gram-negative, flexible cell walls, and bacteriochlorophyll (bchl) *a* and bchl *c, d,* or *e.* Included in the family were two other genera, "Oscillochloris" and *Chloronema.*

Chloroflexus aurantiacus (Pierson and Castenholz, 1974a) is still the only genus and species of the Chloroflexaceae that has been described on the basis of axenic cultures. It is also the only organism for which 16S rRNA data are available. *Chloronema* (Dubinina and Gorlenko, 1975) and "Oscillochloris" (Gorlenko and Pivovarova, 1977) are two genera described and assigned to the Chloroflexaceae, but neither description is based on cultured material, and no molecular phylogenetic data are available for either of these genera.

Phylogenetic analysis from 16S rRNA oligonucleotide catalogs and complete sequence data reveal that *Chloroflexus aurantiacus* forms a very deep division within the eubacteria (Oyaizu et al., 1987; Woese, 1987), being grouped with the nonphototrophic gliding filamentous flexibacterium *Herpetosiphon aurantiacus.* Also in this group, but more distantly related, is *Thermomicrobium roseum.* Another thermophile, *Thermus thermophilus,* appears to branch off the same early line of descent (Hartmann et al., 1989). *Chloroflexus* is not closely related to the other phototrophic prokaryotes, including those of the Chlorobiaceae, and forms the deepest division of all the phototrophs in the eubacterial line of descent.

Heliothrix oregonensis has been described on the basis of co-cultures with the nonphototrophic bacterium *Isosphaera pallida* (see Chapter 203) and on the basis of studies with natural populations in the field (Pierson et al., 1984; 1985). Isolation in pure culture has not been achieved and 16S rRNA data are lacking. *Heliothrix oregonensis* is phylogenetically close to *Chloroflexus aurantiacus,* based on 5S rRNA analysis (Pierson et al., 1985), although the description of the family Chloroflexaceae excludes it.

All four of these filamentous phototrophs (*Chloroflexus,* "Oscillochloris," *Chloronema,* and *Heliothrix*) are now included in the grouping called the "multicellular filamentous green bacteria" (Pfennig, 1989). Although *Chloroflexus, Chloronema,* and "Oscillochloris" all have in common the housing of accessory chlorophylls (bchl *c* or *d*) in chlorosomes adjacent to the cell membrane (hence the term "green bacteria"), *Heliothrix* lacks accessory chlorophylls and chlorosomes. Since on the basis of 5S rRNA analysis, *Heliothrix oregonensis* is more closely related to *C. aurantiacus* than to any other phototrophs (Pierson et al., 1985), a new grouping of the filamentous phototrophs may well be in order (Castenholz and Pierson, 1989).

Other filamentous phototrophs not yet in culture but with possible affinities to these organisms will also be described in this chapter. At this time we prefer to consider all the filamentous phototrophic bacteria containing bchl *a* in one category as the phototrophic flexibacteria. Within this group, which may or may not be phylogenetically coherent, we recognize the filamentous green bacteria including *Chloroflexus, Chloronema,* and "Oscillochloris," which contain chlorosomes and accessory bacteriochlorophylls. Also included are the filamentous bacteria lacking chlorosomes and containing bchl *a* only: *Heliothrix* and two other unnamed organisms described below.

Several marine strains of *Chloroflexus*-like organisms have also been observed, but none has been isolated in axenic culture. These will also be briefly discussed in this chapter.

Two other filamentous gliding phototrophs containing bchl *a* and lacking chlorosomes and bchl *c, d,* and *e* have been described. Neither has been isolated in pure culture, and their descriptions here will be brief. Castenholz (1984) first described a red filamentous organism containing bchl *a* from a thermal mat environment in Yellowstone National Park. D'Amelio et al. (1987) reported filamentous "purple" bacteria containing bchl *a* in hypersaline cyanobacterial mats. The two organisms are ultrastructurally identical (D'Amelio et al., 1987; S. Boomer and B. Pierson, unpublished observations). Both contain bchl *a* only and an elaborate system of stacked internal membranes similar in appearance to those of *Ectothiorhodospira* (see Chapter 171). Relatively little is known of the physiology of the hypersaline organism but the thermal strain bears some striking similarities to *Heliothrix oregonensis* (B. Pierson and R. W. Castenholz, unpublished observations).

Habitats

The anoxygenic filamentous phototrophs are found in a wide range of habitats.

Chloroflexus aurantiacus

Chloroflexus aurantiacus was found originally only in hot springs. All isolates were thermophiles capable of growth in the laboratory from an upper temperature limit of 70°C to a lower temperature limit of 30–35°C (optimum, 52–60°C). *Chloroflexus* forms mixed populations with cyanobacteria in "alkaline" hot springs and warm waters with a pH from 5.5 to 10. These populations are found up to temperatures as high as 70–72°C in hot springs of North America. *Chloroflexus* commonly forms a distinct orange mat of filaments below a thin top layer of cyanobacteria. This structure is found over the temperature range from 35°C to about 68°C (Castenholz, 1973a; Doemel and Brock, 1977; Ward et al., 1989). In these associations with cyanobacteria, it appears that the cyanobacteria provide organic carbon that sustains photoheterotrophic and chemoheterotrophic growth of *Chloroflexus* (Bauld and Brock, 1974; Brock, 1978; Castenholz, 1984; Ward et al., 1984; Bateson and Ward, 1988). In the complex habitat of the mat, however, some of the organic carbon used by *Chloroflexus* appears to come from fermentation products produced in the mat (Anderson et al., 1987).

In this type of mat environment, *Chloroflexus* is subject to major diel fluctuations in pH and oxygen levels in response to the oxygenic photosynthetic activity of the overlying cyanobacteria (Revsbech and Ward, 1984). In these mats with very low sulfide levels, it is doubtful that *Chloroflexus* is growing autotrophically to any great extent. The most likely forms of metabolism for *Chloroflexus* in this habitat are aerobic and anaerobic photoheterotrophy and both aerobic and anaerobic chemoheterotrophy. *Chloroflexus* can probably switch among these modes with the fluctuating environmental conditions.

In hot springs with a significant source of primary reduced sulfur (H_2S, HS^-, S^{2-}), *Chloroflexus* often forms mats (green or orange) independent of cyanobacteria (Castenholz, 1973b; Giovannoni et al., 1987). In this situation, *Chloroflexus* is apparently growing photoautotrophically with sulfide as the electron donor. In situ studies in several springs in the Mammoth Group in Yellowstone National Park revealed a dark green mat of nearly pure *Chloroflexus* totally devoid of cyanobacteria and oxygen. At temperatures above 50°C in these springs, cyanobacteria do not grow due to the presence of sulfide (Castenholz, 1988b) so that pure mats of *Chloroflexus* develop from about 50 to 66°C when primary sulfide is available. In situ studies revealed that under these conditions, *Chloroflexus* strains ("green *Chloroflexus*" or GCF strains) were primary producers of organic carbon, performing sulfide-dependent photoautotrophy (Giovannoni et al., 1987). The strains of *Chloroflexus* isolated from this habitat are obligate anaerobes, lacking the ability to grow aerobically by chemoheterotrophy. Thus they are not identical to other *Chloroflexus aurantiacus* strains. In culture they grow best as photoheterotrophs and not autotrophs. Exposure to atmospheric levels of O_2 inhibits growth completely in darkness, but not irreversibly. Even after 72 hours of aerobic exposure in darkness, surviving cells resume growth rapidly when shifted to anaerobic growth conditions in the light. In the light, exposure to O_2 results in an intensity-dependent loss of bchl *c* but an increase in content of carotenoid pigments. Although potentially most active as a photoheterotroph, "green *Chloroflexus*" shows a greater degree of sulfide-stimulated photoautotrophy than do previously characterized strains of *C. aurantiacus* (Giovannoni et al., 1987).

In other sulfide-containing thermal habitats, *Chloroflexus* may be found growing independently of cyanobacteria at higher temperatures upstream from the cyanobacteria (Castenholz, 1973b). In flowing streams such as these, the *Chlorofexus* mats are usually orange. Under these circumstances, *Chloroflexus* is most likely growing as a photoautotroph (Castenholz,

1988b). In some hot springs containing sulfide, the layers of *Chloroflexus* are found above the cyanobacteria in what has been called an inverted mat (Jørgensen and Nelson, 1988). Under these conditions the supposed autotrophic activity of the *Chloroflexus* in the surface layers consumes adequate sulfide from the vicinity of the cyanobacteria to permit their growth at these temperatures (Jørgensen and Nelson, 1988). In this way, a small pocket of oxygenic photosynthesis may actually occur beneath the anoxygenic *Chloroflexus.*

A mesophilic strain of *Chloroflexus aurantiacus* (var. *mesophilus*) was isolated from mat communities in the bottom mud of lowsulfate stratified freshwater lakes containing some sulfide. These strains had temperature optima from 20–25°C and were otherwise identical with the thermophilic strains (Gorlenko, 1976; Pivovarova and Gorlenko, 1977).

Chloroflexus-like Organisms in the Marine Habitat

Chloroflexus-like organisms have been observed in several marine and hypersaline habitats, although none has been isolated in pure culture. Intertidal sand flats at Great Sippewissett Salt Marsh, Cape Cod, MA, rich in biogenic sulfide, were observed to contain recognizable thin mat layers of *Chloroflexus*-like organisms that migrated to the surface in darkness or dim light. The *Chloroflexus*-like filaments were often associated with species of *Oscillatoria, Chloroherpeton, Beggiatoa,* and some purple sulfur bacteria (Mack and Pierson, 1988). Successful enrichment cultures of *Chloroflexus*-like filaments have been obtained and partial purification achieved from sandy intertidal mats on Mellum Island, West Germany (E. Mack and N. Pfennig, personal communication).

Similar *Chloroflexus*-like organisms have been observed as prominent constituents of well-developed mats in hypersaline environments. The presence of these organisms (identified on the basis of electron microscopy) has been reported in mats at Laguna Figueroa, Baja, Mexico (Stolz, 1983, 1984), Solar Lake in the Sinai (Cohen, 1984; D'Amelio et al., 1989), salt evaporation ponds at Exportadora de Sal, Guerrero Negro, Baja, Mexico (D'Amelio et al., 1989), and Shark Bay, Western Australia (John Bauld and Elisa D'Amelio, personal communication). Filamentous bacteria thought to be similar to *Chloroflexus* were observed in Abu Dhabi mats (Cardoso et al., 1978). The presence of *Chloroflexus*-like organisms in the hypersaline mats at Guerrero Negro has been further substantiated by the presence of bchl *c* and γ carotene in particular layers (Palmisano et al., 1989). In some cases, *Chloroflexus* forms a major recognizable mat layer in the hypersaline environment (B. K. Pierson, unpublished observations). Within these mats, *Chloroflexus*-like filaments are frequently found beneath a layer of cyanobacteria and often in association with *Beggiatoa.* Mats containing layers of nearly pure *Chloroflexus*-like filaments were also observed at salinities greater than 10%, and successful enrichments have been made of these filaments in the medium modified from that used by E. Mack and N. Pfennig (unpublished observations) to enrich for *Chloroflexus* from Mellum (B. K. Pierson, unpublished observations). *Chloroflexus*-like organisms were also found in sulfide-containing mats from hypersaline lagoons of Lake Sivash and the White Sea, USSR (Venetskaya and Gerasimenko, 1988; Gorlenko, 1988).

Chloronema

Chloronema has been observed in the plankton in dimictic freshwater lakes with high ferrous iron content and low H_2S (Gorlenko, 1988, 1989b). The organisms are found in the metalimnion and upper hypolimnion of shallow stratified lakes. They are usually below the chemocline in an anaerobic zone containing other species of purple and green sulfur bacteria. *Chloronema gigantea* has been observed to be the dominant phototroph in the plankton of such lakes (Dubinina and Gorlenko, 1975).

"Oscillochloris"

Species of "Oscillochloris" have been observed as yellow-green mats on the surface of hydrogen-sulfide-containing mud in freshwater habitats over a temperature range of 10–20°C and pH range of 7.5–8.5 (Gorlenko, 1989a). Within this habitat they are often found associated with purple and green sulfur bacteria, *Beggiatoa,* and *Oscillatoria* species in algal/bacterial mats (Gorlenko, 1989a). "Oscillochloris trichoides" has been observed in mats on the surface of freshwater mud containing H_2S. It has been seen in microzones below purple sulfur bacteria. "O. chrysea" has been found on the surface of muds in freshwater streams with high organic content from domestic sewage effluents (Gorlenko and Pivovarova, 1977; Gorlenko, 1988). "Oscillochloris"-like filaments have also been observed in mats from hypersaline ponds in Baja, Mexico (D'Amelio, personal communication).

Bchl-*a*-Containing Filamentous Phototrophs

Heliothrix oregonensis is found in conspicuous masses of nearly pure bright orange motile filaments on top of more compact layers of cyanobacteria in some hot springs in western North America. It is found at about pH 8.5 and at temperatures up to 55°C under conditions of high light intensity (Pierson et al., 1984). The layer of *Heliothrix* often forms conspicuous puffs and tufts that are oxic even in their interior (Castenholz, 1988b; B. K. Pierson, unpublished observations). The habitat is lacking in hydrogen sulfide. On the Warm Springs Indian Reservation (Oregon), small alkaline pools are impressively dominated by *Heliothrix,* whereas in a few other alkaline springs in Oregon and in Yellowstone National Park, *Heliothrix*-like filaments are only observed as localized patches.

Other filamentous bchl-*a*-containing phototrophs form a conspicuous deep red layer below layers of cyanobacteria and *Chloroflexus* in alkaline hot springs in Yellowstone National Park (Castenholz, 1984). These layers were seen in springs lacking H_2S. In more translucent mats this dark red layer of filamentous phototrophs can be found more than 1 cm from the surface. It is not yet known how widespread these organisms are in their distribution. The application of *Chloroflexus*- specific antisera to "Chloroflexus" taken from lower layers of mats in Octopus Spring, Yellowstone National Park, revealed that many nonreactive filaments were present (Tayne et al., 1987). Bchl-*a*-containing filaments other than *Chloroflexus* were abundant in this mat and migrated to the surface when it was darkened (B. K. Pierson, unpublished observations). Some of the nonreactive filaments may be phototrophs that have not yet been identified.

The filamentous bchl-*a*-containing phototrophs described by D'Amelio et al. (1987) were observed in hypersaline mats of Solar Lake and the salt ponds of Guerrero Negro where they were found as free-living or intra-bundle-dwelling organisms in association with *Microcoleus chthonoplastes.* These mats contained hydrogen sulfide and the filaments were found at depths of 0.3–1.2 mm, which is below the zone of maximal oxygen production. Hydrogen sulfide was present at fluctuating levels. Filamentous bchl-*a*-containing bacteria were also seen in mats at Laguna Figueroa (Stolz, 1983).

Isolation

Any mat material collected from alkaline hot springs (at least below 65°C) is likely to contain viable filaments of *Chloroflexus.* In general, the mat from a temperature above 45°C will consist primarily of cyanobacteria. The material may be collected with forceps and transported in vials of spring water. Less than 5% of the aqueous volume should be occupied by mat material. The vials will retain live *Chloroflexus* for one to several weeks if stored in darkness and at temperatures from about 12–25°C. Cooler or warmer temperatures usually shorten the survival time. Freezing should be avoided.

Selective Enrichment

Almost all of the published information pertains to thermophilic *Chloroflexus* (Pierson and Castenholz, 1974a; Castenholz and Pierson, 1981; Castenholz, 1989). Present enrichment techniques for *C. aurantiacus* are nonexclusive, but large population densities can nevertheless be obtained by enriching a basic mineral medium such as D medium (see below) or BG-11 medium (Castenholz, 1988a) with yeast extract (0.1–1.0 g/l), and by adding 3,4-dichlorophenyl-1,1-dimethylurea (DCMU) to 5–10 μM in nearly filled screw-cap tubes or flasks. Fluorescent or incandescent lamps may be used (10–100 W/m^2). Many other nonfastidious photoheterotrophic anaerobes may also develop in 45–50°C enrichments, but incubation at 60°C will exclude all known purple bacteria and heliobacteria (see Chapter 90). However, even at 60°C a number of chemoheterotrophic bacterial species will grow, including *Thermus* spp.

Gorlenko (1976) successfully enriched for mesophilic *Chloroflexus* in glass columns that contained samples of lake-bottom water and mud and were filled with a "semiliquid" medium containing mineral salts and Pfennig's mixture of trace elements (Pfennig, 1965; Pfennig and Lippert, 1966) and supplemented with Na_2SO_4 (0.6 g/l), $Na_2S \cdot 9H_2O$ (0.1 g/l), yeast extract (0.025 g/l), and casein hydrolysate (0.025 g/l). The incubation was at 25–30°C under light of 3,000 lux.

C. aurantiacus is a faculative aerobe and is tolerant of at least some oxygen in the medium while bacteriochlorophylls are being synthesized. The use of sodium sulfide or sodium thioglycollate to lower the redox potential and eliminate O_2 has not been a requirement for growth, although either could be helpful.

The obligately anaerobic "green Chloroflexus" (GCF) may also be enriched for using the Hungate-agar-tube method or liquid medium in sealed vessels, with a medium designed for green bacteria that contains acetate and sulfide (see Sirevåg, 1975; Giovannoni et al., 1987). Isolations may be made from such enrichments or directly from field collections following dis-

persion of the material by passage through an 18-gauge needle. A dilution series is plated on DGN medium containing yeast extract (0.05 g/l) using the pour-plate method, followed by incubation in anaerobic (H_2 + CO_2) Gas Paks illuminated by coolwhite fluorescent and/or incandescent lights. Numerous greenish colonies should arise. After picking some and spreading these on fresh plates, single filaments may be isolated and cut out on agar blocks as described later for *C. aurantiacus*. Although "green Chloroflexus" will not grow under aerobic conditions, it is quite tolerant of exposure to O_2 and can be easily manipulated under normal laboratory conditions.

Enrichment of Cyanobacteria Contaminated with *Chloroflexus*

An essentially foolproof method of establishing thermophilic *Chloroflexus* in a mixed culture is to enrich in a mineral medium for cyanobacteria inoculated from a hot spring source. Cyanobacteria from hot springs may be enriched for in a variety of ways (see this Handbook, Chapter 98 and Castenholz, 1988b). Essentially all enrichments or isolations of thermophilic cyanobacteria are contaminated with heterotrophic bacteria, of which *Chloroflexus* is one. A simple technique for culturing *Chloroflexus* is to incubate a sample of the cyanobacterial mat at a temperature appropriate for its growth in a cotton-plugged flask of inorganic D medium (see below). The one or more species of cyanobacteria that invariably grow will excrete organic matter which will support a population of *Chloroflexus* that will persist over numerous transfers. *Chloroflexus* is actually difficult to eliminate in attempts to purify thermophilic cyanobacteria.

Cyanobacteria may also be inoculated on agar-solidified D medium (agar at 15 g/l). Motile cyanobacteria often move out from the initial inoculum spot in large numbers, sometimes forming fascicles or circling aggregates on the agar. These may be transferred to new plates or to similar liquid medium by using watchmaker's forceps to cut out the block with the filaments. These cyanobacterial filaments usually carry *Chloroflexus* as a contaminant. Occasionally, a two-membered culture may be established.

Direct Isolation

Because of its motility, thermophilic *Chloroflexus aurantiacus* is most easily isolated without prior enrichment by a combination of manual techniques. Solid medium is prepared using 1.5% (wt/vol) agar (e.g., Difco or Oxoid No. 3). The nutrient base used is commonly D medium with 0.8 g/l glycylglycine as buffer. The pH is adjusted to 8.2 with 1–2 M NaOH before autoclaving. This medium is excellent for *Chloroflexus* isolation. The addition of very little yeast extract (10 mg/l) may improve it slightly. The plates are allowed to dry inverted at room temperature for 2 days or more.

A small piece of hot-spring cyanobacterial-*Chloroflexus* mat is placed in the center of each plate. A mass of cyanobacteria or *Chloroflexus* grown as an enrichment may be used. Plates can also be inoculated by dragging a piece of the inoculum back and forth over the surface of the agar with a watchmaker's forceps. The plate is then inverted and incubated at 45–50°C for 1–2 days under tungsten or fluorescent lights (e.g., 10–100 W/m^2). The incubator should be humidified with a pan of water at the base.

Plates are then examined under a good-quality dissecting microscope with a magnification of 15–60×. Transmitted illumination should be carefully adjusted for the best resolution of the pale, orange-colored wisps of *Chloroflexus* that may grow and spread out from the inoculation site. With the fastest-known gliding rates, *Chloroflexus* could move out at the rate of about 3.5 mm/day, but probably will be slower.

Quite frequently, *Chloroflexus* may be recognized as pointed, stringy, or recoiled wisps of a few to several filaments that extend as a fringe beyond the edge of the cyanobacteria or other bacteria (Fig. 1; Pierson and Castenholz, 1974a). If the inoculum included rapidly migrating cyanobacteria, the *Chloroflexus* may often be seen extending from the trails of these other gliding bacteria. On the plates in which inoculum has been dragged along the surface, the *Chloroflexus* filaments may have been spread thinner. Smaller colonies of various shapes may then develop and the plate should be examined again after 2–3 additional days of incubation (Fig. 2).

The removal of *Chloroflexus* is the next stage in the isolation. A fine-pointed watchmaker's forceps should be used. The leading edges or tips of the small wisps of *Chloroflexus*-like filaments may be cut from the rest of the inoculum with the forceps. The agar block containing this material is then moved and inverted on a sterile part of the plate or on a new plate. The block is then pushed in a long streak over the top of the agar, leaving a trail of filaments. Some axenic colonies may arise on this first transfer, but usually the process must be repeated after new growth and gliding occur. The agar medium of the first or second transfer should contain a slightly higher concentration of yeast extract (about 50 mg/l).

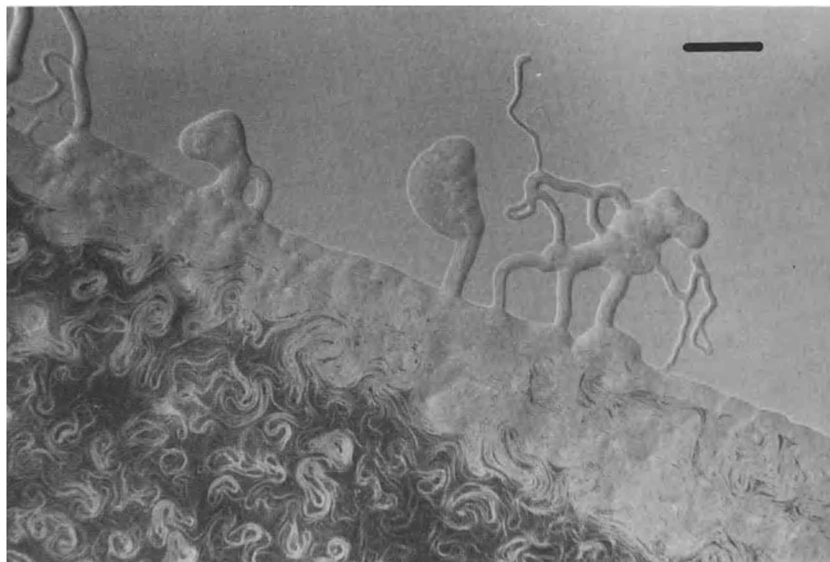

Fig. 1. Dual culture of *Chloroflexus aurantiacus* (NZ-Mar. 62-fl) and the cyanobacterium *Synechococcus lividus* (OH-53-s) on an agar surface (DG medium, 45°C). The dark area at the lower left is the population of *Synechococcus*. The lighter swirls and wisps of filaments advancing toward the upper right are *Chloroflexus*. Bar = 0.2 mm.

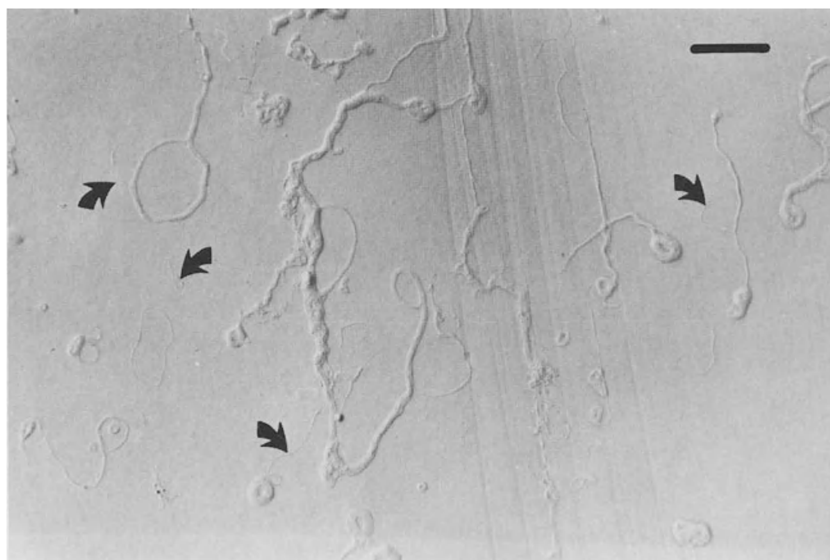

Fig. 2. Culture of *Chloroflexus aurantiacus* (OK-70-fl) on an agar surface at 45°C 10 days after streak dilution. Single and double filaments are indicated by arrows. Bar = 0.2 mm.

An alternative method of doing the first stage of isolation is to pick up the wisp of protruding *Chloroflexus* with the forceps and actually drag it across a sterile area of the same plate. The tip of the forceps should not quite touch the agar. As filaments are moved, some will be left behind (sometimes individually) as a trail.

After each transfer of *Chloroflexus* wisps, a period of a few days for growth and spreading should be allowed before repeating the process. In some strains of *Chloroflexus* presently in culture, the filaments are wide enough (1.0–1.2 μm) to be seen individually under the highest power of a dissecting microscope (Fig. 2). In such cases, blocks of agar with single filaments can be cut from the trail of filaments left by the streaking technique described above. These can then be transferred and inverted on new agar, establishing a definite clone. In the case of thinner filament types (0.5–0.7 μm wide), only pre-

sumptive clones can be established by repeated streakings.

When the colonies isolated appear free of other bacteria (as judged by examination with oil-immersion, phase contrast microscopy at 1,000 ×), colonies may be streaked on plates that contain yeast extract (0.5 g/l) or they may be suspended in liquid medium and serially diluted for introduction into 1.5% agar shake cultures containing yeast extract at 0.5–2.0 g/l. Inoculation of shake cultures should be done when the medium has cooled to about 45°C. Nearly full screw-capped tubes should be used. After inoculation, the tubes are shaken slowly and solidified. *Chloroflexus* grows best as an anaerobic photoheterotroph, and individual filaments will develop into orange to dull green colonies within the agar. The deeper colonies will appear greener due to the higher content of bchl *c* at lower levels of O_2. The addition of a sterile $NaHCO_3$ solution (0.5 g/l from a stock solution of 45 g/l that had been bubbled for 20 min with a stream of pure CO_2) seems to enhance development of colonies.

If contaminating bacteria are still present in the inoculum, this method can also be used for separation and purification by dilution. Tubes or flasks of liquid medium (again with yeast extract at 0.5–2.0 g/l) may be used for culturing, and are particularly useful when searching for possible contaminants. Cotton-plugged Erlenmeyer flasks (e.g., 125 ml) containing 80–90 ml of medium work well when unshaken because both aerobic and facultatively anaerobic contaminants will develop, if present.

Gorlenko (1976) did not explain how he isolated mesophilic *Chloroflexus* after initial enrichment. Presumably, a technique similar to the one for the thermophilic forms could be used.

Cultivation

The culture methods described pertain almost entirely to *Chloroflexus aurantiacus.* A variety of media may be used. The most commonly used base is D medium, (see below) at least for photoheterotrophic or chemoheterotrophic growth. D medium has alternatively been called "Castenholz salts" or Castenholz medium (Claus and Schaab-Engels, 1977). It was originally developed by R. P. Sheridan in Castenholz's laboratory for the culture of thermophilic cyanobacteria.

MEDIA FOR PHOTOTROPHIC CULTIVATION OF *CHLOROFLEXUS.* The following media are currently used in the laboratory at the University of Oregon, for phototrophic cultivation. They are all variations of medium D which is prepared (in order of listing) as a 20-fold concentrated (pH 3) stock that is stored unautoclaved at 4°C. The micronutrient and $FeCl_3$ solutions are included in the D stock. The medium is prepared by diluting the stock, adding other desired chemicals, and adjusting the pH with 1–2 M NaOH. Agar (usually 15 g/l) is added after pH adjustment. Normal medium D is pH 8.2 before autoclaving. After cooling and complete clearing, the pH is 7.5–7.6, when no buffer is used. For growth of *Chloroflexus,* addition of a buffer is needed to maintain the pH from 8.0 to 8.2.

Medium D

Double-distilled water	1 liter
NTA (nitrilotriacetic acid)	0.1 g
Micronutrient solution	0.5 ml
$FeCl_3$ solution (0.29 g/l)	1.0 ml
$CaSO_4 \cdot 2H_2O$	0.06 g
$MgSO_4 \cdot 7H_2O$	0.10 g
NaCl	0.008 g
KNO_3	0.10 g
$NaNO_3$	0.70 g
Na_2HPO_4	0.11 g

Medium DG is medium D to which 0.8 g glycylglycine per liter has been added as buffer.

Medium DGN is medium D to which 0.8 g glycylglycine and 0.2 g NH_4Cl have been added per liter.

Medium ND (lacks combined N except as NTA) is medium D without KNO_3 and $NaNO_3$, but with 0.07 g Na_2HPO_4 and 0.036 g KH_2PO_4 per liter.

Micronutrient solution

Double-distilled water	1,000 ml
H_2SO_4 (concentrated)	0.5 ml
$MnSO_4 \cdot H_2O$	2.28 g
$ZnSO_4 \cdot 7H_2O$	0.50 g
H_3BO_3	0.50 g
$CuSO_4 \cdot 5H_2O$	0.025 g
$Na_2MoO_4 \cdot 2H_2O$	0.025 g
$CoCl_2 \cdot 6H_2O$	0.045 g

For *Chloroflexus aurantiacus* per liter of medium we use 0.8 g glycylglycine (pK′ 8.3) (DG medium) or Tricine (N-tris [hydroxymethyl] methylglycine) (pK′ 8.15) (DT medium) as buffer. For liquid axenic cultures in screw-capped tubes or flasks, we usually include 2.0 g yeast extract and 0.2 g NH_4Cl per liter. When flasks are continuously sparged with any gas mixture, the normal concentration of yeast extract is replaced by 1.0 g yeast extract and 2.0 g casein hydrolysate (e.g., vitamin-free Casamino Acids [Difco]) per liter. The base of D medium has also been modified to exclude nitrate (Castenholz, 1988a) since *Chloroflexus* requires reduced forms of nitrogen (Brock, 1978) and ND medium serves as an adequate substitute for D-based medium. In the German Col-

lection of Microorganisms (Claus and Schaab-Engels, 1977) *Chloroflexus* is usually grown photoheterotrophically in D-based medium with 0.5 g glycylglycine, 0.5 g yeast extract, and 0.4–0.5 g $Na_2S \cdot 9H_2O$ per liter. The latter (for eliminating O_2) is added from a separate sterile solution after autoclaving and cooling. In all cases, the *Chloroflexus* medium is adjusted to pH 8.2 with NaOH prior to autoclaving. For strictly photoheterotrophic growth, tubes or flasks should be filled to the top with preheated medium and inoculum before incubating.

C. aurantiacus, however, is tolerant of O_2 and will produce bacteriochlorophylls even in cotton-stoppered flasks of normal liquid medium if they are not shaken. Presumably, both phototrophic and chemotrophic growth modes are combined under these circumstances.

C. aurantiacus may also be grown as a chemoheterotroph. The same basic medium with yeast extract and Casamino Acids may be used with vigorous shaking or with a sparging system, using sterile filtered line air. Aerobic growth has been sustained in DG medium plus 0.2 g NH_4Cl, 0.5 g yeast extract, 1.0 g Casamino Acids, and 2.0 g sodium acetate per liter (Sirevåg and Castenholz, 1979).

Madigan (in Brock, 1978) and Madigan et al. (1974) have grown *Chloroflexus* with apparently good rates and yields using defined media. A number of sugars, organic acids, and amino acids will serve as carbon sources, but it was found that folic acid and thiamine were required, and the addition of inorganic carbon was needed to sustain normal rates and yields (Madigan et al., 1974; Brock, 1978). Na_2CO_3 or $NaHCO_3$ in water (e.g., 45 g/l) may be autoclaved and cooled, bubbled with pure CO_2 for 20–30 min to lower the pH, and then added to culture medium to make a final concentration of 0.5–2.0 g/l.

Photoautotrophic culturing of *Chloroflexus* is a very slow process, although growth of this type apparently occurs in some hot springs (Castenholz, 1973b; Giovannoni et al., 1987). In the laboratory, $Na_2S \cdot 9H_2O$ (0.5 g/l or about 2 mM final concentration) and inorganic carbon as $NaCO_3$ or $NaHCO_3$ (2.0 g/l) have been used (Madigan and Brock, 1977a; Brock 1978). Photoautotrophic growth has also been achieved with hydrogen as electron donor (Holo and Sirevåg, 1986).

"Green *Chloroflexus*" (GCF) from sulfidic hot springs will grow in the same medium as *C. aurantiacus* providing that anaerobic procedures for preparing and maintaining medium are followed. However, the best medium used for photoheterotrophic growth in liquid was a modification of medium DGN that also contained 0.2–0.5 g yeast extract and 1.0 g D-glucose per liter (Giovannoni et al., 1987). Hungate tubes or other sealed anaerobic vessels may be used.

Mesophilic *Chloroflexus* was cultured by Pivovarova and Gorlenko (1977) within soft agar medium (0.4%) with mineral salts, following the procedure of Pfennig (1965) and Pfennig and Lippert (1966) and supplemented with 0.4 g Na_2SO_4, 0.5 g tryptone, and 0.5 g yeast extract per liter. The pH was adjusted to 7.0.

Maintenance of Stocks

Thermophilic *C. aurantiacus* may be maintained in several ways. Photoheterotrophic cultures are grown at an optimum temperature (52–60°C) in screw-capped tubes that are filled nearly to the top before closing. A tungsten light source (5–10W/m^2 at the tube surface) is used in a table-top incubator with insulated glass door, set at 55°C. Although 45°C is suboptimal for growth, cultures may be maintained at a temperature this low. Transfers of the 55°C cultures should be made at least every 2 weeks, preferably more frequently. As cultures age, total lysis may occur.

Cultures are frequently maintained at 45°C on medium solidified with 1.5% agar in inverted, 20-mm-deep petri dishes. These cultures, although partially chemoheterotrophic, should be illuminated in the same way. Fluorescent lamps (coolwhite or warm white) will also work.

The most dependable method of maintaining *Chloroflexus* is in two-membered culture with a cyanobacterium as the source of organic nutrients. Such cultures can be maintained many weeks (liquid or agar) without transfer. *Synechococcus lividus* (strain OH-53-s), a unicellular cyanobacterium, grows well in DG liquid medium at 45–55°C. Neither the cyanobacterium nor *Chloroflexus* lyses in liquid D medium in cotton-plugged flasks, even when incubated for weeks beyond the regular transfer time of 2–3 weeks. Normally, however, agar plates are used to prevent contamination. These are incubated at 45°C and under coolwhite fluorescent lamps (30 W/m^2). The green-colored lawn of *Synechococcus* is interspersed with nearly macroscopic swirls of *Chloroflexus,* which also form a border or halo around the lawn of *Synechococcus* (Fig. 1). The growth pattern may be easily observed under a dissecting microscope. It is usually impossible to transfer the *Synechococcus* without carrying the *Chloroflexus.* However, *Chloroflexus* may be easily isolated from the dual culture. The normal yeast extract medium is inhibitory to *Synechococcus,* an obligate pho-

toautotroph. If liquid medium containing yeast extract is inoculated with a dual culture and incubated at 60–62°C, the *Synechococcus* will be killed in 4–5 days, leaving an axenic culture of *Chloroflexus*. Another simple method is to cut out with watchmaker's forceps an agar block containing *Chloroflexus* that has spread from the edge of a dual culture. This block can then be inoculated in *Chloroflexus* medium (liquid or agar).

Although O_2 is evolved by the *Synechococcus* in dual cultures, *Chloroflexus* pigment synthesis is not entirely inhibited. The identity of the organic compounds produced by *Synechococcus* in culture and used by *Chloroflexus* has not been determined.

"Green Chloroflexus" (GCF) may be maintained on agar or liquid in Hungate tubes or bottles or other vessels with rubber or soft tops so that they may be flushed or injected with anaerobic gas mixtures (e.g., 99% N_2, 1% CO_2). Plate cultures in "Gaspaks" are less reliable because of frequent failure of the seal. All cultures should be maintained at moderately thermophilic temperatures (45–55°C) in dim light (5–10 W/m^2).

Pivovarova and Gorlenko (1977) have grown mesophilic *Chloroflexus* in soft-agar (0.4%) shake cultures in cotton-plugged tubes that were kept at 3,000 lux (about 30 W/m^2) and 28°C. We have used a similar shake-culture method for maintaining thermophilic *Chloroflexus* but we used screw-capped tubes and 1.0% agar.

Preservation of Cultures

Chloroflexus aurantiacus does not survive air drying or freezing at −15° to −20°C in its own medium. Freeze-drying of *Chloroflexus* is used by the German Collection of Microoorganisms (Claus and Schaab-Engels, 1977). In the culture collection of the University of Oregon, approximately 15 strains of thermophilic *Chloroflexus* have been conserved in plastic cryo-ampules at the temperature of liquid N_2 (−196°C). In one test, all cultures were viable after 2 years of storage. About 0.3–0.5 ml of dense liquid cultures are pipetted directly into the ampules and frozen by direct submergence in liquid N_2. Dual-culture material is scraped off the agar surface with a loop and densely inoculated into an ampule containing sterile DG medium.

Identification

Chloroflexus aurantiacus

Chloroflexus aurantiacus has been isolated from alkaline hot springs in most regions of the world (Pierson and Castenholz, 1974a). It is a narrow (0.5–1.2 μm) (Fig. 3), orange to greenish filament of indefinite length, capable of a slow, gliding motility (0.01–0.04 μm/s). It stains Gram-negative although the chemistry of its wall is not that of a typical Gram-negative organism (see "Cellular Lipids and Cell Envelope"). Under anaerobic conditions it maintains a complement of bchl *a* with larger amounts of bchl c_s (Gloe and Risch, 1978). *C. aurantiacus* var. *mesophilus*, which is very similar in all characteristics except optimum temperature, was isolated from the hypolimnion of a freshwater lake but is no longer in culture (Pivovarova and Gorlenko, 1977).

The bchl *c* of *C. aurantiacus* is contained in chlorosomes that line the cytoplasmic membrane. The bulk of the light-harvesting bchl *a* (B800 and B865 complexes) is located in the cytoplasmic membrane along with the reaction center (Schmidt, 1980; Bruce et al., 1982). A small fraction of the bchl *a* absorbing at 792 nm is associated with the baseplate of the chlorosome at the site of attachment to the cell membrane (Schmidt, 1980; Sprague et al., 1981a). Invaginations of the cytoplasmic membrane occur as mesosomes of rather typical appearance (Pierson and Castenholz, 1974a), but a more elaborate type of membrane of unknown function is sometimes produced (Pivovarova and Gorlenko, 1977). β-Carotene, γ-carotene, and hydroxy-γ-carotene-glucoside comprise 80–95% of the carotenoids for anaerobically grown cells (Halfen et al., 1972; Schmidt et al., 1980). Photosynthesis is anoxygenic, and organic compounds provide the best carbon source for rapid growth. Most strains (but not all) also grow aerobically. Under aerobic conditions, the synthesis of bacteriochlorophylls ceases, but echinenone and myxobactone increase and constitute about 75% of the carotenoids (K. Schmidt, personal communication).

Chloroflexus may be tentatively identified in collected material as fine trichomes (0.5–1.2 μm wide) of indefinite length and essentially colorless as individuals, but generally orange in a mass under a compound microscope. With phase contrast microscopy, thin sheaths may or may not be apparent in *Chloroflexus*. Some members of the flexibacteria (e.g., *Herpetosiphon, Flexibacter, Flexithrix*) are similar in appearance, exhibit gliding motility, and contain somewhat similar carotenoid pigments (see Chapter 199 and Kleinig and Reichenbach, 1977). Neither *Chloroflexus* nor flexibacteria exhibit the characteristic visible red fluorescence of plant-type chlorophyll. Therefore, filamentous cyanobacteria of similar dimensions and behavior may be distinguished under a flu-

orescence microscope. Both *Chloroflexus* and cyanobacteria exhibit infrared fluorescence (Pierson and Howard, 1972).

Large quantities of *Chloroflexus,* collected nearly pure or mixed with cyanobacteria, may be broken by sonication in buffered medium or hot-spring water, cleared by filtration or centrifugation, and tentatively identified by the in vivo absorption maxima at about 740 nm (bchl *c*), 802 nm, and 865 nm (bchl *a*) (Castenholz, 1973b; Pierson and Castenholz, 1974a). Relatively monospecific mats of *Chloroflexus* may be identified as the orange to flesh-colored gelatinous layers in hot springs under a layer of cyanobacteria or occasionally as independent mats in sulfide springs (see Castenholz, 1973b). However, a large number of cyanobacteria in hot springs form extensive mats, yellow to brilliant orange in color, particularly at temperatures below 45–50°C. These may easily be mistaken for *Chloroflexus,* which may be present as only a minor component.

The marine forms of *Chloroflexus* can be initially identified as dark green or olive green filaments often forming a recognizable layer in mats or sediments. Some of the filaments we have observed have been larger than the thermophilic strains, commonly being 1.5 to 2.0 μm in diameter. We routinely identify putative *Chloroflexus*-like filaments on the basis of their olive green color en masse, lack of red fluorescence, and presence of infrared fluorescence. Identification can be substantiated with in vivo absorption spectroscopy. The in vivo absorption maximum for bchl *c* in most marine strains is from 747–755 nm rather than at 740 nm as in the thermophilic strains. Identification can be confirmed with transmission electron microscopy revealing the presence of filaments with chlorosomes lining the cell membrane.

Chloronema and *"Oscillochloris"*

Gorlenko and Pivovarova (1977) suggested that as many as 28 species of filamentous organisms, formerly described as species of *Oscillatoria* or related genera of cyanobacteria, are likely to be anoxygenic phototrophs of the "Oscillochloris" or *Chloronema* type. Several filamentous types have been described from collections in the past as pale, nearly colorless, or yellow-green, rather than blue-green to reddish in color. "Oscillochloris chrysea," for example, was equated to *Oscillatoria coerulescens* described by Gicklhorn (1921).

Samples of "Oscillochloris" and *Chloronema* could be tentatively identified on the basis of habitat, color, and microscopy, but electron microscopy and biochemical analysis would be necessary for more complete identification.

"Oscillochloris" is a larger, rapidly gliding *Oscillatoria*-like trichome (about 5μm wide), which was proposed as a separate genus from *Chloroflexus* on the basis of larger size and lack of sheath. It contains gas vesicles and has an elaborate system of centripetally invaginated partial septa that are lined with chlorosomes (Gorlenko and Pivovarova, 1977). It is yellow-green in color and apparently contains bchl *c* (rather than bchl *d*). Its physiology is thought to be like that of *Chloroflexus.* Two species have been described, "O. chrysea" and "O. trichoides" (Gorlenko, 1989a). "O. chrysea" and "O. trichoides" are distinguished from each other on the basis of filament diameter, cells of "O. chrysea" being wider (4.5–5.5 μm) than those of "O. trichoides" (1.0–1.4 μm). The trichomes of both may contain gas vesicles and are yellow-green in color. Transmission electron microscopy confirms identification of this genus by revealing the characteristic location of chlorosomes along complete and incomplete septa and their absence from the cell membrane parallel to the longitudinal axis of the filament (Gorlenko, 1988).

Chloronema (about 2 μm wide) is similar structurally and possibly physiologically to *Chloroflexus* (Gorlenko, 1989b), but data from cultures are lacking. Its proposed separate generic status is based on the possession of gas vesicles and sheath. The material examined apparently contained bchl *d* rather than bchl *c* (Dubinina and Gorlenko, 1975). The two species described *(Chloronema giganteum* and *C. spiroideum)* were yellow-green in color. Samples from anaerobic zones of lakes with planktonic populations that are predominantly composed of gas vesicle-containing filaments with large amounts of extractable bchl *c, d,* or *e* could be *Chloronema* (Dubinina and Gorlenko, 1975). *Chloronema* is identified by habitat, presence of gas vesicles, and presence of bchl *d* instead of *c* (Gorlenko, 1989b). Strains studied so far were found at lower temperatures (3–15°C) than other species of the Chloroflexaceae. All of these characteristics are of dubious value in distinguishing *Chloronema* as a separate genus from *Chloroflexus,* and studies on pure cultures will be necessary, along with nucleic acid sequence data, to ultimately determine the proper phylogenetic distance of these two genera.

Heliothrix oregonensis

Heliothrix oregonensis is a filamentous gliding anoxygenic phototroph containing bchl *a* as the only chlorophyll. The cells are about 1.5 μm wide and 10 μm long (Fig. 3) and the gliding

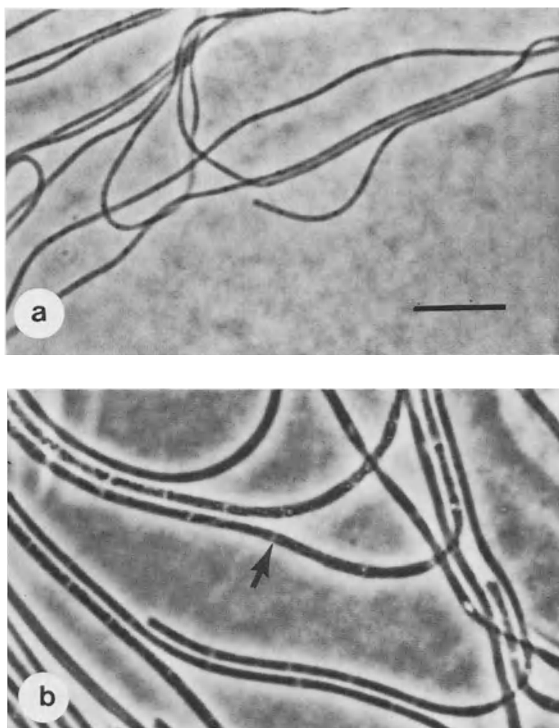

Fig. 3. Phase contrast photomicrographs of wet mounts of *Chloroflexus aurantiacus* (a) and *Heliothrix oregonensis* (b). The narrower filaments are *C. aurantiacus* (strain J-10-fl). The wider *H. oregonensis* filaments have granules (probably PHB) and septa (indicated by the arrow). Septa are also present in *C. aurantiacus* but are not readily visible with light microscopy. (Bar = 10 μm.)

motility is more rapid (0.1–0.4 μm/s) than in *Chloroflexus*. It contains less bchl *a*, and apparently lacks chlorosomes and bchl *c*, *d*, or *e* entirely (Pierson, et al., 1984). Nevertheless, on the basis of morphology, behavior, and types of carotenoid pigments, it appears more closely related to *Chloroflexus* than to other phototrophs. The 5S rRNA analysis confirms this association. First described as "F-1" (Pierson and Castenholz, 1971; Pierson, 1973), *Heliothrix oregonensis* is identified on the basis of the presence of bchl *a* as its only chlorophyll and the absence of chlorosomes and intracytoplasmic membranes.

With the recent discovery of other filamentous bacteria of the same diameter containing bchl *a* as the only chlorophyll and elaborate intracytoplasmic membranes, identification has become more difficult. The identification of these different organisms relies on transmission electron microscopy (TEM) to reveal the presence or absence of intracytoplasmic membranes and in vivo absorption spectra to identify the position of the bchl *a*-protein absorption maxima—factors that could be influenced by conditions of the habitat. Growth in pure or coculture will be essential to determine if the other bchl *a*-containing filaments are really variants of *Heliothrix* or not.

Physiological Properties

Chloroflexus aurantiacus is the only species that has been studied physiologically in pure culture. Thus our discussion of physiological properties will be confined to this species.

Chloroflexus aurantiacus grows in nature primarily as a photoheterotroph. Its best growth rates and yields occur when grown anaerobically in the light on complex organic media. Many strains (but not all) grow well chemoheterotrophically in the presence of oxygen. Some strains (but not all) are capable of photoautotrophic growth. Even those strains capable of photoautotrophic metabolism (such as the GCF strains) grow best as photoheterotrophs. Typically, *Chloroflexus aurantiacus* grows in hot spring mats that are quite oxic during daylight and become anoxic at low-light levels and in darkness. A tolerance for and an ability to use oxygen is definitely advantageous under these conditions. Strains of *Chloroflexus* growing in sulfidic hot springs in the absence of cyanobacteria may never be naturally exposed to oxygen. GCF strains isolated from such conditions could tolerate exposures to oxygen but could not grow aerobically in the dark (Giovannoni, et al., 1987). Light was required for growth.

Autotrophy

Sulfide-dependent photoautotrophy is difficult to demonstrate in the laboratory, yet some strains are most likely using this mode of metabolism in nature as their sole source of energy and carbon (Giovannoni, et al., 1987; Jørgensen and Nelson, 1988). Since there is essentially no competition for light, sulfide, or space in these habitats, the slow growth afforded by photoautotrophy is probably sufficient for dominance of *Chloroflexus*.

Despite the evidence for autotrophy in the field, growth of cultures autotrophically in the laboratory still poses difficulties. One thermophilic strain (OK-70-fl) was successfully grown autotrophically using sulfide while none of the other strains that were tested showed growth (Madigan, et al., 1974). Autotrophic growth was not as good as photoheterotrophic growth. Madigan and Brock (1977a) showed sulfide-dependent CO_2 fixation in autotrophically grown cultures of strain OK-70-fl. Heterotrophic cultures were also able to fix CO_2. Early attempts to de-

termine the pathway of CO_2 fixation produced confusing results (Madigan and Brock, 1977a; Sireväg and Castenholz, 1979). More recently, it has become evident that the confusion was due to the fact that *C. aurantiacus* has a previously undescribed pathway for CO_2 fixation using neither the reductive tricarboxylic acid cycle nor the Calvin cycle (Holo and Sirevåg, 1986). Advances in the study of the autotrophic pathway for CO_2 assimilation were made after developing a method for growing strain OK-70-fl autotrophically with hydrogen (Holo and Sirevåg, 1986). Although photoheterotrophically grown *C. aurantiacus* has doubling times as short as 3–4 h, the lowest doubling time obtained photoautotrophically was 26 h. Using cells grown in this way, Holo and Grace (1987, 1988) found that acetyl-CoA was an important intermediate in autotrophic metabolism. Acetyl-CoA was carboxylated to pyruvate, which could then be reduced and phosphorylated to triose phosphates. Further evidence suggests that 3-hydroxypropionate is an important intermediate in CO_2 fixation and may be involved in a cyclic pathway to regenerate acetyl-CoA (Holo, 1989). More work is needed to completely understand this unique pathway for autotrophy and to discover the basis for the generally poor autotrophic growth obtained in the laboratory.

Heterotrophy

Numerous substrates can support photoheterotrophic growth. In addition to complex substrates such as yeast extract and Casamino Acids, other organic substrates that supported good growth of strain J-10-fl included glycerol, acetate, glucose, pyruvate, glutamate, and lactate (Pierson and Castenholz, 1974a). Aspartate supported good growth of OK-70-fl (Madigan et al., 1974). Other substrates that supported photoheterotrophy, but with significantly lower yields in most strains tested, included glycylglycine, succinate, malate, butyrate, citrate, ribose, galactose, ethanol, and mannitol (Madigan et al., 1974). Growth could be obtained aerobically in the dark in some strains on each of the substrates that supported photoheterotrophy except for glycylglycine (Madigan et al., 1974). Similar results were obtained for three other strains of *C. aurantiacus* (Krasil'nikova et al., 1986). The use of organic substrates was basically the same in the light under anoxic conditions and in the dark under oxic conditions, with acetate, propionate, pyruvate, butyrate, and malate supporting the best growth. Of the sugars tested, glucose, maltose, sucrose, and galactose supported the best growth. Although glycerol supported growth, none of the other 14 alcohols tested, including ethanol and mannitol, was used by any of these strains of *C. aurantiacus* in either the light or the dark (Krasil'nikova et al., 1986). These authors also observed that substantial amounts of poly-β-hydroxybutyrate (PHB) and polysaccharides accumulated in cells growing both phototrophically and chemotrophically. More PHB accumulated in cells grown phototrophically and in cells grown with acetate.

The tricarboxylic acid (TCA) cycle appears to operate under aerobic conditions to supply reductant for respiration and under anaerobic conditions to support the reductive assimilation of organic compounds for photoheterotrophy (Sirevåg and Castenholz, 1979). Activities of the enzymes required for the functioning of a complete TCA cycle were found but the activity of α-keto-glutarate dehydrogenase was low (Krasil'nikova et al., 1986). The activity of citrate synthase increased in cultures grown on acetate. More detailed analyses of the size and activity of the citrate synthase done in crude extracts and with partially purified preparations has revealed that the enzyme from *C. aurantiacus* belongs to the small size class of the enzyme and was not inhibited by NADH or α-keto-glutarate but was inhibited by ATP (Kelly, 1988). The size of the enzyme puts it in the class of those found in Gram-positive bacteria rather than with those found in Gram-negative bacteria. All strains of *C. aurantiacus* also had the two key enzymes of the glyoxylate pathway, isocitrate lyase and malate synthetase, which increased in activity in cells grown on acetate (Løken and Sirevåg, 1982; Krasil'nikova et al., 1986).

C. aurantiacus metabolizes carbohydrates via the Embden-Meyerhof pathway (Krasil'nikova et al., 1986; Krasil'nikova and Kondrat'eva, 1987). When grown on glucose, higher activities of phosphofructokinase and fructose-diphosphate aldolase were detected than when grown on acetate. Enzymes of the pentose monophosphate pathway (glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase) were also detected (Krasil'nikova et al., 1986). Slow growth can be obtained anaerobically in the dark by fermentation of carbohydrates or pyruvate (Krasil'nikova and Kondrat'eva, 1987). Fermentation products of different strains growing on glucose include acetate, pyruvate, lactate, malate, ethanol, and occasionally formate (Krasil'nikova and Kondrat'eva, 1987). The activities of all enzymes tested were maximal between 45 and 70°C (Krasil'nikova et al., 1986).

Nitrogen Metabolism

The nitrogen metabolism of *C. aurantiacus* has been studied by Heda and Madigan (1986). Ni-

trate did not support growth of the strains tested. Several amino acids (alanine, aspartate, glutamate, glutamine, glycine, and serine) supported good growth of all strains. Cysteine supported good growth of most strains. Tyrosine and valine supported growth of all strains but with lower growth yields. A few other amino acids supported limited growth of some strains. Proline, adenine, and urea did not serve as nitrogen sources for any of the strains tested. All strains grew well using NH_4^+ as sole nitrogen source (Heda and Madigan, 1986).

Nitrogen fixation (diazotrophy) was not detected in any of the strains of *C. aurantiacus.* In addition to not growing with N_2 as sole nitrogen source, none of the strains tested showed nitrogenase activity using the acetylene reduction technique (Heda and Madigan, 1986).

The pathways of nitrogen metabolism in *C. aurantiacus* are partially understood. Ammonia assimilation apparently proceeds differently in *C. aurantiacus* than in other phototrophic bacteria. The only enzyme present for ammonia assimilation is a glutamine synthetase, which is not repressed when cells are grown in high-ammonia culture media (Kaulen and Klemme, 1983). No evidence was found for covalent modification of this enzyme by adenylylation/deadenylylation. The possibility that covalent modification could occur, however, has not been completely eliminated (Klemme, 1989). The absence of glutamate synthase (GOGAT) activity may be due to problems of preparation (Klemme, 1989), and details of this aspect of nitrogen metabolism remain to be clarified.

C. aurantiacus grows naturally in microbial mats, usually in close association with cyanobacteria, and readily uses a wide variety of amino acids both as carbon and nitrogen sources, although it can also grow in minimal medium. Glutamate, alanine, and isoleucine are the main constituents of the intracellular amino acid pool in cells grown photosynthetically in minimal medium (Klemme et al., 1988). Therefore, the metabolic pathways for both the synthesis of and degradation of amino acids are of interest. Two different enzymes with L-threonine (L-serine) dehydratase activity were found in *C. aurantiacus* (Laakmann-Ditges and Klemme, 1986). One was sensitive to inhibition by isoleucine and could be biosynthetic for isoleucine since the other key enzymes for its biosynthesis (asparto-kinase, homoserine dehydrogenase, and acetohydroxy acid synthase) were also present in cells grown on minimal medium (Laakmann-Ditges and Klemme, 1988). However, the intracellular pool sizes for isoleucine, threonine, and valine in *C. aurantiacus* suggest that the enzyme would be inactive in vivo (Laakmann-Ditges and Klemme, 1988). These authors also found that the other L-threonine (L-serine) dehydratase is insensitive to inhibition by isoleucine and is regulated at the gene level by glucose-mediated catabolite repression. The level of this enzyme was greatly increased when cells were grown in the presence of L-threonine, L-serine, or L-isoleucine and L-valine and L-leucine (Laakmann-Ditges and Klemme, 1988). This enzyme may therefore be classified as biodegradative and may be important in the growth of *C. aurantiacus* on amino acids.

Sulfur Metabolism

C. aurantiacus strains can use sulfate as a source of sulfur for biosynthesis, and during photoheterotrophic growth thiosulfate can also serve as a source of sulfur (Kondrat'eva and Krasil'nikova, 1988). Although activities were detected for thiosulfate reductase, rhodanese, thiosulfate oxidase, and sulfite oxidase, the use of thiosulfate by cultures appeared to be very limited. Although thiosulfate may serve as an electron acceptor with the accompanying production of hydrogen sulfide, it does not appear to function as an electron donor for photosynthesis (Kondrat'eva and Krasil'nikova, 1988). A variety of compounds (cysteine, glutathione, methionine, sulfide, sulfate) can function as sources of sulfur during photoheterotrophic growth (Krasil'nikova, 1987). The best growth, however, was obtained with sulfate, and high levels of activity were found for ATP sulfurylase, which exhibited optimal activity at 60–70°C (Krasil'nikova, 1987). Madigan and Brock (1975) and Giovannoni et al. (1987) showed that sulfide was oxidized to elemental sulfur that accumulated outside the cells during both photoheterotrophic and photoautotrophic growth.

C. aurantiacus has a membrane-bound Ni^{2+}-stimulated hydrogenase that is repressed by sulfide (Drutschmann and Klemme, 1985), and autotrophic growth at the expense of hydrogen has been obtained (Holo and Sirevåg, 1986).

Cellular Lipids and Cell Envelope

The biochemical composition of the cell envelope and the composition of cellular lipids in *C. aurantiacus* exhibit some unique properties. The total cellular lipids include the bchl and carotenoid pigments, the polar lipids, and a collection of unique wax esters (Beyer et al., 1983). The polar lipids include phosphatidylglycerol, phosphatidylinositol, monogalactosyl diglyceride, diglycosyl diglyceride, and sulfoquinovosyldiglyceride (Kenyon and Gray, 1974; Knudsen et al., 1982), although the presence of the

latter lipid is subject to question (Imhoff, 1988). The fatty acids are predominantly straight-chain saturated and monounsaturated with C_{16}, C_{17}, and C_{18-20} chain lengths predominating with no detectable hydroxylated or cyclopropane-substituted chains (Knudsen et al., 1982). The major lipid fraction was composed of wax esters (C_{28}–C_{38}) containing fatty acids (C_{12}–C_{19}) and alcohols (C_{16}–C_{19}) (Knudsen et al., 1982), which could be isolated in a particulate fraction called wax oleosomes (Beyer et al., 1983). The presence of the wax esters (rare in bacteria) and the predominance of phosphatidylinositol make the lipid composition of *Chloroflexus* unique among phototrophs. Although the presence of highly saturated and somewhat longer-chain fatty acids is consistent with the thermophilic nature of the organism, it is not clear what the function or role of the wax esters is in these bacteria. It will be most interesting to determine the lipid composition of the mesophilic marine, freshwater, and hypersaline strains.

The cell envelope of *Chloroflexus* apparently lacks the lipopolysaccharide (LPS) characteristic of Gram-negative bacteria. No hydroxylated fatty acids and no saccharides typical of outer-membrane LPS were detected in *Chloroflexus* (Knudsen et al., 1982). The absence of LPS and lipoprotein in the envelope of *C. aurantiacus* and the binding of complex polysaccharides to N-acetyl-muramic acid-6-phosphate in the peptidoglycan via phosphodiester bridges is very unlike the structural organization found in typical Gram-negative bacterial envelopes and more strongly resembles that found in Gram-positive bacterial walls (Jürgens et al., 1987). The abundant complex polysaccharide bound to the rigid peptidoglycan layer contains sugar O-methyl ethers of hexoses and rhamnose, mannose, glucose, galactose, xylose, and arabinose (Jürgens et al., 1987). Although the peptidoglycan of *Chloroflexus* contains *N*-acetyl-glucosamine, *N*-acetyl-muramic acid (about 15% of which is phosphorylated), L-alanine, D-alanine, and D-glutamic acid, the presence of L-ornithine instead of diaminopimelic acid in the peptidoglycan of *Chloroflexus* also distinguishes it from the other Gram-negative phototrophs and substantiates the similarity in wall composition with that of Gram-positive bacteria (Jürgens et al., 1987). The unusual biochemical composition of the envelope of *C. aurantiacus* is particularly interesting since the cells stain Gram-negative, and ultrastructurally the envelope appears to be multilayered. A well-defined outer membrane structure typical of Gram-negative cell envelopes, however, is lacking (Pierson and Castenholz, 1974a; Staehelin et al., 1978). It is of interest to note that cells of "Oscillochloris chrysea" stain Gram-positive and have a very thick peptidoglycan layer with no outer membrane (Gorlenko, 1988, 1989a).

Pigment Synthesis and the Development of the Photosynthetic Apparatus

Bacteriochlorophyll synthesis (both bchl *a* and *c*) in *C. aurantiacus* is via the glutamate-C_5-pathway as in the cyanobacteria and the green and purple sulfur bacteria, rather than via the ALA synthase pathway as in some species of nonsulfur purple bacteria (Kern and Klemme, 1989; Avissar et al., 1989). Little is known, however, about the regulation of pigment synthesis at the molecular level in *Chloroflexus*.

The phototrophic activity of natural populations is dependent on the prevailing light conditions in situ, and populations adapted to low-light intensities may show considerable photoinhibition when exposed to higher light intensities (Madigan and Brock, 1977b). In culture, bacteriochlorophyll (bchl) synthesis decreases in the presence of high-light intensity or oxygen (Pierson and Castenholz, 1974b), and the effects of light and oxygen on the structural development as well as on the pigment composition of the photosynthetic apparatus have been well documented (Sprague, 1981a, 1981b; Schmidt et al., 1980; Feick et al., 1982). The change in ratio of bchl *c* to *a* in cells grown at different light intensities and adapted to reductions in oxygen levels suggested independent regulation of the two pigments (Pierson and Castenholz, 1974b; Sprague et al., 1981b). The increase in bchl content seen in cells adapting to decreased light intensities or oxygen tensions was accompanied by an increase in the number of chlorosomes per cell. The increased ratio of bchl *c* to bchl *a* was accompanied by a general thickening of the chlorosomes (Sprague et al., 1981a).

The chlorosomes contain the bchl *c*, a small fraction of bchl *a* (absorbing at 790nm), and most of the carotenoid pigments of the cells (Schmidt, 1980; Sprague et al., 1981a). Some of the γ- and β-carotene were in the cytoplasmic membrane, but most were in the chlorosome, while the hydroxy-γ-carotene-glucoside was the predominant carotenoid in the membrane and was only a small fraction of the total carotenoid in the chlorosomes (Schmidt, 1980). This glucoside of hydroxy-γ-carotene increased relative to the other carotenoids in cells grown at higher light intensities (Schmidt et al., 1980) and may have a role in protecting the membrane-bound photochemical systems from the damaging effects of high-light intensities.

The effect of light intensity on pigment synthesis may be via an indirect effect on growth

rate. By growing *C. aurantiacus* in a chemostat and controlling the growth rate by regulating the dilution factor while keeping the light intensity constant, Oelze and Fuller (1987) were able to show that the specific contents of bchl *a* and *c* increased at lower growth rates. Since light intensity has a direct effect on growth rate, it is difficult to distinguish the relationships among these parameters without growth in a chemostat. Cell protein levels, as well as specific bchl *a* content, increased linearly with decreasing growth rate, while the specific bchl *c* content increased exponentially with decreasing growth rate.

The nature of the regulation remains undetermined. The relationship of the structural features of the photosynthetic apparatus to the quantities of pigments present, however, has become clearer. By quantifying the number of chlorosomes, their dimensions, and the amount of baseplate-covered membrane, Golecki and Oelze (1987) were able to show that the number of chlorosomes and the percentage of membrane surface area covered by baseplates correlated directly with the cellular content of bchl *a*. Under conditions in which the specific bchl *a* content of cells increased linearly, the bchl *c* content increased exponentially. The large increase in bchl *c* was accomodated by increasing the volume of the chlorosomes, the density of the bchl *c* molecules within the chlorosomes, and the number of chlorosomes (Golecki and Oelze, 1987).

Light Harvesting and Primary Photochemistry

A brief discussion of the light-harvesting and photochemical activities of *C. aurantiacus* is included here because of their relevance to understanding the distant phylogenetic relationship of this organism to all other phototrophs. The photosynthetic apparatus of *Chloroflexus* has very interesting similarities to components within several diverse groups of phototrophs.

The photochemical reaction center of *C. aurantiacus* is very similar to the reaction centers of the purple nonsulfur bacteria. There are also some significant differences. The *Chloroflexus* reaction center is the smallest one known, being composed of only 2 polypeptide subunits instead of the 3 or 4 found in other bacteria (Pierson et al., 1983; Shiozawa et al., 1987). The pigment composition also differs from that of purple bacterial reaction centers. *Chloroflexus* has a photoreactive special pair or dimer of bchl *a* molecules as in the purple bacteria, but it has only one additional bchl *a* molecule and 3 bacteriopheophytin *a* molecules, rather than 2 additional bchl *a* and 2 bacteriopheophytin molecules found in the purple bacteria (Pierson and Thornber, 1983; Blankenship et al., 1984). Furthermore, the *Chloroflexus* reaction center lacks carotenoid pigments (Pierson and Thornber, 1983) and menaquinone is the electron acceptor for photochemistry rather than ubiquinone (Vasmel and Amesz, 1983). Functionally, the reaction center of *Chloroflexus* is very similar to that of the purple bacteria, and the intermediate electron acceptor is bph*a* in both (Blankenship et al., 1983, 1984; Kirmaier et al., 1983). The arrangement of the chromophores appears to be similar to that in purple bacteria, based on spectroscopic measurements (Vasmel et al., 1986). The two subunits of the *Chloroflexus* reaction center are probably structurally similar to those of the purple bacteria since the L subunits exhibit 40% sequence homology and the M subunits 42% (Ovchinnikov et al., 1988a, 1988b; Shiozawa et al., 1989). Within the pigment-binding regions of the two subunits, the homology is higher (59–75%) (Shiozawa et al., 1989). Thus, although *C. aurantiacus* is only distantly related to the purple bacteria, the reaction centers have strong structural and functional similarities. The lack of the H subunit in the *Chloroflexus* reaction center, slight differences in pigment composition, and intrinsic thermal stability have little to do with the apparently highly conserved structural and functional characteristics of the sites directly involved in the primary photochemical act.

The molecular organization of the light-harvesting system is particularly interesting in *Chloroflexus* since it has a complex antenna involving accessory bchl *c* housed in chlorosomes adjacent to the cell membrane. The chlorosomes also appear to contain a small component of bchl *a* (Schmidt, 1980; Sprague et al., 1981a; Feick et al., 1982) that appears to be involved in transferring excitation energy to additional antenna components in the cell membrance (Van Dorssen and Amesz, 1988). The low efficiency of transfer mediated by this component (Brune et al., 1987) and the recently developed preparative procedures that produce chlorosomes lacking this component (Griebenow and Holzwarth, 1989) reveal that the nature of the baseplate bchl *a* complex remains uncertain. Although the size, composition, and ultrastructure of the chlorosomes of *Chloroflexus* differ somewhat from those of the green sulfur bacteria, both contain small-molecular-weight bchl *c* binding proteins. The bchl *c* binding polypeptides among different species of green sulfur bacteria have a high degree of homology and an overall homology of about 30% with the comparable polypeptide from *Chlo-*

roflexus (Wechsler et al., 1985b; Wagner-Huber et al., 1988). The green sulfur bacteria, however, do not have an intramembrane or cytoplasmic membrane antenna system similar to that found in *Chloroflexus* and the purple bacteria. The bchl *a* antenna in the cell membrane of *Chloroflexus* is very similar to that in the intracytoplasmic membranes of purple bacteria. In addition to harvesting light energy directly, however, it also funnels excitation energy from the chlorosomes to the reaction center (Brune et al., 1987; Wittmershaus et al., 1988; Van Dorssen and Amesz, 1988). The absorption properties of this antenna, with maxima near 805 and 865 nm, are similar to those of many purple bacteria, and the small-molecular-weight polypeptides that bind the bchl *a* molecules show some homology to the comparable polypeptides in purple bacteria (27–40%) (Wechsler et al., 1985a, 1987).

Electron Transport Systems

The electron transport chains of both phototrophically and chemotrophically grown cells of *C. aurantiacus* have been characterized (Pierson, 1985; Wynn et al., 1987; Knaff et al., 1988; Zannoni, 1986; Zannoni and Venturoli, 1988). Chemotrophically grown cells contain at least three *c*-type cytochromes and at least three *b*-type cytochromes (Wynn et al., 1987; Zannoni, 1986). These cells lack the high-potential cytochrome c_{-554} that functions as the electron donor to the reaction center in phototrophically grown cells (Wynn et al., 1987). The identity of the terminal oxidase for aerobic respiration remains clouded in controversy. Data from two laboratories support the presence of cytochrome aa_3 (Pierson, 1985; Zannoni, 1986), while others have been unable to detect this cytochrome and suggest that a CO-binding, protoheme-containing cytochrome functions in this capacity (Wynn et al., 1987; Knaff et al., 1988). It seems likely that the terminal oxidase may vary depending on the levels of oxygen in the medium during growth of the cells. While there is some evidence for the presence of a putative cytochrome bc_1 in the membranes of chemotrophically grown cells (Zannoni, 1986), complete confirmation of the presence of cytochrome c_1 and a Rieske center is lacking (Wynn et al., 1987). It appears that the respiratory chains present in cells grown under either oxygen-saturated conditions or with lower levels of oxygen are branched chains (Zannoni, 1986; Zannoni and Fuller, 1988), and identification of all terminal oxidases as well as the complete sequence of carriers in each chain remains to be elucidated.

Phototrophically grown cells also contain multiple *b* and *c* type cytochromes, including the electron donor to the reaction center, cytochrome c_{554} (Wynn et al., 1987; Zannoni and Ingledew, 1985). The cells lack a soluble cytochrome c_2, which is clearly not essential for either photosynthesis or respiration in *Chloroflexus* and in some purple nonsulfur bacteria (Zannoni, 1987). There is strong evidence for the presence of a putative cytochrome bc_1 complex in the membranes of phototrophically grown cells (Zannoni and Ingledew, 1985), as well as for the presence of cytochrome *c*-CO binding activity (Pierson, 1985; Wynn et al., 1987; Zannoni and Ingledew, 1985).

Menaquinone is the only quinone present in both chemotrophic and phototrophic cells of *Chloroflexus* (Hale et al., 1983). The shift from aerobic respiration to photosynthesis requires synthesis of both of the bchls and the cytochrome c_{554} required for photochemistry. Lowered oxygen tension appears to be the only signal needed to induce these syntheses, with light having no role in the process (Foster et al., 1986).

Thermophily

The thermophilic aspects of the physiology of *C. aurantiacus* have been studied in several systems. Soluble enzyme activities determined as a function of temperature were found to be maximal between 45 and 70°C, consistent with the optimum growth temperature in this range (Laakmann-Ditges and Klemme, 1988; Krasil'nikova, 1987; Krasil'nikova et al., 1986). Although *sym*-homospermidine is present in *C. aurantiacus* as in many other thermophiles, its presence in several mesophiles makes it difficult to conclude that this polyamine necessarily has any role in contributing to the thermal stability of components in cells of *Chloroflexus* (Norgaard et al., 1983). The isolated photochemical reaction center of *C. aurantiacus* exhibits thermal stability (Pierson et al., 1983). The functioning of membrane-bound proteins at elevated temperatures, however, is dependent on the properties of the membrane as well as the temperature characteristics of the proteins themselves. Oelze and Fuller (1983) determined the temperature characteristics of growth and the membrane-bound enzyme activities of NADH oxidase, succinate 2,6-dichlorophenol-indophenol reductase, ATPase, and light-induced proton extrusion. Enzymatic activities were maximal at 65–70°C, and a major lipid phase transition occurred near 40°C in cells grown at 50°C. Membrane phenomena were significantly altered at temperatures above

60°C, which may reflect denaturation of bulk membrane proteins (Oelze and Fuller, 1983). Although individual enzyme activities were high in this temperature range, proton extrusion was not thermostable above 60°C and growth rates did not increase in this range. Fluorescence from the membrane-bound bchl *a* antenna complexes increased when the temperature decreased from 50 to about 40°C which corresponded to the region of probable lipid-phase transition (Wittmershaus et al., 1988). Fluorescence from the nonmembrane-bound pigments in the chlorosome did not increase at this temperature and it appeared that energy transfer from bchl *c* to bchl *a* within the chlorosome was not temperature-dependent. Within the membrane-bound parts of the photosynthetic apparatus, however, lipid-phase transitions near 40°C may alter the mobility of quinones in the less fluid membrane. The altered mobility may decrease the rate of photosynthesis and produce the observed enhanced fluorescence of the membrane-bound antenna complexes (Wittmershaus et al., 1988).

Physiological Properties of Other Filamentous Phototrophs

Knowledge of the physiological properties of "Oscillochloris," *Chloronema,* and *Heliothrix* is based on studies conducted in the field or on impure collections, enrichments, or cocultures. Since these observations must be subjected to verification with pure cultures, we have not reported them in detail here. Summaries of the important physiological properties of "Oscillochloris" and *Chloronema* have been compiled (Gorlenko, 1988, 1989a, 1989b). The physiology of *Heliothrix* has been studied in situ (Pierson et al., 1984; Castenholz and Pierson, 1989).

The Genus *Thermomicrobium*

JEROME J. PERRY

Thermomicrobium roseum (ATCC 27502) is the sole representative of a phylogenetically distinct branch of the eubacteria. It is an obligately thermophilic organism originally isolated from the effluent of a hot spring in Yellowstone National Park, WY (Jackson et al., 1973). *T. roseum* has been grouped with the green nonsulfur (GNS) bacteria based on ribosomal RNA sequence comparisons (Oyaizu et al., 1987). *Herpetosiphon* and *Chloroflexus*, the other representatives in this branch (Fig. 1), are markedly different phenotypically from *T. roseum*. Although the GNS bacteria share some common ribosomal characters they are the progeny of a deep phylogenetic divergence (Gibson et al., 1985); *Herpetosiphon* is a mesophile and more rapidly evolving than either *Chloroflexus* or *Thermomicrobium*. The deepest branching in eubacterial evolution is predominantly represented by thermophiles (Fig. 1), and these organisms evolved more slowly than the mesophiles. They have consequently retained more of their ancestral character (Achenbach-Richter et al., 1987).

Isolation and Enrichment

The primary enrichment medium for *T. roseum* was composed of 0.1% tryptone and 0.1% yeast extract (TYE) in Allen's salts (see recipe below) (Allen, 1959). (The final pH was adjusted to 7.8.) Enrichment media were inoculated with samples of bacterial mat or water from various springs in Yellowstone National Park and were incubated at 70, 75, 80, and 85°C. After a suitable time, the enrichments were streaked on TYE agar (3.0%) plates made up in Castenholz's salts (Jackson et al., 1973; Castenholz, 1969) (see also Chapter 206).

The enrichment culture inoculated with bacterial mat sample taken from Toadstool Spring in Yellowstone and incubated at 70°C was the only one that yielded unusual colonies. These were compact pink colonies distinctly different from the other isolates that appeared to be mostly of the genus *Thermus*. Transfer by streaking on the TYE agar medium at pH 8.5 and an increased level of tryptone and yeast extract (to 0.5%) led to a pure culture of *T. roseum* (Jackson et al., 1973).

Allen's Salts (mg/liter)

Component	mg/liter
$(NH_4)_2SO_4$	1,300
KH_2PO_4	280
$MgSO_4 \cdot 7H_2O$	247
$CaCl_2 \cdot 2H_2O$	74
$FeCl_3 \cdot 6H_2O$	19
$MnCl_2 \cdot 4H_2O$	1.8
$Na_2B_4O_7 \cdot 10H_2O$	4.4
$ZnSO_4 \cdot 7H_2O$	0.22
$CuCl_2 \cdot H_2O$	0.05
$Na_2MoO_4 \cdot 2H_2O$	0.03
VCL_2	0.03

Adjust the pH to 7.8.

Castenholz's Salts (mg/liter)

Component	mg/liter
Nitrilotriacetic acid	100
$CaSO_4 \cdot 2H_2O$	60
$MgSO_4 \cdot 7H_2O$	100
NaCl	8
KNO_3	103
$NaNO_3$	689
Na_2HPO_4	111
$FeCl_3$	0.28
$MnSO_4 \cdot H_2O$	2.2
$ZnSO_4 \cdot 7H_2O$	0.5
H_3BO_3	0.5
$CuSO_4$	0.016
$Na_2MoO_4 \cdot 2H_2O$	0.025
$CoCl_2 \cdot 6H_2O$	0.045

Habitat

Toadstool Spring (no longer active) was located in the Lower Geyser Basin of Yellowstone National Park. *T. roseum* was isolated from a sample taken near the source of the spring where the water temperature was 74°C with a pH of 8–9. The inoculum was from an orange/red bacterial mat attached to a silica substrate. The mat had accumulated under a piece of wax paper debris that may have offered some protection from the high light intensity and rapidly moving

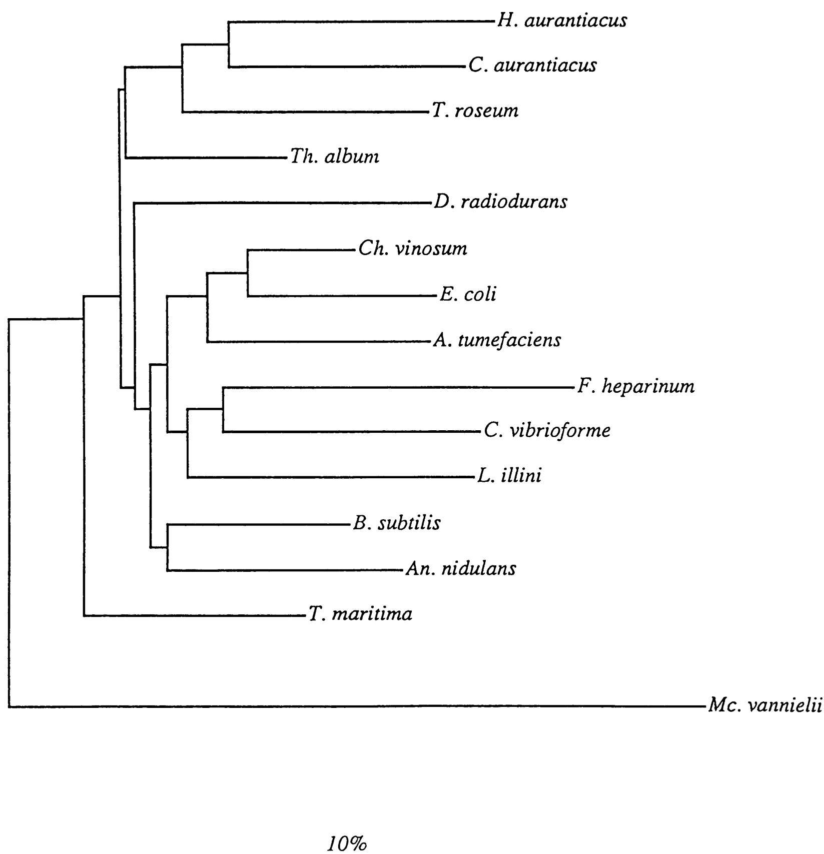

Fig. 1. A phylogenetic tree for the eubacteria, showing also the position of one archaebacterium, *Methanococcus vannielii.* Organisms are: *Herpetosiphon aurantiacus, Chloroflexus aurantiacus, Thermomicrobium roseum, Thermoleophilum album, Deinococcus radiodurans, Chromatium vinosum, Escherichia coli, Agrobacterium tumefaciens, Flavobacterium heparinum, Chlorobium vibrioforme, Lactobacillus illini, Bacillus subtilis, Anacystis nidulans,* and *Thermatoga maritima.* (Personal communication from C. R. Woese.)

water. Although Jackson et al. (1973) suggested that glass slides immersed in the water near the source of the spring exhibited microbial growth that appeared similar to *T. roseum,* microbes have not yet been cultivated from these sources.

A thermophilic organism was isolated from soil by enrichment with *n*-alkanes as substrate and was tentatively assigned to the genus *Thermomicrobium* (Phillips and Perry, 1976). Subsequent DNA-DNA hybridization studies indicated that this isolate should be placed in an entirely different genus (Zarilla and Perry, 1986, 1987.)

Substrate Utilization Patterns

Complex media are the preferred substrate for *T. roseum.* A maximum cell yield was attained with tryptone and yeast extract each added at 0.5%, with a lower level (0.3%) supporting the most rapid growth. Little growth occurred with the substrates added at 1.0%. Levels higher than 1.0% completely inhibited growth. *T. roseum* grew on peptone, casein hydrolysate, brain heart infusion, nutrient broth, trypticase soy broth, and on tryptone or yeast extract (substrate at 0.2%), provided that NH_4^+ (in Castenholz's salts) was incorporated as nitrogen source. Of these, only nutrient broth and yeast extract yielded growth with NO_3^- (in Allen's salts) as the source of nitrogen. *T. roseum* grew on a defined medium with selected substrates and then only on addition of 0.2% glutamate with NO_3^- as nitrogen source. Glycerol and sucrose were adequate carbon sources under these conditions. Sparse growth occurred with glutamate as sole substrate (Allen's salts). Fructose, succinate, mannitol, acetate, and citrate were inadequate as growth substrates (Jackson et al., 1973). Growth with Allen's salts was consistently better than that attained with Castenholz's salts. Apparently, there was some loss of ammonia from the latter at this pH and temperature.

Cultivation

The optimum temperature for growth was 70–75°C at a pH between 8.2 and 8.5. The minimum temperature at which *T. roseum* would grow was 45–48°C, and the pH extreme for growth was 7 to 8.7. Under optimum conditions with tryptone and yeast extract (0.3%) as substrates the organism had a generation time of 5 to 5.5 h.

Identification

T. roseum cells are generally pleomorphic and occur as short, irregular-shaped rods, single or paired, with some cells assuming a dumbbell shape. The organism is 1.3 to 1.8 μm in diameter and 3 to 6 μm in length. The GC content of the DNA is 64.3 mol%. The colonies on agar are compact and pink-pigmented. Although some slight motility was observed in light microscopy, there was no evidence of flagella under electron microscopy, and the organism is considered to be nonmotile (Jackson et al., 1973). Endospores are not visible in *T. roseum* by light, phase contrast, or electron microscopy. The organism is Gram-negative, and thin sections viewed longitudinally have a layered cell wall consistent with this staining character. Electron-dense hexagonal structures were visible in thin sections that may have been bacteriophages, but no lytic activity was observed (Jackson et al., 1973).

DNA hybridization reactions were employed to determine whether there was reassociation of *T. roseum* DNA with DNA from thermophilic *Bacillus* strains, *Thermus aquaticus,* and *Thermoleophilum album.* The results confirmed that *T. roseum* is not related to any of these other organisms (Zarilla and Perry, 1986, 1987). Antibiotic sensitivity tests indicate that *T. roseum* is sensitive to kanamycin, neomycin, and penicillin, but less sensitive to erythromycin and chloromycetin (Jackson et al., 1973).

The pigments were extracted from *T. roseum* with acetone and analyzed spectrophotometrically. The absorbance maxima at 470, 494, and 530 nm indicate that *T. roseum* carotenoid pigments are similar to torulene and 3,4-dehydrolycopene. Extracted pigment from the bacterial mats that served as the enrichment inoculum had equivalent absorptive properties (Jackson et al., 1973).

Physiological Properties

Membrane Lipid Composition

Virtually all eubacterial and eukaryotic cells have membrane lipids composed of fatty acids esterified to α-glycerolphosphate. The membranes of archaebacteria differ markedly in that the lipids of these organisms are composed of isoprenoid chains joined to glycerol by an ether linkage. The membrane lipids of *T. roseum* have neither ester nor ether linkages, but are composed of a series of straight-chain and internally branched 1,2-diols. A typical 1,2-diol is shown in Fig. 2. The carbon length of the diols ranges from C_{18} to C_{23} (Pond et al., 1986).

The cellular lipids account for about 3% of the dry weight of the cell, and, of this, 22.6% is nonpolar neutral lipid and 77.1% is polar glycolipids or phospholipids. Polar lipids were hydrolyzed to remove the polar head groups and the apolar residues were analyzed (Pond et al., 1986). The distribution of the 1,2-diols present in the lipid of *T. roseum* are listed in Table 1. These structures are analogous to the glycerolipids in that the terminal hydroxyl can link to the polar-head group and long-chain fatty acids can be esterified to the secondary hydroxyl. This would provide the hydrophobic chains necessary for a lipid bilayer (Pond et al., 1986). Analysis of the fatty acid constituents of these unusual lipids indicated that they too had normal and internally methylated hydrocarbon chains (Pond and Langworthy, 1987). The distribution of fatty acids in *T. roseum* grown at 70°C is presented in Table 2. Methyl-branched chain fatty acids are also common constituents of eubacterial lipids but generally they are iso- or anteisomethylated fatty acids.

The effect of temperature on the relative amounts of normal to branched chain fatty acids and diols was determined (Pond and Langworthy, 1987) and the results are presented in Table 3. As the growth temperature was increased, the relative percentage of unbranched fatty acids and diols increased, while the rela-

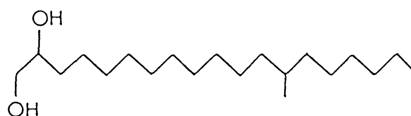

Fig. 2. Typical structure of a long-chain 1,2-diol from the lipid of *Thermomicrobium roseum.* This diol is 13-methyl-1,2-nonadecanediol.

Table 1. Distribution of 1,2-diols in the lipids of *Thermoleophilum roseum* after growth at 75°C.

Compound	Percent of total
11-Methyl-1,2-heptadecanediol	<0.5
1,2-Nonadecanediol	10.6
13-Methyl-1,2-nonadecanediol	21.1
1,2-Cosanediol	6.1
13-Methyl-1,2-cosanediol	2.5
15-Methyl-1,2-cosanediol	0.9
1,2-Eicosanediol	48.5
15-Methyl-1,2-eicosanediol	7.8
1,2-Docosanediol	1.0
1,2-Tricosanediol	1.1
1,2-Tetracosanediol	<0.5

Adapted from Pond et al. (1986).

Table 2. Distribution of fatty acids in *Thermomicrobium roseum* after growth at 70°C.

Compound	Percent of total
n-Hexadecanoic	1.2
10-Methyl-pentadecanoic acid	1.5
n-Heptadecanoic acid	0.5
10-Methyl-hexadecanoic acid	0.7
n-Octadecanoic acid	24.2
12-Methyl-heptadecanoic acid	57.3
n-Nonadecanoic acid	2.6
12-Methyl-octadecanoic acid	1.9
n-Cosanoic acid	8.4
14-Methyl-nonadecanoic acid	1.2

Adapted from Pond and Langworthy (1987).

Table 3. Effect of temperature on the percentage of normal and branched chain fatty acids and diols in *Thermomicrobium roseum*.

Growth temperature (°C)	Percent normal	Percent branched
Fatty Acids		
60	24.1	75.6
75	46.3	52.4
Diols		
60	62.2	37.1
75	87.3	12.5

Adapted from Pond and Langworthy (1987).

tive amount of the methyl-branched constituents decreased (Pond and Langworthy, 1987). The longer chain, normal fatty acids have a higher melting point than the branched homologs, so increased branching as the temperature is lowered may be a mechanism whereby membrane fluidity is retained at lower temperatures.

Cell Wall Structure

Electron microscopy of negatively stained outer cell wall preparations from *T. roseum* indicated that there were regular, repeating structures present in the cell envelope. These structures appear in a consistent mosaic pattern (Ramaley et al., 1978). Analysis of purified cell walls from *T. roseum* suggested that the organism has low levels of peptidoglycan (Merkel et al., 1980), although it is sensitive to penicillin (Jackson et al., 1973). Cell walls were removed from *T. roseum* and purified. This purified cell wall material was readily separated into two fractions (A and B) which were analyzed for amino acid composition (Table 4). Fraction A was composed of an array of amino acids with alanine, glutamic acid, and glycine predominating; lesser amounts of diaminopimelic acid, galactosamine, and muramic acid were detected.

Table 4. Amino acid composition of the two fractions of the cell wall of *Thermomicrobium roseum*.[a]

Component	Fraction A (%)	Fraction B (%)
Threonine	8.1	3.6
Serine	6.2	4.0
Proline	8.1	14.0
Muramic acid	3.1	0
Glutamic acid	12.8	11.9
Glycine	19.3	33.8
Alanine	16.8	11.5
Valine	4.0	1.8
Diaminopimelic acid	1.2	0
Leucine	6.2	3.2
Isoleucine	0	1.8
Tyrosine	4.7	2.2
Galactosamine	3.1	0
Histidine	1.2	3.2
Arginine	3.7	Trace
Lysine	0	Trace
Ornithine	0	7.2
Phenylalanine	0	1.8

[a]Expressed as % of the total amino acid/sugar present.
From Merkel et al., 1978.

Fraction B was a cell wall protein that accounted for 60% of the total cell wall amino-reactive material. It had a M_r of 75,000; the amino acid composition of this protein is presented in Table 4. It is probable that this protein is the principal structural component of the cell wall revealed by electron microscopy (Ramaley et al., 1978; Merkel et al., 1980). How this protein may contribute to the thermostability of *T. roseum* is unknown.

Metabolism

Although *T. roseum* is a strict aerobe, it does not respond to increased oxygen levels by more rapid growth or higher cell yields. This is a common attribute of aerobic thermophiles and particularly of those that grow on hydrocarbon substrates (Allgood and Perry, 1985a, 1985b, 1986). Growth of *T. roseum* under higher O_2 tension did result in increased cellular levels of superoxide dismutase (SOD) and catalase. Addition of methyl viologen to increase superoxide anion generation in cells had little effect on the level of SOD but resulted in increased catalase activity (Allgood and Perry, 1986). That higher oxygen levels do not lead to more rapid growth or cell yield is probably due to factors other than the accumulation of toxic products of oxygen such as superoxide or hydrogen peroxide. Most of the respiratory activity in *T. roseum* is cyanide insensitive. The respiratory pathways in *T. roseum* have not been elucidated further (Allgood and Perry, 1985a, 1985b).

The Genus *Thermoleophilum*

JEROME J. PERRY

Thermoleophilum is a genus of eubacteria obligate for aerobiosis and thermophily. The genus is distinguished by the ability to grow solely on *n*-alkane substrates ranging in length from C_{13} to C_{20} (Merkel et al., 1978a, 1978b; Zarilla and Perry, 1984, 1986). Mud samples obtained from hot springs and from environmental niches generally considered nonthermal have both yielded isolates of the genus *Thermoleophilum.* Thermal elution profiles of DNA duplexes delineate two species within the genus, *T. album* and *T. minutum* (Zarilla and Perry, 1984, 1986). Sequencing of 16S rRNA from *T. album* strain NM affirms that these organisms should be placed in a separate "phylum" within the eubacteria (C. Woese, personal communication; see Fig. 1, Chapter 1). Organisms in this group are progeny of a deep divergence in the eubacterial line of descent. Isolation of strains from environments separated by considerable geographic distance indicates that *Thermoleophilum* strains may be of fairly common occurrence. Efforts to isolate a mesophilic counterpart of *Thermoleophilum* that would also be restricted to growth on *n*-alkane substrates have been unsuccessful.

Thermoleophilum species are Gram-negative, slow growing, small, nonmotile bacteria. They cannot utilize sugars, amino acids, fatty acids, or any substrate tested (except the *n*-alkanes) as source of carbon or energy. During active growth on n-heptadecane, the organism can incorporate a limited amount of acetate into cell material (less than 10% of total cell carbon). Members of this genus have a unique tetrahydrogenated menaquinone that has not been observed in the respiratory pigments of bacteria of any other species. The catalase from *Thermoleophilum* is a manganese-containing enzyme relatively resistant to cyanide inhibition.

Habitat

Thermoleophilum strains have been isolated from mud samples obtained from both thermal and nonthermal environments. The thermal environments included the outlet stream of hot springs in the states of Wyoming, Arkansas, and New Mexico (Table 1). The nonthermal environments were mud samples from Roanoke Rapids and Beaufort, NC. All mud samples were taken from aquatic environments and the temperature of sampling sites in Yellowstone, WY and Hot Springs, AR were near the optimum for growth of the strains isolated (YS-3, YS-4, and HS-5) (Merkel et al., 1978b; Zarilla and Perry, 1984). The nonthermal environmental samples were obtained from dark mud that was constantly exposed to the sun (strains PTA-1 and RR-D). Solar heating can raise the temperature of such dark surfaces to 60°C or higher (Brock, 1970). Growth of these obligate thermophiles in nonthermal environments would probably occur sporadically when the transient temperatures rose to a suitable level.

Attempts to isolate a mesophilic organism restricted to growth solely on *n*-alkane substrates have been unsuccessful. The presence of fast-growing, *n*-alkane-utilizing organisms in most environments of moderate temperature might well preclude the isolation of organisms with growth characteristics equivalent to *Thermoleophilum* species.

Table 1. Locations where *Thermoleophilum* strains have been isolated.

Strain	Source of inoculum	Temperature
T. album		
HS-5	Hot Spring, AR	61°C
NM	Faywood Hot Springs, NM	>50°C[a]
YS-3	Yellowstone National Park, WY	60°C
RR-D	Roanoke Rapids, NC	Ambient
T. minutum		
YS-4	Yellowstone National Park, WY	63°C
PTA-1	Beaufort, NC	Ambient

[a]Close to the water source and above 50°C.
Adapted from Zarilla and Perry, 1984.

Isolation and Enrichment

The primary enrichment medium for the isolation of *Thermoleophilum* species was prepared by adding *n*-heptadecane at 0.1% (v/v) to a mineral basal medium (L-salts) modified from that of Leadbetter and Foster (1958). The recipe for this medium is given below. Nitrogen was provided in the modified medium by adding 1 g/l of NH_4Cl and $NaNO_3$ (Zarilla and Perry, 1984). Mud samples employed as inocula were obtained from both thermal and nonthermal environments (Table 1). Incubation was at 60°C in stationary culture until turbidity was apparent. After repeated transfer in the liquid medium, a pure culture was obtained by streaking on the modified L-salts medium with 3.0% agar added. The *n*-heptadecane substrate was introduced by inverting the inoculated plate and placing 0.2-ml *n*-heptadecane in the cover. The plates were placed in plastic bags (to prevent desiccation) and incubated at 60°C for 5 days. The colonies were small white, dry, and flat. Axenic cultures were difficult to obtain as the organisms grow poorly on agar surfaces.

Mineral-Salts Medium (Modified L-Salts) for *Thermoleophilum* Species

NH_4Cl	1.0 g
$NaNO_3$	1.0 g
$MgSO_4 \cdot 7H_2O$	200 mg
Na_2HPO_4	210 mg
NaH_2PO_4	90 mg
$CaCl_2$	15 mg
KCl	40 mg
$FeSO_4 \cdot 7H_2O$	1 mg
$CuSO_4 \cdot 5H_2O$	5 μg
H_3BO_3	10 μg
$MnSO_4 \cdot 5H_2O$	10 μg
$ZnSO_4 \cdot 7H_2O$	70 μg
MoO_3	10 μg
Distilled Water	1 liter

Cultivation

The optimum temperature for growth of the isolates was 58–62°C at a pH between 6.5 and 7.5 (Table 2). *Thermoleophilum* species are limited to growth temperatures between 45 and 70°C. The generation time was difficult to determine accurately but exceeded 6 hours in every case. Strains are all strict aerobes but do not respond favorably to increased oxygen availability. Under optimal conditions of temperature (60°C), pH (7.0), and substrate (n-heptadecane), the cell yield ranged from 0.1 to 0.3 g/liter (Zarilla and Perry, 1984, 1986).

Substrate Utilization Patterns

None of the *Thermoleophilum* strains grew on any substrate tested other than *n*-alkanes (C_{13} to C_{20}). No growth occurred on shorter or longer chains of *n*-alkanes, l-alkenes, or alcohols of a chain length equivalent to that of the n-alkanes that did support growth. Homologous ketones and branched alkanes (C_{13} to C_{17}) were not utilized. The following substrates did not support growth: arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, melibiose, rhamnose, ribose, sorbose, sucrose, trehalose, xylose, glycerol, mannitol, sorbitol, acetate, propionate, butyrate, citrate, pyruvate, succinate, acetone, nutrient broth, peptone, yeast extract, or tryptone plus yeast extract. All of the strains utilized ammonium chloride as a nitrogen source. Strains HS-5, NM, and RR-D could also utilize sodium nitrate as sole nitrogen source. Two strains, HS-5 and NM, could derive their nitrogen from glycine but growth was poor, and none of the carbon of the glycine was incorporated. Neither alanine nor glutamate could serve as source of nitrogen. Addition of growth factors, e.g., B-vitamins or amino acids, to the growth medium did not alter the growth rate or total growth. Compilation and use of a mineral salts medium similar in composition to the hot springs water of the original sampling site in Yellowstone had no effect on growth rate or cell yield.

Identification

Thermoleophilum species are very small, Gram-negative rods (Table 1 and Fig. 1). The organisms are nonmotile and have no pigmentation. They have been isolated only on n-alkane enrichment substrates (C_{13}–C_{20}) and are readily identified by their inability to grow on any other substrate. *Thermoleophilum* strains have a GC content of 68.8 to 70.4 mol%. The major diamino acid in the cell wall peptidoglycan of the genus *Thermoleophilum* is diaminopimelic acid. All strains demonstrated a confluent growth on agar surfaces with few individual colonies formed. Colonies were small, round, and white, and generally dry and flaky. They were often contaminated with pink-pigmented thermophilic strains on original isolation, and separating the slow-growing *Thermoleophilum* species was a tedious process.

DNA hybridization studies indicated that *T. album* and *T. minutum* are of the same genus but different species (Table 3) (Zarilla and Perry, 1986). There was no homology with *Thermomicrobium roseum, Bacillus thermoleo-*

Table 2. Properties of *T. album* and *T. minutum*.

Strain	Cell length (μm)	Generation time (h)	n-Alkane substrate range	GC content (mol%)
T. album				
HS-5	0.9	6.5	C_{13}–C_{20}	70.4
NM	1.0	9	C_{14}–C_{20}	68.8
YS-3	0.7	6	C_{13}–C_{20}	69
RR-D	1.0	7.5	C_{14}–C_{20}	70
T. minutum				
YS-4	1.5	6	C_{13}–C_{20}	70

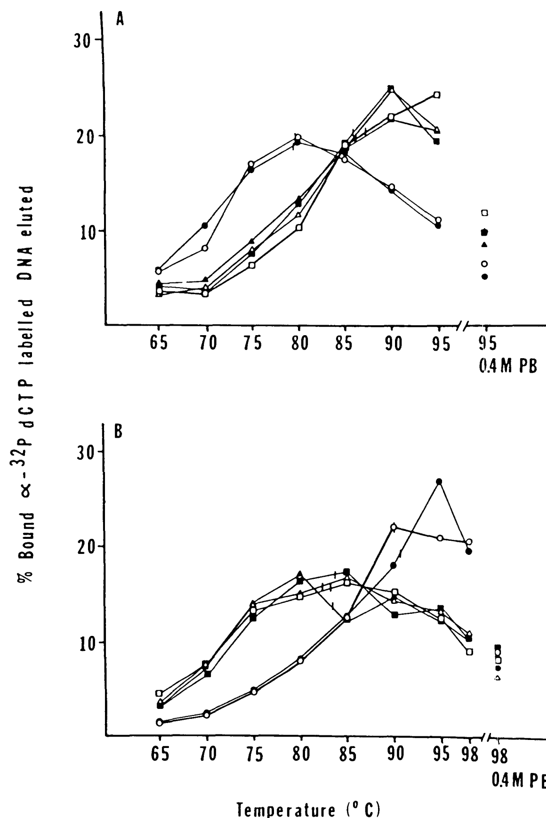

Fig. 2. Thermal elution profiles of *Thermoleophilum* DNA duplexes reassociated at 62°C. One strand of each DNA duplex was made up of [α-^{32}P]deoxycytidine triphosphate (dCTP)-labeled DNA from either *Thermoleophilum album* strain HS-5^T (A) or *Thermoleophilum minutum* strain YS-4^T (B). The other strand was made up of DNA from strain HS-5^T (□), YS-3 (▲), YS-4^T (○), NM (△), RR-D (■), or PTA-1 (●). The homologous duplex is indicated by a thick line. The thermal stability values are indicated by a vertical line on each curve and represent the temperature at which 50% of the double-stranded DNA was eluted from the hydroxyapatite. DNA was eluted with 0.14 M phosphate buffer (PB) containing 0.1% sodium dodecyl sulfate until the maximum temperature was attained, at which point any remaining bound DNA was eluted by using 0.4 M phosphate buffer. Adapted from Zarilla and Perry, 1986.

vorans, or *Thermus aquaticus*. Data presented in Fig. 2 confirm that there are two species within this genus.

Physiological Characteristics

Menaquinones are widely distributed in the plasma membranes of prokaryotes and are generally distinguished by the length of their isoprenyl side chain. The number of isoprenoid units varies from 1 to 15, and there are also species differences in the number of these isoprenoids that are saturated/unsaturated (Collins and Jones, 1981). Generally Gram-negative eubacterial menaquinones are composed of unsaturated isoprenoid units but a few Gram-negative bacterial species have dihydrogenated menaquinones. Examination of the respiratory quinones of *T. album* strain NM led to the isolation of a novel tetrahydrogenated menaquinone, 2 methyl-3-VI, VII-tetrahydroheptaprenyl-1, 4-naphthoquinone, as depicted in Fig. 3 (Collins et al., 1986). The presence of this naphthoquinone in *T. album* readily distinguishes the genus from other Gram-negative, aerobic, obligately thermophilic groups. The genus *Thermus* and *Thermomicrobium roseum* contain saturated menaquinone as their major respiratory quinone.

Superoxide dismutase is induced in aerobic bacteria by high oxygen stress. This enzyme, together with catalase and peroxidase, removes toxic oxygen intermediates generated as by products in the univalent reduction of molecular oxygen. These highly reactive intermediates of oxygen reduction are predominantly superoxide anion, hydrogen peroxide, and the hydroxyl radical. Growth of aerobic organisms at higher oxygen tensions or in the presence of methyl viologen (a superoxide generator) will effectively induce superoxide dismutase (Diguissepi and Fridovich, 1984; Hassan and Fridovich, 1977). Studies suggest that thermophilic bacteria generally react unfavorably to increased oxygen tension (Allgood and Perry, 1985b). As a consequence of this observation, an examination was made of the effect of oxygen stress on the level of superoxide dismutase, catalase, and peroxidase in *T. album* NM. Growth of strain NM in the presence of methyl viologen did not affect the level of cellular superoxide dismutase but caused a marked increase in catalase activity. Peroxidase activity increased a small amount. Increasing the oxygen level also led to higher levels of catalase with a decrease in total growth (Allgood and Perry, 1985a, 1985b, 1986b). The level of oxygen defense enzymes is comparable with that in other aerobic bacteria. It does not appear that products of O_2 reduction are responsible for the negative response to increased aeration.

The catalase from *T. album* NM has been isolated, purified, (>96%), and characterized. The major properties of the enzyme are presented in Table 4. For comparison the properties of the equivalent enzyme from *Escherichia coli, Rhodopseudomonas sphaeroides* and *Lactobacillus plantarum* are included. The catalase from *T. album* is thermoactive and thermostable. It has a low M_r, and the metal present is manganese. This is the only report of a manganese-containing catalase in an aerobic organism. The significance of such a catalase in this ancient thermophile is not for us to understand at this time.

The electrophoretic mobility of several enzymes in crude cell-free extracts from *T. album* strains were markedly different from the equivalent enzyme from other thermophiles (Zarilla and Perry, 1986). Among these enzymes of differing mobility were malate dehydrogenase, catalase, esterase, and superoxide dismutase. Electrophoresis of purified catalase and malate dehydrogenase from *T. album* NM resulted in the same pattern.

T. minutum YS-4 extracts contained all of the enzymes involved with the tricarboxylic acid cycle except α-ketoglutarate dehydrogenase (J. G. McCarthy and J. J. Perry, unpublished observations). Exhaustive attempts to demonstrate this enzyme in any of the *Thermoleophilum* strains have been unsuccessful. An active isocitrate lyase was present in extracts of *Ther-*

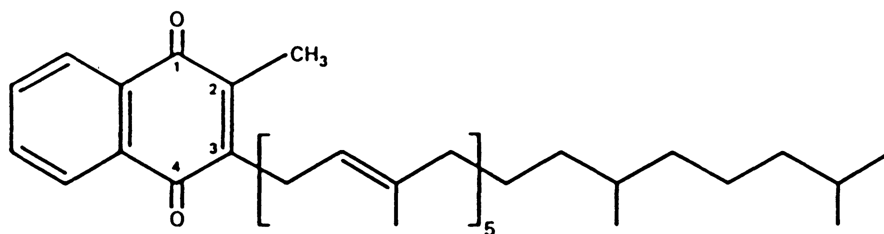

Fig. 3. Structure of the tetrahydrogenated menaquinone from *Thermoleophilum album*. Adapted from Collins et al., 1986.

Table 4. Comparison of the properties of the catalase from *T. album* with that from other bacterial species.

Organism	Metal present	Molecular weight, M_r	Number of subunits
Thermoleophilum album	Mn	141,000	4
Escherichia coli	Fe	337,000	4
Rhodopseudomonas sphaeroides	Fe	232,000	4
Lactobacillus plantarum	Mn	172,000	6

moleophilum, suggesting that an active glyoxylate cycle is present. All strains had NADH and NADPH oxidase activity. *T. album* NM had the large-sized citrate synthase typical of Gram-negative bacteria (K. Weaver and J. J. Perry, unpublished observations). Addition of ^{14}C-acetate to nonproliferating cells of *T. album* NM resulted in little incorporation of acetate. Addition of radiolabeled acetate to a culture during active growth on *n*-heptadecane did result in some incorporation of acetate but at a level of less than 10% of the total cell carbon. Increasing the level of acetate from 0.1 mM to 50 mM did not lead to any increase in incorporation (K. C. Terlesky and J. J. Perry, unpublished observations). The inability of the organism to incorporate more added acetate and the absence of α-ketoglutarate dehydrogenase is reminiscent of these activities in the obligate autotrophs. It may be that the genus *Thermoleophilum* cannot obtain energy from substrates other than the *n*-alkanes utilized.

CHAPTER 209

The Genus *Herpetosiphon*

HANS REICHENBACH

The *Herpetosiphon* species are aerobic, chemoorganotrophic, filamentous bacteria that are Gram-negative but do not have a typical Gram-negative cell wall. The filaments are very long, unbranched, and multicellular, between 0.6 and 1.5 μm wide and usually 300 to more than 1200 μm long (Fig. 1). Short transparent sections ("sleeves": Fig. 2) are seen at the ends of many filaments. These sleeves are characteristic of *Herpetosiphon*, and they make it possible to recognize the organism easily under the microscope.

Sleeves are also found with related organisms, like *Chloroflexus*. Depending on the strain, the medium, and the age of the culture, the filaments may fragment into much shorter pieces and ultimately into single cells. The cells in the filaments are tightly attached to one another, and in living filaments their boundaries can only be seen with a microscope of high resolution at a high magnification, by phase or interference contrast (Fig. 2). They become clearly recognizable if the filament has been dried to the slide and stained (Fig. 2). The cells have the

same width as the filaments and measure 1.5–5 μm in length, rarely more. The filaments may perform slow gliding movements; thus, on suitable substrates, the colonies develop into large spreading swarms (Fig. 3). The surface of the swarm is usually feltlike. Long flamelike projections or protruding strands of curled filaments are seen at the edge (Fig. 3). Normally the colonies are colored in shades of yellow, orange, or brick red, but unpigmented strains do occur. The GC content of the DNA is 45–53 mol%.

Herpetosiphon is a common inhabitant of soil, freshwater, and sewage plants. Some species live in marine environments.

It appears that *Herpetosiphon* was first discussed in the scientific literature under the name of *Flexibacter giganteus* (Soriano, 1945, 1947). Soriano's description of the filaments, the swarm colonies, and their color perfectly matches the cultures now called *Herpetosiphon.* Also, the habitats he studied and the isolation technique he applied must inevitably have led to the discovery of that organism. However, the first valid description of the genus, with one species, *H. aurantiacus,* was provided by Holt and Lewin (1968). The definition was based on three isolates of E. E. Jeffers obtained from the slime coat of a green alga, *Chara* sp., from Birch Lake in Minnesota. Later, a dispute arose about the presence of a sheath in *Herpetosiphon,* and the genus definition was slightly modified to exclude a sheath (Reichenbach and Golecki, 1975). Also, Reichenbach and Golecki (1975) proposed that the species name *aurantiacus* be abandoned in favor of the name *giganteus,* which antedates it. This change could have been done without danger of confusion since Soriano's strain is no longer available. However, there are definitely several *Herpetosiphon* species, and one could argue therefore that Soriano's *H. giganteus* was different from *aurantiacus.* Thus, it may be better to give up the name *giganteus* until we know more about the taxonomy of the genus. Later, five more species were added to the genus (Lewin, 1970). The organism described from Lake Constance (Germany) as a new *Vitreoscilla* species, *V. proteolytica* (Gräf and Perschmann, 1970), is also undisputably a *Herpetosiphon*; strains of this organism are still available and have been studied by the present author. Further, the bacterium isolated from the walls of a sluice of the Neckar river near Heidelberg (Brauss et al., 1969) was most likely also a *Herpetosiphon,* although the authors felt they could rule out that possibility. Also, filamentous organisms connected with bulking sludge in various sewage plants in southwestern Germany have been identified as *Herpetosiphon* and *Herpetosiphon*-related bacteria (Salcher et al., 1982; Senghas and Lingens, 1985; Trick and Lingens, 1984). In the rest of this chapter, the group isolated from sewage will be referred to as *Herpetosiphon,* while those isolated from sludge as *Herpetosiphon*-like bacteria. These organisms are of particular interest because of their practical implications, and because filamentous bacteria in activated sludge have been notoriously difficult to classify (for a summary, see Pipes, 1978).

A comparison of 16S rRNA oligonucleotide catalogs clearly shows a phylogenetic relationship of *Herpetosiphon* to *Chloroflexus* and *Thermomicrobium* (Gibson et al., 1985; Woese et al., 1985). The group is well separated from all other bacteria and represents one of the main branches (a phylum) in the bacterial tree of descent. By the same method, it has been possible to rule out any connection to filamentous, gliding *Vitreoscilla,* as well as to *Beggiatoa* and *Leucothrix,* which belong to the beta and gamma branches, respectively, of the purple bacteria (the class Proteobacteria, as defined by Stackebrandt et al., 1988). Any relationship with the filamentous cyanobacteria (a connection that was discussed for many years) has also been ruled out (Reichenbach et al., 1986; for a summary, see Reichenbach, 1981). Interestingly, the relationship with *Chloroflexus* is also reflected in the very unusual structure and com-

Fig. 2. Filaments of the type strain of *Herpetosiphon aurantiacus* at high magnifications. (a) Filaments from CY agar. Note the enormous variability of the filaments' diameter, which is especially pronounced on peptone media. Slight constrictions at the filaments' surface and dark bands in the interior indicate cell boundaries, which can be particularly clearly recognized in the thick filament in the upper left sector; dark dots seen in many cells may be mesosomelike membrane bodies. (b) The translucent segments seen next to the filaments are empty cell-wall cylinders and correspond to the sleeves often found at the ends of the filaments; here, as in other figures of this table, parallel running filaments approach one another very closely, which seems to exclude the presence of a sheath of any significance. (c) The knots in the filaments testify to their incredible flexibility; the filament on the left contains a necridium; from VY/2 agar. (d) The filament has a short sleeve at the end and a necridium which is almost ready to snap. (e) A short filament with sleeves at both ends and a necridium. (f) In several filaments, cross-walls are recognizable; there is a one- and a two-celled segment, the latter with a living and a dead cell; from CY agar. (g) Decaying filament fragmenting into cell-wall cylinders, each corresponding to one cell. Because the cylinders separate cleanly, there can be no sheath. All micrographs were taken with Zeiss Axiomat, in phase contrast. Bars = 10 μm.

position of the cell walls of the two organisms. Both organisms contain a peptidoglycan in which *meso*-diaminopimelic acid is replaced by L-ornithine, and to which a polysaccharide is covalently bound; and both organisms lack a lipopolysaccharide (Jürgens et al., 1987, 1989).

While some progress has been made, our knowledge of *Herpetosiphon* is still very incomplete (for summaries, see Reichenbach and Dworkin, 1981; Holt, 1989). A film showing the movements of the filaments and the development of the colonies is also available (Reichenbach et al., 1980).

Habitats

Typical *Herpetosiphon* strains are regularly found in freshwater, in soil, and in decaying organic matter, such as rotting wood, dung of herbivorous animals, and compost. *Herpetosiphon* appears to be rather common everywhere in aerobic environments, in the neutral pH range and under mesophilic conditions. Some freshwater habitats have already been mentioned. A study on the distribution of *Herpetosiphon* in the surface layers of Lake Constance, a large, deep, fairly oligotrophic lake in southwestern Germany, demonstrated the organism only in contaminated areas close to cities or at the mouths of rivers, while it was absent in clean stretches of water in the middle of the lake or along uninhabited and undisturbed shores (Gräf and Perschmann, 1970). This suggests that the *Herpetosiphon* population at the lake surface has its origin in the soil of the surrounding country and in contaminated waters running into the lake. The examples mentioned in the introduction show, however, that *Herpetosiphon* also thrives in the benthos of freshwater bodies. therefore, its absence in the surface layers is best explained by a fast sedimentation of the flocs of entangled filaments, which can stay in suspension only in vigorously agitated liquids.

Herpetosiphon and *Herpetosiphon*-like bacteria grow abundantly in the activated sludge of sewage plants (Salcher et al., 1982; Senghas and Lingens, 1985; Trick and Lingens, 1984). In fact, there may be such an explosive development that it leads to the much-feared bulking of the sludge. The reason for mass development is not yet fully understood and is probably not always the same, but one factor could be the presence of a high population of grazing protozoa that remove competing unicellular bacteria (Güde, 1979). Bulking in sludge is not due to the flocs not settling fast enough to become separated from the liquid, since the flocs settle indeed reasonably well. The problem is rather that the flocs show poor compaction properties, so that the sludge removed from the settling tank contains too much water. The cause of bulking sludge is always a microbiological one, and in most cases it is due to the excessive growth of filamentous bacteria. This has been known for many years, and several efforts have been made to classify the various types of filamentous organisms found in sewage (for a summary, see Piper, 1978). Success in understanding bulking was, however, rather limited, mainly because most of those bacteria could not be cultivated (also the case with many *Herpetosiphon* strains, as will be discussed later). *Herpetosiphon* must have been observed many times in sewage material, but it was never recognized as such. Thus, the organism described from a Dutch sewage plant as belonging to group III (van Veen,1973) was almost certainly *Herpetosiphon* (strain Rz in van Veen's Fig. 12 shows the typical empty sleeves at the ends of the filaments). Those bacteria were practically

Fig. 3. Various swarm colony types of *Herpetosiphon aurantiacus.* The colonies of *Herpetosiphon* are very variable and occasionally show striking patterns. (a) Swarm with a rhythmic growth pattern, on VY/2 agar. Bar = 1 mm. (b) Swarm showing surface growth (right), as well as penetration into the agar (light areas). Bar = 1 mm. (c) and (d) Colonies with proboscislike protuberances; (c) survey picture; (d) protuberances at higher magnification. Bar = 1 mm in both (c) and (d). (e) Swarm growing from a streak of autoclaved *E. coli* on water agar; the curly pattern is characteristic for this kind of culture; the cloudy areas in the lower part indicate penetration of the organism into the agar. Bar = 1 mm. (f) and (g) Large swarm on VY/2 agar; the swarm sheet tends to contract and peel off the agar surface, producing large holes surrounded by ridges; this growth pattern is very characteristic for *Herpetosiphon.* Bar = 1 mm in both (f) and (g). (h) Delicately plicated surface of a swarm sheet on VY/2 agar; this is a relatively unusual pattern. Bar = 100 μm. (i) to (l) Knobs; they are sometimes produced in large numbers and arranged in patterns (i, l) that make their resemblance to myxobacterial fruiting bodies even more striking; also, their size is in the range of fruiting bodies. Bar = 1 mm in (i) and (l), 500 μm in (j), and 200 μm in (k). (m) Microcolony showing its composition of long, coiling, and interwoven filaments on CY agar. Bar = 100 μm. (n) Swarm on a streak of autoclaved *E. coli* (center) on water agar spreading in an uncommon pattern of broad, tapelike tongues. Bar = 1 mm. (o) Edge of a swarm growing on a streak of living *E. coli* on water agar; in contrast to the usual pattern on this medium, as shown in (b) and (e), here the swarm ends in a series of compact knobs with delicate, flamelike extensions (swarm center is to the right). Bar = 1 mm. Pictures made with Leitz Aristophot, (a to g); Zeiss Axiomat, (h, j, k, m); and Olympus SZH Stereo Microscope, (i, l, n, o).

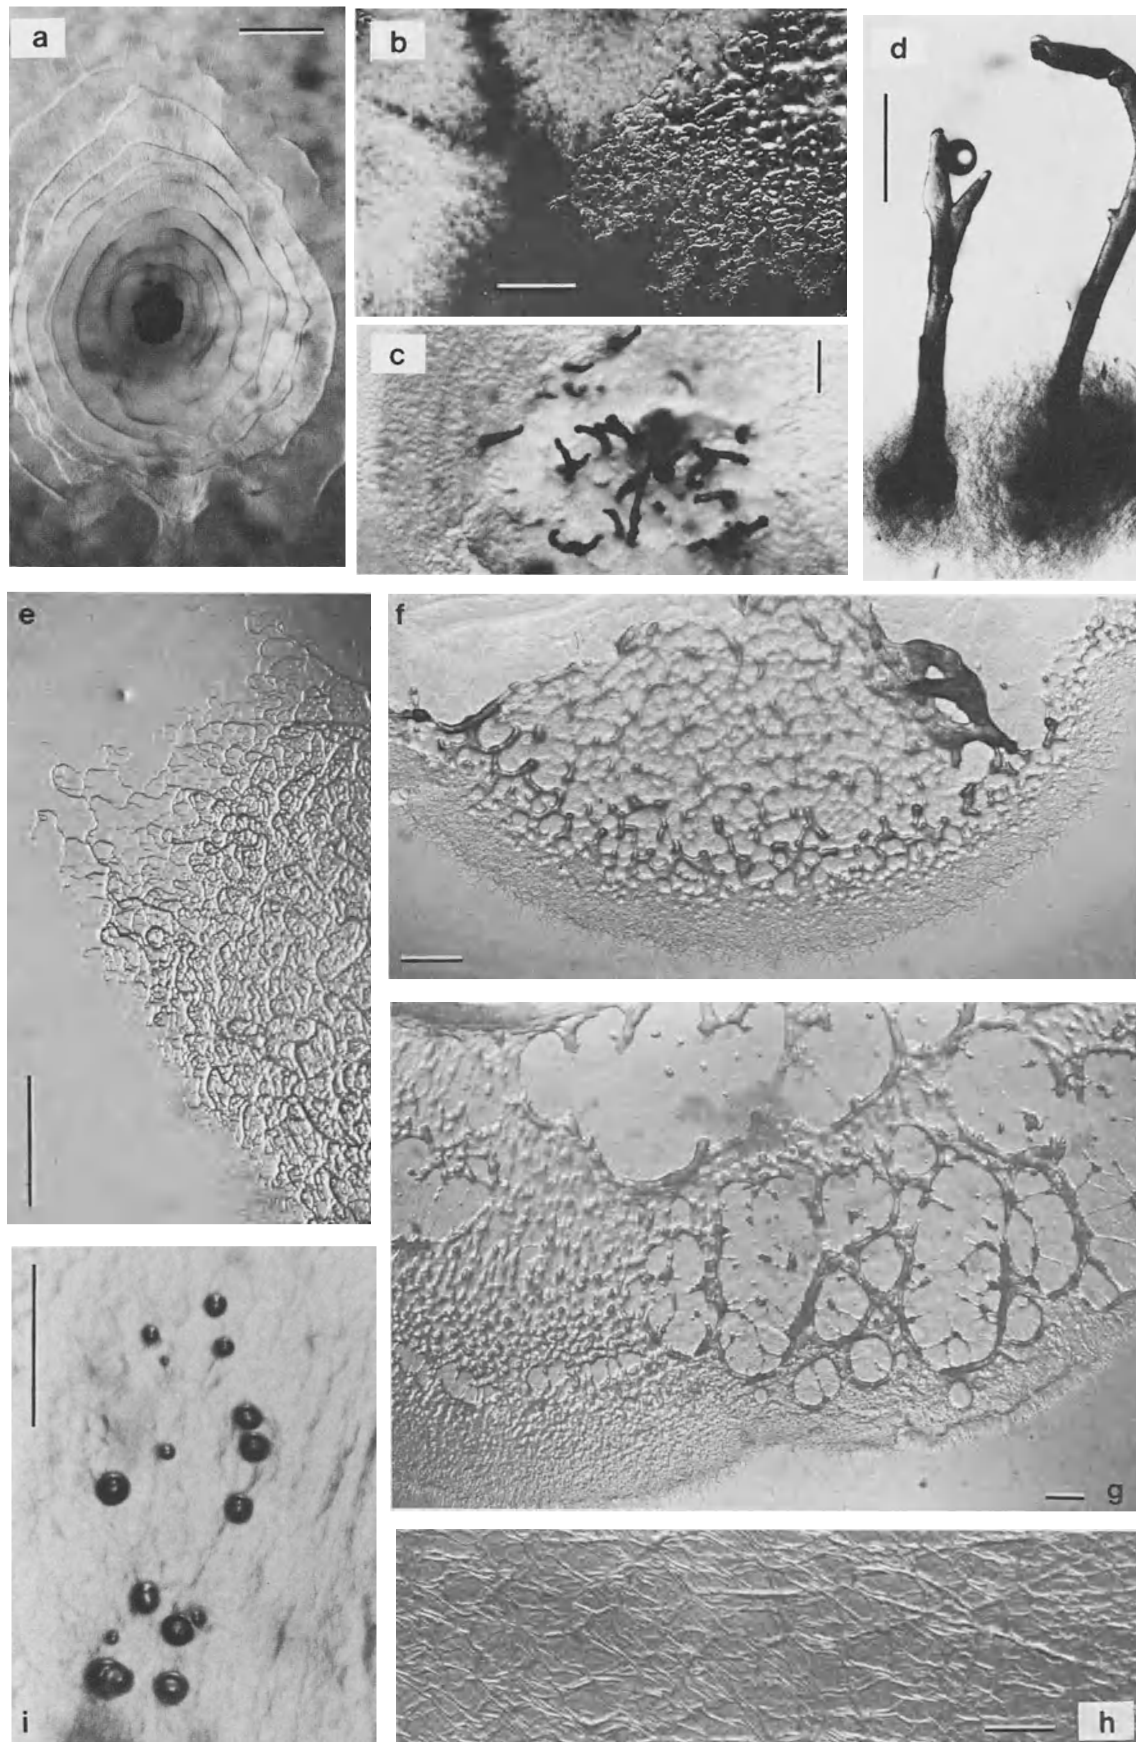

Fig. 3. Parts a to i. (Parts j to o on next page.)

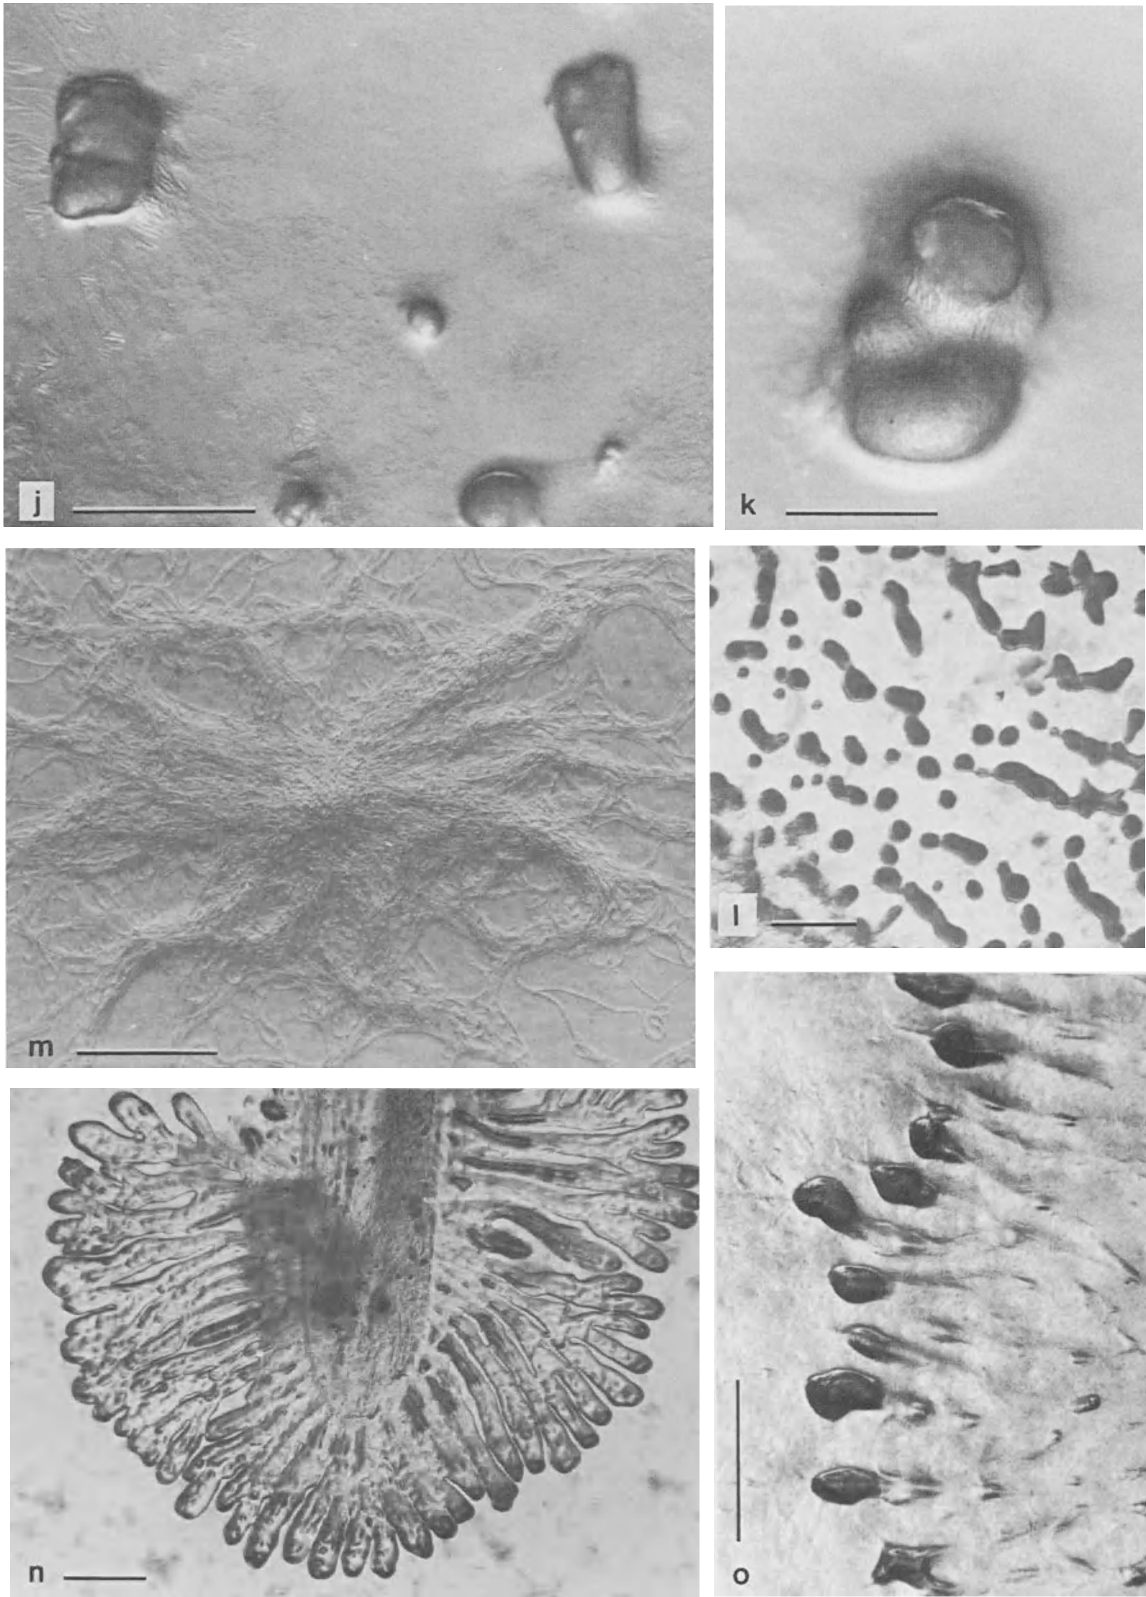

Fig. 3. Parts j to o.

always present in activated sludge and probably also contributed to bulking.

One species, *H. geysericola,* is described from the surroundings of a hot spring (Lewin, 1969, 1970). It is represented by just one strain, which in addition appears to be thermotolerant rather than thermophilic (the literature is completely mute about that important point; but the ATCC catalog lists a growth temperature of 30°C for the strain). The environment from which *H. geysericola* was isolated is of interest insofar as this is the typical habitat of the related *Chloroflexus.* In a study in a Yellowstone hot spring it was shown that the bacterial mat contained two other types of filamentous bacteria besides *Chloroflexus* (Tayne et al., 1987). Unfortunately, the antiserum used to identify *Chloroflexus* was not applied to *Herpetosiphon* out of all bacteria tested for cross-reactions. Perhaps *Herpetosiphon* is more common in that environment than has so far been assumed.

Several *Herpetosiphon* strains came from marine enviroments and were classified as separate species (Lewin, 1969, 1970). The organisms require at least half-strength seawater for growth and thus must be regarded as genuinely marine bacteria. The present author's own experience with isolating gliding bacteria from marine sources shows me, however, that *Herpetosiphon*-type organisms cannot be particularly common in that environment; Lewin also isolated only three marine strains among 90 other gliding bacteria, although in his marine samples he observed a few more *Herpetosiphon*-like organisms, which he could not isolate.

While *Herpetosiphon* obviously is a very common inhabitant of freshwater, it is equally at home in nonaquatic environments. As a byproduct during the isolation of myxobacteria, we have isolated in the course of 20 years more than 200 *Herpetosiphon* strains from soil samples, dung pellets, rotting wood, and similar materials collected all over the world in various climate zones, including decidedly hostile, dry, and hot environments, like semi-deserts in Tunisia and Arizona, steppe habitats in Mediterranean countries, the Canary Islands, and gypsum hills on Cyprus (H. Reichenbach, unpublished observations).

Isolation

Herpetosiphon may be isolated from any of the sources mentioned above. The terrestrial strains usually survive desiccation so that dry samples can also be used. We were able to obtain *Herpetosiphon* from rotting wood after 8 years storage, from filter-paper preserves of contaminated myxobacteria after 6 years, and from soil after 2 years of storage in the dry state at room temperature. It has been noted that strains from sewage plants are also extremely resistant to desiccation (Trick and Lingens, 1984).

No specific enrichment techniques are known. For isolation use is made of the ability of the organism to glide away from the inoculum and to produce a typical swarm pattern. To elicit gliding and to suppress excessive growth of contaminants, media very low in organic constituents are recommended. The simplest medium is plain water agar, to which cycloheximide may be added to prevent the development of fungi:

WAT Agar

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Adjust the pH to 7.2 with KOH. When used for crude cultures, cycloheximide (25 μg/ml medium) may be added after autoclaving, from a filter-sterilized stock solution (yielding WCX agar).

Several small samples of soil or other source of inoculum (size of a lentil) are placed on the surface of the dry plate, a few cm from each other, and the culture is incubated at 30°C. After 2 to 20 days, the typical swarm colonies with long flares and coils of entangled filaments at the edge may be observed (Fig. 3). The very delicate pattern can only be seen, however, if an oblique light beam produced by a tiltable mirror is applied from below. We have had success with WAT agar plates with three thin, parallel streaks of living *Escherichia coli,* each of which is inoculated at one end. *Herpetosiphon* grows in a spreading fashion within the streaks, usually without lysing the *E. coli* cells and often only appears along the edges of the streaks in the form of long flamelike structures or a loose pattern of separate, coiling strands of filaments. Sometimes, however, large and more or less dense swarm sheets are produced that spread over much of the plate. An especially high yield of *Herpetosiphon* can sometimes be obtained if such cultures are incubated at 38°C.

In a similar way, marine strains can be obtained by streaking littoral silt and mud on seawater agar.

Seawater Agar (Lewin and Lounsbery, 1969)

Tryptone (Difco)	0.02%
Agar	1%

In seawater.

After autoclaving, cycloheximide (100 μg/ml) is added from a filter-sterilized stock solution.

The cultures are incubated at room temperature (24°C) and examined over a 2 to 3 week period for the appearance of spreading organisms.

The strains on which the definition of the genus is based were isolated by making a single streak from the slimy coat of *Chara* on a plate with 0.3% peptonized milk (Difco) and 1.5% agar. The culture was incubated at room temperature. Evidently, this relatively rich medium can be used only if the sample contains few other microorganisms (Holt and Lewin, 1968).

For the isolation of planktonic *Herpetosiphon* in freshwater, between 0.5 and 1 liter of lake or river water is passed through a sterile membrane filter (pore size, 0.4 μm). The filter is then cut into pieces, and the segments are placed on a low-nutrient agar medium. In the original study, rabbit dung agar was used, but any other lean medium would certainly also do.

Rabbit Dung Agar (Gräf and Perschmann, 1970)

Dry dung pellets from wild rabbits (20 g) are boiled in 1 liter of distilled water for 20 min. The filtrate is used with 1.5% agar. The pH is adjusted to 7.2.

The cultures are incubated at 33°C. After about 6 days, swarm colonies begin to spread from the edges of the filter.

The strains from activated sludge were isolated by streaking a drop of the sludge sample on BG-11 agar (originally designed for the isolation of cyanobacteria) or on I agar (Salcher et al., 1982; Trick and Lingens, 1984).

BG-11 Agar (Stanier et al., 1971)

$NaNO_3$	1.5 g
K_2HPO_4	0.04 g
$MgSO_4 \cdot 7H_2O$	0.075 g
$CaCl_2 \cdot 2H_2O$	0.036 g
Citric acid	0.006 g
Ferric ammonium citrate	0.006 g
EDTA (Na_2-Mg salt)	0.001 g
Na_2CO_3	0.02 g
Trace element solution A5	1 ml
Agar	15 g
Water	1 liter

The trace element stock solution A5 contains per liter: H_3BO_3, 2.8 g; $MnCl_2 \cdot 4H_2O$, 1.8 g; $ZnSO_4 \cdot 7H_2O$, 0.2 g; $Na_2MoO_4 \cdot 2H_2O$, 0.4 g; $CuSO_4 \cdot 5H_2O$, 0.08 g; $Co(NO_3) \cdot 6H_2O$, 0.05 g.

I Agar (Salcher et al., 1982; from van Veen, 1973, modified)

Glucose	0.15 g
$(NH_4)_2SO_4$	0.5 g
$Ca(NO_3)_2$	0.01 g
K_2HPO_4	0.05 g
$MgSO_4 \cdot 7H_2O$	0.05 g
KCl	0.05 g
$CaCO_3$	0.1 g
Agar	15 g
Water	1 liter

After autoclaving, 10 ml of a filter-sterilized vitamin solution is added. The vitamin solution contains per liter: Ca pantothenate, 10 mg; nicotinic acid, 10 mg; biotin, 0.5 mg; cyanocobalamin, 0.5 mg; folic acid, 0.5 mg; pyridoxine·HCl, 10 mg; *p*-aminobenzoic acid, 10 mg; thiamine pyrophosphate, 10 mg; thiamine, 10 mg; inositol, 10 mg; riboflavin, 10 mg.

As sewage organisms are notoriously fastidious and adapted to very low nutrient levels, I have suggested those complicated media; whether they are really required or could be replaced by simpler recipes has not been determined. While this is consistent with the behavior of the isolated, pure strains, those strains taken immediately from sewage may behave differently from those that have adapted to cultivation. The cultures are incubated at 25°C and examined with a phase contrast microscope over several weeks, because these organisms developed very slowly (Salcher et al., 1982).

Pure cultures can be obtained by transferring filaments from the advancing swarm edge to the same media again, or, as soon as the culture is sufficiently pure, to richer media (see "Cultivation," this chapter). We often have good results with transfers to streaks of autoclaved *E. coli* on water agar, although many *Herpetosiphon* strains do not grow on autoclaved bacteria (see below). As the organism has to be carefully removed from the contaminated plate, transfers are made best by cutting out a piece of the swarm edge on a small agar block using a drawn-out glass rod or, more conveniently, a fine steel injection needle (e.g., on a 1-ml disposable syringe). The procedure is repeated until the strain is pure. Two recently discovered properties of *Herpetosiphon* may substantially speed up purification: I have found that all *Herpetosiphon* strains tested so far grew at 38°C (some even at 40°C), and that all are resistant to 250 mg kanamycin sulfate per liter.

Cultivation

It appears that, in general, *Herpetosiphon* prefers low nutrient levels. Thus, one of our strains, Hp g175, produced good growth over six transfers on plain water agar, obviously living off minute quantities of contaminating material in the agar but without visibly attacking the agar itself. Rich media, like nutrient agar or nutrient broth, are often not suitable at all.

About one strain out of three that is isolated from soil on streaks of living *E. coli* can be

cultivated without difficulty on complex media, such as VY/2 agar and CY agar. Those strains usually produce heavy growth, and often spread within a few days over the entire plate. Some strains tend to penetrate into the agar (Fig. 3). The yeast in VY/2 agar may or may not be lysed.

VY/2 Agar

Bakers' yeast (fresh weight of commercial yeast cake)	0.5%
$CaCl_2 \cdot 2H_2O$	0.1%
Cyanocobalamin	0.5 μg/ml
Agar	1.5%

Adjust to pH 7.2.

CY Agar

Casitone (Difco)	0.3%
Yeast extract	3 g
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Adjust to pH 7.2.

The cultivation of the remaining 70% of those strains is essentially an unsolved problem. A few of them respond favorably to a reduction of the nutrient concentration and can be grown on media like VY/5 agar (as VY/2 agar, but yeast concentration reduced to 0.2%). Others grow more or less poorly on *Escherichia coli* overlay agar, but most of them can barely be kept alive on streaks of autoclaved or living *E. coli* on water agar.

Escherichia coli Overlay Agar

The growth of four culture plates of *E. coli* (on any suitable medium) is suspended in 100 ml of water agar (WAT agar, see "Isolation"). The suspension is autoclaved and poured as a thin layer on top of water agar plates.

Many strains survive only on living bacteria, presumably because they require some labile growth factor. The alternative explanation, that *E. coli* removes some inhibiting component, seems less likely because the *Herpetosiphon* filaments often creep far away from the *E. coli* streak. All our efforts to identify growth factors have been unsuccessful, although many possibilities have been tested (different vitamins, sugars, and amino acids; plant oil; chitin, catalase, cell fractions of *E. coli* and of cultivable *Herpetosiphon* strains; anaerobic and microaerophilic conditions; different agar concentrations, temperatures, pH values; illumination).

The freshwater strains can be grown on the same or on similar media as mentioned above. *H. geysericola* was cultivated on medium 2 (Lewin, 1970):

Medium 2 (Lewin and Lounsbery, 1969)

Casamino acids	0.1%
Na glycerophosphate	0.01%
Tris buffer	0.1%
KNO_3	0.01%
$CaCl_2 \cdot 2H_2O$	0.01%
$MgSO_4 \cdot 7H_2O$	0.01%
Thiamine	1 mg/l
Cyanocobalamin	1 μg/l
Agar	1%
Glucose	0.1% (added after autoclaving)

Adjust to pH 7.5.

Medium 2 was used as a standard medium for the cultivation of many different organisms; thus, not every component may be required by *Herpetosiphon* (e.g., thiamine).

For the sewage and sludge strains, either EC medium or ATCC medium 810 was used:

EC Medium (Enriched *Cytophaga* Medium: Pate and Chang, 1979)

Tryptone (Difco)	0.2%
Yeast extract (Difco)	0.05%
Na acetate	0.02%
Agar	1.5%

ATCC Medium 810 (Myxo 810 Medium)

Skim milk powder	0.5%
Yeast extract	0.05%
Agar	1.5%

The pH is not adjusted.

The seawater organisms grow well on medium 1 (Lewin, 1970):

Medium 1 (Lewin and Lounsbery, 1969)

Tryptone (Difco)	0.5%
Yeast extract (Difco)	0.5%
Na glycerophosphate	0.1%
KNO_3	0.05%
Agar	1%

In seawater.
The pH is adjusted to 7.0.

Most of the cultivable strains also grow in liquid media, in shake flasks, and in fermentors. A good medium for many strains is HP74 liquid medium. Other strains grow equally well or better in peptone-containing media, e.g., in CAS liquid medium or in MDl liquid medium.

HP74 Liquid Medium

Na glutamate	1%
Yeast extract (Difco)	0.2%
$MgSO_4 \cdot 7H_2O$	0.2%
Glucose (autoclaved separately as a 20% stock solution)	1%

Dissolve the ingredients in phosphate buffer (pH 6.5) at 1 mM. The buffer is autoclaved separately as a 50 mM stock solution.

CAS Liquid Medium

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH should be 6.8; do not adjust.

MDl Liquid Medium

Casitone (Difco)	0.3%
$CaCl_2 \cdot 2H_2O$	0.07%
$MgSO_4 \cdot 7H_2O$	0.2%
Cyanocobalamin	0.5 μg/ml

Trace element solution (see below) is added after autoclaving. The pH should be 6.8; do not adjust.

Casitone (Difco) may be replaced by other enzymatically digested casein peptones, but then the pH has to be adjusted to about 7.

Trace Element Solution

$MnCl_2 \cdot 4H_2O$	100 mg
$CoCl_2$	20 mg
$CuSO_4$	10 mg
$Na_2MoO_4 \cdot 2H_2O$	10 mg
$ZnCl_2$	20 mg
LiCl	5 mg
$SnCl_2 \cdot 2H_2O$	5 mg
H_3BO_3	10 mg
KBr	20 mg
KI	20 mg
EDTA, Na-Fe_3^+ salt (trihydrate)	8 g
Water	1 liter

Sterilized by filtration, this solution is stable for months at room temperature due to its high EDTA content. The mix is used at 1 ml per 1 medium.

In agitated cultures the organisms may grow as homogeneous suspensions, but often the filaments stick together to form flakes or tight spherules. One of our strains, Hp a2 (DSM 589), forms flakes when inoculated into HP74 liquid medium; the cultures become completely uniform after a few days, but the organism forms flakes again upon transfer into fresh medium. Growth is not particularly fast: the doubling time is in the range of 15–20 h, and the cultures do not enter the stationary phase until after 4–6 days of cultivation (30°C, HP74 liquid medium, shake flasks). Wet-weight yields are in the order of 1–3 g/liter in shake flasks, and 2–4.5 g/liter in fermentors (HP74 liquid medium. The dry weight amounts to roughly 20% of the wet cell mass.

For the cultivation of *Herpetosiphon* from sewage and sludge, EC medium (as above, without agar) is recommended (Trick and Lingens, 1984; Senghas and Lingens, 1985). The organisms were grown at 25°C, their temperature optimum; and the doubling time was 20–25 h. The cell yield after 5–6 days was 2–3.5 g/liter and 0.5–1 g/liter (dry matter), respectively, with the two sets of strains. The phosphate optimum of the sewage strains was at 0.01%.

The marine species were grown in medium 1 (as above without agar). They require a salt concentration between 0.5-fold and twofold that of seawater (Lewin and Lounsbery, 1969).

All known strains are strictly aerobic. The temperature range differs with different strains. In general, the freshwater and marine strains seem to prefer lower temperatures, around 25°C, while the soil and some freshwater strains grow very well at 30°C and above. All soil strains tested by us grew at 38°C, and some strains still grew vigorously at 40°C (e.g., Hp g196). The sewage strains showed a temperature minimum at 15°C, a maximum at 37°C, and an optimum at 25°C. *H geysericola* comes from the vicinity of a hot spring but can be cultivated at 30°C (see "Habitats"). The optimal pH range is 7–7.5, although pH values of 8–9 seem occasionally be tolerated.

Preservation

Most *Herpetosiphon* strains survive on agar media at 30°C or room temperature for up to 3 months. Slant cultures, stored at 4°C, have been successfully subcultured after 14 months. Stock cultures should be transferred every 3–4 weeks. A good medium for such cultures is VY/2 agar.

Herpetosiphon strains may be preserved by any of the standard procedures. A convenient and reliable method is storage at −80°C. The bacteria are suspended in 1 ml of CAS or HP74 liquid medium and simply put into the deep freeze. Thawing should be fast, best accomplished by immersing the tube in cold water, and transfers to a suitable growth medium have to be made immediately after thawing. We have been able to reactivate such preserved cultures with no problems after 8 years of storage, the longest period tested. Alternatively, the bacteria can be frozen in liquid nitrogen. In one study, the filaments were suspended in growth medium (medium 1 or 2 as above, without agar), supplemented with 10% of either glycerol or dimethyl sulfoxide (DMSO) (Sanfilippo and Lewin, 1970). All five strains survived freezing and thawing with both additives. Only the glycerol preserves were tested again after 1 year, and all strains were still viable. When stored in growth medium without additives at −22°C, three out of four strains survived for 21 weeks (the longest period tested) and one for 6 weeks. Strains dried in skim milk could always be reactivated after storage for up to 12 years. We do not freeze-dry the organism itself, but only the skim milk: A few drops of a thick suspension

of *Herpetosiphon* filaments, taken from a young plate culture, are added to a plug of freeze-dried skim milk in an ampule. The plug absorbs the liquid without liquifying itself. The ampule is then dried at room temperature in a desiccator on a vacuum pump for several hours. After filling the desiccator with nitrogen gas, the ampules are sealed.

Characterization

The morphology of *Herpetosiphon* is so distinct that the bacterium can readily be recognized under the microscope. Only the phylogenetically related genus *Chloroflexus* has a similar appearance, but it is a thermophilic, facultative phototroph found only in hot springs. *Herpetosiphon* forms extremely long, unbranched, multicellular filaments of uniform diameter (Fig. 1). The filaments often measure 300 to more than 1200 μm in length. The cells in a filament cohere tenaciously so that the filament does not break easily. Unconstrained filaments in a liquid medium appear straight and stiff, but in fact they are extremely flexible and can sharply bend back and twist around themselves in a ropelike fashion or intertwine into plaitlike masses (Fig. 1). The width of the filaments varies with different strains from 0.5 to 1.7 μm, mostly between 0.7 and 1.2 μm, there is also considerable variation within the same culture (Fig. 2). Thus I have measured filament diameters between 0.7 and 1.6 μm in an 11-day-old culture of the type strain of *H. aurantiacus* on CY agar. In older cultures or under unfavorable conditions, the filaments often swell substantially and may become completely irregular in outline. In old cultures, the filaments also tend to become shorter, especially on peptone-containing media, simply because more and more cells die and the filaments snap at such sites. The fragments can be as short as one cell. In old cultures, particularly on agar, short, optically refractile, irregular filaments are often seen (Fig. 4). As those are the only structures left in old, drying, but still viable cultures, they appear to be desiccation-resistant resting forms. However, their germination has not been directly observed so far.

The filaments consist of cylindrical cells that have the same diameter as the filament, and they are so closely attached to one another that only exceptionally shallow notches can be seen at the surface. Under a microscope with a high resolution using phase or interference contrast, the cells can sometimes be seen in living filaments (Fig. 2). The septa become more conspicuous in older cultures, particularly when the organism is grown on a peptone-rich medium, like CY agar. In such filaments the intracellular membrane bodies (see below) can often also be recognized (Fig. 2). The cells become clearly distinguishable if the filaments are first dried to the slide and then stained, e.g., with Loeffler's methylene blue, crystal violet, or alcoholic fuchsin (rosaniline; Fig. 2). The lengths of the cells vary even within one filament, which suggests that the cells do not divide synchronously. The cell length may also vary with the culture medium, the culture age, and the strain. With many strains, cell lengths between 1.5 and 4.5 μm have been measured. The type strain of the genus appears to have especially long cells, measuring between 3 and 7, and sometimes 10 μm.

A most characteristic feature of *Herpetosiphon* is the presence at the ends of many filaments of transparent sections, which we call sleeves (Fig. 2). The sleeves have the same diameter as the filaments and are 1.4–5.5 μm, usually 1.5–3.5 μm long (the measurements are those of strain Hp a2). The interpretation of those sleeves is still controversial. Some investigators have regarded them as an indication of a sheath (Holt and Lewin, 1968; Skerman et al., 1977) or at least of a microsheath (Trick and Lingens, 1984). We prefer a different explanation (Reichenbach and Golecki, 1975): The filaments appear to multiply by breaking at the sites of necridia, i.e., dead cells along the filament. Such necridia can occasionally be observed in young cultures, and their number increases substantially with the age of the culture (Fig. 2). Their length (1.5–3.7 μm) is in the size range of ordinary cells. Trichome division by breakage at necridial cells is well known from other bacteria and has been described, e.g., for *Oscillatoria* (Lamont, 1969) and *Beggiatoa* (Strohl and Larkin, 1979). When a filament snaps, the empty cell wall cylinder of the necridium remains attached to the end of one daughter filament and gives rise to a sleeve. In strain Hp a2, the outer wall seems to rupture at one of the ends of the necridium near the cross-wall rather than across its middle, for the shortest and the longest sleeves correspond exactly to the lengths of the shortest and the longest cells. This would also explain why only some of the filaments' ends bear a sleeve, although it seems that the sleeves may also be shed; often empty sleeves can be seen lying in between the filaments. With the type strain of *H. aurantiacus,* on the other hand, the sleeves are exceptionally short, with a size distribution corresponding approximately to one-half that of the cell length, so that here the necridia seem to break preferentially in their center. There are,

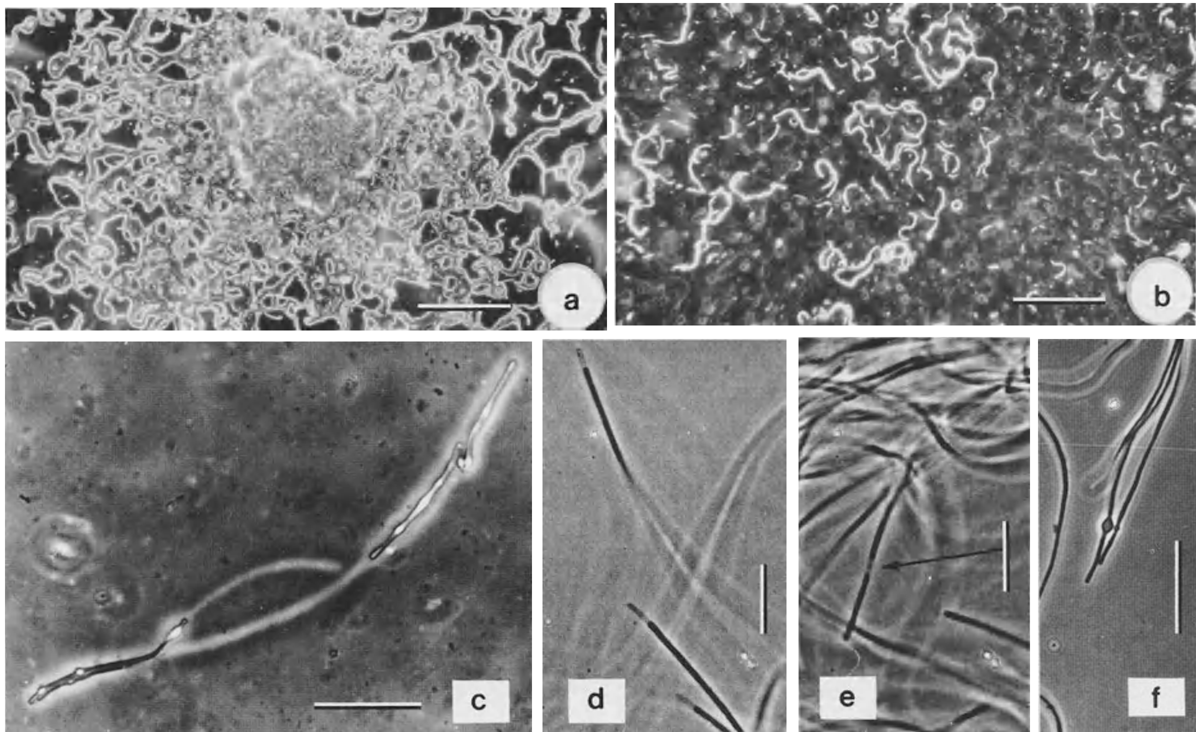

Fig. 4. Special structures of *Herpetosiphon aurantiacus.* (a to c) Desiccation-resistant filaments in a chamber culture. (a) and (b) Survey pictures; dark field; Bars = 200 μm: (a) 9 days old, with the filaments still essentially intact; (b) 32 days old, with only remnants of the filaments left. Bar = 200 μm. (c) At high magnification, the remaining segments of the old filaments appear irregular in outline and optically refractile; there are conspicuous slime tracks. Bar = 30 μm. (d) The empty sleeves that are visible here at the ends of many filaments are easy to recognize, even at a relatively low magnification, and thus help to quickly identify an isolate as a *Herpetosiphon.* Bar = 10 μm. (e) A necridium (arrow). Bar = 10 μm. (f) Bulbs. Bar = 20 μm. Zeiss Standard Microscope, (a) to (c). Zeiss Axiomat, (d) to (f); (c) to (f) in phase contrast.

however, at least six more arguments against the presence of a sheath: 1) The filament glides as a whole, with its empty end-pieces in position, which would seem unlikely if the cells were enclosed in a sheath. 2) There is no movement of cells within the filament, e.g., at the site of a necridium, nor a release of cells at the ends of the filament. This was observed by Holt and Lewin (1968), and also by the present author. But the literature is not in complete agreement on these points. Movement of a filament within its sheath has been described and "verified" by timelapse photography (Skerman et al., 1977); however, it is my impression that what was described as a sheath may really be a slime trail. Also, it was stated that single, gliding cells were released from the filaments (Brauss et al., 1969), but in this case it has not been ruled out that what was seen were simply short fragments that broke off the ends of the filament. 3) If the sleeve were a piece of a sheath, it would be difficult to understand why, as a rule, it does not exceed the length of a cell. 4) If a sheath were present, one could expect an occasional false branching of the filaments. 5) When a whole filament dies and decays, it falls apart into cell-sized pieces (Fig. 2). Obviously, there is no sheath to hold them together. 6) We have never been able to demonstrate anything resembling a real sheath under the electron microscope, with specimens prepared by freeze-etching, negative contrast, metal shadowing, or by thin-sectioning after several different fixation protocols (Reichenbach and Golecki, 1975; see also Gräf and Perschmann, 1970). This is also true for the type strain (Fig. 5). However, the thin, tubelike structure composed of fibrils, which has been described by several investigators and has been interpreted as a microsheath (Skerman et al., 1977; Senghas and Lingens, 1985; Holt, 1989), probably has a different explanation.

How can these differences of opinion about the existence of a sheath in *Herpetosiphon* be reconciled? Differences among strains can be ruled out, for we included the type strain in our studies and found no significant divergence from strain Hp a2. A sheath is a morphologically distinct structure, a hollow cylinder with

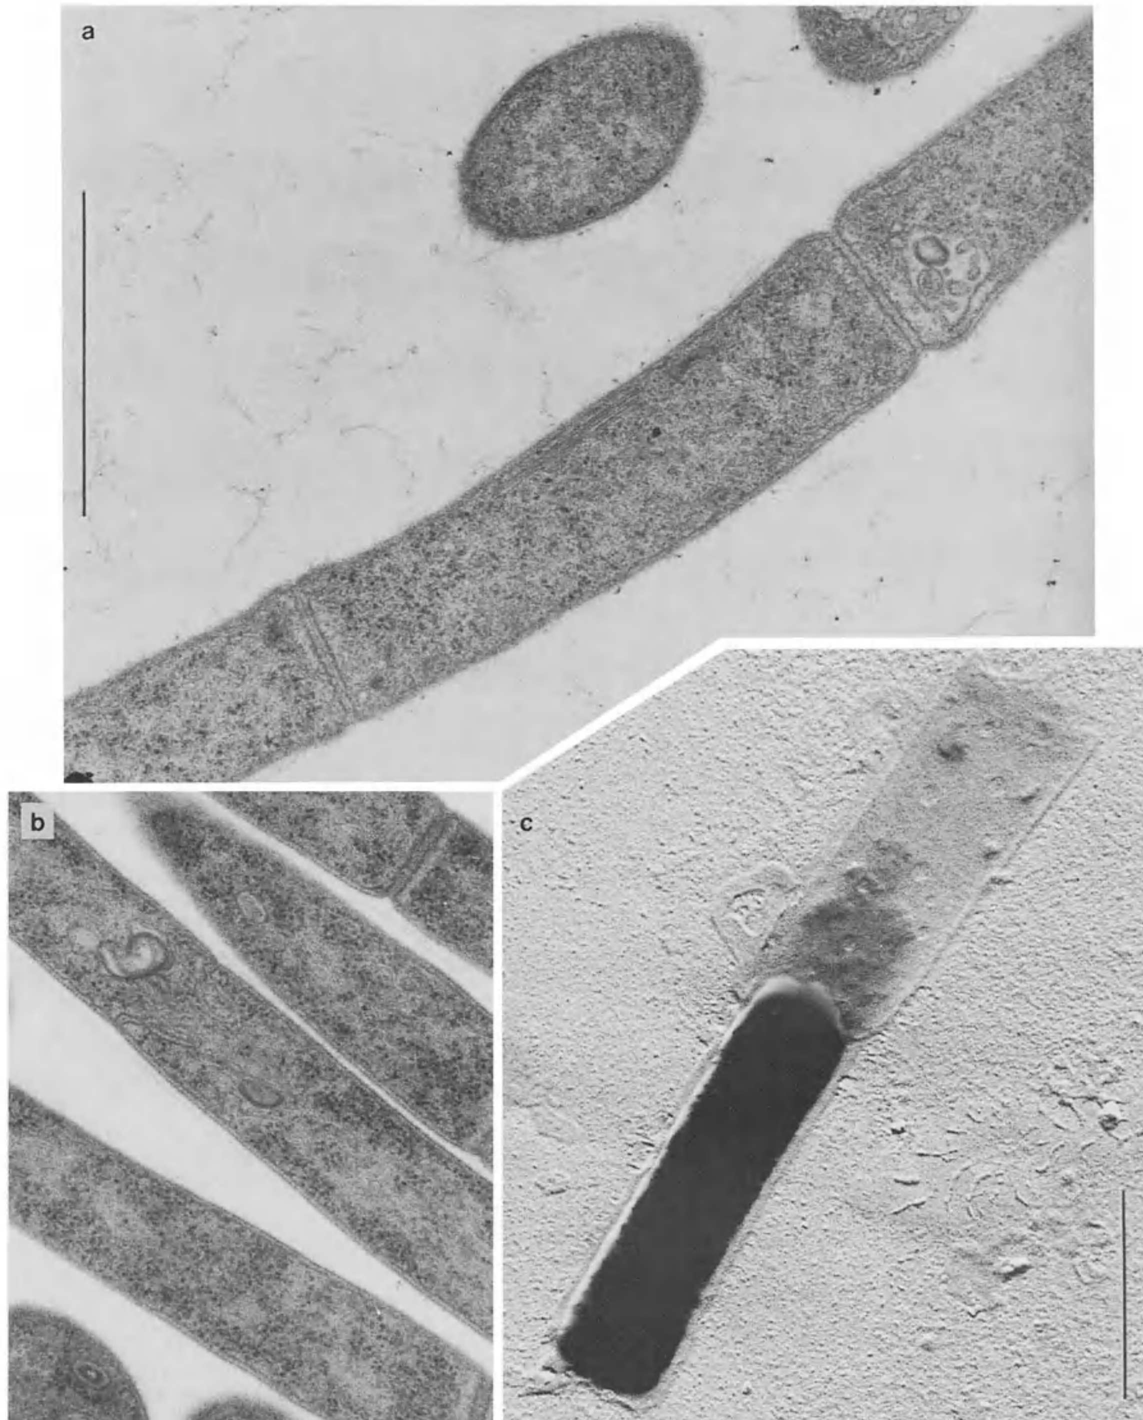

Fig. 5. Electron micrographs of the type strain of *Herpetosiphon aurantiacus.* (a) and (b) Ultrathin sections; the peptidoglycan layer can be clearly distinguished, but while there is plenty of extracellular slime material, no structure resembling a sheath can be located on the surface; also, the close juxtaposition of the filaments in (b) speaks against a sheath. Within the cells, membrane bodies can be seen. (c) Shadowed preparation; an end piece with an empty cell-wall cylinder, or sleeve, is visible; again there is no sign of a sheath. Zeiss EM 10B electron microscope. Bars = 1 μm; the magnification is identical for (a) and (b). (Courtesy of H. J. Hirsch.)

a discrete outer boundary, excreted by the cells and not covalently bound to their surface. Under the light microscope, a sheath should be clearly recognizable, e.g., after negative staining with nigrosin or India ink. Under the electron microscope, a sheath may be difficult to visualize in thin sections, because of poor contrast with the usual techniques, but with negative contrast or metal shadowing, it should be seen. Like all gliding bacteria, *Herpetosiphon* excretes slime, and slime fibrils can always be observed in the neighborhood of the trichomes, but this material is more or less diffuse. Under certain conditions this slime may condense, perhaps as a consequence of dehydration during fixation, and then it may appear as a dense tube. This is probably what has been taken as evidence for a sheath by various investigators (Skerman et al., 1977; Senghas and Lingens, 1985; Holt, 1989). Typically in all those cases cited, a wide gap opens between the filament and the thin, dense tube. More recently, efforts were made to demonstrate a sheath in the sludge organisms by first lysing the cells in the filament with lysozyme and then staining the remains with crystal violet. In that case, indeed, a long thin tubelike structure could be produced (Senghas and Lingens, 1985), but this still is not an unequivocal proof of a sheath, for the technique gives reliable results only if the organism has a normal bacterial cell wall.

Electron microscopy of thin sections reveals, however, that *Herpetosiphon* has an unusual cell wall structure (Reichenbach and Golecki, 1975). Outside the cytoplasmic membrane there is a well-defined peptidoglycan layer, 4–6 nm thick, but no outer membrane can be resolved. In fact, that membrane seems to be absent. Rather there is a thin additional layer, 21–25 nm thick, granular in thin sections, fibrillar in freeze-etch preparations, on top of the peptidoglycan. This layer follows the peptidoglycan into the shallow notches between adjoining cells, but not into the cross-septa where only the peptidoglycan layer can be distinguished. We have never found any other defined layer outside the fibrillar layer and in particular have found no layer running smoothly across the cell junctions, as would be expected for a sheath. This peculiar wall structure is corroborated by chemical analyses of the cell envelope (see below) and may be directly connected with the sheath problem. It appears that the additional layer is considerably more resistant to decomposition than the usual lipopolysaccharide-containing outer membrane, and it may give the peptidoglycan, to which it seems to be covalently bound, a higher stability.

Within the cells there are extensive intracellular membrane systems, some of which originate at the cross-septa, others from the cytoplasmic membrane along the longitudinal walls. They become especially conspicuous when the negative-contrast technique is applied. As mentioned above, under certain conditions they can even be seen in the light microscope.

In old cultures, the filaments are often locally inflated and form large, spherical structures, or "bulbs," with a diameter of 2.5–3.5 μm (Fig. 4; Reichenbach and Golecki, 1975; Trick and Lingens, 1984). Under the electron microscope a membrane body at the end of a septum-like stalk can always be seen within the bulb. Those bulbs seem to be a degeneration phenomenon, and outgrowth or further development has never been observed from them.

In wet mounts, *Herpetosiphon* filaments often can be seen to bend slowly and sometimes to oscillate back and forth. In contact with a suitable interface, i.e., one to which the organism can stick, like a glass or an agar surface, the filaments glide slowly and, during this movement, deposit characteristic slime tracks (Fig. 1). Gliding filaments often bend laterally to form hairpinlike loops (Fig. 1). In liquid media, the filaments apparently move along themselves. They may coil around themselves or one another and produce all kinds of loops and knots (Figs. 1 and 2).

The colonies, or swarms, usually spread quickly over agar surfaces and may completely cover a culture plate within a few days. On poor media, the migrating filaments remain more or less separate and appear in the form of characteristic curls and whirls (Fig. 3). Such colonies may become extremely delicate and are barely recognizable even if oblique illumination is applied. On media that allow good growth, dense and tough swarm sheets arise, with a rough, dry, peltlike surface. Sometimes the swarm surface is completely uniform, with an even, curly, or felt texture. But often elegant networks, massive concentric ridges, a pattern of large and small holes, or large, massive knobs are produced (Fig. 3). These last-mentioned knobs are particularly impressive and have been observed with many different isolates (Holt and Lewin, 1968; Brauss et al., 1969; Reichenbach and Golecki, 1975; Trick and Lingens, 1984). Their diameter varies between 200 and 2000 μm, and, as was noticed repeatedly, they strikingly resemble myxobacterial fruiting bodies, especially since they often are bright red or orange. But the filaments inside those knobs seem not to differ from those in other parts of the swarm, either morphologically or physiologically. Also, the ridges and knobs are not permanent struc-

tures, but shift continuously from place to place and may even dissolve completely again. This can be seen, e.g., in the movie mentioned earlier (Reichenbach et al., 1980). All those structures seem to originate from chance interactions of the long, migrating filaments that locally pull together, tangle, and pile up. The dynamics of the excreted, drying, and contracting slime may also be involved. Even more spectacular are long, sometimes branched, fingerlike protuberances rising up to 5 mm above the swarm surface (Fig. 3). They consist of interwoven filaments and seem to be produced only by certain strains.

Chemically, the cell wall of *Herpetosiphon* (*H. aurantiacus* type strain and strain Hp a2) consists of a peptidoglycan that contains L-ornithine in place of diaminopimelic acid, a very unusual character for a Gram-negative bacterium (Jürgens et al., 1989). A heteropolysaccharide composed of heptose, hexoses, pentoses, and *O*-methyl sugars appears to be covalently bound to the peptidoglycan via muramic acid-6-phosphate. This heteropolysaccharide is probably the material seen in electron micrographs as the granular/fibrillar layer on the surface of the longitudinal walls. The peptidoglycan-polysaccharide complex amounts to 20% of the cell dry weight, with a polysaccharide portion of 70%. No evidence for a lipopolysaccharide was found, which would explain the absence of an outer membrane in thin sections; nor was there evidence for the presence of additional sheath material. The cell wall of *Herpetosiphon* thus closely resembles that of *Chloroflexus,* in both its electron microscopic appearance (Pierson and Castenholz, 1974) and in its chemical composition (Jürgens et al., 1987; Meissner et al., 1988). Incidently, the filaments of *Chloroflexus* also often end with a sleeve, which for this organism also has been taken to suggest the existence of a sheath (Pierson and Castenholz, 1974). Hydrolysates of extracellular slime yielded arabinose and glucosamine as the main constituents (for sewage strains; Trick and Lingens, 1984).

The fatty acid composition has been determined for one of the sludge organisms and for strain Hp a2 (Senghas and Lingens, 1985). It is dominated by $C_{16:0}$, $C_{18:0}$, $C_{16:1}$, and $C_{18:1}$, while branched-chain fatty acids, which are so typical for many other gliding bacteria, are essentially absent. Hydroxy fatty acids are completely lacking. The sludge strain contained, in addition, substantial amounts of $C_{19:0}$ and 8-methyl $C_{17:0}$. The novel sulfonolipids, or capnoids, discovered in gliding bacteria of the *Cytophaga* group, were not found in *Herpetosiphon* (Godchaux and Leadbetter, 1983). The respiratory quinones are exclusively menaquinones (Kleinig and Reichenbach, 1977; Reichenbach et al., 1978; Senghas and Lingens, 1985). The main menaquinone in *H. aurantiacus* is MK-6, and 10% is MK-7.

The harvested cell mass and dense colonies on agar plates may be brightly colored in shades of yellow-orange to brick-red. But some strains are very pale or even totally unpigmented. The pigmentation also depends on the growth medium and is usually more intense with peptone-containing substrates. The pigments are cell bound. Chemically, they are carotenoids (Kleinig and Reichenbach, 1977; Reichenbach et al., 1978). The pigment patterns are remarkably uniform, at least with *H. aurantiacus,* the sewage strains, and the sludge organisms (Trick and Lingens, 1984; Senghas and Lingens, 1985), showing only quantitative but no qualitative variation. The dominant compound has a 4-oxo-α-carotene chromophore, with a hydroxyl in C-1′ to which a disaccharide consisting essentially of glucose is connected via a glycoside bond. One of the sugars bears an ester-bonded fatty acid (Fig. 6). Composite carotenoids of this type are well known from myxobacteria, but in these latter organisms only monosaccharides are found as sugar constituents. Carotenoids with a disaccharide component are unique so far among prokaryotic pigments.

It has been reported that *Herpetosiphon* (sewage and sludge strains) contain granules of poly-β-hydroxy-butyrate (Trick and Lingens, 1984; Senghas and Lingens, 1985), but analytical details have not been given, and I have not seen any evidence for such material either under the light microscope nor in a large number of electron micrographs, including those published by the authors themselves.

The protein patterns as revealed by SDS-electrophoresis correspond rather well between different *Herpetosiphon* types, and they appear to contain elements characteristic for the group as a whole as well as for the various types (Senghas and Lingens, 1985).

The DNA of *Herpetosiphon* of the *aurantiacus* type shows little variation in its content: 48 to 50 mol% (buoyant density). The marine strains range between 45 and 52 mol%. The *Herpetosiphon*-like strains isolated from bulking sludge (Senghas and Lingens, 1985) have a higher GC content: 59 mol%. The base sequence of the 5S rRNA of one of the sludge organisms (strain Wie 2) has been determined (van den Eynde et al., 1987). While the *Herpetosiphon* sequence corresponds, in general, quite well with the model of eubacterial 5S rRNA structure, there are several deviations—in two cases in highly conserved sites not modified in any

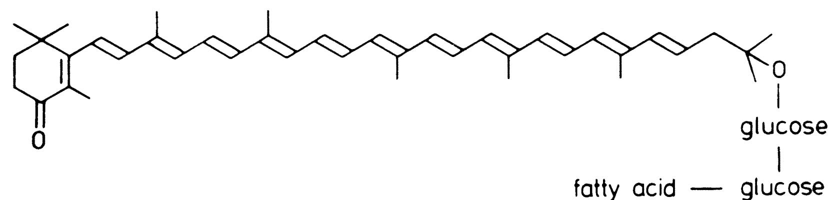

Fig. 6. Chemical structure of the main pigment of *Herpetosiphon aurantiacus*. (From Kleinig and Reichenbach, 1977.)

other eubacterium. Also, the 16S rRNA of *Herpetosiphon aurantiacus* has been completely sequenced (see "Taxonomy," this chapter) (Oyaizu et al., 1987). The unique multicopy single-stranded DNA (msDNA) common in gliding myxobacteria and also found in *Flexibacter* could not be demonstrated in *Herpetosiphon* (Dhundale et al., 1985).

The nutritional requirements, the physiology, and the biochemical capabilities of *Herpetosiphon* are not yet fully understood. *Herpetosiphon* is a strict organotroph, but because it is often able to grow on media very low in organic constituents, the results of substrate-utilization experiments must be interpreted with great care. There seem to be substantial differences among individual strains, and even more among the three main types that can currently be distinguished: 1) the *aurantiacus* group, including "*H. giganteus,*" *H. geysericola,* and the sewage strains (Trick and Lingens, 1984); 2) the *Herpetosiphon*-like organisms isolated from bulking sludge (Senghas and Lingens, 1985); and 3) the marine strains (Lewin and Lounsbery, 1969). The marine strains have not been further studied.

Although all known *Herpetosiphon* strains are aerobic, they seem to prefer microaerophilic conditions. Catalase is positive for the *aurantiacus* group and negative for the sludge and the marine strains. Oxidase is positive with *aurantiacus,* including the type strain for which it originally was claimed to be negative (Holt and Lewin, 1969); in our hands, however, young cultures on VY/2 agar give a strong positive reaction. The sludge organisms are oxidase negative and tolerate up to 2% NaCl, but the other terrestrial strains are rather sensitive to elevated salt concentrations.

It appears that many strains are able to grow on inorganic nitrogen sources (NH_4^+ or NO_3^-), but unequivocal data are often not available. Suitable N sources for the marine strains are tryptone, casamino acids, glutamate, and, for one strain, also nitrate. Nitrate reduction was shown for the sewage organisms, but only under anaerobic conditions, and it did not allow growth in the absence of molecular oxygen. Nitrogen fixation has been ruled out in all cases that have been investigated.

Early reports suggested that carbohydrate utilization by *Herpetosiphon* is poor, but we have found this not to be the case. The sewage strains utilize various hexoses, pentoses, and sugar alcohols as sole C sources, although without gas or acid production. Organic acids, with the exception of β-hydroxybutyrate, do not support growth. The sludge organisms grow on many different sugars and sugar alcohols, mostly with acid production. Some organic acids allow modest growth (H. Reichenbach, unpublished observations).

The *aurantiacus*-type organisms show impressive hydrolytic capabilities, while the sludge and the marine organisms are much less active in this respect. The low activity of sluice strains (Brauss et al., 1969) suggests that they may be similar to the sludge organisms. The data are summarized in Table 1. It should be understood that the results of those digestion experiments sometimes critically depend on the medium and the material used. In the case of pectin, a wide variety of preparations are available that give quite different results. With pectin from apple (38% methyl ester), I found pectin degradation by the (few) *Herpetosiphon* strains I tested. Also, in contrast to reports in the literature, I have found that virtually all *aurantia-*

Table 1. Degradation of biopolymers by *Herpetosiphon.*

+, positive; −, negative; ND, not determined.
[b]Crystalline cellulose in the form of filter paper or cellulose powder.

cus-type strains decompose xylan. Cellulose digestion is often seen among *aurantiacus*-type strains, but the type strain and strain Hp s2 are negative (H. Reichenbach, unpublished observations). *H. geysericola* decomposes cigarette paper (Lewin, 1970). In cultures on filter paper placed on a mineral salts agar like ST6 or ST21 agar, [in which $(NH_4)_2SO_4$ is replaced by 0.1% KNO_3], I have found that the filter paper is only very slowly attacked (recognizably after 20–30 days at 30°C). Cellulase activity can, however, quickly and reliably be detected on CEL1 agar (see below), on which large lysis zones are produced within 8–12 days, reaching far beyond the swarm colony. This suggests that cellulose decomposition by *Herpetosiphon* is achieved by diffusible exoenzymes (H. Reichenbach, unpublished observations).

CEL1 Agar

Cellulose powder	0.5%
$(NH_4)_2SO_4$	0.1%
Agar	1%

Adjust to pH 7.2. After autoclaving, the medium is poured as a thin layer on top of ST6 agar plates. A suitable cellulose powder, MN 300, is produced by Macherey and Nagel (Germany).

ST6 Agar

Part A:

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$MnSO_4 \cdot 2H_2O$	0.01%
$FeCl_3 \cdot 6H_2O$	0.02%
Trace elements	

The above ingredients are dissolved in one-third of the water volume.

Part B:

K_2HPO_4	0.1%
Yeast extract	0.002%
Agar	1%

The above ingredients are dissolved in two-thirds of the water volume.

After autoclaving, Parts A and B are combined and poured into plates.

Chitin decomposition becomes clearly recognizable on CT7 or CT agar (see Chapter 176, on *Lysobacter*). With many strains, I have observed DNA hydrolysis on DNA agar, but in some studies (sewage and sludge organisms) tests for DNase were negative. Some, but not all, strains show β-hemolysis (sheep and human erythrocytes; Gräf and Perschmann, 1970; Trick and Lingens, 1984).

Most investigators report the lysis of living and dead bacteria, but not all types of bacteria are equally sensitive. For instance, in contrast to many other enterobacteria, *E. coli* turned out to be particularly recalcitrant (Quinn and Skermann, 1980; H. Reichenbach, unpublished observations). Also, not all *Herpetosiphon* strains show identical lysis patterns. The sludge organisms do not lyse bacteria at all. The autoclaved yeast cells in VY/2 agar are often, but not always destroyed.

The H_2S, indole, acetoin, and phosphatase tests were negative (where looked for), the urease test was only rarely positive. Tyrosine in tyrosine agar is often degraded. It was observed that *Herpetosiphon* (*aurantiacus* type) is coprophilic, i.e., growth was stimulated by fecal extracts, but the specific factors responsible for this effect are not known (Gräf and Perschmann, 1970). Little is known about the antibiotic sensitivity of *Herpetosiphon.* The marine strains are inhibited by low concentrations of penicillin. I have found that practically all strains are resistant to high levels of kanamycin sulfate (250 mg/liter).

Taxonomy

Herpetosiphon is phylogenetically related to *Chloroflexus* and, on a much lower level, to *Thermomicrobium roseum.* This was deduced from 16S rRNA studies, specifically from analyses of oligonucleotide catalogs via binary association coefficients (S_{AB} values) or through oligonucleotide signatures (Gibson et al., 1985); a comparison of the complete base sequence has also been made (Oyaizu et al., 1987). The *Herpetosiphon*-like sludge organisms are clearly related, but not identical with *Herpetosiphon* (S_{AB} values with *Herpetosiphon*: 0.39, for *Chloroflexus*: 0.40, *Herpetosiphon/Chloroflexus*: 0.31). The four genera together form the phylum of the so-called green nonsulfur bacteria.

Among remarkable conclusions that can be drawn from these studies, are the conclusion of a very high age for the group. This high age is reflected in its unique base sequences, e.g., the one from base 607 to 630 which is identical in all eubacteria and archaebacteria but different in *Herpetosiphon.* The group shows a very deep branching point among the eubacteria, which is surpassed only by *Thermotoga.* As the cyanobacteria appear significantly younger, it seems clear that the earliest, 3500 million-year-old stromatolites may have been deposited by *Chloroflexus*-like organisms rather than by cyanobacteria, as had always been previously assumed. In this connection, the unusual cell wall structure of *Herpetosiphon* is also of interest, and it can perhaps be interpreted as a primitive structure. In contrast to the other members of the group, *Herpetosiphon* appears to be a rapidly evolving line, moving away from its ther-

mophilic ancestors. The high thermotolerance of many *Herpetosiphon* strains (growth at 40°C and greater) may reflect those roots.

Table 2 gives the distinguishing characteristics of the five presently recognized *Herpetosiphon* species and the *Herpetosiphon*-like organisms.

Considering the wide distribution of *Herpetosiphon* and its abundance in nature, these organisms must have been observed by many investigators, and in the older literature on indeed occasionally finds morphological descriptions that fit *Herpetosiphon.* A good candidate would be *Oscillatoria angusta* from lakes in central and northern Europe (Koppe, 1924,) later reclassified as *Achroonema angustum* (Skuja, 1956), although neither description mentions the typical sleeves. Since no strains were ever isolated and cultivated, their relation to *Herpetosiphon* can only be decided after a systematic study of the genus *Achroonema.*

As far as one can tell, the *H. aurantiacus* complex includes organisms previously called "*Flexibacter giganteus*" (Soriano, 1945; 1947), *Vitreoscilla proteolytica* (Gräf and Perschmann, 1970), the sewage *Herpetosiphon* (Trick and Lingens, 1984), probably *H. geysericola* (Lewin, 1970; see below), and perhaps also the organism isolated from a river sluice (Brauss et al., 1969; but see comment under "Characterization"). It also includes my own isolates labeled *H. giganteus* (Reichenbach and Golecki, 1975). The species epithet *giganteus* was never meant to name a new species but to replace *aurantiacus* in favor of the older *giganteus.* This does not imply, however, that all these organisms belong to only one species. While they are very similar in some respects, e.g., in their GC content, pigment, and menaquinone patterns, there are also substantial differences, e.g., in the diameter of the filaments, their enzymatic properties, and their growth requirements, which makes it likely that several species may be included in this assemblage.

Also standing on unstable taxonomic ground is the so-called "thermophilic" species *H. geysericola,* which was isolated from the vicinity of a hot spring and is not thermophilic but rather thermotolerant. Such thermotolerance, however, is not unusual for *aurantiacus*-type strains, which often grow very well at 38°C–40°C and probably even higher (H. Reichenbach, unpublished observations). From the published data only one clear difference between *H. geysericola* and *H. aurantiacus* can be seen, cellulose decomposition. Perhaps the cellulose-degrading *aurantiacus*-type *Herpetosiphon* would be better classified as *H. geysericola* (which then would become another misnomer). Originally it was suggested (Lewin, 1970) that *H. geysericola* is identical to *Phormidium geysericola* (Copeland, 1936), but this appears very unlikely, because that organism was found at the rim of a geyser and in various alkaline hot springs in Yellowstone, in water between 60 and 84°C. It thus is definitely a thermophile and would hardly grow at 30°C as does *H. geysericola.* Also, we know today that the bright orange mats found in alkaline hot springs in the western United States may contain a variety of filamentous gliding bacteria, such as *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974) and *Heliothrix oregonensis,* which according to 5S rRNA analyses, may be another relative of *Chloroflexus* and *Herpetosiphon* (Pierson et al., 1985). There still may be un-

Table 2. Characteristics of the *Herpetosiphon* species and related organisms.[a]

Characteristic	*H. auranticus*	*H. geysericola*	*H. cohaerens*	*H. persicus/nigricans*	Sludge organisms
GC content (mol%)	48 (48–50)	48	45	52	59

+, positive; −, negative; ND, not determined.

[a]Parentheses indicate characteristics of strains other than the type strain.

[b]Pigment extracts were examined spectrophotometrically, so that identification is preliminary only. *H. persicus* and *H. nigricans* seem to differ in their pigmentation.

[c]Pigments behave chromatographically and spectrophotometrically like those of *H. aurantiacus.*

known and unnamed species (Tayne et al., 1987). Apparently many of the filamentous organisms in hot springs previously described as blue-green algae (cyanobacterial) are in fact chlorophyll-free, because even when they are collected from the very same spring from which the species was originally reported, they often do not show the red fluorescence characteristic of chlorophyll (Brock, 1968).

The marine *Herpetosiphon* species are poorly understood. *H. persicus* can only be distinguished from *H. nigricans* by pigmentation, the latter producing a diffuse dark pigment on peptone medium, probably a melanin-like compound that may be of little taxonomic relevance (see Table 2). Obviously, more marine strains have to be isolated and characterized.

In conclusion, it is apparent that the taxonomy of *Herpetosiphon* is not yet settled, and further taxonomic studies based on larger collections of strains are needed.

Practical Aspects

The involvement of *Herpetosiphon* and related organisms in the formation of bulking sludge has been discussed above. Considering the hydrolytic capabilities of *Herpetosiphon aurantiacus,* it may be assumed that the bacterium participates in the degradation of macromolecules and, perhaps, in the control of microbial populations in sewage and in nature.

A screening for restriction endonucleases among gliding bacteria demonstrated the presence of such enzymes in nearly all *Herpetosiphon* strains tested (Mayer and Reichenbach, 1978). The enzymes seem to be located in the periplasm. A whole family of 17 enzymes has been more or less completely characterized with respect to their recognition and cleavage specificities (Brown et al., 1980; Kröger et al., 1984). All appear to be class II endonucleases, producing cohesive ends, either in the 5′-strand or, in the cases of endonucleases *Hgi* AI and *Hgi* JII, in the 3″-strands. Most interact with hexanucleotide sequences, and some with pentanucleotide sequences, but virtually all recognition sequences are degenerate. The availability of such a large family of endonucleases is of considerable theoretical interest because it allows a comparative study of the mechanisms of protein-DNA interaction as well as of molecular evolution. The known *Herpetosiphon* enzymes can be arranged in such a way that their recognition sequences overlap and the whole set thus becomes a continuous system (Kröger et al., 1984). One of the enzymes, *Hgi* EII, has a unique recognition sequence of 2 × 3 bases separated by six unspecific nucleotides. When the recognized bases are read in sequence, they give the recognition sequence of *Hgi* CI, and it has been proposed that enzyme *Hgi* EII originated by a inversion of the two enzyme subunits so that the recognition sites are now on the surface rather than in the center of the enzyme. Isoschizomeres can be found for almost all *Herpetosiphon* recognition sequences, e.g., *Sal* I is one to *Hgi* CIII and *Hgi* DII. Interestingly, no hybridization was found between *Sal* I gene probes and *Herpetosiphon* DNA, whereas two other producers of *Sal* I isoschizomeres, *Rhodococcus rhodochrous* and *Xanthomonas amaranthicola,* showed clear DNA homology under stringent conditions (Rodicio and Chater, 1988). While this suggests that the latter organisms and *Streptomyces albus* G have at least partially homologous enzymes, the high GC difference of 20 mol% between *Herpetosiphon* and *Streptomyces* could have obscured, through codon replacement, a structural relationship between their enzymes. A comparison of the base sequences of the genes, or of the amino acid sequences of the various enzymes should answer the question.

The role of *Herpetosiphon* and the *Herpetosiphon*-like bacteria in sewage disposal and sludge bulking has already been discussed.

CHAPTER 210

The Genus *Verrucomicrobium*

HEINZ SCHLESNER

Introduction

Heterotrophic bacteria with multiple appendages (prosthecobacteria) have been grouped with the genera *Prosthecomicrobium, Ancalomicrobium,* and *Stella* (see Chapter 103 and 104). These genera are mainly defined by morphological criteria such as prosthecae shape, number, length, and location. The members of the genus *Prosthecomicrobium* exhibit 10 to 30 prosthecae per cell, which extend in all directions from the cell surface. They are typically shorter than 2 μm and conical in shape (Staley, 1984). *Ancalomicrobium adetum,* the only species in that genus, normally has less than eight prosthecae, which are tube-like and about 3 μm long (Staley, 1968). Cells of *Stella* are flat, six-pronged stars with prosthecae less than 0.5 μm long (Vasilyeva, 1985). No differentiation of the tips of the prosthecae has been observed. The GC content of the DNA of the above genera ranges from 65 to 73.5 mol% (Staley and Mandel, 1973; Staley, 1984; Vasilyeva, 1985).

New isolates of prosthecate bacteria with bundles of fimbriae extruding from the tips of the prosthecae were placed in a new genus *Verrucomicrobium* with the single species *V. spinosum* (Schlesner, 1987). This species has a significantly lower GC content (57.9–59.3 mol%), thus indicating a low degree of relationship to the previously mentioned genera. This was supported by the determination of the phylogenetic position of *V. spincsum* made by analyzing the 16S rRNA by oligonucleotide cataloging and reverse transcriptase sequencing (Albrecht et al., 1987). Similarity coefficients (S_{AB} values), calculated by comparing the RNase T_1 catalog of *V. spinosum* with about 460 catalogs of eubacterial strains, were found to be as low as those separating individual eubacterial phyla, indicating that *V. spinosum* represents a new division (Albrecht et al., 1987).

Habitats

Prosthecate bacteria with fimbriae have rarely been observed. Such bacteria occurred in an enrichment culture of Lake Plußsee water to which vitamin solution no. 6 (see below) was added (P. Hirsch, personal communication). Lake Plußsee is a small eutrophic lake near Plön, FRG. *V. spinosum* was isolated from Lake Vollstedter See (Holstein, FRG), a shallow (maximum depth, 2 m), eutrophic lake. One strain of *Verrucomicrobium* sp. came from the "Schrevenparkteich," a pond in a public park in Kiel, FRG. This pond is very eutrophic because numerous waterfowl live there and are fed by visitors to the park.

Enrichment and Isolation

Verrucomicrobium spp. can be enriched in Erlenmeyer flasks with 50 ml of enrichment medium over a sediment of $CaCO_3$.

Enrichment Medium Composition

The enrichment medium is composed of:

N-Acetylglucosamine	1.0 g
Hutner's basal salts (see below)	20 ml
Vitamin solution no. 6 (see below)	10 ml

Add distilled water to 1 liter. Adjust pH to 9.7. After autoclaving and cooling to room temperature, add $NaH_2PO_4 \cdot H_2O$ aseptically to a final concentration of 0.65 mM.

Hutner's basal salts (Cohen-Bazire et al., 1957)

Nitrilo triacetate (NTA)	10.00 g
$MgSO_4 \cdot 7\ H_2O$	29.70 g
$CaCl_2 \cdot 2H_2O$	3.34 g
$NaMoO_4 \cdot 2H_2O$	12.67 mg
$FeSO_4 \cdot 7H_2O$	99.00 mg
Metal salts solution "44" (see below)	50.00 ml
Double-distilled water	900.00 ml

The NTA is first dissolved by neutralization with KOH. The other salts are then added. Adjust pH to 7.2 with KOH or H_2SO_4. Adjust volume to 1 liter with double-distilled water. Store in the cold (5°C). The solution should be clear.

Metal salts solution "44"

Ethylene diaminotetraacetate (EDTA)	250.0 mg
$ZnSO_4 \cdot 7H_2O$	1095.0 mg
$FeSO_4 \cdot 7H_2O$	500.0 mg
$MnSO_4 \cdot H_2O$	154.0 mg
$CuSO_4 \cdot 5H_2O$	39.2 mg
$CoCl_2 \cdot 6H_2O$	20.3 mg
$Na_2B_4O_7 \cdot 10H_2O$	17.7 mg
Double distilled water	1 liter

To retard precipitation, add a few drops of H_2SO_4 before making to volume. Store in the cold (5°C).

Vitamin solution no. 6 (Staley, 1968)

Biotin	4.0 mg
Pyridoxine hydrochloride	20.0 mg
Thiamine hydrochloride	10.0 mg
Calcium pantothenate	10.0 mg
p-Aminobenzoic acid	10.0 mg
Folic acid	4.0 mg
Riboflavin	10.0 mg
Nicotinamide or nicotinic acid	10.0 mg
Vitamin B_{12}	0.2 mg
Double distilled water	1 liter

Stirring of the mixture improves solubility. Sterilize by filtration only. Store in the dark and cold (5°C).

Isolation of *Verrucomicrobium spinosum*

When subsequent microscopic checks indicate an increase in prosthecate bacteria, make streaks on the following agar-solidified medium M 13 (Schlesner, 1986):

Agar	18.0 g
Peptone	0.25 g
Yeast extract	0.25 g
Glucose	0.25 g
Hutner's basal salts	20 ml
Vitamin solution no. 6	10 ml
0.1 M Tris HCl, pH 7.5	50 ml
Artificial sea water (see below)	250 ml
Distilled water	670 ml

Artificial sea water (Lyman and Fleming, 1940)

NaCl	23.477 g
$MgCl_2$	4.981 g

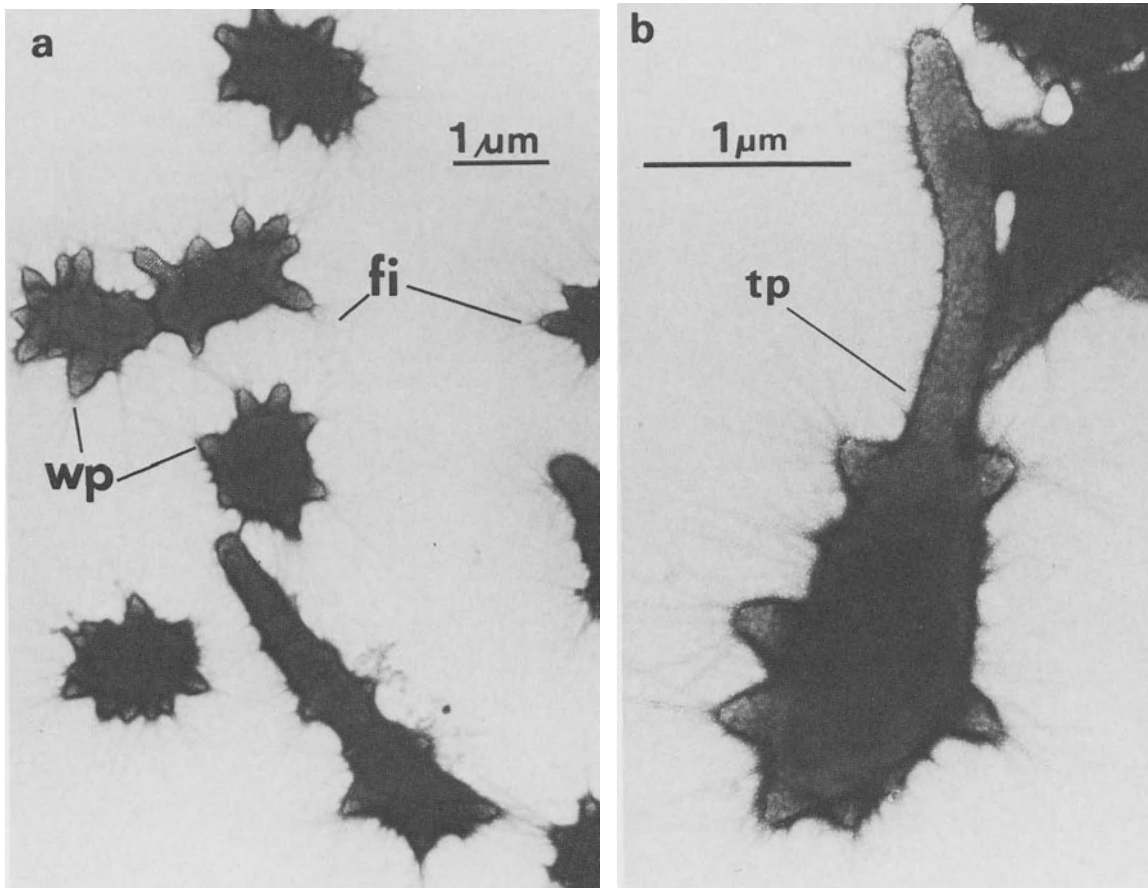

Fig. 1. Morphology of *Verrucomicrobium spinosum.* (a) Cells with wart-like prosthecae (wp), from the tips of which fimbriae (fi) extrude. (b) A cell with a polarly inserted tube-like prostheca (tp). (From Schlesner, 1987).

Na_2SO_4	3.917 g
$CaCl_2$	1.102 g
KCl	0.664 g
$NaHCO_3$	0.192 g
KBr	0.096 g
H_3BO_3	0.026 g
$SrCl_2$	0.024 g
NaF	0.003 g

Colonies that appear should be examined microscopically for the presence of prosthecate cells. This is conveniently done by applying the timesaving toothpick-procedure (Hirsch et al., 1977), which allows the examination of very small colonies: sterile wooden toothpick is stabbed into a colony and then on the agar surface of a petri dish containing the appropriate medium, thus inoculating the agar. To allow inoculation of a single petri dish with bacteria from a large number of colonies, a grid (with squares of about 5 mm in length) can be drawn with a marker on the bottom of the petri dish. After inoculation of the agar medium, the toothpick still generally contains enough bacteria to prepare a smear for microscopic examination. Three specimens can be prepared on one slide.

Identification

When studied with a phase contrast microscope, cells of *Verrucomicrobium* spp. resemble those of *Prosthecomicrobium* spp., i.e., the unicellular organisms have conical prosthecae extending in all directions from the cell surface. These prosthecae are about 0.5 μm long (Fig. 1a). Occasionally, one or two longer prosthecae (up to 2 μm) may occur, and often one of them is polarly inserted (Fig. 1b). Under the electron microscope, bundles of fimbriae of varying number and length extruding from the tips of the prosthecae are visible. The Gram-negative cells are nonmotile. Colonies on medium M 13 are light yellow. Growth of *V. spinosum* is optimal between 26 and 33°C and the maximum growth temperature is 34°C. The organism has a low salinity tolerance. Only 50% artificial sea water and 1% NaCl are tolerated. *V. spinosum* is facultatively anaerobic. Various sugars are fermented without gas formation, but nitrate is not reduced under anaerobic conditions.

Only a limited number of substrates can be utilized as sole carbon and energy source, mainly hexoses, di- or trisaccharides, and derivatives of glucose. One- and two-carbon compounds are not utilized, and neither are fatty acids or amino acids (Schlesner, 1987). Ammonia, urea, nitrate, and *N*-acetylglucosamine are suitable nitrogen sources. *V. spinosum* produces exoenzymes that can be demonstrated by the hydrolysis of gelatin and starch. However, casein and Tween 80 are not hydrolyzed. Catalase, cytochromeoxidase, phosphatase, and urease are produced, but neither H_2S (from thiosulfate) or NH_3 (from peptone) is produced. The cell wall contains *m*-diaminopimelic acid. The GC content of the DNA is 58.6 ± 0.2 mol% (T_m) for strain IFAM 1439^T = DSM 4136 = ATCC 43997.

CHAPTER 211

The Order Thermotogales

ROBERT HUBER and KARL O. STETTER

The order Thermotogales is a unique group of extremely thermophilic microorganisms, phylogenetically distant from all other eubacteria. 16S rRNA analysis indicates that the Thermotogales represent the deepest branch and the most slowly evolving lineage within the kingdom of eubacteria (Achenbach-Richter et al., 1987; Woese, 1987; see also Chapter 1). A phylogenetic tree based on comparative studies of eubacterial DNA sequences of the elongation factor Tu is in good agreement with the 16S rRNA tree (Bachleitner et al., 1989).

The following common characters are uniform for the order Thermotogales: thermophilic, rod-shaped, anaerobic, fermentative eubacteria with an outer sheath-like envelope ("toga"); nonsporeforming; Gram-negative, but *meso*-diaminopimelic acid is not present in the peptidoglycan; lysozyme sensitive; inhibition of growth by molecular hydrogen; unusual long-chain dicarboxylic fatty acids present in the lipids.

Up to now, the Thermotogales are represented by only one family, the Thermotogaceae, which consists of the genera *Thermotoga* (Huber et al., 1986), *Thermosipho* (Huber et al., 1989), and *Fervidobacterium* (Patel et al., 1985; Huber et al., 1989).

Habitats

Members of the order Thermotogales are widespread and cosmopolitan. They thrive within active geothermal areas but they have not been found in any other sites. The Thermotogales occur in two different biotopes: 1) shallow and deep-sea marine hydrothermal systems; and 2) continental solfataric springs of low salinity. Up to now, they have only been isolated from samples from habitats of high temperature (55–100°C) and slightly acidic to alkaline pH (5–9).

Isolation

Selective Enrichment

To enrich members of the *Thermotoga maritima* group, starch-containing anaerobic seawater medium is used. Selective enrichment is carried out by incubation of the medium at a temperature of 85°C. Selective enrichment methods for *Thermotoga thermarum, Thermosipho,* and *Fervidobacterium* are not known. In contrast to thermophilic archaebacteria, media devoid of sulfur and hydrogen seem to favor growth of these latter eubacteria. Furthermore, carbohydrates, traces of yeast extract, and an incubation temperature of around 75°C are necessary for a successful enrichment.

Isolation Procedures

Various anaerobic culture media are inoculated with 0.5–1 ml samples, incubated at the appropriate temperatures, and examined microscopically over a period of around four weeks. After growth occurs in the enrichment cultures, the bacteria are transferred five times in sequence into fresh medium. The isolates are obtained by serial dilutions (three times) followed by plating (see below).

PLATING. For solidification, 1.5–2% agar is added to the media. After autoclaving, the plates are poured in the anaerobic chamber and dried for 24 hours in a closed pressure cylinder (Balch et al., 1979) at the temperature to be used later for incubation. Serial dilutions from 10^{-1} to 10^{-8} are plated in parallel. The gas phase in the cylinder is exchanged 10 times. The cylinder is then pressurized using the desired gas phase (150 kPa) and 2% H_2S (v/v) is added. The plates are incubated at the appropriate growth temperature (see above) and are examined for

growth at intervals of four days in the anaerobic chamber.

Cultivation

For the cultivation of the Thermotogales, strictly anaerobic growth conditions are necessary; the anaerobic technique described by Balch and Wolfe (1976) is suitable. For cell masses, the isolates are grown in batch cultures at the optimal growth temperature in 15-liter stainless steel fermentors and in 50- to 300-liter enamel-protected fermentors (HTE, Bioengineering, Wald, Switzerland). To increase the cell yields, the fermentors are gassed with nitrogen to get rid of inhibitory hydrogen which is produced by the bacteria.

PRESERVATION OF CULTURES. The bacteria are grown up to the stationary growth phase and are stored afterwards in the growth medium at 4°C. For all isolates, a transfer into fresh medium at three-month intervals is sufficient.

Identification and Physiological Properties

The Genus *Thermotoga*

Morphologically, these bacteria are rod-shaped cells with an average size of 5 μm in length and 0.6 μm in width. They are surrounded by a sheath-like outer structure, "the toga," ballooning over the ends (Figs. 1 and 2). This sheath, visible in all phases of growth, is composed of a regularly arranged outer membrane protein that may have porin-like function (Rachel et al., 1988). Nonmotile and motile species are known. On solid media, white, round colonies are formed. The pH optimum for growth is around 7, and growth occurs in a pH range between 5.5 and 9.0.

Fig. 1. Electron micrograph of a flagellated dividing cell of *Thermotoga maritima*. Bar = 1 μm.

Up to now, three species have been described, which can be placed in two different groups:

THERMOTOGA MARITIMA-NEAPOLITANA GROUP. *Thermotoga maritima* MSB8, DSM 3109 (Huber et al., 1986; Int. J. System. Bact., 1986), *T. neapolitana* NS-E, DSM 4359 (Belkin et al., 1986; Jannasch et al., 1988; Int. J. System. Bact., 1989), and 21 related isolates. This group is characterized by the ability to grow at both high salt concentrations (6.0% NaCl) and low salt concentrations (0.25% NaCl). The growth optimum is around 2.7% NaCl.

Members of this *Thermotoga* group are the most extremely thermophilic eubacteria presently known, with growth up to 90°C and an optimal growth temperature around 80°C. The minimum temperature for growth is around 55°C. *T. maritima* was originally isolated from a geothermally heated, marine sediment at Vulcano, Italy (Huber et al., 1986). The second species, *T. neapolitana* (Jannasch et al., 1988), was obtained from a submarine thermal vent at Lucrino near Naples, Italy (Belkin et al., 1986) and from continental solfatara fields from Lac Abbé, Djibouti, Africa (Windberger et al., 1989). Further members of this group were isolated from shallow marine habitats in Italy (Ischia), the Azores, Indonesia, Kolbeinsey (north of Iceland; depth: 106 m) and from deep-sea sediments from the East Pacific Rise (Guaymas Basin, Gulf of California; depth: 2000 m).

T. neapolitana can be distinguished from *T. maritima* on the basis of its nonmotile character, its rate of growth at optimum growth temperature (*T. maritima:* 75 min; *T. neapolitana:* 45 min), its 5%-lower GC content (*T. maritima:* 46 mol%), and their low DNA homology of around 25%.

These bacteria are fermentative microorganisms metabolizing a variety of carbohydrates, e.g., ribose, glucose, maltose, raffinose, starch, salicin, and cellulose. Main fermentation products on glucose are D(+)-lactate, acetate, CO_2, and H_2. H_2 is a potent inhibitor of growth and H_2 inhibition can be overcome by the addition of sulfur, but not by the addition of sulfate, sulfite, thiosulfate, nitrate, fumarate, or oxaloacetate. The bacteria produce H_2S in the presence of sulfur and under these conditions do not produce inhibitory H_2. The cells are able to fix molecular nitrogen and to use it as a nitrogen source (R. Huber and K. O. Stetter, unpub-

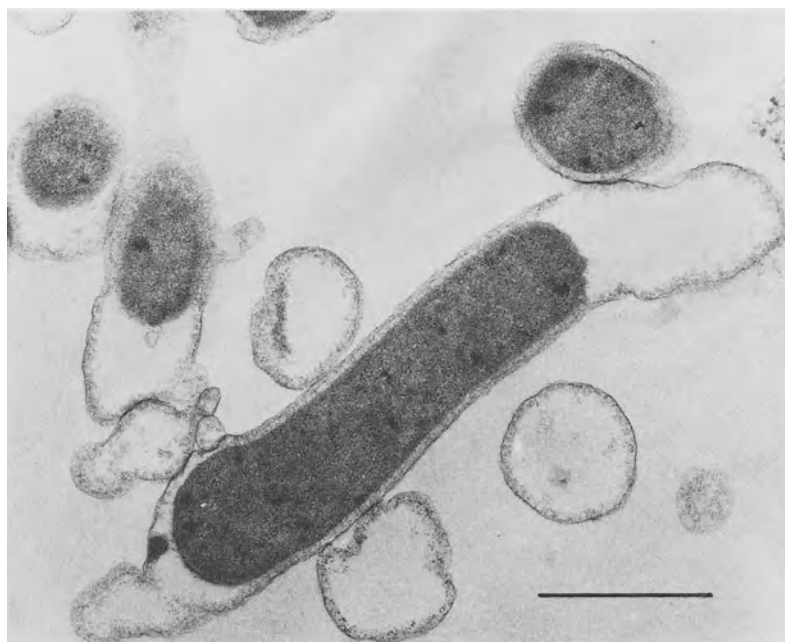

Fig. 2. Thin section of *Thermotoga maritima,* using lead citrate and uranyl acetate for contrast. Bar = 1 μm.

lished observations). Members of the genus *Thermotoga* possess a number of important features atypical for eubacteria: 1) the cells are insensitive to 100 μg rifampicin/ml, and the purified RNA polymerase is resistant to 1 μg rifampicin/ml; 2) growth is not inhibited by 10 μg/ml of aminoglycoside antibiotics and the purified ribosomes are also resistant to this antibiotics (Londei et al., 1988); 3) the peptidoglycan contains D- and L-lysine, which has never before been found in Gram-negative organisms; and 4) the majority of the lipids appear to be of novel structure; also, a new lipid structure was identified in *T. maritima* (Fig. 3; De Rosa et al., 1988).

Culture Medium for *T. maritima, T. neapolitana,* and Related Marine Isolates

The medium contains per liter of distilled water:

NaCl	6.93 g
$MgSO_4 \cdot 7H_2O$	1.75 g
$MgCl_2 \cdot 6H_2O$	1.38 g
KH_2PO_4	0.5 g
$CaCl_2$	0.38 g
KCl	0.16 g
NaBr	25 mg
H_3BO_3	7.5 mg
$SrCl_2 \cdot 6H_2O$	3.8 mg
KI	0.025 mg
$(NH_4)_2Ni(SO_4)_2$	2 mg
Trace mineral solution (see below)	15 ml
Resazurin	1 mg
Starch	5 g
Yeast extract (Bacto Difco)	0.5 g

Trace mineral solution (Balch et al., 1979):

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3 g
$MnSO_4 \cdot 2H_2O$	0.5 g
NaCl	1 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoCl_2$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnSO_4$	0.1 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$KAl(SO_4)_2$	0.01 g
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
Distilled water	1 liter

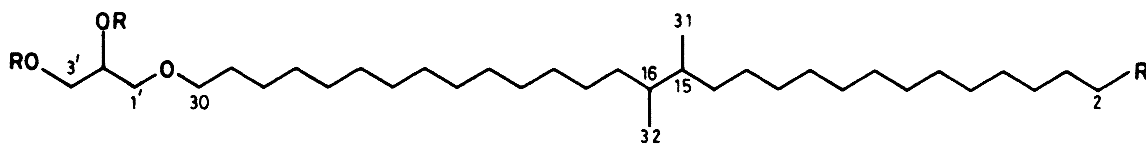

Fig. 3. A new 15,16-dimethyl-30 glyceryloxytriacontanoic acid from *Thermotoga maritima.* (Figure kindly provided by M. De Rosa and A. Gambacorta.)

In a stoppered glass bottle, 1 liter of the medium is flushed with nitrogen for 20 min, 0.5 g $Na_2S \cdot 9H_2O$ is added with a syringe, and the pH is adjusted to 7 by the addition of H_2SO_4. In an anaerobic chamber, the medium is placed in 28-ml serum tubes in portions of 10 ml each. The tubes are closed with rubber stoppers and on a gas station, a gas exchange is carried out (three times). N_2 as the desired gas is pressurized (300 kPa), and the tubes are autoclaved for 20 min. In order to establish the optimal ionic strength for growth, inorganic compounds of the medium are simultaneously increased or decreased by the same ratio.

THERMOTOGA THERMARUM GROUP. *Thermotoga thermarum* LA3, DSM 5069 (Windberger et al., 1989): this isolate is characterized by its ability to grow only at low salinity in a salinity range between 0.2% and 0.55% NaCl. The growth optimum is around 0.35% NaCl.

T. thermarum (Fig. 4) and two strains of *T. neapolitana* were isolated from continental solfatara fields at Lac Abbé, Djibouti (Africa). The isolation of these bacteria demonstrates for the first time the occurrence of the genus *Thermotoga* in low salinity environments also.

T. thermarum is able to ferment carbohydrates, but so far growth has only been observed in medium containing yeast extract. As for the other *Thermotoga* species, molecular H_2 is a potent inhibitor of growth. In contrast, *T. thermarum* is unable to form H_2S from S^0 and cannot grow on substrates when H_2 and S^0 is present in the culture medium. Furthermore, *T. thermarum* differs from all other known *Thermotoga* species by its lower upper temperature limit for growth (max. 85°C), its lateral flagellation pattern, and its high sensitivity to rifampicin (1 μg/ml). The RNA polymerase of *T. thermarum* exhibits subunits significantly smaller in molecular weight than that of the other members of the genus *Thermotoga.* Only partial immunological identity of the RNA polymerase is evident by spur formation of the precipitin lines with antibodies against the purified RNA polymerase of *T. maritima.* Using DNA-DNA hybridization, *T. thermarum* shows no significant homology against *T. maritima* and *T. neapolitana.*

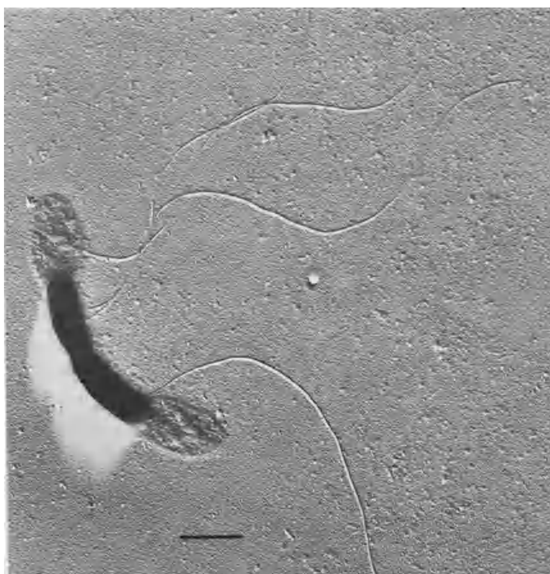

Fig. 4. Electron micrograph of a cell of *Thermotoga thermarum,* showing lateral flagellation. Bar = 1 μm.

Culture Medium for *T. thermarum*

NaCl	3.46 g
$MgSO_4 \cdot 7H_2O$	0.88 g
$MgCl_2 \cdot 6H_2O$	0.69 g
KH_2PO_4	0.5 g
$CaCl_2$	0.09 g
KCl	0.08 g
NaBr	12.5 mg
H_3BO_3	3.75 mg
$SrCl_2 \cdot 6\ H_2O$	1.9 mg
KI	0.006 mg
$(NH_4)_2\ Ni(SO_4)_2$	3 mg
Trace mineral solution	15 ml
Ethylenediaminetetraacetate-tetra-sodium-salt	0.9 g
Resazurin	1 mg
Starch	5 g
Yeast extract (Bacto Difco)	0.5 g
Distilled water	1 liter

The anaerobic culture medium is prepared in the same way as described for *T. maritima.* The trace mineral solution is the same as used for the cultivation of *T. maritima.*

The Genus *Thermosipho*

From marine hydrothermal springs and hot sandy sediments of the Gulf of Tadjoura southwest of Obock (Djibouti, Africa), three isolates of thermophilic eubacteria were obtained. Within the Thermotogales, they represent the genus *Thermosipho* with the type species *Thermosipho africanus* (Ob7; DSM 5309; Huber et al., 1989).

The rod-shaped cells (average size: 3–4 μm; width: 0.5 μm) possess a surrounding sheath with ballooning ends, reminiscent of members of the genus *Thermotoga.* In contrast to *Thermotoga,* however, *Thermosipho* can grow in chains (up to 12 rods) surrounded by the sheath (Fig. 5).

The taxonomic position of *Thermosipho* as a second genus within the Thermotogales is based on 16S rRNA sequencing analysis. The two 16S rRNAs of *T. africanus* (partial sequence deposited in the Gene Bank under accession no. M24022) and *Thermotoga maritima* are 89%

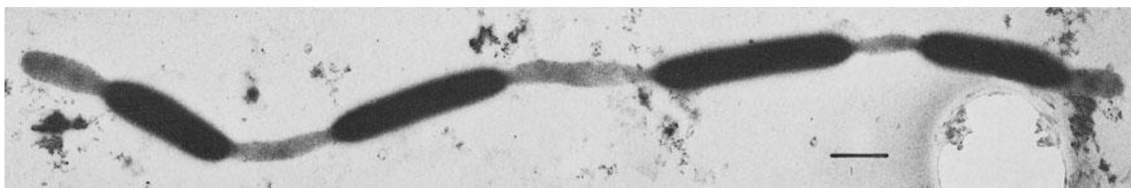

Fig. 5. *Thermosipho africanus.* Four cells within a tube-like sheath. Bar = 1 μm.

similar. Therefore, the bacteria are specific relatives on the level of two different genera. This taxonomic position is reflected moreover in a significant difference in the GC content of the two 16S rRNAs (*T. africanus:* 60 mol%; *T. maritima:* 63 mol%).

Thermosipho can be furthermore clearly distinguished from members of the genus *Thermotoga,* by its ability to grow at much lower temperatures (growth range: 35–77°C), a GC content of only 30 mol%, and an RNA polymerase which shows no serological cross-reaction with the same enzyme from *Thermotoga maritima.*

Thermosipho africanus grows within a pH range from 6.0 to 8.0, with an optimum around 7.2. The shortest doubling time is 35 min at the optimal growth temperature of 75°C. No growth is detected at 32°C or 80°C. Growth is observed between 0.11% NaCl and 3.6% NaCl.

Members of the genus *Thermosipho* are obligately heterotrophic bacteria, unable to grow on defined homogeneous carbon sources. For growth, the bacteria need complex organic materials such as yeast extract, peptone, or tryptone as well as cysteine. Molecular hydrogen inhibits growth but H_2 inhibition can be overcome by the addition of elemental sulfur. Under these conditions, H_2S is formed.

Since *T. africanus* grows at salt concentrations as low as 0.11% NaCl, members of the genus *Thermosipho* may possibly be present in nature also in low-salinity environments. *T. africanus* can grow even within the mesophilic temperature range (35°C: 15-h doubling time) and may therefore even exist in moderately heated environments like black soils and shallow waters.

Culture Medium for *T. africanus* and Related Isolates

The medium contains per liter of distilled water:

NaCl	18 g
$MgCl_2 \cdot 6H_2O$	4.30 g
$MgSO_4 \cdot 7H_2O$	3.45 g
KCl	0.34 g
NH_4Cl	0.25 g
$CaCl_2 \cdot 2H_2O$	0.14 g
K_2HPO_4	0.14 g
$(NH_4)_2Fe(SO_4)_2 \cdot 7H_2O$	2 mg
$(NH_4)_2Ni(SO_4)_2$	2 mg
Trace mineral solution	10 ml
Vitamin solution	10 ml
Sodium acetate	1 g
Yeast extract (Bacto Difco)	2 g
Trypticase peptone (Merck)	2 g
Resazurin	1 mg

Trace mineral solution (Balch et al., 1979):

The same trace mineral solution as for the cultivation of *Thermotoga maritima* is used.

Vitamin solution (Balch et al., 1979):

Biotin	2 mg
Folic acid	2 mg
Pyridoxine hydrochloride	10 mg
Thiamine hydrochloride	5 mg
Riboflavin	5 mg
Nicotinic acid	5 mg
DL-Calcium pantothenate	5 mg
Vitam B_{12}	0.10 mg
p-Aminobenzoic acid	5 mg
Lipoic acid	5 mg
Distilled water	1 liter

The medium is prepared in the same way as described for *T. maritima.* As reducing agent, a mixture of 0.5 g $Na_2S \cdot 9\ H_2O$ and 0.5 g cysteine HCl is used. The pH is adjusted to 7.0 with formic acid, the gas phase consists of N_2/CO_2 (80:20; 300 kPa).

The Genus *Fervidobacterium*

The first thermophilic eubacterium known to be a relative of *Thermotoga maritima* (Woese, 1987) was an isolate, now called *Fervidobacterium,* obtained from a continental solfatara field at Hveragerthi, Iceland (strain H21; Huber et al., 1990). Comparison of 16S rRNAs indicates that this bacterium is related to the genus *Thermotoga* and *Thermosipho* at the rank of a third genus. The RNA polymerase of *Fervidobacterium* strain H21 shows no serological cross-reaction with the same enzyme of *T. maritima,* confirming that this isolate is related to *Thermotoga* above the species level.

The rod-shaped motile cells of *Fervidobacterium* (average size: 1.8 μm, width 0.6 μm) can be easily distinguished from those of *Thermotoga* and *Thermosipho* by phase contrast microscopy. *Fervidobacterium* cells do not produce a sheathlike outer structure, but they do tend to form additional spheroids (Figs. 6 and

7). These spheroids occur terminally, and only one spheroid is produced per cell (Figs. 6 and 7). In addition, the bacteria tend to form aggregates and, very rarely, show growth in chains or the formation of rotund bodies (Patel et al., 1985). In their ability to form spheroids, they resemble an eubacterial isolate from a New Zealand hot spring, which was described as *Fervidobacterium nodosum* (Rt-17B; ATCC 35602; Patel et al., 1985). Together with eight further isolates, these organisms were placed in the new genus *Fervidobacterium* (Patel et al., 1985), but a further taxonomic classification was not done. Comparison of the 16S rRNAs of isolate H21 and *F. nodosum* confirmed the presumption that H21 is related to the genus *Fervidobacterium.* Within this genus, however, H21 represents a new species, which is described as *Fervidobacterium islandicum* (isolate H21, DSM 5733; Huber et al., 1990). *F. islandicum* can be clearly distinguished from *F. nodosum* by a 6% higher GC content (*F. nodosum:* 33.7 mol%) and an insignificant DNA homology.

The optimum growth temperature for members of the genus *Fervidobacterium* is 65°C to 70°C, the maximum 80°C, and the minimum greater than 40°C. Growth occurs between a pH of 6.0 to 8.0 with an optimum at 7.0 to 7.5. The optimal doubling time of *F. islandicum* at optimal temperature is 150 min; for *F. nodosum,* doubling time is 105 min.

F. islandicum and *F. nodosum* ferment a variety of carbohydrates. The main products formed during growth on glucose are D(+)-lactate, acetate, ethanol, CO_2, and H_2. In addition, traces of *n*-butyric acid and *n*-valeric acid *(F. islandicum)* or isobutyric acid and isovaleric acid *(F. nodosum)* are formed.

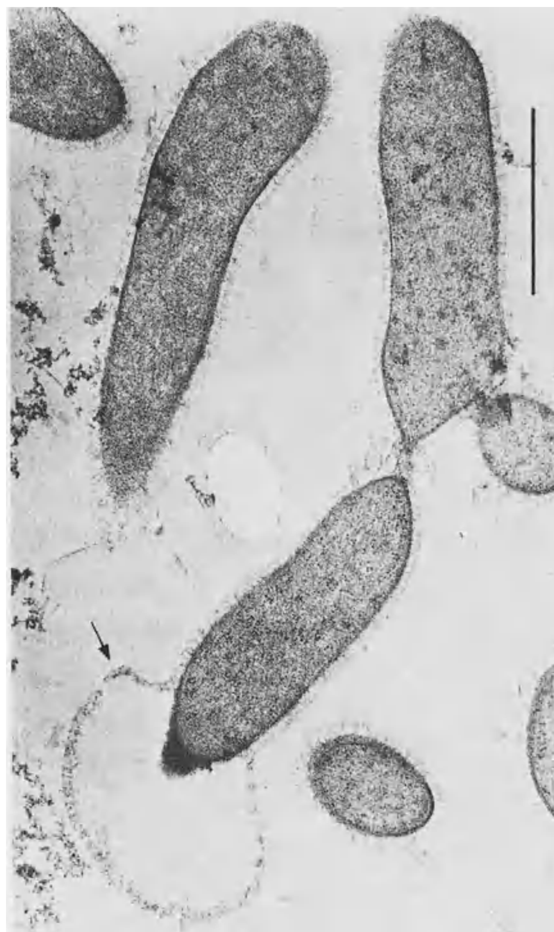

Fig. 7. Thin section of cells of *Fervidobacterium islandicum;* the arrow shows a spheroid. Bar = 1 μm.

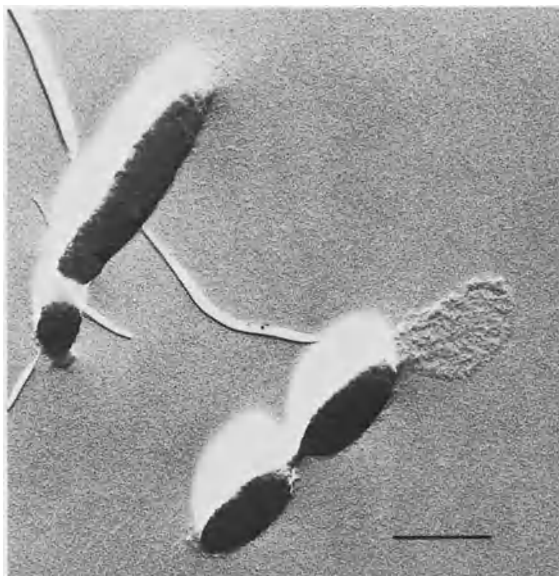

Fig. 6. Electron micrograph of dividing cells of *Fervidobacterium islandicum;* platinum-shadowed. Bar = 1 μm.

Both species can reduce elemental sulfur, forming H_2S, and the addition of molecular hydrogen inhibits growth. In contrast to *Thermotoga* and *Thermosipho, F. islandicum* and *F. nodosum* are unable to grow in the presence of hydrogen when sulfur is added to the medium.

Culture Medium for *F. islandicum* and *F. nodosum*

The medium contains per liter of distilled water:

NH_4Cl	0.90 g
$MgCl_2 \cdot 6H_2O$	0.20 g
KH_2PO_4	0.75 g
$K_2HPO_4 \cdot 3H_2O$	1.97 g
$FeSO_4 \cdot 7H_2O$	3 mg
Trace minerals (see below)	9 ml
Vitamin solution (see below)	5 ml
Glucose	5 g
Trypticase peptone (Merck)	10 g
Yeast extract (Bacto Difco)	3 g

Resazurin	1 mg

Vitamin solution (Balch et al., 1979):
The same vitamin solution as for the cultivation of *T. africanus* is used.

Trace minerals (Patel et al., 1985):

Nitrilotriacetic acid	12.5 g
$FeCl_3 \cdot 4H_2O$	0.2 g
$MnCl_2 \cdot 4H_2O$	0.1 g
$CoCl_2 \cdot 6H_2O$	0.017 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnCl_2$	0.1 g
$CuCl_2$	0.02 g
H_3BO_3	0.01 g
$NaMoO_4 \cdot 2H_2O$	0.01 g
NaCl	1 g
Na_2SeO_3	0.02 g
Distilled water	1 liter

The medium is prepared in the same way as described for *T. maritima.* 1 g $Na_2S \cdot 9\ H_2O$ per liter of medium is used as reducing agent. The pH is adjusted to 7.2 with H_2SO_4, the gas phase consists of N_2 (300 kPa).

PART V

Symbiotic Associations

CHAPTER 212

Cyanobacterial Symbioses

HAINFRIED E. A. SCHENK

Introduction, Terminology, and Overview

The cyanobacteria appear to be an ancient class of organisms, well adapted to most habitats around the earth and often acting as pioneer "plants." They are a large and morphologically diverse group of prokaryotes, containing both unicellular and filamentous forms (some with specialized cells). However, sequence data of 16S rRNA have shown that the other major eubacterial taxa diverged significantly before the diversification of the modern photoautotrophic cyanobacteria (Giovannoni et al., 1988). The chloroxybacteria (prochlorophyta) are included in this chapter, because, in a dendrogram constructed by cluster analysis of either 5S or 16S RNA sequences, they are situated in a cluster containing all cyanobacteria as well as the Prochloron (Van den Eynde et al., 1988; Giovannoni et al., 1988). Obviously, the prochlorophytes branched off after the divergence of the cyanobacteria.

The cyanobacteria together with the prochlorophytes differ from all other prokaryotes by possessing a water-oxidizing photosynthesis like that of higher plants. In addition, many cyanobacterial strains possess an active nitrogenase, an oxygen-intolerant enzyme system. Nitrogen-fixing unicellular cyanobacteria combine within the same cell both photosynthesis, an oxygenic process, and nitrogen fixation, an oxygen-sensitive process. The filamentous nitrogen-fixing cyanobacteria, on the other hand, have solved this problem of oxygen sensitivity by segregation of the nitrogen-fixation apparatus in heterocysts, which are specialized cells with the capacity for nitrogen fixation. The heterocysts are semiheterotrophic and this ability for semiheterotrophic growth seems to be a prerequisite for intimate symbiotic associations (Korinek, 1928). The water-splitting photosynthesis system, in connection with excretion or loss of respiratory useful metabolites and/or the dinitrogen fixation with donation of amino-compounds to the partner, are the main reasons supporting the origin and development of a symbiotic association between cyanobacteria and other uni- or multicellular organisms.

How is the term "symbiosis" defined? Anton de Bary (1879) introduced this term with the phrase " . . . Zusammenleben ungleichnamiger Organismen. . . .," the (permanent or long-lasting) association of differently named organisms (two or more bionts). This broad definition includes both mutualistic and (in contrast to the colloquial usage) parasitic associations. Mutualistic relationships have also been called eusymbioses, and the parasitic ones dyssymbioses (Schaede, 1962; for further definitions of organismic associations, see Ahmadjian and Paracer, 1986; and Smith and Douglas, 1987). It is likely that all or most symbiotic partners are antagonists, and therefore there exist transition forms between eusymbioses and dyssymbioses. Also, in many associations, the relationships are not static and can change directions, depending on environmental conditions or endogenous factors, or on the ontogenetic phases of the symbiotic partners.

One can also distinguish between "ectosymbiosis," including episymbiosis, in which both partners have only external physical contact, and "endosymbiosis," in which one partner lives within the other. For the case that the endosymbiont exists extracellularly within the host soma, I propose the term "endosomabiosis" for extracellular endosymbiosis (see later, Table 2). As an endosomabiont, the guest can live either "intracavitously" (within cavities inside the host tissue), or "intercellularly" between cells in host tissue). If the endosymbiont lies intracellularly within the host cell, it is termed an "endocytobiont" (Schwemmler, 1979, 1989). Likewise, an intracellular endosymbiosis is termed an "endocytobiosis" (Schnepf, 1975). Besides more ecological relations, these four main forms of symbiotic associations (epibiotic, intracavitous, intercellular, intracellular) are found in cyanobacterial symbioses.

Pascher (1914) proposed the name "syncyanosis" for the symbiosis of cyanobacteria with other organisms. Later (Pascher 1929), he differentiated between "endocyanoses" (syncyanoses with intracellular cyanobacteria) and "ectocyanoses" (syncyanoses with extracellular cyanobacteria). The whole consortium was termed a "cyanome," and the symbiotic living cyanobacterium was termed a "cyanelle" (these terms have no taxonomic relevance). Geitler (1959) introduced a more restricted terminology: syncyanoses are symbiotic associations of cyanobacteria with regularly chromatophoreless unicellular host organisms (bacteria, flagellates, rhizopodes, apochlorotic algae, fungi, perhaps also ciliates). More recently, the term cyanelle (cyanella) has been used in a more restricted manner, referring only to unicellular endocytobiotic cyanobacteria (those "living intracellularly") (Reisser, 1984). In addition, it should be mentioned that today the term cyanelle is almost always (and preferably) used for plastid-like cell compartments that show a more or less clear descent from originally endocytobiotic cyanobacteria, but which are, like other eukaryotic cell organelles, unable to grow autonomously. However, it remains questionable whether it would not be better to follow Trench (1982) in applying the term cyanelle(s), or cyanella(e), for "any symbiotic cyanobacteria, without attempting to guess at or speculate on the level of integration achieved by the components of the association."

In this chapter, the term syncyanosis is used in the broadest way for all cyanobacterial symbioses, ectocyanosis for extracellular, and endocyanosis for intracellular syncyanoses. Thus the symbiosis of a cyanophilic lichen or the *Azolla-Anabaena*-symbiosis, would be considered as ectocyanoses, while the cyanome *Cyanophora paradoxa* and the *Geosiphon-Nostoc*-symbiosis may be examples of endocyanoses. The term "cyanobiont" is used for each symbiotic cyanobacterium which has or will have a taxonomic name. Likewise, the term "cyanelle" is used for each (preferable unicellular; Reisser, 1984), at least in principle taxonomically determinable eusymbiotic cyanobiont, which can live intracellularly, is often not virulent, and often no longer able to live outside the host cell. The term "cyanoplast" is reserved here for the intracellular inclusions (organelles) which are obviously derivable from cyanobionts, forming a "symbiogenetic organelle" (new term), characterized by the impossibility of an easy taxonomic classification, and, with regard to some or all of its own proteins, by a real "genetic dependence on the eukaryotic host nucleus" as demanded by Cavalier-Smith and Lee (1985). In the section on "Symbiogenetic Organelles" (see later), the term is used in this sense.

A final terminological question: Since the definition of Pascher (1914), the "main organism" is placed first in the name of a syncyanotic consortium (e.g., *Azolla-Anabaena*-symbiosis). The "main organism" is ordinarily considered to be the host. But who is the host in cyanophilic basidiolichens and in some cyanophilic ascolichens such as *Collema?* It is also apparently not clear in each case whether the "main organism" is an active or passive partner with regard to the establishment of the syncyanosis. In some cases, the cyanobacteria are obviously the actively invading partners. An overview on the broad spectrum of different syncyanotic consortia is given in Table 1. It is not the intention of the author to modify Pascher's nomenclature, but in view of the aims of this Handbook, the names of the symbiotic cyanobacterial strains are placed first in Table 1.

With the help of the references given in Table 1, the interested reader should be able to find reviews or relevant original papers, that will provide more information than that given in this chapter. Additionally, the reader is referred to the reviews of symbiotic cyanobacteria by Reisser (1984) and by Rai (1990b).

The description of interspecific associations in the present paper, is limited to rather mutualistic symbioses (eusymbioses) in which there is intimate contact between the partners (Tables 1 and 2). More ecologically epiphytic and pure ecological relations (see e.g., Gallucci and Paerl, 1983; Korinek, 1928; Mora-Osejo, 1977; Wickstrom and Castenholz, 1978) are usually not discussed in this review. Also not discussed are the known examples of entecy: cyanobacteria within the branchial chambers of marine lobsters (Jennings and Gelder, 1976), *Nostoc* in degraded cells of *Sphagnum lindbergii* and *S. riparium* (Granhall and Hofsten, 1976), nor cyanellae (Nostoc?) in the sporangium of *Andreaea rupestris* (Bryophyta) recently discovered by Filina and Filin (1989). Furthermore, only some very interesting ectocyanoses of epibiotic cyanobacteria on unicellular organisms shall be mentioned, as described by Pascher (1914) (see also Fritsch, 1952), e.g., to a distinct small cyanobacterium epibiotic on *Spirillum* or to the cyanobacterium *Chroostipes linearis* epibiotic on the monad *Oicomonas syncyanotica.* Also not discussed are such associations in which the cyanobacteria are hosts for still-smaller biological systems, such as viruses (cyanophages) (Barnet et al., 1981) and bacteria (Jensen and Bowen, 1970; Wilkinson, 1979; Wujek, 1979).

[b]The symbiont has not been identified.

[c]cyanoplast (new term, see Table 2 and text).

Table 2 gives an overview of all the cyanobacterial genera containing strains capable of forming syncyanoses. The third column shows abbreviations for the divisions of the eukaryotic partner (macrosymbiont) followed by the lowest taxon, which still comprises the symbiotic strains, species, or genera, of this division. It is not possible in all cases to discriminate clearly between ecto- and endocyanoses, e.g., in *Gunnera* and in some sponges. As shown in Table 2, members of all systematic groups of cyanobacteria are involved in ectocyanoses. But the Pleurocapsales and Stigonematales occur as cyanobionts only in ectocyanotic associations, and that exclusively with lichen fungi. Within the other ectocyanoses, the prochlorophytes (Chloroxybacteria) form a marine association (with ascidians), and the Chroococcales form two marine associations (besides aerophilic lichen associations). Only the Hormogonales have a wider spectrum of symbiotic partners (one association with a marine alga, some associations with land and freshwater plants, and one with invertebrates), although the lichen fungi here too are the dominant group of macrosymbionts. Within the endocytobioses (endocyanoses), the situation is different. Here we find members of many different host families, but only one fungus as partner and host organism *(Geosiphon).* All other endocyanoses, with the exception of the two endocytobioses of *Gunnera* and *Trifolium alexandrinum,* are marine. Only members of the Chroococcales and Hormogonales are found as endocytobionts (as mentioned above). The main cyanobacterial group seems to be that of the Hormogonales, but this impression may be changed in the future by further discoveries of intracellular symbioses. Section 4 in Table 2 lists those endocyanoses in which the original endocytobiotic cyanobacterium has reached the status of a eukaryotic cell organelle, a "symbiogenetic organelle" (new term, see above). These marine or freshwater organisms are all unicellular. Typical representatives are the Glaucocystophyta (Kies and Kremer, 1986b).

There have also been some attempts to construct artificial symbioses (Gusev, 1990). One idea is that cell reconstruction techniques (e.g., cell fusion, micromanipulation) can be used as models to study the putative formation of eukaryotic cells via endocytobiotic events (Bradley, 1979, 1983) using cyanobacteria or cyanoplasts (cyanelles) isolated from *Glaucocystis nostochinearum.* The application of these methods is also considered as one of the new ways for modification of plant cells, e.g., infection of protoplasts of higher plants, such as *Allium cepa, Daucus carota, Nicotiana tabacum,* and *Zea mays,* by Agafodorova et al., 1982 (with

[b]Presumptive proposal with regard to the phylogenetic status of this plastid-like organelle within the given organismic group, formerly called Cyanelle.

Chlorogloea fritschii, Anabaena variabilis); Burgoon and Bottino, 1976 (with *Gloeocapsa*); Bradley and Duke, 1987 (with *Anabaena* sp., *Plectonema* sp., *Gloeothece* sp.); Cheong et al., 1986, 1987 (with *Nostoc muscorum*); Gusev et al., 1984 (with *Anabaena variabilis*), and Meeks

et al., 1978 (with *Anabaena variabilis*). Gusev et al. (1986) have also used whole plants for producing improved agricultural plants and transferring nitrogen-fixing ability from microorganisms into higher plants (*Anabaena variabilis* in the intercellular space of tobacco shoot regenerates). The results of these hopeful investigations have been rather disappointing as yet, because of the instabilities of the synthesized syncyanoses or of their low growth rates.

Ectosymbiosis and Endosomabiosis

In this section all the symbiotic consortia characterized by an ectocyanotic relationship of the symbiotic partners are described. The cyanobionts live extracellularly, in physical or chemical (e.g., mucilaginous shell) contact with the cell surface of the macrobiont. The manner of the symbiosis can be paraphrased as epibiotic or, if the cyanobiont is living inside a multicellular macrobiont, as endosomabiotic (see "Introduction"). It is not possible in all cases to discriminate clearly between ecto- and endocyanoses. In *Gunnera* and in sponges, both types of syncyanoses are usually found, e.g., in *Gunnera* cells the cyanobionts are surrounded with cell wall material of the plant cell. Therefore, *Gunnera* is included in this section (endosomabiosis), whereas the cyanophilic sponges, in which the cyanobionts are within the cytoplasm of the sponge cells, are placed among the endocyanoses. Some ectocyanoses are ecologically very successful and are mostly pioneers in their ecological niches. In this section, the cyanolichens and the *Azolla-Anabaena* association will be described. For information with respect to the other ectocyanoses the reader is directed to the literature cited in Table 1.

Cyanophilic Lichens

Lichens constitute those symbiotic associations between fungi (serving as morphological hosts but metabolic guests) and algae or cyanobacteria as extracellular symbionts (serving as metabolic hosts) in which a new morphological entity is formed, a stable thallus or body of specific structure (different from the original growth form of both partners). This definition rules out all loose lichen-like associations (Ahmadjian, 1965). The morphological transformation (morphogenesis) during the association is controlled primarily by the fungus, the mycobiont, rather than the alga, the phyco- or photobiont (see e.g., Honegger, 1984). Despite the fact that lichens are not a separate systematic taxon, they are classified into three subdivisions (Hawksworth, 1988a, Eriksson and Hawksworth, 1988), into orders, families, genera, and species (in parentheses, nomenclature after Henssen and Jahns, 1974): 1) Ascomycotina (Ascomycetidae) with 80 (43) families and 13,250 lichenized species: 2) Basidiomycotina (Holobasidiomycetidae) with four (three) families and 50 lichenized species; and 3) Deuteromycotina with 200 lichenized species. Within the fungal subdivision of the Mastigomycotina, with more than 1,100 species, only one is lichenized. (The mastigomycete [phycomycete] species *Geosiphon pyriforme,* in a non-lichen-like association with endocytobiotic cyanobacteria, is considered in an own section in this chapter.) Taxonomically, both the myco- and the phycobiont have binary Latin names, but, unofficially, only the name of the fungus is used for the name of the related lichen (Int. Code for Botanical Nomenclature, article 13, 1983). There are about 13,500 (Hawksworth and Hill, 1984; Galun, 1990) to 15,000 (Ahmadjian and Paracer, 1986) named species of lichen-forming fungi. Interestingly, only approximately 30 different types of unicellular or simple filamentous algae and cyanobacteria are reported as lichen-photobionts: one species of the Xanthophyceae, one of the Phaeophyceae, 22 genera of the Chlorophyceae, and 11 to 16 cyanobacterial genera (see Tables 4 and 5). Within 45 (11) orders, representing the 84 (46) known families of lichen fungi, only 18 (14) families of ascolichens and two families of basidiolichens are recorded that include cyanophilic species (Table 3).

Most of the families 7 (10) with cyanophilic species are observed within the order Lecanorales. Thwaites (1849) was the first to regard the unicellular "gonidia" of some members of the Lichinaceae as identical with free-living cyanobacteria; later, Schwendener (1869) identified some phycobionts of the Lichinaceae as species of the cyanobacterial genera *Gloeocapsa* and *Chroococcus.* Since that time, many other families and species of cyanobacteria in lichens have been found about all in ascolichens (Table 4), only few in basidiolichens (Table 5). Although the lists in Table 4 (and considerably less in Table 5) are incomplete, they allow one to estimate the distribution of the different cyanobiont genera within the lichens. Most of the lichen cyanobionts are filamentous (Tables 4 and 5) and belong to the Hormogonales to the common heterocystous genera *Nostoc* and *Scytonema.* In homoiomerous lichens (where the symbionts are distributed more or less uniformly throughout the thallus), the structure of the symbionts is similar to that in culture. In

Table 3. Taxonomy of lichen families (Eriksson and Hawksworth 1988), including the cyanophilic species, and their cyanobacterial type.

Order	Family	Cyanobacterial type[a]
Opegraphales[b]	Opegraphaceae	u, 1
Gyalectales	Stictidaceae[c]	f, 1
Lecanorales	Arctomiaceae	f, 1

[h]Formerly (Henssen and Jahns 1974) within the Sphaeriales.
[i]Formerly (Henssen and Jahns 1974) Microglaenaceae.
[k]With the only known cyanophilic basidiolichen families.
[l]Now Dictyonemataceae (see, e.g., Slocum and Floyd 1977).

contrast, in heteromerous lichens (where the symbionts are positioned in a discrete layer, the "symbiont layer"), the filaments of the symbionts are often contorted, appearing as packets. About half of the cyanophilic lichens also contain (eukaryotic) algal symbionts. Here, the algae are mostly found in the symbiont layer and the cyanobacteria are in cephalodia.

The true identity of the cyanobionts has not been established for many cyanophilic lichens, as we can see regarding the new taxonomic identification of the symbiotic cyanobacteria of some members of the lichen family Lichinaceae or the observation of cyanobiont diversity in the Lichinaceae and Heppiaceae, recently reported (Büdel and Henssen, 1983; Bubrick and Galun, 1984; Büdel, 1985). The interaction between the symbionts results in an organism which is mostly morphologically and physiologically distinct from either of the components (Green and Smith, 1974). Cyanobacterial symbionts are often altered to the extent that their origin becomes completely obscured (Marton and Galun, 1976). For example, the symbiotic *Nostoc* of *Nephroma laevigatum* appears in the intact thallus as enlarged, shapeless, and usually separated cells but upon isolation and culturing, *Nostoc* undergoes remarkable modifications and reverts to its typical free-living, filamentous growth form (Kardish et al., 1989). Recent publications have clearly demonstrated that it is not sufficient to identify lichen phycobionts solely on microscopic observations within the lichen thallus. It is essential, therefore, when making a taxonomic determination, first to separate the phycobiont from the mycobiont and to cultivate the isolated phycobiont. By growing free of the mycobiont, the phycobiont is able to change its lichen phenotype to the phenotype of the free-living form. In this state, it may be possible to classify the isolated strain with regard to morphology, fission pattern environmental requirements, physiology, and chemotaxonomical criteria, as a basis for a taxonomic determination. (For definitions of cyanobacterial genera see Rippka et al., 1979; and Chapters 97 and 98. For lichen biology, especially cyanophilic lichens, see the following books and reviews: Ahmadjian, 1965, 1967, 1973; Ahmadjian and Paracer, 1986; Galun, 1988; Hale, 1983; Henssen and Jahns, 1974; Ozenda and Clauzade, 1970; Poelt, 1969; Rai, 1990a; Wirth, 1980).

The basidiolichens (Table 5) represent only a very small group of tropical and subtropical lichens in contrast to the thousands of ascolichens, but their biology is diverse (Oberwinkler, 1970) and seems highly evolved in some fungus species (like *Dictyonema*). The evolution of these organisms may have led from a parasitic to a symbiotic (and partly endosymbiotic) association (Oberwinkler, 1980). The *Dictyonema* association shows a dense hyphal sheath around the cyanobacterial *Scytonema* filaments and an intracellular "central hypha" as an "endosymbiotic organ" (Oberwinkler, 1980). This group contains the only known case of symbiotic eukaryotic guests in prokaryotic host cells.

Lichens occur in most terrestrial habitats, from the equator to the polar regions, but very few species occur in permanently submerged habitats. Only seven truly submerged marine lichen species have been found e.g., the cyano-

[a]See Table 4 for abbreviations and Table 3 for list of families. Adapted from Oberwinkler (1970, 1980, 1984) and Ahmadjian (1982).

[b]Aphyllophorales (overall, Corticiaceae).

[c]Probably synonymous with *Cora pavonia* = *C. montana.*

[d]Obviously also synonymous with *Corella wainio.*

[e]Synonymous with *Rhipidonema.*

philic *Halographis* (Kohlmeyer and Volkmann-Kohlmeyer, 1988; see also Kohlmeyer, 1974).

The range and complexity of symbioses between fungi and algae (or cyanobacteria) can be seen to be still rather complex (Kohlmeyer and Kohlmeyer, 1979; Hawksworth, 1988b). In more recent times, observations have been reported of many fascinating cases of epiphytic, parasymbiotic, symbiotic, or parasitic algae (and cyanobacteria), bacteria, fungi, lichens, or mosses as additional bionts associated with established lichens, which collectively contribute to the century-old debate over the nature of lichen associations, and provide indications about their evolutionary significance (Santesson, 1967). Considering mutualistic and parasitic (see e.g., Duebbeler, 1980) relationships of fungi to the symbiotic partners, Hawksworth (1988b) suggested that symbioses should be discussed only in terms of the number of participating organisms, or bionts, e.g., four-biont symbioses (3 photobionts to one mycobiont) as reported for *Nephroma arcticum*, which contains two morphologically distinct cyanobacteria in addition to the principal one, *Coccomyxa* (Jordan and Rickson, 1971).

Separation and Cultivation of Symbionts

CYANOBIONTS. Cyanobacterial photobionts of some lichen families have been isolated and cultivated in pure culture (some of them are available from culture collections, e.g., *Chroococcidiopsis* sp. SAG 33.84 [Sammlung von Algenkultufen, Universität Göttingen, Göttingen, FRG] from *Psorotichia*). Different methods for separation of the phycobiont from the mycobiont can be used, such as irradiation of thallus fragments with ultraviolet light (Henrickson, 1951) and treatment with antibiotics (Watanabe and Kiyohara, 1963). Detailed instructions are given by Ahmadjian (1967, 1973). Some more recent publications are listed in the next section.

Cultivation of *Chroococcidiopsis* from Lichinaceae (Büdel and Henssen, 1983)

The lichen thalli were washed in a washing chamber (Renner, 1980) for about 30 min. Sections of 30–40 μm thickness were cut with a microtome, placed in 6-cm petri dishes on BG-11 medium containing 1.5% agar (Waterbury and Stanier, 1978) and incubated at 20°C under continuous light at 2,000 lux (Osram, universal white, fluorescent light, 40 W). The recipe for BG-11 medium is given in Table 6. After 6–8 weeks, the first free colonies of the cyanobiont were observed within the disintegrating thallus sections and were transferred to fresh agar plates and incubated under the same conditions. Washed lichen fragements were incubated in 10-ml bottles in liquid Bristol medium (Degelius, 1954) at 20°C and 2,000 lux. From such fragments, colonies of the phycobiont may be harvested after approximately 4 months.

In contrast to the growth of these cyanobionts in ASM-1 medium (Gorham et al., 1954), growth in BG-11 (Stanier et al., 1971) and KM-D (Kratz and Myers, 1955) media was unpredictable, and hence these two media were not routinely used by Bubrick and Galun (1984).

Table 6. Recipe for culture medium BG-11.[a]

	Concentration (g/l)
BG-11 medium:	
$NaNO_3$	1.5

Cultivation of *Nostoc* from Peltigeraceae (Boissiere et al., 1987)

Two methods are described, but only one, the more rapid, is given here. A lobe of thallus is carefully and repeatedly washed with water, finally with distilled water. Then the lobe is opened with a vertical and a radial cut and put on a small sterilized glass plate covered with a thin liquid layer of BG-11 medium with 0.14% agar. The plate is placed on sterilized solid agar (1.1% agar in BG-11) in a petri dish (culture conditions: 20°C; 150 μ Einsteins/m²/s; light/dark cycle: 12 h/12 h). After 3 weeks, colonies of *Nostoc* can be observed with a binocular microscope. The colonies are transferred into new petri dishes containing the same medium for further proliferation. It is possible to purify such cultures from both, contaminating bacteria and mycobiont, to an axenic stage. Two further methods have been described. No difference in growth morphology was found between axenic cultures and cultures contaminated with bacteria (Boissiere et al., 1987). *Nostoc* isolates from *Nephroma laevigatum* are described by Kardish et al., 1989.

MYCOBIONTS. Ahmadjian has done pioneering work on the cultivation of lichen fungi (Ahmadjian, 1973) and the experimental synthesis of lichen symbioses (Ahmadjian and Jacobs, 1983). Two strategies are known for obtaining pure cultures of lichen fungi. The best way

seems to be to use spores from lichen ascocarps originating from the mycobiont (Ahmadjian, 1961, 1963; Lallemant, 1985). In the other method, hyphal fragments from the lichen thallus have been used but the results of this strategy seem to be uncertain with regard to obtaining the true mycobiont, because lichen thalli are substrates for many parasitic and parasymbiotic fungi whose hyphae are in intimate contact with the cells of the phyco- and mycobiont (Ahmadjian, 1964; see also Hawksworth, 1988b). Lichen fungi on agar media (2% glucose) form compact, elevated colonies, which vary widely in size, shape, and color (Ahmadjian 1961, 1963, 1964, 1989).

For cultivation and axenic resyntheses of lichens, including questions of recognition and resistance, see Ahmadjian and Jacobs (1983), Ahmadjian (1989), and Stocker-Wörgötter and Türk (1989). Although lectins occur in different lichens (Petit, 1982; Lallemant and Savoye, 1985), the authors doubt that a lectin-mediated recognition system exists in lichens because such systems imply close affinities between the symbionts. On the other hand, studies on lichen synthesis raised the possibility that some type of recognition occurs between algal and fungal symbionts (Ahmadjian et al., 1980; Ahmadjian and Jacobs, 1981; Galun, 1988).

Biochemistry, Physiology, and Ecological Significance

For metabolite exchange, the partners need regular intimate physical contact. Five principal types of contacts have been described (Smith and Douglas, 1987): 1) thin-walled fungal hyphae enter the gelatinous sheath of algal colonies (e.g., *Nostoc*) but do not come into contact with the cell wall layers of the photobionts; 2) close wall-to-wall contact between myco- and phycobiont without apparent formation of specialized attachment structures (nevertheless, the fungus may dramatically influence the structure and cell wall composition of the cyanobiont, as demonstrated by Kardish et al., 1989, with regard to the *Nostoc* of *Nephroma laevigatum*); 3) close contact of the hyphae to the phycobiont through the formation of specialized attachment structures (comparable with appressoria); 4) "intraparietal haustoria" (hyphae form plug-like projections in the phycobiont cell without penetrating the phycobiont cell wall; and 5) "intracellular haustoria" (hyphae penetrate the phycobiont cell wall but not its cytoplasmic membrane).

The best explanation of the relationship between fungus and "alga" may be the view that lichens are examples of a controlled parasitism (Ahmadjian, 1982b; Ahmadjian and Paracer, 1986). The fungus accepts photoassimilated products from the alga (Green and Smith, 1974) and, in the case of cyanobacteria, also fixed nitrogen. The fungus provides the alga with water, minerals, and protection from desiccation and high light intensities by using, in part, secondary metabolites, the "lichen acids" (Culberson et al., 1977). These usually extracellularly in the cell wall material occurring and often crystalline "lichen substances" are usually only produced during symbiosis (Culberson and Ahmadjian, 1980; but see Honegger and Kutasi, 1990). It is not certain whether the respiratory carbon dioxide exchange has evidence for the symbiosis, as discussed by (Coxson et al., (1982). In cyanophilic lichens, the carbohydrate released from the cyanobiont and transferred into the fungus is glucose (Drew and Smith, 1967; Smith and Douglas, 1987), in contrast to the algae which release specific alcohols (polyols) as photosynthates. Free-living cyanobacteria do not excrete glucose (Galun, 1990). The other contribution of the cyanobiont to the fungus is ammonia. All investigated cyanophilic lichens (Millbank, 1984) fix nitrogen and are photoassimilating (Galun and Bubrick, 1984). Where filamentous cyanobacteria are the sole symbionts, the heterocyst frequency is 4–8%, and both photoassimilation and dinitrogen fixation rates are comparable to values for non-symbiotic cyanobacteria. But when the cyanobionts are the second symbionts and restricted to cephalodia, a striking change occurs: heterocyst frequency is higher (14–36%) (Kershaw, 1985), as is the nitrogen fixation rate, because the synthesis of the cyanobacterial enzymes for ammonia assimilation (glutamine synthetase and glutamate synthase) are suppressed (Rai et al., 1981; Stewart et al., 1983) and the rate of photoassimilation is reduced (Smith and Douglas, 1987), e.g., glutamine synthetase is present in high levels in free-living *Nostoc* but only in traces in symbiotic *Nostoc* (see also Champion-Arnaud and Lallemant, 1986). Approximately 50% of the fixed nitrogen is excreted as ammonia and assimilated via glutamate dehydrogenase by the mycobiont (Galun, 1990). An unsolved problem is the regulation of phycobiont/mycobiont relation. It is conceivable that the mycobiont, as an heterotrophic organism, produces urea via the urea cycle including the reversible arginase reaction. The urea is decomposed by the enzyme urease (inducible by urea) into carbon dioxide and ammonia, molecules which are inductors and substrates for metabolic processes in the phycobiont. Via photosynthesis the phycobiont produces more primary metabolites which, partially, move to the

fungus. Here they induce the synthesis of more secondary metabolites including usnic acid, a competitive inhibitor of urease. In this way, the offer of carbon dioxide and ammonia will be reduced for the phycobiont and, in the following, the growth of the phycobiont is diminished. Even, if these "urease theory" could explain (Ahmadjian and Paracer, 1986) how the fungus may control the rate of polyol excretion by chlorophycean photobionts (see also Perez-Urria et al., 1990) and therewith the population density of the phycobiont, its function in the regulation of growth of nitrogen-fixing and ammonia-releasing cyanobionts remains uncertain.

Lichens with cyanobionts are important contributors to the nitrogen economy of various ecosystems. *Lobaria oregana* is abundant in the Douglas fir forests of the Pacific Northwest (USA), and when its thalli fall off the trees onto the ground, they decay and release significant amounts of nitrogen (2.3 kg fixed N/ha). Organic nitrogen compounds may also leach out from lichen thalli during heavy rains (Ahmadjian and Paracer, 1986).

Lichens are very sensitive to air pollutants, especially to sulfur dioxide (e.g., Sharma et al., 1982) but species vary in their sensitivity. Therefore, the species composition and growth forms on substrate can be used as accurate indicators for air pollution (Hawksworth and Rose, 1976). Lichens show a differential sensitivity to heavy metals (Brown and Beckett, 1983). Because lichens are respiratory and photosynthetic consortia, it was to be expected that certain plant-protective substances would influence cyanophilic lichens (Da Silva et al., 1973; Hallbom and Bergman, 1979).

For further information, see reviews by, e.g., Boissiere et al. (1987); Brown (1985); Büdel (1985); Büdel and Henssen (1988); Galun and Bubrick (1984); Hale and Culberson (1966); Lallemant et al. (1986); Lawrey (1984); Millbank (1984); Peveling (1987); Pirocynski and Hawksworth (1988); Smith and Douglas (1987); Stewart (1977); and Tschermak-Woess (1988).

The Azolla-Anabaena Symbiosis

Taxonomy, Morphology, and Development of the Symbiosis

The *Azolla-Anabaena* symbiosis is a eusymbiotic association between the nitrogen-fixing cyanobacterium *Anabaena azollae* and the eukaryotic freshwater fern, *Azolla.* The genus *Azolla* was established by J. B. Lamarck as early as 1783 (Svenson, 1944). It comprises either seven or eight species (Table 7). Whether *Azolla pinnata* var. *imbricata* is a variety or an independent species (Lin, 1980) is not clear. To date, more than 40 fossil species of *Azolla* have been described (Fowler, 1975; Hills and Gopal, 1967). The genus used to be included with *Salvinia* in the Salviniaceae (Smith, 1955), but in the 1960s, it was placed in a separate family, the Azollaceae (Sculthorpe, 1967; Moore, 1969; Konar and Kapoor, 1972, Lumpkin and Plucknett, 1980). The small, fast-growing water ferns of temperate and tropical aquatic ecosystems around the world float freely on the surface of freshwater ponds and marshes. The swimming plant (sporophyte, Fig. 2) has tiny roots and a short, branched stem (rhizome), which is covered with small, overlapping leaves. The sporophyte has a dorsiventral organization (Peters and Calvert, 1983) and each rhizome apex has an upcurved meristem (see Fig. 1). Roots and lateral branches are derived from further divisions of the ventral cells of this meristem whereas leaves are derived from the corresponding dorsal cells. Each leaf is divided into a dorsal and a ventral lobe. The thin ventral lobe (its distal half is only one cell thick) is nearly colorless and floats on the water surface. The mature dorsal leaf lobe is aerial and has a clearly defined multilayered mesophyll as well as adaxial and abaxial epidermal tissues. The abaxial epidermis has many stomata and single-celled papillae. Each mature dorsal leaf lobe has an ellipsoidal cavity formed by an infolding of the adaxial epidermis in the proximal half of its lamina. The cavity normally contains the endophytes, the cyanobacterium *Anabaena azollae,* and in addition Gram-positive, non-nitrogen-fixing bacteria (Gates et al., 1980), identified as *Arthrobacter* spp. (Wallace and Gates, 1986; Petro and Gates, 1987; Grilli Caiola et al., 1988). Vegetative *Anabaena* cells, the "apical *Anabaena* colony," are also found in the pocket of the apical meristem formed by the upcurved meristem and the young overarching dorsal leaf lobe (Fig. 1).

Development of the leaf cavity begins in the young leaves. An area of premesophyll tissue at the base of the dorsal leaf lobe enlarges much less than the more distal mesophyll, causing a depression to form in the adaxial epidermis. As the apical meristem continues to grow and becomes further displaced from each leaf, filaments of the apical *Anabaena* colony become associated with each developing leaf in the area of its forming cavity. The actual partitioning process appears to involve a specialized epidermal hair called the "primary branched hair" (PBH) (Calvert and Peters, 1981). Each leaf has only one PBH. It originates from the axil of the primordial leaf and grows with its terminal cells

Table 7. Taxonomy of the *Azolla-Anabaena* symbiosis.[a]

Cyanobiont[d]	Properties[e]	*Azolla* species
		Section: Euazolla (New World species)
Anabaena azollae	F, e, f, N	*Azolla caroliniana* Wilidenow
A. azollae	F, e, f, N	*Azolla filiculoides* Lamarck (type species)
A. azollae	F, e, f, N	*Azolla mexicana* Presl

A. azollae	F, e, f, N	*Azolla pinnata* var. *pinnata*

[a]Cyanobiont: *Anabaena azollae* Strasburger; host: *Azolla* (Azollaceae, Salviniales, Filicopsida, Pteridophyta).
[b]*A. rubra* was also reported as *A. japonicum* (Peters et al., 1979; but see Zimmermann et al., 1988).
[c]Listing is incomplete (see Lumpkin and Plucknett, 1982; Zimmermann et al., 1988).
[d]In the future, the "species" *Anabaena azollae* will probably be split into several different species.
[e]Abbreviations: see Table 4.

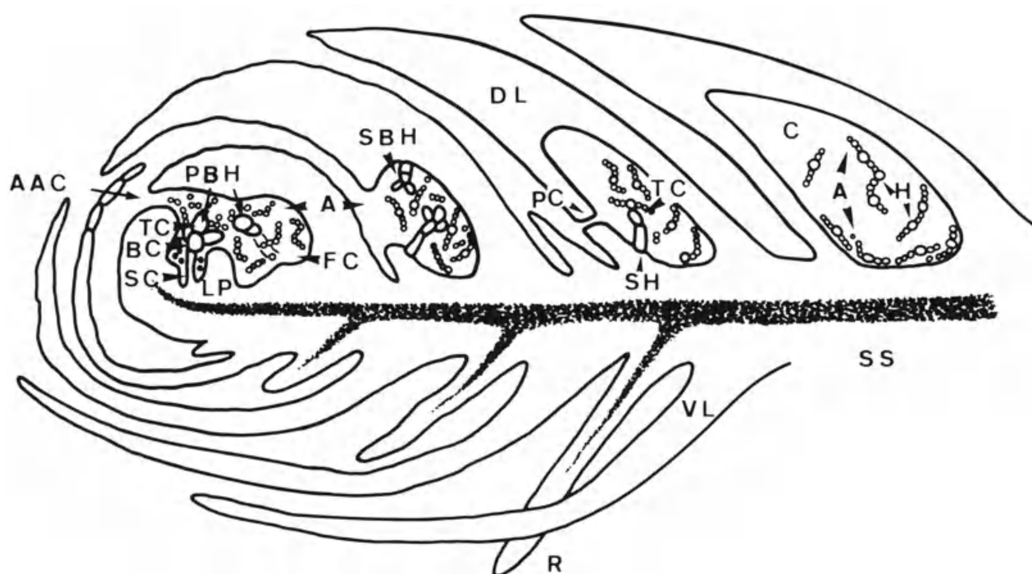

Fig. 1. Anatomy of the *Azolla-Anabaena azollae* symbiosis. Schematic, vertical, longitudinal section of an *Azolla* branch with the apical meristem, illustrating: the apical *Anabaena* colony (AAC) with vegetative *Anabaena* cells (A); differentiation of *Anabaena* cells into heterocysts (H) during maturation of leaves; different stages in the formation of the leaf cavity (C) in the dorsal leaf lobe (DL); and of the transmission of the *Anabaena* cells from the apical colony in the leaf cavity. Abbreviations: BC, body cell; FC, forming cavity; LP, leaf primordium; PBH, primary branched hair; PC, pore closure of the cavity; R, root; SBH, secondary branched hair; SC, stalk cell; SH, single hair; SS, stem stele; TC, terminal cell; VL, ventral leaf lobe. (Drawing based on an illustration from Peters and Calvert, 1983; also using electron micrographs from the same article and unpublished observations of H. E. A. Schenk.)

into the apical *Anabaena* colony. Some *Anabaena* filaments seem to be attracted to the PBH in the apical region and are, in the following development, separated from the apical colony, whereas the PBH is now positioned at the proximal end of the cavity depression. Cells around the rim of the depression become meristematic and produce epidermal cells, which form the

cover of the cavity engulfing the PBH with its associated *Anabaena* filaments. Now, some *Anabaena* filaments begin to differentiate heterocysts, and additionally, many epidermal hairs begin to form on the cavity wall. One of these, the "secondary branched hair" (SBH), is positioned at the back of the cavity. The other hairs (which have, during maturation of the cavity, increased in number up to 25 per cavity), termed "single hairs" (SH), consist of two cells, the stalk cell (SC) and the terminal cell (TC). Both cells (the terminal one, more quickly) differentiate a so-called transfer cell ultrastructure (TCU) as well as the different cell types of the PBH and the SBH. TCU is characterized by the presence of numerous cell wall elaborations and an organelle-rich, dense cytoplasm which contains abundant rough endoplasmic reticulum. For further detail, readers are directed to reviews by Peters and Calvert (1983); Shi and Hall (1988); and Braun-Howland and Nierzwicki-Bauer (1990). Besides biochemistry and physiology, the above-mentioned authors have also comprehensively reviewed the genetics of the *Azolla* system. The capability for high dinitrogen fixation rates is a fascinating characteristic of this symbiosis. The observed production of molecular hydrogen probably will rather remain a limited side effect (Newton, 1976).

Reproductive Cycles of *Azolla*

The Taxonomy of the plant *Azolla* is based above all on characteristics of its reproductive structures. *Azolla* can reproduce either sexually by sporocarp development or asexually by vegetative fragmentation (Rao, 1936; Watanabe, 1982) (Fig. 2). The latter mode was found to be the main method of reproduction. It is rapid in *Azolla,* with a doubling time of about 2 days under optimal conditions (Peters et al., 1980). The less frequently observed type of reproduction is the sexual cycle via sporocarp formation. The most important factors controlling the life cycle are light intensity (Becking, 1979; Watanabe, 1982; Singh and Srivastava, 1985a), temperature (Becking, 1979; Watanabe, 1982), plant density (Becking, 1979; Watanabe, 1982), and photoperiod (Holst and Yopp, 1979; Singh and Srivastava, 1985b). The sexual life cycle enables the plants to overwinter and withstand desiccation (oversummering). The two generalized reproductive cycles of *Azolla* are shown in Fig. 2.

MAINTENANCE OF THE SYMBIOSIS. The symbiotic association between *Anabaena* and *Azolla* is maintained during both sexual and asexual (Fig. 2) modes of reproduction. Akinetes and/or filaments (Becking, 1978) of *Anabaena* (indicated by the asterisk) are apparently present during the development of both the mega- and the microsporocarps (generative life cycle), but are retained to maturity only in the former (Peters and Calvert, 1983). The continuity of the *Anabaena* endophyte throughout the life cycle of *Azolla* does not preclude the possibility of a free-living form of the endophyte, but it does eliminate the necessity for such a free-living form. In this view, the *Azolla-Anabaena* symbiosis is distinct from all other prokaryote-plant associations. Also each plant produced by fragmentation (vegetative life cycle) carries its own *Anabaena* inoculum, because each branch apex of the generative sporophyte contains a vegetative apical *Anabaena* colony. A very interesting problem is the control of the cell cycle of the cyanobiont by the macrobiont. In the growing point of the macrobiont, more rapidly dividing cells of the cyanobiont are observed than in its mature regions. The pattern of photosynthetic carbon and nitrogenase functions change during thallus development. Hill (1989) suggested two operating controls on the cyanobiont cell cycle: 1) nutrient supply for cell maintenance and cell growth; and 2) constraint or stimulation of commitment to divide. The separate operation of these controls leads to cyanobiont cells being in two possible stages: phase I, generative cells associated with growing host tissues and phase II, differentiated cells in the mature regions of the host.

Anabaena azollae

The cyanobacterial endophytes of all *Azolla* species are members of the family Nostocaceae and are collectively referred to as *Anabaena azollae* Strasburger. However, Candales et al. (1988) have stated that because of its life cycle, the cyanobiont in *Azolla* may belong in the genus *Nostoc.* In recent years studies have been made to determine whether the cyanobiont is the same in all *Azolla* species. Immunofluorescence studies (Gates et al., 1980; Ladha and Watanabe, 1982) suggest that the cyanobionts of all *Azolla* species are similar (if not identical). In contrast to these results, studies with lectin hemagglutination tests (McCowen et al., 1987; Mellor et al., 1981) indicate that the cyanobionts are different in at least three *Azolla* species. From restriction enzyme analysis of the *nifDH* region, Franche and Cohen-Bazire (1987) established that all nine symbiotic *Anabaena* strains investigated (from four Euazolla species and five Rhizosperma species) derive from a common ancestral *Anabaena azollae*

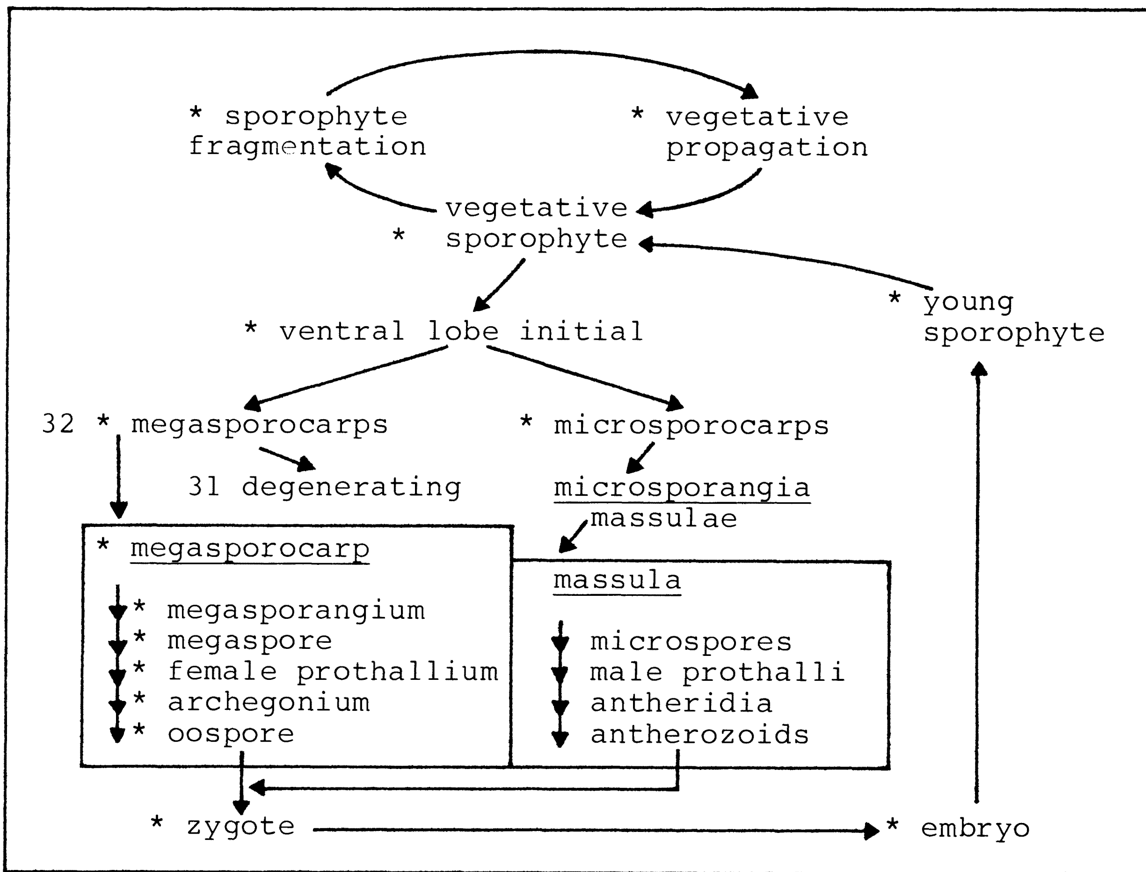

Fig. 2. Reproductive life cycles of *Azolla*. The asterisk indicates that *Anabaena azollae* is present. (Schematic diagram based on Braun-Howland and Nierzwicki-Bauer, 1989; Peters and Calvert, 1983; Shi and Hall, 1988.)

and belong to two slightly divergent evolutionary lines, the Euazolla and the Rhizosperma line. Many authors (e.g., Ashton and Walmsley, 1976) claim to have grown *A. azollae* after isolation, and Newton and Herman (1979) described a new isolation procedure, the "bundles" method. But, although these cultured isolates have exhibited some characteristics different from general free-living cyanobacteria (Newton and Herman, 1979; Newton and Cavin, 1985; Rozen et al., 1986; Shi et al., 1987; Tel-Or and Sandovsky, 1982), there are still doubts. For example, a difference in surface antigenicity appeared to exist between freshly isolated *A. azollae* cells and those obtained from in vitro cultures (Arad et al., 1985; Gates et al., 1981; Ladha and Watanabe, 1982, 1984). Another point of view is the possibility that the major constituent of *Azolla* cavities is an obligate endosymbiont, and that free-living isolates may be minor constituents of the cavity that are selected for during isolation (Meeks et al. 1988; Braun-Howland and Nierzwicki-Bauer, 1990). Identification of strains as effective cyanobacterial symbionts of *Azolla* will require a reinfection of cyanobacteria-free plant material with the in vitro cultivated cyanobiont (Koch's postulates) as was reported by Liu et al. (1984) and Lin et al. (1988).

Cultivation of Symbiotic Consortia and of Partner-Free Symbionts

Cultivation of the *Azolla-Anabaena* Consortium

Kulasooriya et al. (1988) give the following instruction: *A. filiculoides, A. caroliniana,* and *A. pinnata* var. *imbricata* were grown in a phytotron under a light/dark regime of 16:8 h, at temperatures of 27/22°C, respectively. *A. filiculoides* was grown in Hoagland medium diluted 1:8, *A. caroliniana* and *A. pinnata var imbricata* were grown in the medium of the International Rice Research Institute (IRRI) (Watanabe et al., 1977). For *A. caroliniana,* Kaplan and Peters (1988) used the N-free medium of Peters et al. (1980).

Cultivation of *Anabaena*-free *Azolla*

Anabaena-free *Azolla* plants (Lin and Watanabe, 1988) are grown on IRRI's culture solution (Watanabe et al., 1977) containing ammonium nitrate at 50–70 mg/l, placed in a lighted growth cabinet (120 W m^{-2}, (day/night), 75% humidity). The culture solution should be changed every 3 days.

Culture of the Endophyte *Anabaena azollae*

For laboratory culture (Peters and Mayne, 1974), the *Azolla* fronds were grown in Erlenmeyer or Fernbach flasks in a growth chamber in N-free medium or in a medium containing nitrate as N source. Temperature, 23/18°C; 16 h light/8 h dark; illumination with mixed light of cool-white fluorescent and incandescent lamps, 200 or 400 foot candles.

N-free medium: 2 mM KCl, 2 mM $CaCl_2$, 0.4 mM KH_2PO_4, 0.8 mM $MgSO_4$; each liter contained 1 ml of a stock solution of sesquestrene NaFe (FeEDTA) containing 5 mg Fe/ml and of a micronutrient solution (Allen, 1968), pH 5.4–5.6 (see below).

Laboratory Cultures of *Anabaena* (Boussiba, 1988)

The cyanobacteria (isolate courtesy of E. Tel-Or, Rehovot) were cultivated in 500-ml sterilized glass columns in a circulating water bath (30°C, controlled water temperature); a constant photon flux of 175 μ Einsteins/m_2/s at the surface of the growth vessel by eight cool-white fluorescent lamps. Continuous aeration was provided by bubbling filtered air containing 1.5% carbon dioxide. Under these conditions, the pH was maintained at 6.8–7.0. The standard growth medium was BG-11 (Stanier et al., 1971; see Table 6).

Outdoor Cultures of *Anabaena* (Boussiba, 1988)

2.5-m^2 oval-shaped ponds with two channels forming a single loop were used. The culture (isolate of E. Tel-Or, Rehovot), 250-liter in volume (grown in medium BG-11) and 10-cm depth, was stirred by a paddle wheel. Carbon dioxide was supplied to maintain the pH at a range of 6.5–7.5. Temperature, dissolved oxygen, and pH of the pond were monitored daily. Light intensity ranged from 900 to 1250 μEinsteins/m^2/s, between March to August, respectively. To maintain steady-state growth, excess culture liquid was removed as required. In all outdoor experiments, the biomass concentration was kept between 6–8 mg chlorophyll/liter. Outdoor mass production (maximum yield of ash-free dry weight) *Anabaena azollae* was as follows:

August, 17.9 g/m^2 d; March, 5.6 g/m^2 d.

Separation of Symbionts

Endophyte-free plants rarely occur in nature but can be generated by several techniques (Peters and Mayne, 1974; Hill 1975, 1977; Lin and Watanabe, 1988). Also axenic cultures of *A. azollae* can be obtained (Bai et al., 1979; Newton and Herman, 1979).

Methods for Isolation of the Cyanobacterial Endophyte

1. Peters-Mayne or "Gentle" Method (Peters and Mayne, 1974): A single layer of *Azolla caroliniana* fronds was placed in a shallow porcelain pan, and N-free BG-11 medium (see Table 6) supplemented with 1% PVP-40 (polyvinyl pyrrolidone) was added until the fronds began to float. A teflon roller was used to gently squash the fronds. The resulting mixture was passed through four, then eight layers of cheesecloth, and centrifuged at low speed at room temperature for 2 min. The pellets were resuspended in N-free BG-11 medium, passed through two layers of 100-μm nylon mesh, centrifuged and resuspended in a small volume of the N-free medium. The entire procedure was carried out utilizing sterile techniques.
2. For isolation of the endophytic *Anabaena azollae,* fronds grown in N-free medium were harvested and their fresh weight determined. Fronds were then put in the N-free medium containing 1% soluble PVP-40 (8 ml/g fresh weight) and ground for 30–60 s in a motor-driven, ice-cold, teflon homogenizer. The homogenized material was sequentially passed through 4 and then 8 layers of cheesecloth and a 110 μm nylon mesh, followed by rinsing with the grinding medium. The filtrate was centrifuged at low speed for 20–30 s and the supernatant decanted. The pellet, containing the endophyte filaments, was resuspended in 2 ml of the growth medium without PVP-40 and recentrifuged prior to final resuspension in the same medium for use in specific studies (Peters and Mayne, 1974).
3. Further methods for isolation of the cyanobiont were recently described by Candales et al. (1988).

Two Methods for Preparing Cyanobacterium-Free *Azolla*

1. Antibiotic treatment method (Peters and Mayne, 1974):

Antibiotics were employed individually and in various combinations and concentrations. Cultures were left in nutrient medium with antibiotics for 1 week with one change to fresh antibiotic-containing medium, transferred to antibiotic-free media for 1 week, and then transferred to media containing different antibiotics. This procedure was continued until four different combinations or individual antibiotics had been employed. Three of the sequential treatments were successful and gave fronds which remained free of the symbiont and incapable of acetylene reduction during a 6-month period. For more details the reader is referred to the original publication.

2. Lin-Watanabe method (Lin and Watanabe, 1988):

The apical membranes and the indusium of each megaspore of harvested megasporocarps of *A. microphylla* or *A. filiculoides* to which massulae were attached were decapitated with a razor blade just beneath the level of the apical membrane. The decapitated megaspores were placed vertically on slightly sloping filter paper soaked with water in a petri dish. Sporocarp germination was induced at 24–48°C under fluorescent light (5 W/m^2). When the first leaf emerged, the young *Azolla* plants were transferred to IRRI's culture solution (Watanabe et al., 1977) containing ammonium nitrate at 50–70 mg/liter and placed in a lighted growth cabinet (120 W/m^2, (day/night), 75% humidity). The culture solution was changed every 3 days.

Reinfection of symbiont-free *Azolla* megasporocarps with *Anabaena azollae* and artificial reconstruction of the symbiotic consortium is described by Lin et al. (1988).

Ecological Significance and Agricultural Use of *Azolla*

Growth, mineral nutrition, and agricultural use of *Azolla* has been reviewed by Nierzwicki-

Bauer (1990). Under optimal laboratory conditions, *Azolla* species have a rapid vegetative propagation with biomass doubling time of 2 days or less. The consortium necessarily requires light, air, water, and the same macronutrients as those, essential to other aerobic photoautotrophs (except for nitrogen, which can be supplied in total by dinitrogen fixation). Under natural conditions, their rapid growth enables these ferns to completely cover water surfaces and, depending upon where they occur, the plants can be considered either noxious weeds or a crop plant with agronomic potential. Therefore it seems not surprising that the cultivation of *Azolla(-Anabaena)* has a long history of use as a green manure for rice and as fodder for poultry and livestock in China, Vietnam, and other Far-eastern countries (Tuan and Thuyet, 1979; Liu, 1979; Peters and Calvert, 1983; Shi and Hall, 1988). According to Liu (1979), referred to in Shi and Hall (1988), one of the earliest mentions of *Azolla* seems to be in a Chinese book on agricultural techniques written by Jia Si Xue (540 A.D.), entitled "Qi Min Yao Shu" (The Art of Feeding the People). Within the part of the book on applied plant cultivation, Jia Si Xue describes the cultivation of *Azolla* and its use in rice fields. In Vietnam, the use of *Azolla* was described by a Buddhist monk named Kongh Minh Kongh, who promoted the cultivation of *Azolla* in the 11th century (Tuan and Thuyet, 1979). As the beginning of the 17th century there were many local records of its use as a green manure in China. However, because *Azolla imbricata* (the only species native in China) cannot overwinter and propagates slowly in early spring, the modern use of *Azolla* in China did not begin to expand markedly until 1962 (Liu, 1979). "Perhaps the most significant breakthrough for the improvement of *Azolla* cultivation in China was the importation of an usually cold-resistant variety of *A. filiculoides*" (Lumpkin and Plucknett, 1982), which allowed the cultivation of *Azolla* to expand into northern and northeastern China. Its use currently has been extended to approximately 1.34 million ha (Peters and Calvert, 1983). Therefore it was not until the last 30 years that techniques for cultivation of *Azolla* and its use as an alternative to chemical nitrogen fertilizers were extensively developed.

Numerous factors influence the *Azolla* nitrogen input. Among others, they include the agricultural system used, fertilization requirements of the field, the presence of soluble iron, and problems with pests. Maximum estimated inputs during exponential growth of *Azolla*, assuming unlimited growth, range from 335–670 kg/ha/year (Becking, 1979). If account is taken of more natural growth conditions, such as discontinuous light intensity and variation in temperature, winds, humidity, water depth, and nutrient availability in different geographical areas and with different *Azolla* species, the values may vary from 80–162 (rarely to 500) kg N/ha/year. *Azolla* is rich in proteins, fats, and amino acids, and in addition to its use as a fodder for different animals, above all for pigs, it has even been suggested as food for humans (Singh, 1979). It may serve as a weed suppressor when grown in dual culture with rice (Watanabe, 1982) and might be useful for improvement of water quality (Cohn and Renlund, 1953).

Endocytobioses (Endocyanoses)

This Chapter (see Table 1) summarizes the properties of all facultative or obligate endocytobiotic consortia (eukaryotic host organisms with intracellularly living cyanobionts). Such consortia are composed of genetically independent symbiotic partners. Most of these consortia are marine, and it seems that they are all difficult to cultivate under laboratory conditions, with exception of the terrestrial *Trifolium alexandrinum*. But this consortium, with both *Nostoc* and *Rhizobium* as endosymbionts, must probably be understood rather as an endosomabiosis (ectocyanosis, because obviously most cyanobacteria are living in the intercellular space of the nodules) than as an endocytobiosis. Further studies are necessary to clarify the real relationships of this symbiosis.

A very interesting area for research concerns the cyanophilic sponges. At least four different cyanobacteria occur as symbionts both intra- and intercellularly within marine sponges (this number may expand as other sponges are examined). Two unicellular cyanobionts are described as species of *Aphanocapsa* (Sara, 1971) although they are unlike free-living species of this genus. A multicellular cyanobacterium has been designated as *Oscillatoria spongeliae;* another unicellular form is yet to be named, but it resembles *Synechocystis trididemni* (Rützler, 1981). One of the unicellular species, *Aphanocapsa feldmanni,* is by far the most widely distributed, occurring in at least 14 sponge orders of the classes Calcarea and Desmospongia (Wilkinson, 1980). Cyanobacterial symbionts are only recorded in sponges from warm temperature to tropical habitats and only those growing in relatively shallow water (< 30 m depth). The host species may be divided into two categories on the basis of the number of symbionts and the contribution made to the sponge. Most species have a thin layer of tissue

containing the cyanobionts in those parts exposed to light, whereas some flattened sponges contain numerous symbionts distributed throughout the tissue.

It is not the intention to deal with all the numerous associations (see papers listed in Table 1). However, one very fascinating biological system, *Geosiphon pyriforme,* is based on the work of Mollenhaver (1988).

Geosiphon pyriforme

Geosiphon pyriforme (Phycomycotina, Endogonales, phycomycete of unknown systematic classification, but probably within the relationship of *Glomus* Tulasne), first described by Wettstein (1915), forms a well-known, but rarely observed, unique, facultative endocytobiosis (Fig. 3) between a hormogonal cyanobacterium, related to *Nostoc punctiforme* (Mollenhauer, 1988) and the siphonous fungus *Geosiphon pyriforme* (Knapp, 1933). The only known occurrence at present (Mollenhauer, 1988) is near Biebergemünd, Germany, on ridges of extensively used crop fields (geology: German Trias: Buntsandstein). The fungus colonizes bare soil between liverworts, mosses, and dwarf phanerogams, forming an ecological association called the Centunculo-Anthocerotetum-association. The fungus regularly occurs in intimate association with a moss protonema (not yet satisfactorily identified) which may be a *Dicranella* species (Mollenhauer and Mollenhauer, 1988). It is clear that this endocytobiotic consortium does not represent a lichen ("phycomycotina lichen," as described by Henssen and Jahns, 1974), because the cyanobacterium lives intracellularly within cytoplasmic vacuoles (Schnepf, 1964, 1966) of the fungus and a typical lichen thallus is not formed. Additionally, the synthesis of extracellular lichen substances is unknown, and the morphology of the partners is not strongly modified during the symbiosis, except for the development of the symbiont-containing vesicles of the fungus. The fungus vesicles are observed on the soil surface whereas the uninfected hyphae grow below the soil surface between the soil particles. Besides the dark blue-green vesicles, *Geosiphon* also forms whitish globular bodies, which serve as resting spores (presumably "sporocarps" very similar to those of *Glomus* species), being able to form new hyphae (Mollenhauer, 1988).

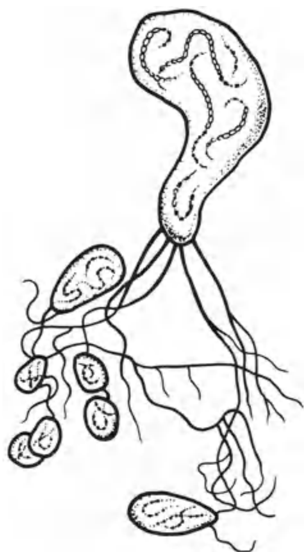

Fig. 3. *Geosiphon pyriforme:* mycelium with vesicles containing the endocytobiotic *Nostoc* filaments. Different times of infection result in vesicles of varying age, and therefore, of varying size. (Based on a photograph in Mollenhauer, 1988.)

It has been possible to cultivate symbiont-free and symbiotic *Geosiphon* (Mollenhauer and Mollenhauer, 1988) and to demonstrate, in part, the mode of the infection of the fungus by motile hormogonia of the cyanobacterium (Mollenhauer, 1988). This very interesting process of active infection attack by the motile hormogonia and the following endocytosis by the fungus (in the region of the apical end of young hyphae) is described in the original papers of D. and R. Mollenhauer (see "Literature Cited").

After colonization of *Geosiphon,* the *Nostoc*-containing filaments develop heterocysts. Besides photo assimilated carbon, the cyanobacterium also contributes fixed nitrogen to the fungal host. A transport system in the plasmalemma of the cyanobiont shows a high affinity for glutamate and a lower one for aspartate (Strasser and Falkner, 1986). Some observations give indication that the symbiosis is a highly balanced equilibrium which, dependent on the environmental conditions, turns from a eusymbiotic into a dyssymbiotic relationship. In the parasitic state, the fungus digests the endocytobiotic cyanobacteria in the vesicles (Mollenhauer, 1988).

CULTIVATION AND SEPARATION OF THE SYMBIONTS. Endocytobiotic *Nostoc* strains from *Geosiphon* were isolated by W. Koch (Göttingen: SAG) and by D. Mollenhauer (Forschungsinstitut Senckenberg, Lochmühle, Biebergmünd), from where strains are also available. For the Mollenhauer strain, batch and agar culture conditions are described by Strasser and Falkner (1986).

Using water exudates of the accompanying moss Dicranella, or, still better, of *Funaria hy-*

grometrica, it is possible to cultivate mycelia of *Geosiphon pyriforme* (Mollenhauer, 1988).

Symbiogenetic Organelles ("Endocyanoses")

Introduction and Taxonomic Overview

Symbioses of cyanobacteria with other organisms as hosts are defined as syncyanoses (Pascher, 1914), and as ecto- or endocyanoses (Pascher, 1929) (see discussion of terminology in "Introduction, Terminology, and Overview"). The endosymbiotic cyanobacterium (e.g., Chroococcaceae or Nostocaceae) of an endocyanome is termed a "cyanelle" in analogy to "zoochlorelle" or "zooxanthelle" (Pascher, 1929). The nonsystematic term "cyanelle" was later restricted to only unicellular endocytobiotic cyanobacteria (Geitler, 1959). However, it is obvious that this cannot be more than a simple microscopic view of classification. Using this more restricted terminology, we shall easily arrive at confusing situations, because it is known that filamentous cyanobacteria can change phenotypically into unicellular forms during symbiosis. Additionally, constructing a phylogenetic tree by using 16S rRNA sequence data, it could be demonstrated (Giovannoni et al., 1988) that the morphotypes of section I (unicellular cyanobacteria) and section III (nonheterocystous, filamentous cyanobacteria) in the classification system of Rippka et al. (1979) are dispersed throughout the tree, indicating multiple evolutionary origins for these species. Therefore, taxonomic classifications of cyanobacteria based principally on morphology do not necessarily reflect phylogenetic relationships. Notwithstanding, for the purpose of this section on the organisms described here, the restricted term for cyanelles given above is used because most of these so-called cyanelles have reached a high degree of genetic adaptation to the "host" cell. At the end of this introduction, a proposal for the further use of the term "cyanelle" is given.

The first discovery of an endocyanosis in a unicellular organism was that of the thecamoeba *Paulinella chromatophora* described by Lauterborn (1895). After this time, more cyanelle-bearing endocyanomes (Pascher, 1914, 1929; Geitler, 1936; Schiller, 1954) were described (Table 8). They are reviewed (also with regard to plastid evolution) by Pringsheim (1958), Geitler (1923, 1959), Echlin (1970), Taylor (1970), Schenk (1973a, 1973b, 1977), Trench (1982), Kies (1984a, 1984b, 1979), Schenk et al. (1987), Smith and Douglas (1987), and Kies and Kremer (1986a, 1986b, 1989). For along time most of these organisms were classified as cyanomes, but some of them, have more recently been proposed as endocyanomes, such as *Cyanidium caldarium* (Kremer et al., 1978; Kremer, 1983). Many endocyanomes were found only one or two times, and, only a few are stored in culture collections. The SAG has: two strains of *Cyanophora paradoxa* (Pringsheim and Kies); *Glaucocystis nostochinearum; Gloeochaete wittrockiana; Glaucosphaera vacuolata;* and *Cyanidium caldarium.* L. Kies (Botan. Inst., Univ. Hamburg has a strain of *Cyanoptyche dispersa.* Researching and understanding the endocyanoms is crucial, since these consortia represent all the steps from facultative to obligate endocyanoses. Therefore it would be desirable to rediscover the formerly described cyanoms (Schiller, 1954; Pringsheim, 1958), to discover new forms and to isolate and cultivate these consortia (certainly an important research field for limno- and phycologists) as sources for a broad research in cell evolution. At this point, it seems necessary to return to the classification problem of regarding the cyanelles as intracellular symbiotic cyanobacteria. By definition, a biological system, a living organism, and therefore also a symbiont, has its own life cycle, its own independent genome, and is a representative of its species as defined by a taxonomic binary name. The difference between a symbiont and an aposymbiotic organism is a more or less strong metabolic or morphological dependence on the symbiotic partner (also in obligate symbioses). Extensive studies with the "cyanome" *Cyanophora paradoxa* have shown that the cyanelles of *C. paradoxa* possess a genome of reduced size comparable to that of chloroplasts (Herdman and Stanier, 1977; Löffelhardt et al., 1980) and nucleus-encoded proteins (Bayer and Schenk, 1986; Burnap and Trench, 1989c; Bayer et al., 1990).

If genes coding (originally) for endogenic proteins of such a cyanelle (endocytobiotic cyanobacterium) are found to be located on the nuclear genome of the "host" cell, the endocytobiont should no longer be characterized as a "biont," but rather as a cyanoplast (Schenk and Hofer, 1972; Schenk et al., 1987b), indicating that the cyanelle has reached more or less the status of a eukaryotic cell organelle, and can hence no longer be considered an endocytobiont qualified to possess its own taxonomic name. Therefore, with regard to Cavallier-Smith's suggestion (Cavallier-Smith and Lee, 1985), such cyanelles cannot be considered to be one partner of a two-biont symbiosis but only a cell organelle (Schenk, 1990) of a new organismic unit, a new species, descended from

Table 8. Unicellular metacyanomes (phylogenetic descendants of endocyanomes; see text).[a]

(1983), Seckbach et al. (1990), and (10) Kremer et al. (1978) and Maid et al. (1990).

an original endocyanome. Skuja (1950) has argued, in a similar manner in the case of *Glaucocystis* and *Gloeochaete,* that these "associations involve such inseparable integration between the components that they may be considered as one." Pringsheim (1963) agreed and suggested that these "cyanelles should perhaps not be referred to the Cyanophyceae, although

they may well have arisen from them." That was also recognized intuitively by Schenk and Hofer (1972), Herdman and Stanier (1977), Löffelhardt et al. (1980), Trench (1981), Heinhorst and Shively (1983), Bohnert and Löffelhardt (1984), Marten and Brandt (1984), Kies (1984a), and by Kies and Kremer (1986a, 1986b). Without accepting this position, in the future, all plant organisms may be called symbiotic consortia and their plastids renamed with taxonomic binary names. Consequently, I would like to propose that such developed descendants of endocyanomes be called "metacyanomes" (a new, nonsystematic term) and descendants from cyanelles be called "cyanoplasts." The originating "metacyanomic" cell is also no longer the eukaryotic "host" cell. The original host and symbiont cells have coevolved to a new eukaryotic cell type with a new, more complex intracellular, cybernetic system. Today, one could say that it was not correct to consider the species given in Table 8 as symbiotic consortia (what cyanomes really should be by definition) or to call the cyanoplasts of these organisms as cyanelles (what, by definition, these "cyanelles" truly are not). It remains undisputed that, apart from *Cyanophora paradoxa,* this should be demonstrated for each case, in the future. If we wish to retain the term cyanelle, we should use it again in the sense of Pascher (1929), assuming that cyanoplasts are descendants of originally endocytobiotic cyanobacteria, the endocyanelles, and knowing that cyanoplasts are not real cyanelles, but symbiogenetic organelles like the other plastids of plant organisms. But this does not say whether cyanoplasts are representatives of missing links or blind alleys with respect to chloroplast evolution. However, endocyanomes together with their cyanelles, as well as metacyanomes with their cyanoplasts, are clearly important analogous model organisms (Schnepf et al., 1966; Echlin, 1966; Taylor, 1970, Schenk and Hofer, 1972) for studying the mechanisms of plastid evolution with reference to the "(Endo) symbiosis Theory" (Altmann, 1890; Mereschkowsky, 1905, 1910; Geitler, 1923; Sagan, 1967; Margulis, 1970) and the "Serial Endosymbiosis Theory" (Taylor, 1974; Margulis, 1981).

Metacyanomes

THECAMOEBA. *Paulinella chromatophora,* a thecamoeba with two longish cyanobacterial-like entities called cyanelles, was observed in freshwater habitats and in brackish water up to a salt content of ca. 1% (Pankow, 1982). It apparently lives autotrophically (Pascher, 1929) since no food vacuoles could be observed either in the light or electron microscope (Kies, 1974, 1980). All attempts to cultivate this fascinating cyanome or its separated cyanelles have been unsuccessful (Kies and Kremer, 1979). Physiological studies (Kies and Kremer, 1979) have demonstrated the photoassimilation of carbon dioxide (at a rate comparable to free-living cyanobacteria) and an incorporation of up to 22% of the fixed carbon dioxide into glucose, obviously not unsimilar to the behavior found in cyanophilic lichens with one phycobiont. Pascher (1929) observed an elongation by growth of a cyanelle, dividing after isolation, so that it can be assumed that this rhizopode is really still an endocyanome with cyanelles. But the isolated cyanelles have not been cultivated (Kies and Kremer, 1979), and because of the strong internal control of cyanelle number (Kies, 1974, 1984b), a genetic integration seems likely. Therefore, *Paulinella chromatophora* could be one of the phyletically youngest representatives of the known metacyanomes.

DIATOMS. All diatoms listed in Table 8 are found in freshwater habitats in the littoral zone (periphyton) of lakes and ponds. They have been reported from middle Europe, *(D. vanheurcki* and *E. zebra* var. *saxonica),* "Sunda" in Sumatra (Ranau lake), and (USA) *(E. adnata)* in lake Michigan. In addition to the conventional diatom chloroplast, they contain differing numbers of bluish-green inclusions, so-called "sphaeroid bodies" (Hutstedt 1930), which are transmitted from one generation to the other. During cell division, each daughter cell receives at least one spheroid body. The epithemiacean *D. tenuis* is an exception, not bearing such spheroid bodies (Geitler, 1953). Drum and Pankratz (1965) concluded from electron microscopic studies that because they have a thick five-layered cell wall, these bodies presumably are modified coccoid cyanobacteria. The thylakoids are not concentrically arranged as in most other cyanelles, but more radially, and phycobilisomes seem to be absent (Floener and Bothe, 1980). Some characteristics of these bodies indicate their cyanelle nature: 1) The number per cell is not constant; 2) the number is different in the various species, e.g., *E. zebra* bears 1–16 bodies/cell, *E. sorex* normally only 2, and *Rhopalodia gibba* 2–5; 3) the division of the bodies is not synchronized with that of the diatom cell; and 4) their multilayered cell wall, which is comparable to that of aposymbiotic unicellular cyanobacteria. These bodies must have the capability for dinitrogen fixation, because cells of *Rhopalodia gibba* fix nitrogen at a low overall rate, as measured by acetylene reduction: 10 nmoles ethylene formed

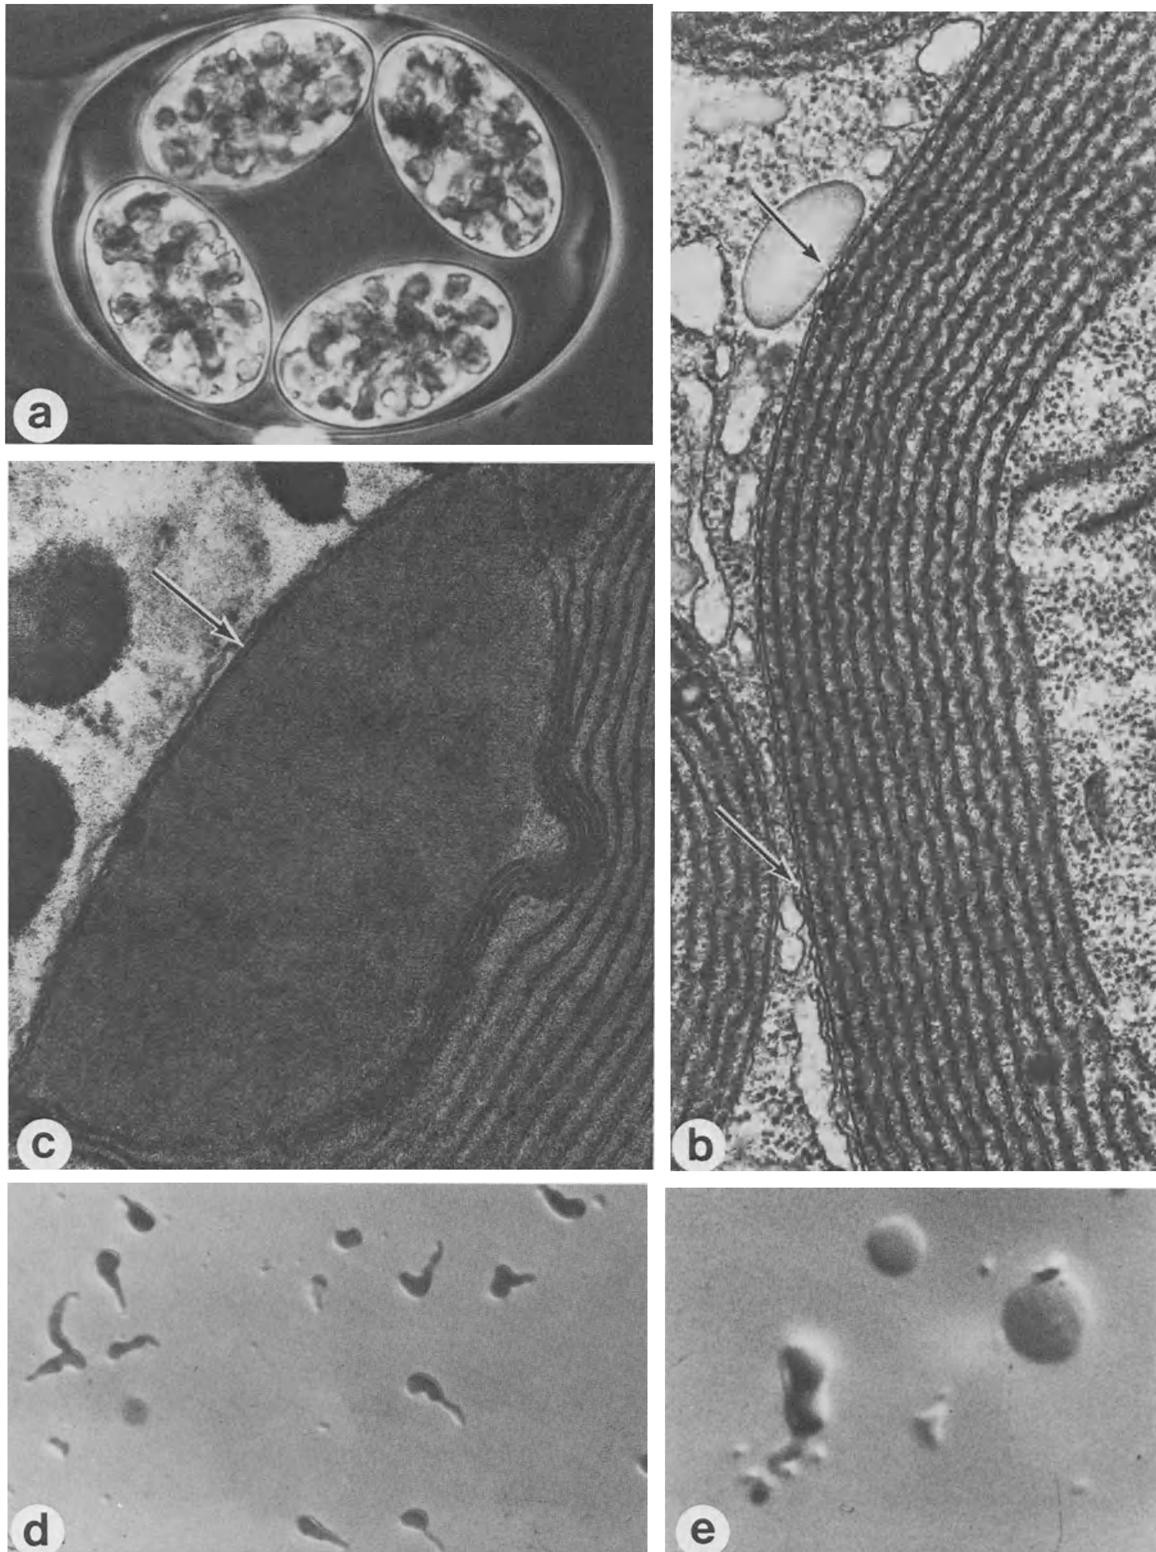

Fig. 4. *Glaucocystis nostochinearum:* (a) four daughter autospores (about 20 μm in length) within an old autospore mother cell wall (phase contrast); (b) crenulating outer membrane surrounding the cyanelle shown by arrows; (c) horizontal striations suggesting a crystalline substance in the lammelar-free region of an immature cyanelle. Electron-dense layer interpreted as peptidoglycan is visible at arrow; (d) cyanelles (about 6 μm in length) isolated in *Glaucocystis* culture medium, 24°C; (e) spheroplast formation of cyanelles in an osmoticum containing sorbitol (0.6 M) and lysozyme (5 μg/ml), 24°C. (From Scott et al., 1984; with permission of H. Bonnett.)

per mg protein and per h (Floener and Bothe, 1980). Lowe et al. (1984) could demonstrate that the ability to fix nitrogen offers *Epithemia* and *Rhopalodia* a competitive advantage in nitrogen-poor habitats. The question of whether these bodies really are cyanelles or are a new (dinitrogen-fixing) kind of cyanoplast still has to be examined.

GLAUCOCYSTOPHYTA. Recently, the Glaucocystophyta with one class, the Glaucocystophyceae, have been redefined on the basis of new biochemical and ultrastructural data (Kies and Kremer, 1986b; Skuja, 1954). Some main characteristics of this class are: 1) a system of peripheral lacunae; 2) dorsi-ventrally shaped motile stages; and 3) two subapical inserted heterokont and heterodynamic flagella (see also Heimann et al., 1989), both with nontubular mastigonemes. The Glaucocystophyceae include unicellular or colonial, monadoid, capsalean, or coccoid eukaryotic algae which instead of chloroplasts contain blue-green cell compartments called "cyanelles," which resemble endocytobiotic cyanobacteria. Although it is relatively easy to isolate these cyanelles, it is impossible to cultivate them. Because they are dependent not only metabolically but also genetically on the eukaryotic cell (nucleus), we prefer to call them "cyanoplasts" (see above). These entities are globular or elongated structures, mostly surrounded by remnants of a cell wall (Fig. 4) (except for the cyanoplasts of *Glaucosphaera*). This wall is, as demonstrated for *Cyanophora* (Schenk, 1970, 1977; Heinz, 1973; Aitken and Stanier, 1979) and for *Glaucocystis* (Scott et al., 1984), a murein sacculus consisting of peptidoglycan. This wall around the cyanoplasts (of *Cyanophora, Cyanoptyche, Glaucocystis,* and *Gloeochaete*) is one of the main morphological differences between them and the plastids of other algae and plants. The existence of this wall suggests that cyanoplasts are phylogenetically derived from cyanelles (endocytobiotic cyanobacterial ancestors). The cyanoplasts of the Glaucocystophyceae bear within the centroplasm or assymmetrically located at the smaller end of the plastid *(Glaucocystis),* a dense polyhedral body called a carboxysome (Mangeney and Gibbs, 1987). The carboxysomes of *Cyanoptyche* (Kies, 1989) and *Gloeochaete* (Kies, 1976) cyanoplasts are surrounded by "some sort of membrane which is not a unit-membrane." For more information the reader is directed to the review by Kies and Kremer (1989).

Glaucocystis nostochinearum

This species and other representatives of the genus *Glaucocystis* are found around the world (e.g., Griffiths, 1915; Chodat, 1919; Bourelly, 1960; Prasad, 1961; Fenwick, 1966; Tell, 1979). Colwell and Wickstrom (1976) have investigated the interrelationships between cell division in cyanoplast and "host." They conclude that host cell and cyanelle division mechanisms are partially independent of each other. The first ultrastructural investigation was published by Ueda (1961), followed by those of Schnepf (1965, 1966), Lefort (1965), Echlin (1966), Schnepf et al. (1966), Schnepf and Koch (1966), Hall and Claus (1967), Robinson and Preston (1971a, 1971b), Schnepf and Brown, (1971), Willison and Brown (1978), Kies (1979), and Lefort-Tran (1981). The pigments were analyzed by Chapman (1966): chlorophyll *a*, β-carotene, zeaxanthin, *C*-phyco- and allophycyanin; and by Schmidt et al. (1979): β-cryptoxanthin (perhaps already detected by Chapman, 1966). Typical cyanobacterial carotenoids are absent. The lipid pattern was investigated by Scott (1987). The ^{14}C-incorporation during photosynthetic carbon dioxide assimilation was mentioned by Schenk and Hofer (1972), and demonstrated by Kremer et al. (1979). The latter authors concluded that from a taxonomic point of view, the results support the assumption that *Glaucocystis* may not be regarded as a representative of the Rhodophyceae as suggested by Schnepf and Brown (1971).

Cyanophora paradoxa

This alga (Fig. 5) represents the most extensively and best-investigated species within the

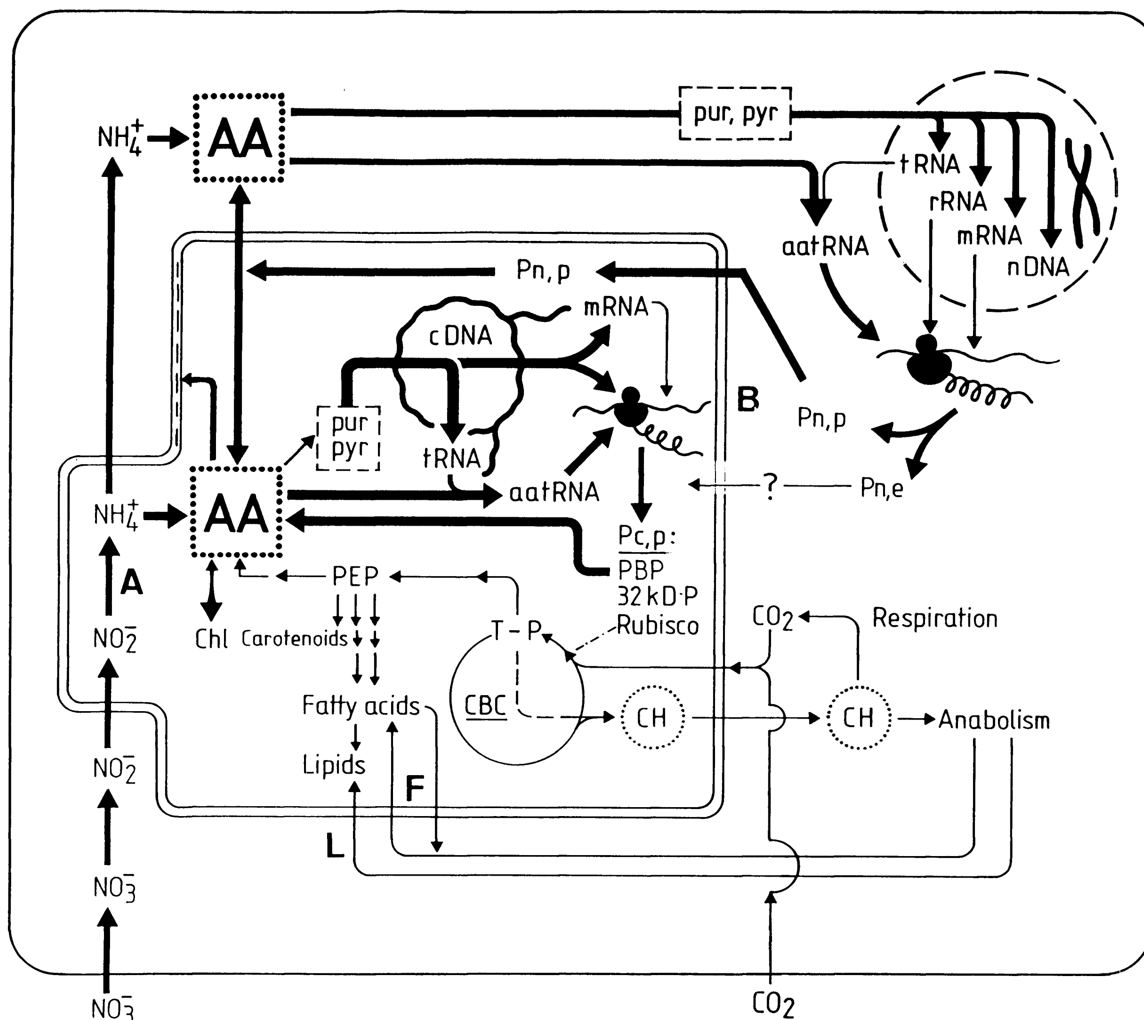

Fig. 6. *Cyanophora paradoxa:* metabolic relationships between the cytoplasmic space (outer rectangle) and the cyanoplast compartment (inner rectangle). Abbreviations: A: nitrite reductase, export of ammonia and amino acids; AA: presumed amino acid pool; B: import of nucleus-encoded proteins; Pn,p: originally prokaryotic proteins—probably as a result of gene transfer; Pn,e: eukaryotic proteins, or protein substitution/not found as yet; CBC: Calvin (-Benson) cycle; CH: carbohydrate pool; F: C_{18} fatty acid export and C_{20} fatty acid import; L: phospholipid (PE) import (for more description see text).

Glaucocystophyceae. In addition it is very interesting that two strains have been found, the Pringsheim and the Kies strains, with different cyanoplast ("cyanellar") DNA (cyDNA) (Löffelhardt et al., 1983; Breiteneder et al., 1988). The cyDNA diversity between the two strains resembles plastid DNA diversity between different species of the green alga *Chlamydomonas.* The inner envelope membrane of the cyanoplasts, observed in freeze-fracture, resembles cyanobacterial plasma membranes and is dissimilar to the chloroplast envelope membranes of red or green algae (Giddings et al., 1983). The pigments were investigated qualitatively by Chapman (1966), Trench and Ronzio (1978), and Schmidt et al. (1979) and seem to be comparable to those of *Glaucocystis;* a method for routine measurements by in vivo visible light spectroscopy with regard to quantitative estimations of carotenoids, chlorophyll *a,* phycocyanin, and allophycocyanin was given by Schenk at al. (1983). Michalowski et al. (1990) were able to detect a third phycobiliproteid, namely, a second allophycocyanin gene.

The metabolic relationships between the cyanoplast compartment and the cytoplasmic space are summarized in Fig. 6. Carbon dioxide photoassimilation (CBC in Fig. 6) was described by Schenk and Hofer (1972), Trench et al. (1978), and Kremer et al. (1979): Besides the incorporation of ^{14}C in the metabolites of the Calvin cycle, it also shows a rapid incorporation into dicarboxylic acids. Kremer et al. (1979) stated that glucose is the main carbohydrate

transferred (from cyanoplast to cytoplasm). Floener et al. (1982) could demonstrate that, similar to the chloroplasts of higher plant cells, only nitrite is reduced in the cyanoplasts (see A in Fig. 6) and not nitrate. A surprising observation was the discovery of polyunsaturated eicosenoic acids, i.e., arachidonic and eicosapentaenoic acid, as main fatty acids besides palmitic acid in the cyanoplasts (Schenk et al., 1985; Kleinig et al., 1986; Zook et al., 1986). These eicosenoic acids have as yet not found in cyanobacteria. They seem to be derived from C18 fatty acids, synthesized in the cyanoplast compartment, and formed by elongation and dehydrogenation of C18 fatty acids in the cytoplasmic space and finally, retransferred to the membranes of the cyanoplast, a process that represents a typical case of "metabolic substitution" (Schenk, 1990). The phycobiliproteids in *C. paradoxa* not only have the function of accessory pigments but also that of nitrogen-storage proteins (Schenk et al., 1983, 1987a) (arrow from PBP to AA in Fig. 6). It seems that the phycobiliproteids of *G. nostochinearum* do not share nitrogen-storage functions (Schenk et al., 1987a). The amino acid sequence of ferredoxin is a typical cyanobacterial one (Stevanovic et al., 1989; Neumann-Spallart et al., 1990). Jehn and Zetsche (1988) reported in vitro synthesis of cyanoplast proteins by isolated cyanoplasts and cyanoplast RNA. Information on the gene localization of cyanoplast proteins is given in Table 9. It seems of interest that the cyanoplast genome, unlike the chloroplast genome, still codes for the SSU small subunit of nibulose-bisphosphate carboxylase (Rubisco) (Heinhost and Shively, 1983), for ferredoxin (Bayer and Schenk, 1989) and for the ribosomal L3 protein (Evrard et al., 1990a, 1990b). Up to 90% (Bayer and Schenk, 1986) or more than 80% (Burnap and Trench, 1989a, 1989b) of the soluble cyanoplast proteins are encoded on the nuclear genome. That could be demonstrated with crossed inhibition experiments of translation and transcription, and in the same manner also for the ferredoxin-$NADP^+$-oxidoreductase (Bayer et al., 1990), a first indication of the existence of "gene transfer." Burnap and Trench (1989c) were able to detect some indication of precursor proteins (with "transit sequences": 1.5–7 kDa) of nucleus-encoded cyanoplast proteins. For further information about this interesting organism, the reader is directed to the reviews by Trench (1982), Wasmann et al. (1987), and Schenk (1990). Cluster analyses with 5S rRNA sequences (Van den Eynde et al., 1988) and with 16S rRNA partial sequences (Giovannoni et al., 1988) suggest that the cyanoplast of *C. paradoxa,* indeed, is not situated within the cyanobacterium-plastid cluster but rather is contained within the cyanobacterial radiation.

Acknowledgements

I am very grateful to my coworkers, M. G. Bayer for helpful discussion of proposed new terms, and T. L. Maier for compiling Table 9, and, with regard to lichen systematics, especially to Dr. V. Wirth (Staatliches Museum für Naturkunde Stuttgart, Germany) and Prof. Dr. F. Oberwinkler (University of Tübingen, Germany). My thanks also go to the colleagues who provided me with information, and to Mrs. V. Uhle-Schneider for help in preparation of the figures 1, 2, 3 and 6. Grants of the Deutsche Forschungsgemeinschaft (SPP Intrazelluläre Symbiose) also have supported this study.

CHAPTER 213

Prokaryotic Symbionts of Amoebae and Flagellates

KWANG W. JEON

Amoebae and flagellates have long been known to be associated with both extracellular and intracellular symbionts (Hall, 1969; Kirby, 1941a; Lee et al., 1985). The presence of prokaryotic symbionts on and in flagellates and in some amoebae, as observed by light microscopy, was reported by several authors during the late 1800s and the early part of this century, as was comprehensively reviewed by Kirby (1941a). Symbiont-bearing flagellates were chiefly found in termite guts, and only a few free-living flagellates were found to have adhering symbionts. Hall (1969) extensively reviewed the literature on symbionts of protozoa published since 1941. Both in flagellates and amoebae, the suspected presence of some of the small bacterial symbionts had to be confirmed later by more sophisticated methods such as electron microscopy and specific staining.

Amoebae and flagellates represent two very diverse groups of protozoa and it is not possible to cover all known prokaryotic symbionts in depth. In this chapter, we shall simply list known symbionts described in the above two reviews in a tabular form (Tables 1 and 2) and then consider newly found symbionts or results of recent studies on earlier symbionts in some detail. The significance of symbiotic relationships remains obscure in most cases and in only a few instances has the host-symbiont relationship been studied in detail. Some disagreements remain about whether the term "symbiosis" should be limited to associations where definite benefits have been proven to exist or not. In this chapter, we shall use the broader definition of symbiosis to include parasitism, commensalism, and mutualism, as did Kirby (1941a) and Hall (1969). Thus, the list of prokaryotic symbionts will include those whose relationships to their hosts are not known or may not be mutually beneficial.

The heightened interest in cellular symbiosis in recent years has been stimulated, in part, by the notion that eukaryotic cell organelles such as mitochondria, chloroplasts, and microtubules may have originated from endosymbionts, i.e., the Serial Endosymbiosis Theory (Sagan, 1967; Margulis, 1970, 1981; Taylor, 1974; papers in Lee and Fredrick, 1987). Some authors have felt that the role of endosymbiosis in the origin of eukaryotic cell organelles has not yet been clearly established (Gray and Doolittle, 1982), but the theory is gaining wider support in view of recent results on the close relationship between the ribosomal RNAs of prokaryotes and those of chloroplasts and mitochondria (e.g., Watson et al., 1987). It should be noted that an opposing view has existed, according to which such organelles evolved as a result of autogenous intracellular differentiation

without involving symbionts (Cavalier-Smith, 1975; Raff and Mahler, 1972; Uzzel and Spolsky, 1974, 1981).

Meanwhile, it is interesting to note that *Pelomyxa palustris,* which does not have mitochondria (Daniels et al., 1965; Leiner and Wohlfeil, 1953) contains several types of intracellular symbionts (Daniels, 1973), and the suggestion has been made that such symbionts may carry out metabolic functions in place of mitochondria (Chapman-Andresen, 1971). Bacteria present in *P. palustris* have been found to be methanogenic (van Bruggen et al., 1983, 1985; see also Chapter 33) and may function as electron sinks related to energy production, comparable to mitochondrial function in aerobic eukaryotic cells.

In the case of amoeba-bacteria symbiosis, the D strain of *Amoeba proteus* became spontaneously infected with a large number (60,000–150,000 bacteria per amoeba) of rod-shaped Gram-negative bacteria (Jeon and Lorch, 1967). Initially, the bacteria were harmful and brought about damaging effects to their hosts, called xD amoebae, such as reduced cell size, slower cell growth, increased membrane fragility, sensitivity to starvation, and a poor clonability. When introduced into symbiont-free D amoebae, the bacteria multiplied and killed their new hosts within a few host cell generations. However, adverse effects of infection gradually diminished over a period of about 1 year, and the bacteria became less virulent, bacteria-bearing xD amoebae growing well with near-normal growth

rates. Also, some of the newly infected D amoebae survived, indicating a reduced virulence as compared to earlier infection.

Within a few years, host amoebae became dependent on their endosymbionts (Jeon, 1972). Thus, xD amoebae lost viability when they were deprived of endosymbionts either by nuclear transplantation (Jeon and Jeon, 1976), by treatment with antibiotics (Jeon and Hah, 1977), or by raising the culture temperature (Jeon and Ahn, 1978). Aposymbiotic xD amoebae could be resuscitated only by reintroducing live X-bacterial symbionts (Lorch and Jeon, 1980). Newly infected amoebae became dependent on their symbionts after about 200 cell generations or 18 months. The reason for the hosts' dependence is not known, but preliminary evidence suggests that a symbiont-synthesized protein may be required for the survival of hosts. When xD amoebae are grown in the presence of chloramphenicol (100–700 μg/ml) or rifampicin (125 μg/ml), the synthesis of a unique 29-kDa polypeptide by endosymbionts is instantly suppressed and xD amoebae die much sooner than do symbiont-free D amoebae (Kim and Jeon, 1986, 1987a). The symbiont's gene coding for the xD-specific protein has been cloned (Park and Jeon, 1988) and its nucleotides sequenced (Park and Jeon, 1989). The symbiotic bacteria were found to accumulate host actin selectively (Kim and Jeon, 1987b), as studied using a monoclonal antibody against the amoeba actin. Thus, in this example, the transition of spontaneously infecting parasites to required cell components was observed while it occurred (Jeon, 1980, 1983, 1986, 1987). While the host's dependence on symbionts developed over 200 host cell generations, some physiological characters changed after a few host cell divisions (Lorch and Jeon, 1981, 1982).

In *Blastocrithidia culicis* and *Crithidia oncopelti,* symbiotic bacteria were found to supply their hosts with lysine (Gill and Vogel, 1962, 1963), hemin (Guttman and Eisenman, 1965; Chang and Trager, 1974; Newton, 1956, 1957), and other nutritional factors. An aposymbiotic host, produced by growing symbiont-bearing cells in the presence of chloramphenicol, required exogenous hemin for growth. The ectosymbiotic spirochetes on *Myxotricha* were found to help their host move by their coordinated undulation while the host's flagella functioned only to steer its movement (Cleveland and Grimstone, 1964). Flagella of prokaryotic symbionts attached to *Cryptotermes* were also found to help propel the host cell (Tamm, 1978b).

These are a few examples in which protozoan hosts and prokaryotic symbionts have developed an intimate relationship, and symbiont integration and host-symbiont interactions have been experimentally studied.

Habitats

General

The host-symbiont relationship appears to be somewhat specific for both ecto- and endosymbionts, since certain symbionts are almost always found associated with given hosts (Hall, 1969; Kirby, 1941a). However, the mechanism for specific recognition of the host by symbionts is not known. For ectosymbionts, their only requirement for continuing symbiotic association with their hosts would be to stay attached to their host-cell surfaces. Some symbionts cover the whole surface of their host, while others are limited to certain areas of the host's body (Kirby, 1941a). In some cases, specialized attachment sites such as brackets and underlying network of fibrous strands are present, as in *Myxotricha* (Fig. 1A; Cleveland and Grimstone, 1964). On the basis of extensive electron-microscopic observations, Cleveland and Grimstone reconstructed the attachment complexes as shown in Fig. 1B. Tamm (1978a) also found membrane specialization where two kinds of bacteria, rod-shaped and filamentous, were attached to *Crytptotermes cavifrons.* Thus, the attachment of ectosymbionts is not haphazard but appears to be helped by structural adaptations on the part of host cells.

For endosymbionts, their habitat in the cytoplasm of host cells can be considered to be an extreme environment comparable to hot springs and salt lakes (Moulder, 1979), although most symbionts live within symbiont-containing vesicles and the membranes protect them from direct exposure to the host cytoplasm. These symbiont-containing vesicles have been called "symbiosomes" (Fig. 2; Roth et al., 1988). It appears that endosymbionts have adapted in various ways to overcome adverse effects of the harsh environment, e.g., the possession of rigid cell walls to withstand digestive action of the hosts' hydrolytic enzymes (Drozanski and Chmielewski, 1979; Han and Jeon, 1980) or prevention of lysosomal fusion with symbiosome membranes, thus avoiding exposure to hosts' digestive enzymes (Ahn and Jeon, 1979; Armstrong and Hart, 1971; Jeon, 1983).

Amoebae

In amoebae, all known bacterial symbionts are intracellular. This is understandable since amoebae do not have a firm cortex and ecto-

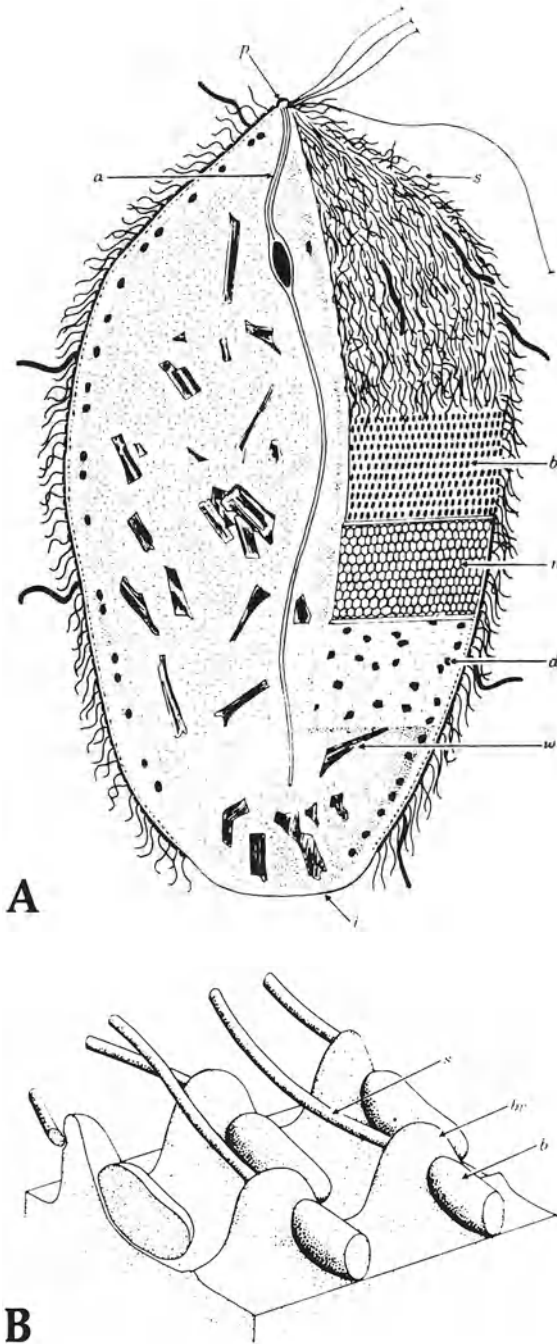

Fig. 1. A diagram of *Myxotricha paradoxa* showing the attachment of ectosymbionts on the cell surface (A) and a reconstruction of a small area of the cell surface showing the attachment complex (B). (A) An optical section is shown on the left and surface structures are shown on the right. b, bacteria; br, brackets; n, fibrous network; s, spirochetes. (From Cleveland and Grimstone, 1964.)

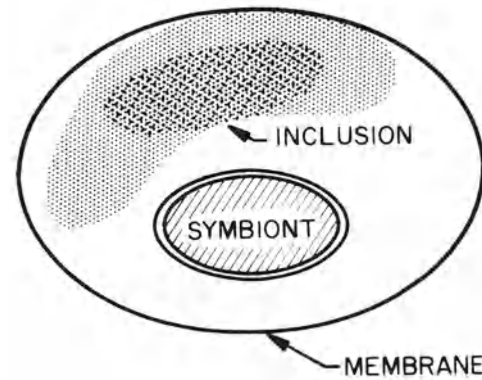

Fig. 2. A schematic diagram of a symbiosome to show its components. Each line represents a membrane and the intrasymbiosome space is shown to contain inclusions. (From Roth et al., 1988.)

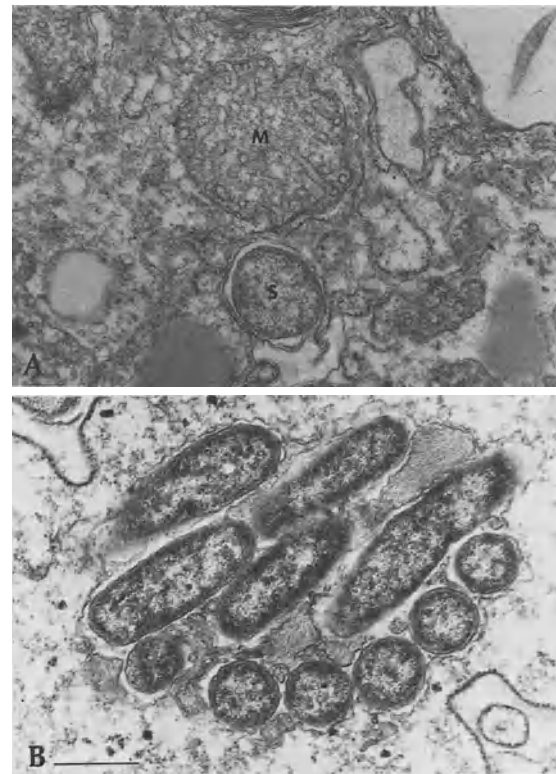

Fig. 3. Electron micrographs of symbiosomes in amoebae. (A) A small symbiosome with a single round symbiont (S) called a "DNA-containing body" and (B) a larger symbiosome with several rod-shaped symbionts. (A) A mitochondrion (M) with tubular cristae is shown for comparison. (B) The interbacterial space is filled with inclusions containing fibrous matter. Bar = 0.5 μm. (Fig. 3B from Jeon, 1987.)

symbionts cannot permanently attach to them as do flagellates. Several different bacterial types have been reported in the cytoplasm of amoebae, mostly enclosed in symbiosomes singly or in groups (Fig. 3). Roth and Daniels (1961) were among the first to confirm by electron microscopy the bacterial nature of previously reported bacteria-like particles (0.5 $\times$ 2 μm) in vacuoles of *Amoeba proteus* (Cohen, 1957). These sym-

bionts could not be eliminated by starvation or penicillin treatment. Chapman-Andresen and Hayward (1963) found rod-shaped bacteria (0.5 × 3–5 μm) in a strain of *A. proteus* (about 4000 bacteria per cell), that could not be detected by light microscopy. Drozanski (1963a) reported Gram-negative rods (0.6–0.8 × 1.3–2.1 μm) that caused a fatal infection in *Acanthamoeba castellanii.* These bacteria first multiplied in food vacuoles and later in the cytoplasm. Other reports followed that confirmed the presence of a large number of bacteria in various strains of amoebae (Jeon and Lorch, 1967; Wolstenholme and Plaut, 1964). In one strain of *Pelomyxa palustris,* Daniels et al. (1966; Daniels and Breyer, 1967) found rod-shaped bacteria (0.3 × 3 μm) within individual vesicles characteristically surrounding the nuclei, while another type of bacteria of similar size was located in other parts of the cytoplasm. In *Acanthamoeba* (Drozanski, 1963a; Hall and Voelz, 1985; Proca-Cibanu et al., 1975), symbionts are found throughout the cytoplasm. In the large, free-living *Amoeba,* all symbionts were enclosed in symbiosomes located in all parts of the cell (Jeon and Lorch, 1967; Wolstenholme and Plaut, 1964). So far, no endonuclear symbionts have been found in amoebae. Many unsuccessful attempts have been made to grow symbiotic bacteria in vitro (Drozanski, 1963b; Jeon and Lorch, 1967; K. Jeon, unpublished observations), and none of the reported bacterial symbionts of amoebae has been grown outside living cells.

The fact that symbionts of amoebae cannot be cultured outside amoebae indicates the symbionts' dependence on their hosts, but in many cases the dependence does not appear to be species-specific. Thus, bacteria isolated from infected *Acanthamoeba castellanii* were able to infect trophic forms of *Hartmannella rhysodes, Schzopyrenus resselli, Didasculus thorntoni,* and other unidentified amoebae of *Limax* type (Drozanski, 1963b). Jeon and Jeon (1982) found that X-bacteria isolated from xD amoebae *(Amoeba proteus)* cross-infected an unrelated species of giant amoeba, *Chaos carolinensis.*

Flagellates

Unlike amoebae, all of whose symbionts are intracellular, flagellates have symbionts in various parts of the cells, some as ectosymbionts and others in the nucleus, in the endoplasmic reticulum, in chloroplasts, or free in the cytoplasm. Most of the prokaryotic symbionts of flagellates were first found as ectosymbionts by light microscopy early in the 20th century (Table 2), and the hosts were mostly flagellates living in termite guts. Some suspected prokaryotic endosymbionts were reported in those flagellates, but confirmation of the bacterial nature of such endosymbionts had to await electron-microscopic observation and advanced biochemical tests. Thus, definitive reports of the presence of endosymbionts in flagellates started to appear in the late 1950s. For example, Roth (1959) found rod-like bacteria within the nucleus of *Peranema,* several hundred per nucleus, while others reported endocytoplasmic symbionts in *Volvox* (Kochert and Olson, 1970). Since then many other flagellates have been found to harbor endosymbiotic bacteria. Gromov (1977) described the presence of Gram-negative bacteria in the surface cortical region of *Trichonympha turkestanica* and suggested that the symbiotic bacteria play a role in the host flagella operation. Gerola (1978) reported inclusion bodies of several bacteria-like elements in *Euglena* cells from an alpine water pool rich in organic residues; the endosymbionts were free in the host cytoplasm, but there was no sign of cytoplasmic reaction around the symbionts detectable by electron microscopy. Endosymbiotic bacteria living inside the endoplasmic reticulum were reported in *Ochromonas monicis* isolated from a saline pool (Doddema and van der Veer, 1983), and these authors thought that the symbionts enabled their hosts to survive in vitamin-poor water. Sousa-Silva and Franca (1985) studied the ultrastructure of two species of dinoflagellates, *Gyrodinium instriatum* and *Glenodinium foliaceum,* harboring bacterial symbionts, some of which were in the nucleus while others were in the cytoplasm, and the third group appeared to live in both.

Chesnick and Cox (1986) presented a summary of results from 17 studies reporting the presence of endosymbiotic bacteria in algal species. In most cases, bacterial symbionts were usually found in small vesicles. However, in the marine alga *Penicillus,* bacteria were contained in one large central vacuole, with occasional presence found in the tip cytoplasm (Turner and Friedmann, 1974). Wilcox (1986) found small bacteria-like symbionts within chloroplasts of the dinoflagellate, *Woloszynskia pascheri,* and suggested that the bacteria may have been in a symbiotic relationship for some time, although no supporting evidence was presented. The author also consider it possible that the "symbionts" may represent regions where chloroplasts' nucleic acids are packaged in membranes. Different species of *Giardia* have been found to have mycoplasma-like organisms attached on the surface of trophozoites while harboring intracellular bacteria in trophozoites and cysts (Feely et al., 1988).

While the roles of many symbionts are not clear, the presence of symbionts has some effects on the structure and physiology of their hosts. Freymuller and Camargo (1981) compared the ultrastructure of symbiont-bearing and symbiont-free species of trypanosomatids and found some differences. For example, paraxial rods of flagella or intraflagellar structures were present only in symbiont-free species, while branching of mitochondria was found exclusively in symbiont-bearing species. Endonuclear symbionts of *Peranema trichophorum* appeared to cause structural changes in their hosts, such as fragmented karyosome and granulation of DNA and RNA within the nucleus (Radchenko, 1983). McLaughlin et al. (1983) found differences in lectin agglutinability between symbiont-bearing and aposymbiotic strains of *Crithidia* and *Blastocrithidia*. Later, it was found that aposymbiotic hosts failed to incorporate detectable amounts of fucose into a major surface glycopeptide (McLaughlin and Cain, 1985a). These authors attributed the differences in lectin agglutinability to different carbohydrate compositions of the flagellates' surfaces. In contrast, McLaughlin and Cain (1985b) failed to detect differences in the incorporation of labeled leucine and methionine between symbiont-bearing and aposymbiotic strains of these hemoflagellates. Krylov et al. (1985) detected many differences between symbiont-bearing (Sym^+) and symbiont-free (Sym^-) strains of *Crithidia oncopelti* and proposed that the two strains be named as different species; observed differences included cell size, flagellum length, colony shape and size, rate of movement, electrophoretic mobility of malate dehydrogenases, growth rate at 32°C, oxygen consumption, and sensitivity to antibiotics. In most other cases, however, host-symbiont relationships have not been clarified.

There have been some reports for the presence of blue-green algae as endosymbionts in various species of dinoflagellates (reviewed by Gaines and Elbrachter, 1987; Steidinger and Baden, 1984). Some of the symbiotic algae appeared to have nutritional importance to their hosts and others were thought to produce toxins.

Isolation

Since all the known endosymbiotic prokaryotes of flagellates and amoebae are obligatory symbionts and do not grow in vitro, the only sure source for their isolation would be symbiont-bearing hosts. Even for facultative ectosymbionts of flagellates that may live free from their hosts at one time or another, their natural host is the best source. *Amoeba proteus* cells are grown in dilute salt solution (Goldstein and Ko, 1976; Jeon and Jeon, 1975). Since these amoebae are strictly phagocytic, they have to be fed live prey organisms, commonly used food organisms for mass culture being *Tetrahymena* cultured axenically in a rich, complex medium containing various vitamins and mineral additives with proteose peptone and liver extract as the main ingredients (Goldstein and Ko, 1976). Amoebae are fed with washed *Tetrahymena* daily or every other day, depending on the desired growth rate. *Acanthamoeba* are cultured axenically in a medium containing proteose peptone, yeast extract, and glucose (Drozanski, 1984). Various media have been used to culture hemoflagellates and other flagellates as hosts of bacterial endosymbionts (e.g., Chang and Trager, 1974).

Bacterial endosymbionts have been isolated in mass from a few species of amoebae and flagellates. No reports are found for mass isolation of ectosymbionts from flagellates. For example, symbiotic bacteria have been isolated from xD amoebae *Amoeba proteus* (Ahn and Jeon, 1982; Han and Jeon, 1980) and *Acanthamoeb castellanii* (Drozanski et al., 1984). In the first example (Han and Jeon, 1980), symbionts were collected by Ficoll gradient centrifugation from lysed amoebae. Later, the method was modified to apply filtration through nylon screens to remove larger pieces of cell debris first (Ahn and Jeon, 1982). Pure bacteria were collected after centrifugation on a sucrose-step gradient. In either procedure, the recovery of symbionts could be greater than 90%. Symbiotic bacteria from *A. castellanii* were obtained by centrifugation from lysed amoebae (Drozanski et al., 1984).

Chang (1975) isolated endosymbionts of hemoflagellates by a sequential treatment of host flagellates by hypotonic shock, complement-dependent immune lysis, and needle passage. Host flagellate cells were incubated in Trager buffer (Trager, 1959) containing guinea-pig serum and rabbit antiserum against flagellates, followed by DNase digestion and differential centrifugation. The final fraction was free of contamination, and the recovery of symbionts was about 20%.

Identification

Since symbionts of amoebae and flagellates cannot be cultured in vitro, the traditional methods of identifying and classifying them (e.g., *Bergey's Manual,* see Buchaman and Gibbons,

1974) cannot be used. Thus, these symbionts have been simply identified as fusiform, rod-shaped, round, or filamentous on the basis of their external morphology based on light or electron-microscopic observations. Most of the bacterial endosymbionts have been reported to be Gram negative, either as a result of Gram staining or by electron microscopic examination for the presence of characteristic surface membranes. More specialized methods are available to identify bacterial species, such as serological tests, bacteriophage typing, and DNA and rRNA sequencing. In particular, the use of specific oligodeoxynucleotide probes, which can be applied in identifying single microbial cells (Giovannoni et al., 1988), should be helpful in dealing with endosymbionts that cannot be grown in vitro. It is also desirable to culture isolated symbionts in vitro for their definitive identification based on their metabolic, physiological, and biochemical characteristics.

Concluding Remarks

This short survey reiterates that many prokaryotic organisms live on and in a wide variety of flagellates and amoebae as symbionts. Their presence is known to bring about various structural, physiological, and biochemical changes in the host. However, many questions still remain unanswered regarding the host-symbiont relationship. For example, it is not clear in many instances how the host and symbionts recognize each other and establish a specific association, how endosymbionts escape digestion by their host, how the symbiont population is controlled, and how the host and symbionts benefit or suffer from their association. Studies of prokaryotic symbionts in flagellates and amoebae have lagged behind those in ciliates (see Chapter 214), where identification and culture of symbionts in vitro and the clarification of the genetic interaction between the host's and symbionts' genomes have been well established. It is hoped that similar advancement will be achieved soon with symbionts in flagellates and amoebae.

Acknowledgments

I thank Drs. L. E. Roth and W. S. Riggsby for their helpful comments on the manuscript. The research work from my laboratory described in this chapter was supported by a grant from the National Science Foundation.

CHAPTER 214

Prokaryotic Symbionts of Ciliates

KLAUS HECKMANN and HANS-DIETER GÖRTZ

Prokaryotes living in ciliates were first noticed over a century ago by J. Müller (1856). Rod-shaped structures were observed in the macronuclei and micronuclei of a number of ciliates, and less commonly, in their cytoplasm. In the beginning, it was not clear whether they were parasites or spermatozoa because the micronucleus was considered to be a testis and the macronucleus an ovary, while chromosome filaments and endonuclear symbionts were mistaken for spermatozoa. This view was corrected by Bütschli (1876), who also wrote the first review on parasites in ciliates (Bütschli, 1889). Accounts of early observations of bacteria in protozoa that followed this initial period were reviewed by Kirby (1941), Wichterman (1953), and Ball (1969).

Interest in prokaryotic endosymbionts of ciliates arose again in the 1950s when it was discovered that a "killer" phenotype is frequently associated with them. The phenomenon that cells of certain ciliate strains may kill cells of other strains by a toxic agent, liberated into the medium, had first been noticed by Sonneborn (1938) in paramecia during experiments on mating types that involved mixing different strains. He found that under certain conditions conjugation could be brought about between killer and sensitive paramecia so that genetic analysis of these traits became technically feasible. Sonneborn (1943) demonstrated that the killer phenotype was an inherited trait that was transmitted via cytoplasmic particles, which he named *kappa*. His findings aroused great interest among geneticists and other biologists, because it furnished one of the first clear examples of a cytoplasmic genetic factor. That *kappa* was an endosymbiont was not known at that time. From data obtained in studies using X rays, Preer (1948a) determined that *kappa* was similar in size to bacteria. He subsequently demonstrated the presence of *kappa* in the cytoplasm of killer paramecia as Feulgen-staining bodies (Preer, 1950). In the following years, cytological, biochemical, and physiological studies by a number of workers established that *kappa* was actually a Gram-negative bacterium. In 1974 it was given a binomial designation—*Caedobacter taeniospiralis*, since changed to *Caedibacter taeniospiralis* (for a detailed review, see Preer et al., 1974, and Preer and Preer, 1984).

After the initial discovery of the first killer paramecia, other types were found. Siegel (1953) described "mate-killers," whose toxins act only during cell-to-cell contact at conjugation, and Schneller (1958) described "rapid-lysis" killers, which may injure sensitives in 10 min and kill them in 30 min, a process that is much more rapid than when *kappa* is the killing agent. In each of these killer paramecia, particles were found that later proved to be prokaryotic symbionts. One only needed to wash the paramecia free of bacteria, crush the ciliates, and observe the resulting preparations in a phase contrast microscope to ascertain the presence of the symbionts. This procedure also revealed, however, that some strains carry endosymbionts without showing any kind of killing ability. The symbionts of nonkiller paramecia were named *nu* (Sonneborn et al., 1959).

Bacterial symbionts have been studied most extensively in the *Paramecium aurelia* species complex (for reviews see Beale et al., 1969; L. B. Preer et al., 1972; Gibson, 1974; Preer et al., 1974; Soldo, 1974; Preer and Preer, 1984). They have also been found and studied in other ciliates, particularly in *Paramecium caudatum* (for reviews, see Ossipov, 1981; Görtz, 1983) and in *Euplotes* species (reviewed by Heckmann, 1983). More recently the presence of endo- and episymbionts of marine and freshwater ciliates living in anaerobic habitats have generated interest among ecologists and microbiologists. In these habitats, many of the symbionts were identified as methanogenic bacteria (Stumm and Vogels, 1989).

None of these symbionts have found commercial or technical applications, and it is unlikely that they will in the future. The symbionts comprise a heterogeneous group of mostly Gram-negative bacteria, which are grouped in

many unrelated genera, but are alike in that their habitat is the cytoplasm or the nucleus of a ciliate. As will become apparent, many of these symbionts appear to be well adapted to their environment; they are no longer free living and have genomes that are reduced in size, indicating a lengthy period of symbiont-host association. Most of the symbionts are not infectious, but a few are. They have developed specific features that guarantee uptake and transport to the sites where they can multiply. In most cases, it is not clear whether the symbionts provide their host with a selective advantage, and under laboratory conditions, most of the symbionts have proved to be dispensable. On the other hand, it is significant that the majority of cells of *Paramecium biaurelia* freshly collected from nature contain symbionts (Beale et al., 1969), and work by Landis (1981, 1987) suggests that paramecia that bear *kappa* have a selective advantage over those that are free of *kappa.* Moreover, *Polynucleobacter necessarius* (formerly called *omikron*) and the closely related *omikron*-like symbionts occurring in several freshwater *Euplotes* species have been shown to be necessary for survival of their hosts (Heckmann, 1975; Heckmann et al., 1983). Since in these cases the hosts depend on their symbionts and these in turn depend upon their hosts—they are no longer free living—the distinction between "symbiont" on the one hand and "organelle" on the other hand becomes blurred.

Ciliates can usually be handled easily, and some of them—particularly species of the *Paramecium aurelia* complex—have been investigated so thoroughly that they can be manipulated in a variety of ways. This has led to a wealth of information about their symbionts that is unparalleled. Since the endosymbionts of the *P. aurelia* complex have been reviewed repeatedly, we will treat them here less extensively than they deserve. We are also not able to list all the types of symbionts of ciliates encountered. Their number is very large, and we are sure that many more will be added to this list. Few of them, however, have been deposited in stock cultures and have been investigated in such a way that they can easily be identified when found again. An even smaller number have been described in keeping with the international rules of nomenclature and have received binomial names. It is however, primarily these last ones that will be discussed in detail in this chapter. We hope that this chapter will generate interest in symbionts of ciliates among microbiologists who have never been very active in investigations of this subject.

Prokaryotic Symbionts of *Paramecium*

With respect to endosymbionts, *Paramecium* is by far the best-studied ciliate genus. In the *Paramecium aurelia* species complex, consisting of 14 sibling species described by Sonneborn (1975) and named *P. primaurelia* to *P. quadecaurelia,* many different types of endosymbionts have been discovered. They have been thoroughly reviewed by Preer et al. (1974) and a detailed description by L. B. Preer appeared in the first edition of this handbook (L. B. Preer 1981). Figs. 1 to 5 and valuable information on their isolation and identification are taken from this chapter. We have added information on endosymbionts of other *Paramecium* species and have enlarged the coverage of symbionts of the genus *Holospora.* The latter differ from most of the *Paramecium* symbionts in being infectious and in their ability to invade nuclei for reproduction. The holosporas are now being investigated to elucidate the mechanisms that allow a prokaryote to invade a eukaryote. Being relatively large, they have the advantage that their route of infection and the changes that they undergo after entering a cell can be followed under a light microscope.

Habitat and Biology of the *Paramecium* Symbionts

Intracellular symbionts may be found in the micronucleus, in the macronucleus, in the perinuclear space, and in the cytoplasm of paramecia. Different types of symbiont invade different parts of the cell and they are moreover often adapted to one *Paramecium* species only. The cell compartment in which a symbiont multiplies and the species in which it occurs are therefore important taxonomic characters.

Most of the endosymbionts are easy to observe. Paramecia are collected from ponds and brought into the laboratory. With the help of a micropipette, a few cells are placed on a microscope slide, covered with a cover slip, and then observed with a light microscope using phase contrast optics. Crushing of the paramecia is sometimes necessary (Preer and Stark, 1953). Staining of the paramecia according to the technique of Beale and Jurand (1966) may facilitate the observations. Many of the paramecia brought in from nature are found to contain symbionts. Usually there are hundreds and sometimes even thousands of symbionts per paramecium (see Figs. 1–5).

Many of these symbionts confer on their hosts the ability to produce toxins capable of killing sensitive *Paramecium* strains of the same spe-

cies and even of other species. If the toxins are liberated into the medium, the toxin producers are called "killers" and their victims "sensitives." If the toxins act only during cell-to-cell contact at conjugation, the toxin producers are called "mate-killers." Different killer stocks of *Paramecium* induce different prelethal symptoms in sensitives mixed with killers. These symptoms include spinning, vacuolization, paralysis, formation of aboral humps, and rapid lysis. The symptoms are valuable characters for identification of a symbiont. In addition to making their hosts capable of producing toxins, the symbionts also confer upon the hosts specific resistance to the toxins produced. When a symbiont is lost from a killer strain the paramecia lose both toxin production and toxin resistance (Sonneborn, 1959). Killer strains have been reported not only for species of the *P. aurelia* complex but also for *P. caudatum* (Schmidt et al., 1987c, 1988), *P. bursaria* (Chen, 1955; Dorner, 1957), and *P. polycaryum* (Takayanagi and Hayashi, 1964). In the latter two species, however, symbionts were not observed although it is likely that they were present and were responsible for the killing properties of the paramecia.

Several symbionts have been shown to require the presence of specific *Paramecium* genes for their maintenance (Sonneborn, 1943; Siegel, 1953; Schneller et al., 1959; Gibson and Beale, 1961). It is not known whether the genes that assure the maintenance of the symbionts are active—e.g., providing the symbionts with some essential metabolite—or whether they are merely inactive alleles, the active ones preventing growth of an "invader" (Preer et al., 1974). In this connection it should be mentioned that, although not all species of the *P. aurelia* complex have been studied with the same thoroughness, the species 3, 7, 9, 10, 11, 12, 13, and 14 have never been found to contain symbionts (Preer and Preer, 1984).

It has been argued that symbionts profit from living inside a paramecium by being better protected from digestion, as compared with free-living species of bacteria, and that symbionts are provided with a convenient and abundant supply of nutrients (Beale et al., 1969). Which metabolites of the host are used, however, is not known. Although many of the symbionts have a smaller genome size than free-living bacteria (Soldo and Godoy, 1973) and some of the associations are probably very ancient (Preer, 1977), no indications for a transfer of genes from symbiont to host nucleus have been discovered, as has been found in the case of mitochondria (Gellissen and Michaelis, 1987). Schmidt (1984), studying the association of *Caedibacter varicaedens* with *P. biaurelia* was unable to obtain evidence for a sharing of the translational systems of host and symbiont. His observations indicate that all major proteins found in *Caedibacter* are synthesized in the symbiont itself.

That the host cells profit from bearing symbionts has been demonstrated in only a few cases; Soldo (1963) and Soldo and Godoy (1973a) found that it was not necessary to provide a *Paramecium* stock bearing *Lyticum flagellatum* (formerly called *lambda*) with folic acid, while the same stock freed of this symbiont required the vitamin. Holtzman (1959) observed that *P. pentaurelia* bearing *Pseudocaedibacter falsus* was more resistant to killer paramecia bearing *Lyticum flagellatum* than *P. pentaurelia* strains that were free of symbionts. And Landis (1981, 1987) showed that under natural conditions paramecia with killer properties have a selective advantage over nonkillers. On the other hand, in the laboratory the symbionts are all dispensable and many of them are lost when paramecia are cultured for some time. The reason for such loss is in most cases a rapid multiplication of the paramecia, resulting in a dilution of the symbionts and then in their loss. Although there is little information about what occurs in nature, it appears highly unlikely that re-infection of paramecia that have lost their symbionts plays a major role. Most symbionts are not infectious and are propagated in the host cells by division only. An exception to this rule is provided by symbionts of the genus *Holospora*. In addition to being propagated during cell division, they develop forms specialized for infection that are released and infect new cells upon being taken up with food. Unlike most other endosymbionts, they tend to harm their hosts and can therefore be regarded as parasites, although it cannot be excluded that under certain conditions the host cells may have advantages from presence of these symbionts (Görtz, 1983).

Isolation of the *Paramecium* Symbionts

The techniques used in collecting and cultivating paramecia have been described by Sonneborn (1950, 1970). Paramecia are easily detected in samples of pond or lake water with the help of a dissection microscope. Paramecia do not form cysts and, unless they have been introduced with the water added, cannot be obtained from infusions of straw or hay. When brought in from nature, the paramecia must be grown slowly at low temperature (about 16°C) without adding any antibiotics, if the purpose is to look for symbionts. Their presence can be

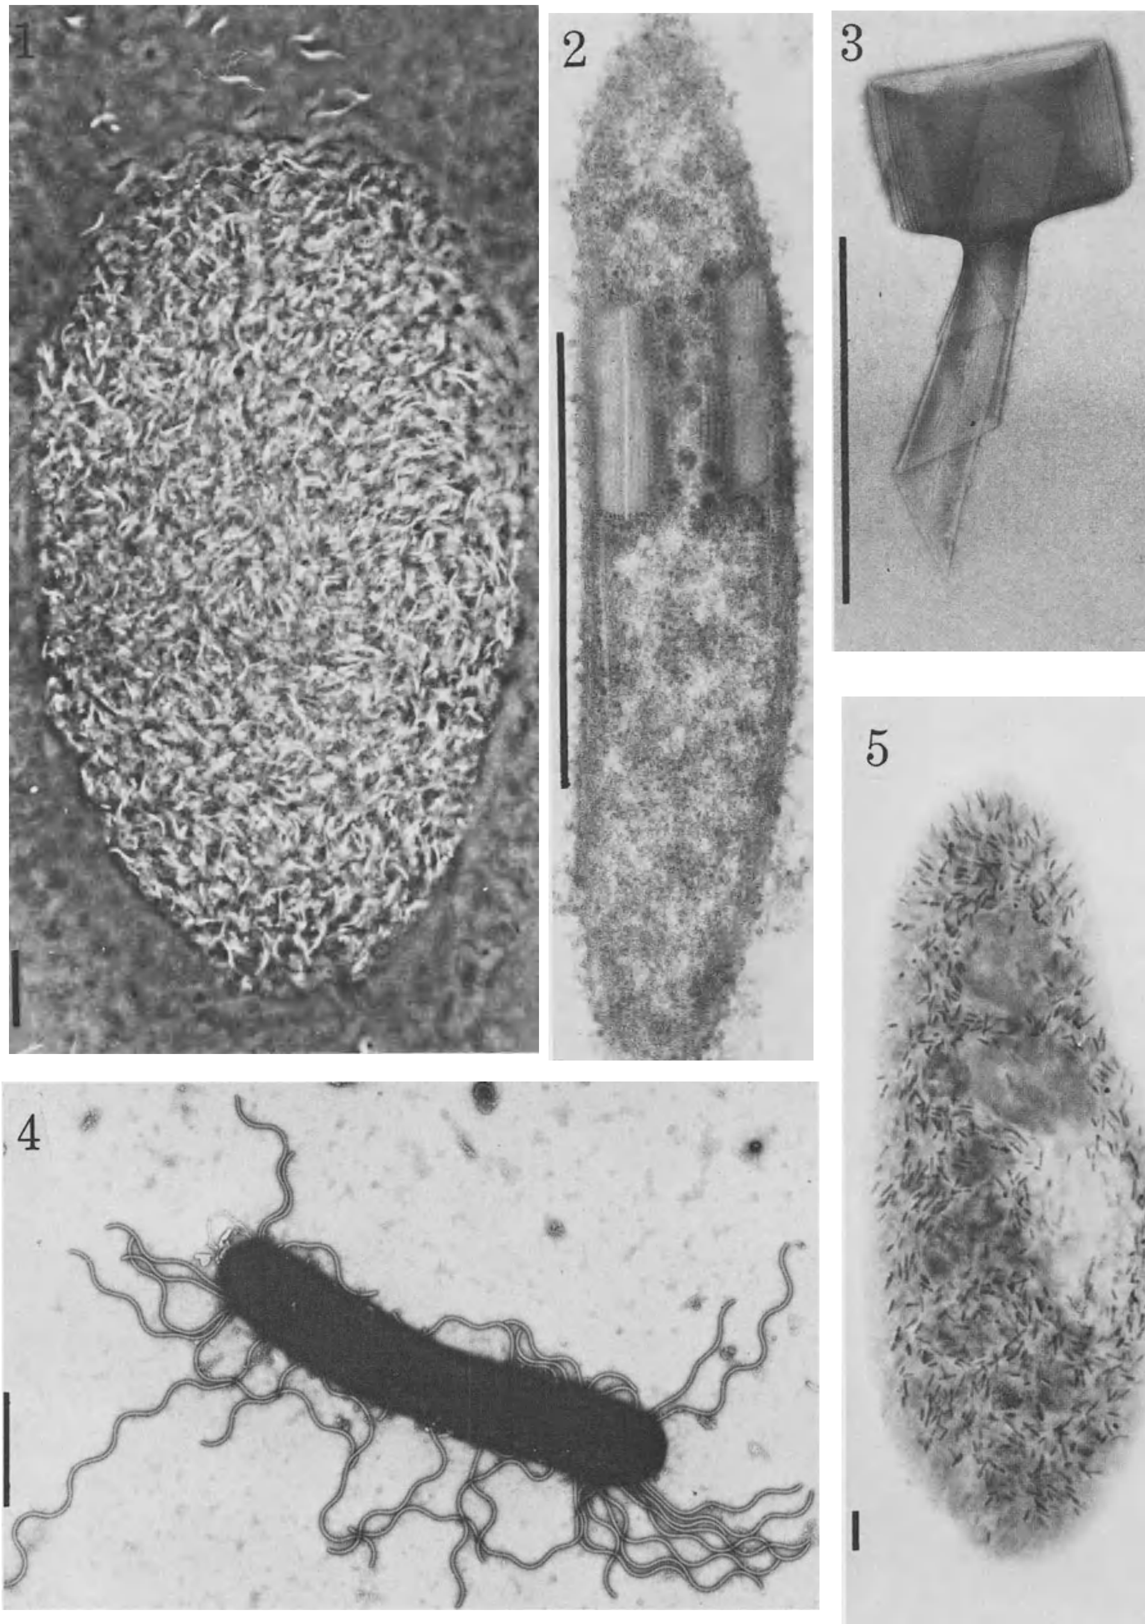

Fig. 1. Vegetative macronucleus of *Paramecium biaurelia* stock 562. The spiral endosymbionts filling the macronucleus are cells of *Holospora caryophila*. A few symbionts are also visible in the cytoplasm. Osmium-lacto-orcein preparation, whole mount, bright phase contrast. Bar = 10 μm. (From L. B. Preer, 1969.)

monitored as described above. If the paramecia are grown at high fission rates, their symbionts often become diluted and may even be lost.

Natural populations of *Paramecium* are infected with symbionts to varying degrees. Most strains carry only one kind of symbiont. A culture containing only one type of symbiont may be obtained, therefore, by isolating a single paramecium and growing it into a clone. If a strain of *Paramecium* does carry more than one type of symbiont, it is often possible to obtain pure cultures by growing the strain at a high fission rate until the symbionts are diluted down to no more than one symbiont per paramecium. Cells isolated at that time and cultured at a low fission rate will grow into populations containing one type of symbiont only. This technique has also been used to separate different types of symbionts (Preer, 1948b).

A simple method of culturing paramecia involves the use of bacterized Cerophyl medium (Sonneborn, 1970). For a stock solution, 75 g of Cerophyl (now available from Sigma under the name "dehydrated cereal leaves") are boiled for 15 min in 1 liter of distilled water. The solution is then filtered, diluted with water (1:30), buffered with Na_2HPO_4, and autoclaved. A day before use, the autoclaved medium is inoculated with *Enterobacter aerogenes, Klebsiella pneumoniae,* or another bacterium suitable as food for *Paramecium.* The medium should have a pH of about 7. The growth rate of *Paramecium* can be regulated by varying the temperature and the amount of bacterized medium that is added to a culture.

An even simpler method is to culture paramecia in autoclaved straw or hay infusions. However, this method is less reproducible than the one using Cerophyl medium. For preparing the straw or hay medium, 3 to 5 g per liter of straw or hay is boiled, filtered, buffered with Na_2HPO_4 (pH 6.8 to 7.0), and then autoclaved. After cooling and a day before use, the medium is inoculated with bacteria.

Unfiltered straw medium, with the straw remaining in the medium, may be used for maintaining stock cultures. In these cultures, paramecia with or without symbionts can be kept for months at low temperatures (6 to 16°C) without special care. Another, even safer, method for maintaining stocks is to freeze the paramecia and to keep them in liquid nitrogen, from which they may be recovered with their symbionts on thawing (Simon and Schneller, 1973). A great number of *Paramecium* stocks bearing symbionts are maintained in the frozen state at the American Type Culture Collection, Rockville, MD, USA.

Paramecia can also be grown axenically. For sterile growth, the paramecia must first be washed free of bacteria. This is achieved by allowing the paramecia to swim through sterile medium for a time sufficient to permit the bacteria in the food vacuoles to be eliminated (Sonneborn, 1950; Van Wagtendonk and Soldo, 1970). A simple method modified from Heatherington (1934) is to place several paramecia at one edge of a depression filled with wash fluid, allow them to swim to the other side, and then to transfer them to a new depression. The procedure should be repeated four times before the cells are left in the fifth wash for an hour. They should then be transferred to a new depression and this should be repeated hourly for another 4 hours. The paramecia must be taken up each time in a new sterile micropipette with as little fluid as possible; slides and wash fluid have to be sterile. The use of antibiotics to obtain bacteria-free cultures is to be avoided, because such substances may harm the symbionts.

A method for culturing paramecia without bacteria involves use of the photoautotrophic alga *Chlamydomonas reinhardtii* as a food organism (L.B. Preer et al., 1974). The medium contains 1 g of yeast autolysate, 0.25 g sodium acetate, 0.625 g Cerophyl, and 0.125 g Na_2HPO_4 in 1 liter of double-distilled water. The medium is dispensed into test tubes, autoclaved, and stored. Before it is used, the medium is inoc-

ulated with a small number of *Chlamydomonas* and incubated under light for two days. A single bacterium-free paramecium, put into a tube half-filled with this *Chlamydomonas* medium, usually will multiply and ingest most of the algae within 3 to 4 days.

Most of the axenic media used for growing paramecia are based on a recipe initially designed by Soldo et al. (1966). Recent modifications by Thiele et al. (1980) and Schönfeld et al. (1986) have proved particularly valuable for large-scale cultures of *P. tetraurelia*. A modification (Soldo, 1987) that should be capable of supporting the axenic growth of paramecia and many other ciliates of fresh-water and marine origin follows.

Medium for Axenic Growth of Marine and Freshwater Ciliates

Component	Amount
Proteose peptone	10.00 mg/ml
Trypticase	5.00 mg/ml
Yeast nucleic acid	1.00 mg/ml
Biopterin	0.50 μg/ml
Folic acid	0.50 μg/ml
Nicotinamide	2.50 μg/ml
D-Pantothenate, Ca	7.50 μg/ml
Pyridoxal hydrochloride	2.50 μg/ml
Riboflavin	2.50 μg/ml
Thiamine hydrochloride	0.01 μg/ml
DL-Thioctic acid	0.01 μg/ml
Phospholipid (oleate-containing)	250.00 μg/ml
Stigmasterol	2.00 μ/ml

The medium is prepared in distilled water for freshwater ciliates and in sea water (density 1.015–1.026 g/ml) for marine forms. The final pH is 7.2. Stigmasterol is added from a stock solution (0.5 g stigmasterol dissolved in 100 ml hot absolute ethanol, stored at 4°C in a tightly capped plastic bottle) by injection into the culture medium from a syringe.

It is important to transfer paramecia gradually from a bacterized to an axenic medium. The ciliates need to be allowed to adapt slowly. Several procedures have been proposed for this transfer (see e.g., Van Wagtendonk and Soldo, 1970; Fok and Allen, 1979). An adapting medium (called VS medium) based on that of Allen and Nerad (1978) is one containing all the vitamins of the axenic medium given above plus stigmasterol, but not the other components, the pH being adjusted to 7.0. In VS medium, bacteria (e.g., *Klebsiella pneumoniae* previously grown in a tryptone medium) are suspended and adjusted to $OD_{590} = 3.0$ by dilution. The bacteria are then dispensed in 1-ml portions in screw-cap tubes and placed in the deep freeze. The final medium is prepared, about a week's supply at a time, by adding 1 ml of the frozen bacterized VS medium to 9 ml of unbacterized VS medium. This medium is autoclaved and inoculated with paramecia. The protozoa grow in this medium at a rate of 1/2 to 2 fissions per day. Not all stocks of *Paramecium* can be adapted to an axenic medium. Furthermore, some media were found to support growth of paramecia, but the latter were not able to maintain their symbionts under these conditions.

The purification of symbionts from paramecia (i.e., separation from host cell material) has been achieved in a number of ways: passage of cell homogenates through ion-exchange cellulose columns (Mueller, 1963; Smith, 1961), through filter paper columns (Preer et al., 1966), and centrifugation (Soldo et al., 1970) have all been used. Depending on the type of symbionts, different methods of purification may be necessary. For example the R-body-containing *Caedibacter caryophila* particles can best be isolated with the help of a discontinuous 70% Percoll gradient, while isolation of *Caedibacter caryophila* containing no R bodies, is better achieved by means of an ECTEOLA (anion exchanger) column (Schmidt et al., 1987b, 1988). For explanation of R bodies, see "Identification of *Paramecium* Symbionts."

For the isolation of holosporas, two different approaches have been followed. One method starts with homogenization of the host cells, the other involves separation of the macronuclei from the cytoplasm and then isolation of the symbionts. The latter method involving prior isolation of nuclei (Freiburg, 1985) proved especially useful for preparing clean reproductive forms of the symbionts, because it avoids contamination with bacteria from food vacuoles. For isolation of nuclei, the paramecia are lysed in a buffer containing 10 mM Tris, pH 7.9, 0.25 M sucrose, 3 mM $CaCl_2$, 8 mM $MgCl_2$, plus 0.1 mM phenylmethylsulfonyl fluoride, 0.1% w/v spermidine, and 0.2% Nonidet P40 (Shell Co., FRG) by gently stirring the cells in an ice-bath and subsequently passing the suspension 5 to 10 times through a 20-ml pipette. The nuclei are concentrated on a cushion of 1.6 M sucrose by spinning for 10 min at 700 × g. The purified nuclei are then homogenized in a Mg-free buffer, and the bacteria are pelleted. Two different forms of the bacteria, the infectious and reproductive forms can be separated by sedimentation. The infectious form sediments at 350 × g within 10 min, while the reproductive form remains in the supernatant (Görtz et al., 1988).

Protocols for isolating holosporas directly from cell homogenates have been published by Fujishima and Nagahara (1984), Schmidt et al. (1987a), and Görtz et al. (1988). Infected cells are homogenized in sodium phosphate buffer

with a hand homogenizer. The Teflon pestle should fit tightly. The homogenate is then centrifuged at about 3,000 × g for 10 min. The pellet is resuspended in buffer and centrifuged in a preformed continuous gradient of 70% Percoll for 12 min at 40,000 × g. In order to maintain the gradient, it is advisable to use a centrifuge with an acceleration rate control. For *H. obtusa, H. elegans*, and *H. undulata* the infectious forms then concentrate in a sharp band which is usually uncontaminated with food bacteria and cell debris. The reproductive forms do not form a band in a continuous Percoll gradient. These forms can be obtained with the help of a discontinuous gradient (at 10,000 × g) where—depending on the species—they are found above a step of about 60% Percoll. Most of the cell organelles of *P. caudatum* do not enter at the 50% Percoll step.

The isolation procedures described here have been helpful for studying ultrastructural details and protein composition of symbionts, their R bodies, and their DNA. Attempts to culture endosymbionts outside their hosts have usually been unsuccessful (Preer et al., 1974).

Identification of the *Paramecium* Symbionts

Since endosymbionts do not multiply outside their hosts, characterization based on metabolism and growth, as is customary for bacteria, is not possible. Instead, morphological and biological features and sometimes data on the GC content of the symbiont's DNA, have to be used for identification. Nonetheless, a preliminary identification is often possible with the help of a light microscope equipped with phase contrast. A very useful staining procedure that allows observations in regular bright field is given by Beale and Jurand (1966): Paramecia are placed in a small drop on a slide, as much of the fluid as possible is withdrawn by a micropipette, the paramecia are lightly fixed by exposure to OsO_4 vapor for a few seconds, and immediately stained with a small drop of lacto-orcein (1 g orcein dissolved in 25 ml of hot 45% acetic acid, mixed with 25 ml lactic acid, diluted with water 1:1, and then filtered). A coverslip, with vaseline applied around the edges, is placed over the drop of stained paramecia and is lightly pressed down, flattening but not disrupting the cells. The preparations can then be observed with a 100 × oil immersion objective. In order to remove lipids that sometimes obscure observation of endosymbionts, the paramecia can be treated with a drop of acetone or a 3:1 mixture of ethanol and acetic acid before staining.

In addition to microscopical observations, killer tests should be performed when a stock is brought in from nature. Standard sensitives (e.g., cells of stock 152 of *P. triaurelia*) may be employed in such tests. Equal volumes of the culture to be tested and a culture of sensitive cells are mixed in a depression slide and observed with appropriate controls for prelethal effects. Mate killing can only be detected by mating sensitive cells with symbiont bearers. Any symbiont-free strain that will mate with an unknown strain is usually adequate.

A feature unique to the genus *Caedibacter* is the ability to produce R bodies. These are proteinaceous ribbons, 20–30 μm long, coiled inside the bacterial cell to form a hollow cylindrical structure (Figs. 2 and 3). This structure has a diameter of about 0.4 μm in all species and is about 0.4 μm long, except in *C. caryophila* where the R bodies are approximately 0.8 μm in width and length. R bodies unroll when ingested into a phagosome and also under certain in vitro conditions, e.g., when placed at low pH (Preer et al., 1966). With respect to the shape of the ends and the mode of unrolling, the different types of R body vary (for details see Preer et al., 1974; Quackenbush, 1988; Pond et al., 1989).

It has been suggested that the R bodies play an important role in the killing mediated by *Caedibacter.* Mueller (1963) and Smith-Sonneborn and Van Wagtendonk (1964) demonstrated that only *Caedibacter* particles that contained R bodies were toxic to sensitive paramecia. In addition, R bodies purified from certain strains of *C. varicaedens* have been shown to be toxic to sensitive paramecia (L. B. Preer and Preer, 1964; L. B. Preer et al., 1972). However, neither the toxin itself nor its mode of action have yet been identified, nor is it known how paramecia are protected from the toxic action of their own symbionts.

The genetic determinants of R bodies are probably plasmids or bacteriophages that have lost the ability to lyse their host cells—the symbiotic bacteria—upon maturation of the virions (Preer and Preer, 1967; Preer et al., 1974). Dilts (1976) isolated plasmid DNA from *C. taeniospiralis* 51 and suggested that the extrachromosomal DNA might be the determinant of the R bodies. Further investigation revealed that plasmids are present in all strains of *C. taeniospiralis* and that they are highly homologous, as determined by restriction-endonuclease mapping (Quackenbush, 1983). Evidence that the genetic determinant for R-body synthesis resides on the plasmid was presented by Quackenbush and Burbach (1983), who cloned portions of a plasmid and obtained expression of

the R-body-encoding sequences in *Escherichia coli.* Analysis of various subclones allowed them to determine the approximate location of the R-body-encoding sequence. The DNA required for type 51 R-body synthesis is about 1.8 kbp in size and has been completely sequenced (D. P. Heruth, Ph.D. thesis; see Pond et al., 1989). However, none of the R-body-producing *E. coli* clones was found to be toxic to sensitive paramecia. The DNA sequence required for toxin production has not yet been located. It is believed to also reside on the plasmid (Pond et al., 1989).

Recently Dilts and Quackenbush (1986) have provided evidence that R bodies are required for the killing trait to be expressed but not for resistance of the ciliate host to killing mediated by *Caedibacter taeniospiralis.* They described a mutant strain of *C. taeniospiralis* 169 that simultaneously lost the ability to produce R bodies and to kill sensitive paramecia, but still rendered its host resistant to killing. Investigations of the R-body-encoding plasmid isolated from the mutant revealed that a transposon-like element had been inserted within the R-body-encoding region, thereby eliminating R-body production. Unless two separate mutational events occured in the same cell, one inactivating the R-body-encoding sequence and the other inactivating the toxin-encoding sequence, this shows that R bodies are crucial to expression of the killer trait. Their exact role remains, however, unknown. Evidence indicates that their action probably involves delivery of the toxin to the sensitive paramecium and to its target site by unrolling and penetrating the food vacuole membrane (Dilts, 1986).

The R bodies of other species of the genus were shown to be associated with icosahedral viral capsids (Preer and Jurand, 1968; Grimes and Preer, 1971). The capsids were in most cases found to contain DNA (Preer et al., 1971). The relationships between genomes of different phages of *kappa* and between R-body-encoding plasmids and kappaphage genomes have been studied by restriction-endonuclease analysis and by DNA-DNA hybridization (Quackenbush, 1978; Quackenbush et al., 1986). These studies demonstrate that the R-body-encoding plasmids show little or no homology with kappaphages, and that there is also considerable diversity among the kappaphages.

R bodies have also been reported in the free-living bacteria *Pseudomonas taeniospiralis* (Lalucat et al., 1979) and *P. avenae* (Wells and Horne, 1983). However, with respect to antigencity, genetic determinants, and other features, these R bodies appear to be unrelated to the R bodies of *Caedibacter* species (Bedingfield et al., 1984; Gibson, 1984; Meenaghan et al., 1984; Kanabrocki et al., 1986; Lalucat et al., 1986). R bodies have also been reported for *Rhodospirillum centenum,* a novel nonsulfur photosynthetic bacterium (Favinger et al., 1989). Since R bodies are often present at low frequencies, it appears likely that R-body-producing bacteria are more common than previously suspected.

Species of the genus *Holospora* are host-specific as well as nucleus-specific, i.e., they infect only one type of nucleus, either the micro- or the macronucleus (Ossipov, 1973; Ossipov et al., 1975). They can form short, reproductive rods that undergo binary fission as well as long, infective forms that leave paramecium and infect others very efficiently (Ossipov and Podlipaev, 1977; Wiemann and Görtz, 1989; Wiemann, 1989; Fig. 6). The infectious forms have a structure unique among bacteria. The cytoplasm is condensed and located toward one end of the symbiont, while a voluminous periplasmic area is located mainly at the other end. The periplasm consists of finely granular, strongly osmiophilic material. Some less osmiophilic material is located at the end, distal from the cytoplasm (Fig. 7). When an infective form has been taken up by a paramecium and is on its way into the nucleus, the periplasmic material disappears while the cytoplasm expands (Fig. 6). It is assumed that the periplasm of the infectious form contains substances that interact with host membranes during the infection process (Görtz et al., 1988; Görtz and Wiemann, 1989). The further development of the infectious form into the short, reproductive form is completed in the nucleus.

The infectious form differs from the reproductive form not only in morphology, but also in the protein patterns produced on SDS-polyacrylamide gel electrophoresis (Fig. 8). Some proteins specific for the infectious form of *H. obtusa* are located in the periplasm as shown by means of immune electron microscopy using poly- and monoclonal antibodies as probes against these proteins (M. Wiemann and H.-D. Görtz, unpublished observations).

The fine structure of the reproductive forms of species of *Holospora* resembles that of Gram-negative bacteria. Freeze-fracture studies of *H. obtusa* revealed that the outer membrane of the reproductive form has a density of intra-membrane particles (IMPs) that is similar to that of the inner membrane. In contrast to this, the outer membrane of the infectious form was found to contain only very few IMPs (Görtz et al., 1989). These differences correlate with a difference in the behavior of the two forms during the division of the host nuclei. The infectious

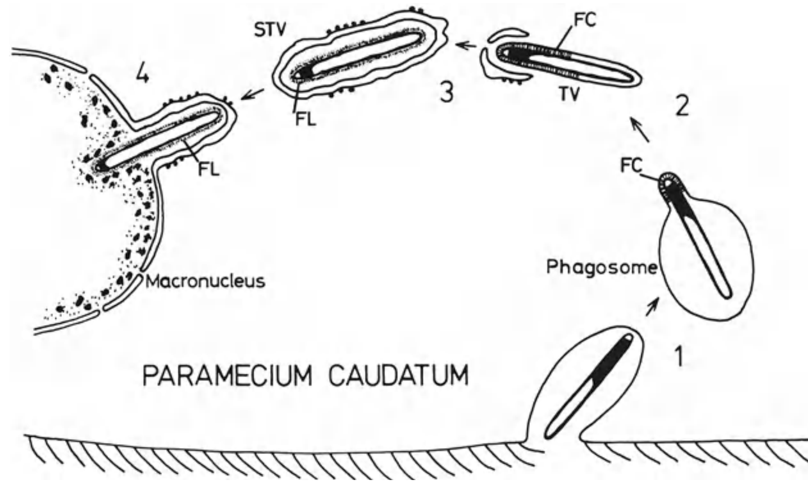

Fig. 6. The route of *Holospora obtusa* into the macronucleus of *Paramecium caudatum*. 1) The infectious form of the bacterium (long rod) is ingested by the paramecium into a phagosome (food vacuole). Fibrillar connections (FC) are established between the bacterial surface and the phagosome membrane. 2) The bacterium is sluiced out of the phagosome. It remains encircled by a host membrane that forms a transport vesicle (TV). 3) Fibrillar connections (FC) are established between the host membrane and the bacterium. Later on, the transport vesicle is surrounded by flat vesicles, some of them bearing ribosomes. These vesicles finally form a secondary transport vesicle (STV). 4) The TV membrane disintegrates or becomes part of a fibrillar lamina (FL) enclosing the bacterium. The STV membranes fuse with the nuclear membranes. Thus, the bacterium is incorporated into the macronucleus. (From Görtz and Wiemann, 1989.)

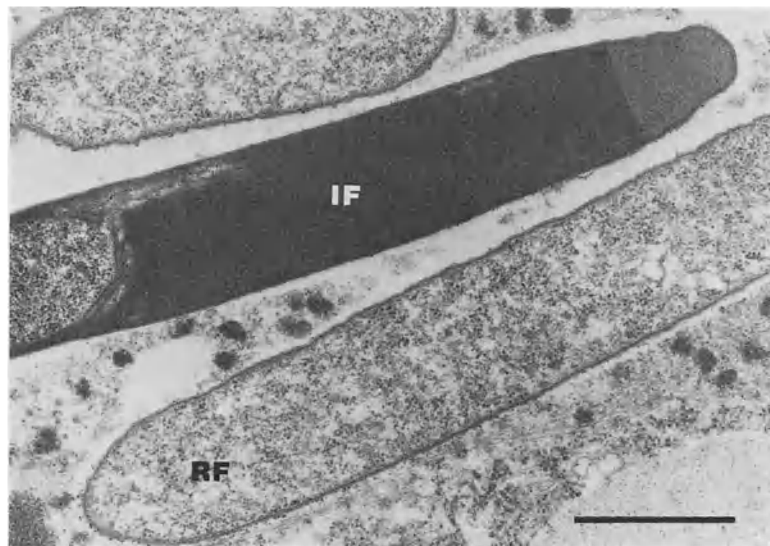

Fig. 7. *Holospora obtusa* in the macronucleus of *Paramecium caudatum*. IF, infectious form; RF, reproductive form. Bar = 1 μm. (From Görtz et al., 1988.)

forms of *H. obtusa* are concentrated in the connecting piece around the separation spindle of the dividing nucleus and are later released from the host cell. The reproductive forms are transported to the poles and in this way get into the daughter nuclei (Ossipov et al., 1975; Ossipov, 1981; Wiemann, 1989; Wiemann and Görtz, 1989). It is of interest that *H. obtusa* makes use of the division apparatus of the host nucleus.

The classification of the endosymbionts of *Paramecium* is based on the following characteristics: morphology; killing activity; the species in which they live; DNA base ratios calculated from the buoyant density (Bd) or from thermal denaturation profiles (T_m), and interstrain DNA/DNA hybridizations. Type strains which have been deposited at the American Type Culture Collection (ATCC), are listed be-

Lane 1, *H. obtusa*, infectious form (from 2×10^7 cells); lane 2, *H. obtusa*, reproductive form (from 2×10^8 cells); lane 3, *E. coli* (from 5×10^7 cells). The position and size (kDa) of marker proteins are indicated on the right. (From Görtz et al., 1988.)

low by their ATCC numbers. Some type strains have also been deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, Leningrad University, and can be obtained from that source.

GENUS *CAEDIBACTER* PREER AND PREER 1982. Straight rods or coccobacilli, 0.4–1.0 μm in diameter and 1.0–4.0 μm in length. Usually less than 10%, but sometimes up to 50% of the symbionts contain refractile (R) bodies. Cells containing R bodies are usually larger than cells that do not contain R bodies. In addition to R bodies, many spherical phage-like structures or covalently closed circular DNA plasmids are present. The symbionts are Gram-negative and nonmotile. The GC content of the DNA is 40–44 mol%. For a detailed description of this extensively studied genus, see Preer et al., 1974; Preer and Preer, 1984; Pond et al., 1989. The following five species have been described:

1. *Caedibacter taeniospiralis* Preer and Preer 1982. Rods, 0.4–0.7μm in diameter and 1.0–2.5 μm long. The GC content is 41 mol%. Found in the cytoplasm of *P. tetraurelia* only. R bodies unroll from the inside and contain plasmids. Ingestion of R-body-containing symbionts by sensitive paramecia results in the development of clear small blisters on their surface in 2 to 3 hours. During the 4th to 5th hour, a bulge develops first in the posterior part of the oral side and later moves to the posterior aboral side. The position of the bulge gave rise to the designation "hump-killer." Death takes place in 1 to 2 days, the corpses remaining intact for sometime. Type strain: in ATCC strain 30632 (stock 51 of *P. tetraurelia;* see Preer et al., 1974).
2. *Caedibacter varicaedens* Quackenbush 1982. Rods, 0.4–1.9 μm in diameter and 2.0–4.0 μm long. The GC content is 40–41 mol%. Found in the cytoplasm of *P. biaurelia*. Different strains cause either vacuolization, paralysis, or rapid reverse rotation while swimming (spin-killing) of sensitive cells. Vigorous rotation to the right becomes nearly uninterrupted by the 4th to 6th hour and then becomes slower. R bodies unroll from the outside. The outer terminus of the unrolled R body is blunt. The R body is usually associated with bacteriophage capsids. Type strain: in ATCC 30637 (stock 7 of *P. biaurelia;* see Preer et al., 1974).
3. *Caedibacter pseudomutans* Quackenbush 1982. Cigar-shaped rods, approximately 0.5 μm in diameter and 1.5 μm long. The GC content is 44 mol%. Found in the cytoplasm of *P. tetraurelia*. Cause rapid reverse rotations of sensitive paramecia while swimming (spin-killers). R bodies of the *C. varicaedens* type. Type strain: in ATCC strain 30633 (strain 51 ml of *P. tetraurelia;* see Preer et al., 1974).
4. *Caedibacter paraconjugatus* Quackenbush 1982. Small rods. Contain phage-like structures. Less than 1% of the symbionts contain R bodies of the *C. varicaedens* type. Found in the cytoplasm of *P. biaurelia*. Ingestion of symbionts by sensitive strains does not produce any observable toxic effect. Cell-to-cell contact between host and sensitive paramecia is required for toxic effects to be observed in the sensitive paramecia (mate-killers). Type strain: in ATCC strain 30638 (stock 570 of *P. biaurelia;* see Preer et al., 1974).
5. *Caedibacter caryophila* Schmidt, Görtz, and Quackenbush 1987. Rods, 0.4 to 0.7 μm wide and up to 2.5 μm long. Those with R bodies are larger than those without R bodies. The GC content is 34.6 mol%. Found in the macronucleus of *P. caudatum*. R bodies unrolling from the inside, outer terminus blunt, in-

ner terminus acute. R bodies are associated with phages. Width of R bodies after isolation 0.8μm. Sensitive strains are killed by paralysis. Coinfections with *Holospora obtusa, H. undulata* and *H. elegans* may occur in natural populations (H.-D. Görtz, unpublished observations). Type strain: in ATCC strain 50168 (clone C221 of *P. caudatum,* see Schmidt et al., 1987c).

GENUS *PSEUDOCAEDIBACTER* QUACKENBUSH 1982. Rods, 0.25–0.7 μm in diameter and 0.5–4.0 μm long. Do not produce R-body-containing cells. The symbionts are Gram-negative and nonmotile. The GC content is 35–39 mol%. The genus includes some species that confer a killer trait on their hosts, some that render them mate killers, and others that do not produce any killing ability. Four species have been described:

1. *Pseudocaedibacter conjugatus* Quackenbush 1982, formerly *mu.* Rods, 0.3–0.5 μm in diameter and 1.0–4.0 μm long. The GC content is 35–37 mol%. Found in the cytoplasm of *P. primaurelia* and *P. octaurelia* where a mate-killer phenotype of the hosts is produced. Type strain: in ATCC strain 30796 (stock 540 of *P. primaurelia;* see Preer et al., 1974).
2. *Pseudocaedibacter minutus* Quackenbush 1982, formerly *gamma.* Rods, often double; single rods 0.25–0.35 μm in diameter and 0.5–1 μm long. The GC content is 38 mol%. Found in the cytoplasm of *P. octaurelia.* In the host cell, the symbiont is surrounded by an extra set of membranes, apparently continuous with the endoplasmic reticulum of the host. The paramecia which bear these symbionts are very strong killers that cause sensitives to develop vacuoles, accompanied by swelling of the cells, finally becoming spherical and undergoing lysis. Death occurs after about 8 hours. Type strain: in ATCC strain 30699 (stock 214 of *P. octaurelia;* see Preer et al., 1974).
3. *Pseudocaedibacter falsus* Quackenbush 1982, formerly *nu* and *pi.* Rods, 0.4–0.7 μm in diameter and 1.0–1.5 μm long. The GC content of the DNA is 36 mol%. No toxic actions known. Found in the cytoplasm of *P. biaurelia, P. tetraurelia,* and *P. pentaurelia.* Type strain: in ATCC strain 30640 (stock 1010 of *P. biaurelia;* see Preer et al., 1974).
4. *Pseudocaedibacter glomeratus* Fokin and Ossipov 1986. Small rods, about 0.3 μm wide and up to 1.2 μm long. Found in the cytoplasm of *P. pentaurelia.* No toxic actions known. Symbionts are individually enclosed in vacuoles which are tightly associated with the endoplasmic reticulum. Type strain: in strain Bp 171 of *P. pentaurelia* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, Leningrad University, USSR).

A symbiont living in the cytoplasm of *P. bursaria* and found to be antagonistic to symbiotic chlorellae was named *Caedobacter chlorellopellens* by Skoblo et al. (1985), who did not know that the genus name *Caedobacter* had been changed to *Caedibacter. Caedibacter* was then restricted to symbionts that produce R bodies and confer killer traits upon their host paramecia (Preer and Preer, 1982). The symbiont in *P. bursaria* is egg-shaped, rarely rod-shaped, 0.35 μm wide and up to 1.4 μm long. Since no R bodies were observed and no toxic actions on sensitives were observed, the species should be placed in the genus *Pseudocaedibacter.*

GENUS *LYTICUM* PREER AND PREER 1982. Large rods, 0.6–0.8 μm in diameter and 3.0–5.0 μm long. Resemble bacilli in general appearance and bear numerous peritrichous flagella (Figs. 4 and 5), but are not obviously motile. They are enclosed in vacuoles in the cytoplasm of their hosts. They do not contain R bodies. The GC content is 27 mol% in one type and 45–49 mol% in another type. The symbionts are Gram-negative. They produce toxins that kill sensitive paramecia by lysing them within 10 to 20 min (rapid lysis killing). Two species have been described:

1. *Lyticum flagellatum* Preer and Preer 1982 (formerly *lambda*). Straight rods, 0.6–0.8 μm in diameter and 2.0–4.0 μm long. The GC content is 27 mol% in one strain and 49 mol% in another. Found in the cytoplasm of *P. tetraurelia* and *P. octaurelia.* Type strain: in ATCC strain 30700 (stock 299 of *P. octaurelia;* see Preer et al., 1974).
2. *Lyticum sinuosum* Preer and Preer 1982, formerly *sigma.* Curved or spiral rods, 0.7–0.9 μm in diameter and 2.0–10 μm long, sometimes forming chains of 2–3 cells. The GC content is 45 mol%. Found in the cytoplasm of *P. biaurelia.* Type strain: in ATCC strain 30696 (stock 114 of *P. biaurelia;* see Preer et al., 1974).

GENUS *PSEUDOLYTICUM* BOSS, BORCHSENIUS, AND OSSIPOV 1987. Large symbionts with numerous flagella. No motility observed. May contain refractile bodies consisting of polyhydroxybutyric acid. No killer activity and no infectivity could be detected. Only one species known, *Pseudolyticum multiflagellatum* Boss, Borchsenius, and Ossipov 1987. Straight rods,

1.0–2.0 μm in diameter and 3.5–14 μm long. Found in the cytoplasm of *P. caudatum.* The symbionts are individually enclosed in vacuoles. The membrane of these vacuoles forms numerous projections that are continuous with the endoplasmic reticulum. No toxic actions known.

GENUS *TECTIBACTER* PREER AND PREER 1982. The species of this genus are distinguished from other symbionts by a layer of electron-dense material surrounding the outer of the two membranes. The symbionts have sparse peritrichous flagella and show slight motility on occasion. They appear not to be toxic. For a more detailed description see Preer et al., 1974. Only one species described, *Tectibacter vulgaris* Preer and Preer 1982, formerly *delta.* Straight rods, 0.4–0.7 μm in diameter and 1.0–2.0 μm long. Gram-negative. Hosts: *P. primaurelia, P. biaurelia, P. tetraurelia, P. sexaurelia,* and *P. octaurelia.* Type strain: in ATCC strain 30697 (stock 225 of *P. sexaurelia;* see Preer et al., 1974).

GENUS *NONOSPORA* FOKIN, OSSIPOV, SKOBLO, RAUTIAN, AND SABANEYEVA 1987. Rod-like symbionts living in the macronucleus. Flagella have not been observed. No toxic actions known. The symbionts are retained in macronuclear fragments of exconjugants and enter macronuclear anlagen by fusion of old fragments with the anlagen (Fokin et al., 1987a). Only one species described, *Nonospora macronucleata* Fokin, Ossipov, Skoblo, Rautian, and Sabaneyeva 1987. Symbionts rodlike, 0.2–0.3 μm in diameter and mostly about 1.0 μm long, sometimes forming chains up to 10 μm long. The surface of the symbionts appears irregularly wavy in the electron microscope. Found in the macronucleus of *P. caudatum,* often clustered in the center of the nucleus.

GENUS *HOLOSPORA* (EX HAFKINE 1890) GROMOV AND OSSIPOV 1981. Symbionts of this genus live in the micronucleus or the macronucleus of *Paramecium* and exist in two forms: a short rod, 1.0–3.0 μm long and 0.5–1.0 μm wide that can replicate; and a long form 5.0–20 μm long and 0.8–1 μm wide that cannot replicate. The long form is released from the host and can infect other paramecia. The infective form is differentiated into a refractile portion with a less electron-dense, pale tip and a posterior part that contains typical bacterial cytoplasm, stains with DNA-specific dyes, and appears dark in phase contrast. An unnamed symbiont of this type has been observed repeatedly in *Stentor multiformis* and in *S. polymorphus* (Görtz and Wiemann, 1987), and another one has been observed in the peritrich ciliate *Zoothamnium pelagicum* by Laval (1970). This indicates that symbionts of the genus *Holospora* are not restricted to *Paramecium.* Some strains of *Paramecium* were found to be harmed after infection with holosporas, whereas other strains apparently remained unaffected. Six species have been described:

1. *Holospora undulata* (ex Hafkine 1890) Gromov and Ossipov 1981. Lives in the micronucleus of *P. caudatum.* Two forms are seen, a short, spindle-shaped reproductive form, about 0.8 μm in diameter and 1.5–2.0 μm long, and a long, spiral-shaped infectious form that has tapered ends and is 7.0–15 μm long. Type strain: in clone M1-48 of *P. caudatum* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, Leningrad University, USSR).
2. *Holospora obtusa* (ex Hafkine 1890) Gromov and Ossipov 1981. Lives in the macronucleus (Fig. 7). Reproductive form: short rod, 0.8 μm in diameter and 1.5–2.5 μm long. Infectious form: long rod with rounded ends, 0.8–1.0 μm in diameter and 7.0–20 μm long. Type strain: in clone M-115 of *P. caudatum* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, Leningrad Univerity, USSR).
3. *Holospora elegans* (ex Hafkine 1890) Preer and Preer 1982. Lives in the micronucleus. Reproductive form: short rod, 0.8 μm in diameter and 1.5–2.0 μm long. Infectious form: long rod with tapered ends, 0.6–0.8 μm in diameter and 7.0–18 μm long. Type strain: in ATCC strain 50008 (stock C101 of *P. caudatum,* Görtz and Dieckmann, 1980).
4. *Holospora caryophila* Preer and Preer 1982, formerly *alpha.* Lives in the macronucleus of *P. biaurelia;* may also be found in *P. caudatum* (Görtz, 1987). Reproductive form: thin, fusiform rod, 0.4 μm in diameter and 1.0–3.0 μm long. Infectious form: spiral shaped with tapered ends, 0.5 μm in diameter and 5.0–6.0 μm long. Type strain: in ATCC strain 30694 (stock 562 of *P. tetraurelia;* see Preer et al., 1974).
5. *Holospora acuminata* Ossipov, Skoblo, Borchsenius, Rautian and Podlipaev 1980. Lives in the micronucleus of *P. bursaria.* Reproductive form: fusiform rod, 0.6 μm in diameter and 2.0–2.5 μm long. Infectious form: straight fusiform rod with tapered ends, 0.8–1.0 μm in diameter and 4.0–6.0 μm long. Type strain: in stock AC61-10 of *P. bursaria* (deposited in the culture collection of the

Laboratory of Invertebrate Zoology, Biological Research Institute, Leningrad University, USSR).

6. *Holospora curviuscula* Borchsenius, Skoblo and Ossipov 1983. Lives in the macronucleus of *P. bursaria.* Infects only certain strains of three syngens. In other strains the development into the infectious form is not completed. Occasionally, infection of both macro- and micronuclei was observed (Skoblo and Lebedeva, 1986). Reproductive form: fusiform rod, 0.8 μm in diameter and 1.5–2.0 μm long. Infectious form: slightly curved rod with tapered ends, approximately 0.8 μm in diameter and 6.0–10 μm long.

The striking similarity of the biology and cytology of the different *Holospora* species led to their classification in one genus. A comparison of the protein patterns of *H. obtusa* and *H. elegans,* however, revealed great differences. Moreover, the hybridization of the total DNAs and a comparison of DNA banding patterns after digestion with restriction enzymes indicate that the two species may not be as closely related as originally assumed (Schmidt et al., 1987a). The differences at the molecular level suggest that the genus *Holospora* has coevolved with ciliates for a long time.

SYMBIONTS OF *PARAMECIUM* WITHOUT BINOMIAL NAMES. Jenkins (1970) described a Gram-negative bacterium living within bulbous distensions of the outer membrane of the nuclear envelopes of both the micro-and macronucleus of a strain of *P. multimicronucleatum.* It is a very short rod, sometimes appearing nearly coccoid, approximately 0.35 μm in diameter with longer forms reaching 0.7 μm in length. It was named *epsilon.*

Another symbiont, reported to occur in the perinuclear space, has been described by Fokin (1988). It was found inside the nuclear cisternae of the macronucleus of *P. duboscqui.* The symbiont is 0.3 μm in diameter and 0.7–1.4 μm long, looks spindle-shaped and is Gram-negative. No killing activity was observed when symbiont bearers were tested against non-symbiont bearers.

A symbiont occurring in the macronucleus of *P. caudatum* has been studied by Estève (1978). It confers a killer trait on its host. When it was investigated cytologically, a greatly enlarged macronucleus was observed to contain numerous kappa-like bacteria, some of which contained R bodies. Electron micrographs of this bacterium showed spherical phages inside the R bodies. Schmidt et al. (1987c) assumed that the symbiont is identical with *Caedibacter caryophila* recently described and named by them.

A so-far-unnamed symbiont living in the micronucleus of *P. bursaria* was found by Görtz and Freiburg (1984). It is a small rod, 0.5 μm in diameter and up to 2 μm long. Its ultrastructure suggests that it is a Gram-negative bacterium. No flagella were found and no killing capacity of its host was observed.

Another symbiont of the nonkiller type was discovered in the cytoplasm of *P. woodruffi,* a ciliate living in brackish water. The symbiont is a Gram-negative rod, 0.2–0.8 μm in diameter and 0.6–2.5 μm long. It has no flagella. It was found to contain hexagonal viroid particles (Fokin et al., 1987b).

A bacterial endosymbiont of *P. sexaurelia* was repeatedly observed by Görtz (1981) to invade the macronucleus but not the micronucleus. Once the symbiont has entered the macronucleus it tends to disappear from the cytoplasm. The bacterium is slightly curved with a diameter of 0.5–0.8 μm and up to 25 μm long. When present in the cytoplasm, the symbiont tends to be closely associated with food vacuoles. Once the symbiont has entered the macronucleus, it multiplies there without causing nuclear hypertrophy. After autogamy the symbiont is found only in the cytoplasm and not in new macronuclear anlagen. It remains there until a new infection of the macronucleus occurs.

The following key to the prokaryotic symbionts of *Paramecium* only includes symbionts that have been given binomial names. The key is based on the one proposed by L. B. Preer (1981) and on information from articles cited in this chapter.

Key to the Prokaryotic Symbionts of *Paramecium*

I. Host paramecia are killers or mate-killers
- A. 2–50% of symbiont population contain R bodies
  - 1. Host paramecia are killers
    - a. Kill by producing aboral humps on sensitive paramecia; R bodies unroll from inside at low pH, reroll at high pH; found in *P. tetraurelia* .... *Caedibacter taeniospiralis*
    - b. Kill in ways other than producing aboral humps
      - (1) Found in *P. tetraurelia;* R bodies unroll from outside irreversibly when exposed to high temperature or certain detergents .... *Caedibacter pseudomutans*
      - (2) Found in *P. biaurelia;* R bodies unroll from outside irreversibly when exposed to high temperature or certain detergents .... *Caedibacter varicaedens*
      - (3) Found in *P. caudatum,* found in the macronucleus only; R bodies unroll from inside .... *Caedibacter caryophila*

2. Host paramecia are mate-killers
.... *Caedibacter paraconjugatus*

B. Symbiont population does not contain R bodies
1. Host paramecia are killers
a. Rapid lysis killer; symbionts are large flagellated cells
(1) Straight rods found in *P. tetraurelia, P. octaurelia*
.... *Lyticum flagellatum*
(2) Sinuous rods found in *P. biaurelia*
.... *Lyticum sinuosum*
b. Kill by vacuolization; symbionts are very small cells, often doublets
.... *Pseudocaedibacter minutus*
2. Host paramecia are mate-killers
.... *Pseudocaedibacter conjugatus*

II. Host paramecia are nonkillers
A. Symbionts are present only in the cytoplasm
1. Symbionts lack flagella
a. Host: *P. bursaria;* egg-shaped, rarely rod-shaped, up to 1.4 μm long. Antagonistic to symbiotic algae (*Chlorella*) of the host
.... *Caedobacter chlorellopellens*
b. Hosts: *P. biaurelia, P. tetraurelia, P. pentaurelia;* rods, up to 1.2 μm long
.... *Pseudocaedibacter falsus*
c. Host: *P. pentaurelia;* rods, up to 1.2 μm long: the symbiont-containing vacuole is surrounded by endoplasmic reticulum
.... *Pseudocaedibacter glomeratus*
2. Symbionts with flagella
a. Host: *P. caudatum;* rods, 3.5 to 14 μm long; refractile inclusions (polyhydroxy butyric acid); with numerous flagella, but no motility observed
.... *Pseudolyticum multiflagellatum*
b. Host: *P. primaurelia;* rods, up to 2 μm long; Gram-negative with a thick surface layer visible in EM; with sparse flagella, occasionally slight motility; coexists with other symbionts such as *Caedibacter* and *Pseudocaedibacter*
.... *Tectibacter vulgaris*

B. Symbionts are present almost exclusively in the nuclei
1. Symbionts exclusively in the micronucleus, show two morphologically distinct forms, and are highly infectious
a. Long form of symbiont (infectious form), spiral-shaped with tapered ends, 7–15 μm long; host: *P. caudatum*
.... *Holospora undulata*
b. Long form of symbiont (infectious form), straight rod with tapered ends
(1) Host: *P. caudatum;* long form 7–18 μm long
.... *Holospora elegans*
(2) Host: *P. bursaria;* long form 4–6 μm long
.... *Holospora acuminata*
2. Symbionts exclusively in the macronucleus
a. Symbionts are highly infectious, two morphologically distinct forms often observable
(1) Host: *P. biaurelia* (sometimes also observed in *P. caudatum*); long form with tapered ends, 5–6 μm long
.... *Holospora caryophila*
(2) Host: *P. caudatum;* long form, straight rod, with rounded ends, 7–20 μm long
.... *Holospora obtusa*
(3) Host: *P. bursaria;* long form slightly curved, with tapered ends, 6–10 μm long
.... *Holospora curviuscula*
b. Symbionts are weakly infectious, only one morphological form observable. Host: *P. caudatum;* rods small, about 1 μm long, sometimes forming "chains" that are up to 10 μm long; mostly aggregated in the center of the macronucleus; may coexist with *H. obtusa* or *H. undulata*
.... *Nonospora macronucleata*

Prokaryotic Symbionts of *Euplotes*

Endosymbiotic bacteria are also very common in *Euplotes,* a ciliate genus that comprises both freshwater and marine species. So far, only one of the symbionts has been given a binomial name. The others are still referred to by Greek letters, as was formerly customary for cytoplasmic elements. Several *Euplotes* symbionts remained unnamed or were provisionally given Latin letters as names when they were encountered. However, most of these symbionts are not well characterized.

Habitat of the *Euplotes* Symbionts

All except one of the bacterial symbionts of *Euplotes* are confined to the cytoplasm. They can easily be observed with a phase contrast microscope. Fixation and staining of *Euplotes* with aceto-carmin or aceto-orcein can be helpful for the observation and identification of these endosymbionts. When stained, *Polynucleobacter necessarius* (formerly *omikron*) and the closely related "*omikron*-like" bacteria reveal many nucleoids (Heckmann, 1975; Heckmann et al., 1983). It appears that most of the *Euplotes* symbionts cannot grow outside their hosts, although this has been investigated thoroughly only for *P. necessarius.* Like *Caedibacter* and other symbionts of the *P. aurelia* species complex, the *Euplotes* symbionts appear not to be infectious, at least under laboratory conditions. The symbionts found to date have not been observed to be harmful to their hosts, which, however, in some cases are converted by infection into killers or mate-killers. *P. necessarius* and the closely related *omikron*-like bacteria are essential for their hosts (Heckmann, 1983).

The names of the prokaryotic endosymbionts of *Euplotes,* their properties, and the species in which they were found are listed in Table 1.

Isolation of the *Euplotes* Symbionts

Euplotes minuta, E. crassus and *E. vannus* are marine species. They can be isolated from water

Table 1. Characteristics of the prokaryotic endosymbionts of the genus *Euplotes*.

Symbiont designation	*Euplotes* species[a]	Site	Killing type	Reference
Polynucleobacter necessarius	*E. aediculatus* (15)	Cy	NK	Heckmann and Schmidt, 1987
Omikron-like symbiont	*E. eurystomus* (25)	Cy	NK	Heckmann et al., 1983
Omikron-like symbiont	*E. plumipes* (24)	Cy	NK	Heckmann et al., 1983
Omikron-like symbiont	*E. daidaleos* (13)	Cy	NK	Heckmann et al., 1983
Omikron-like symbiont	*E. octocarinatus* (11)	Cy	NK	Heckmann et al., 1983
Omikron-like symbiont	*E. patella* (5)	Cy	NK	Heckmann et al., 1983
Omikron-like symbiont	*E. woodruffi* (22)	Cy	NK	Heckmann et al., 1983
Epsilon	*E. minuta* (K_1,K_3,K_7)	Cy	K	Heckmann et al., 1967
Epsilon-like	*E. minuta* (VF_{17})	Cy	K+MK	Heckmann et al., 1967
Eta	*E. crassus*	Cy	K	Nobili et al., 1976
A	*E. crassus*	Cy	NK	Rosati et al., 1976
B_1	*E. crassus* (C_8)	Cy	MK	Dini and Luporini, 1976
B_3	*E. crassus*	Cy	NK	Rosati et al., 1976
C	*E. crassus*	Cy	NK	Rosati et al., 1976
D	*E. crassus*	Cy	NK	Rosati et al., 1976
Unnamed	*E. crassus*	Ma	NK	Rosati and Verni, 1975
Unnamed	*E. vannus*	Cy	K+MK	Demar-Gervais and Genermont, 1976

Symbols: Cy, cytoplasm; Ma, macronucleus; NK, nonkiller; K, killer; MK, mate-killer.
[a]The typical strain designation is given in parentheses.

samples containing algae or detritus collected at the seashore. All these species can be easily grown in the laboratory in seawater with *Dunaliella salina* as the food organism (for details see Heckmann, 1963). The other *Euplotes* species listed in Table 1 are freshwater organisms that may be collected from ponds. They can be grown in a diluted soil medium (Ruthmann and Heckmann, 1961) or in culture medium (CME) for *Euplotes* (Kuhlmann and Heckmann, 1989) and fed with *Chlorogonium elongatum* or *Chilomonas paramecium*. Most *Euplotes* species can also utilize bacteria as food.

Since the symbionts may differ in different strains of a host species, it is advisable to start *Euplotes* cultures from single cells, so that the cultures maintained in the laboratory form clones. In most cases, this will ensure that one is dealing with homogeneous populations of endosymbionts. However, double and triple infections have also been observed.

Polynucleobacter necessarius is the only endosymbiont of *Euplotes* known so far that has been isolated. In this case, cells of strain 15 of *E. aediculatus* were homogenized mechanically, and the symbionts were then purified by applying the homogenate to an ECTEOLA column, followed by elution with phosphate buffer (Heckmann, 1975; Schmidt, 1982). The procedure basically followed the one developed for the isolation of kappa symbionts from *Paramecium* by Smith-Sonneborn and Van Wagtendonk (1964) and resulted in very clean preparations of symbionts.

Identification of the *Euplotes* Symbionts

The bacterial symbionts of *Euplotes* can be identified by direct observation with a phase contrast microscope, by observation of physiological effects produced on other *Euplotes* cells that lack symbionts, or by a combination of these methods.

GENUS *POLYNUCLEOBACTER* HECKMANN AND SCHMIDT 1987. These are obligate endosymbiotic bacteria living in the cytoplasm of freshwater ciliates of the genus *Euplotes*. The symbionts are characterized by multiple nucleoids, are essential for their host species, are nonmotile, and Gram-negative. The type species is *Polynucleobacter necessarius*.

Polynucleobacter necessarius Heckmann and Schmidt 1987, formerly called *omikron*. Slightly curved rods, about 0.3 μm in diameter and 2.5–7.5 μm long. If stained with DNA-specific dyes, usually 3 to 9 but, in some cases up to 12 intensely stained and regularly spaced dots become visible (Fig. 9). They are considered to be nucleoids. When examined with the electron microscope, these nucleoids differ from those of most free-living bacteria by exhibiting an electron-dense central core that resembles the chromatin of eukaryotes (Fig. 10). Whether this core is formed by proteins associated with DNA or some other material is not clear (Heckmann, 1975).

The symbionts are individually contained in vesicles, to which ribosomes are often attached. *P. necessarius* reproduces by transverse binary fission in a typical bacterial manner. However, the fission products have often been found to differ in size. Frequently, a 7-μm-long rod containing eight to nine nucleoids was observed to bud off a 2.5-μm piece that contained three nucleoids (Heckmann, 1975). The GC content of

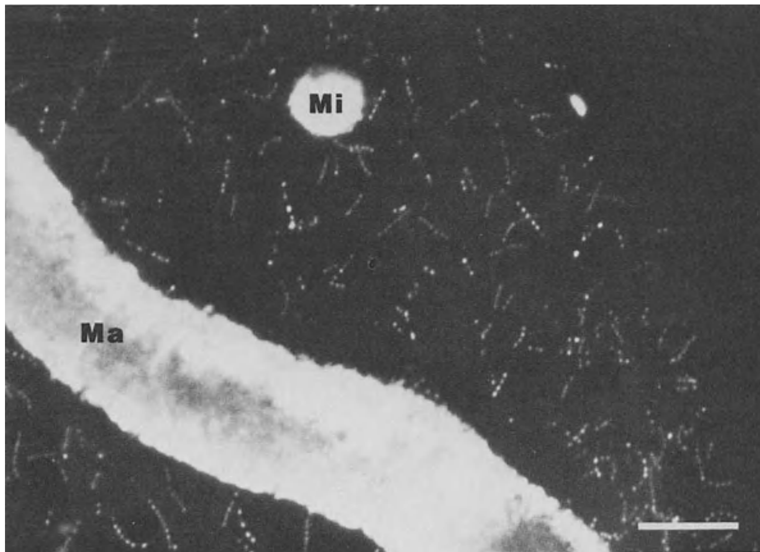

Fig. 9. Fluorescence micrograph of *Polynucleobacter necessarius* in the cytoplasm of a slightly crushed *Euplotes aediculatus* cell after staining with N,N'-diethylpseudoisocyanin chloride. The symbionts are revealed by the DNA-specific yellow fluorescence of their nucleoids. Ma, macronucleus; Mi, micronucleus. Bar = 10 μm. (From Heckmann, 1975.)

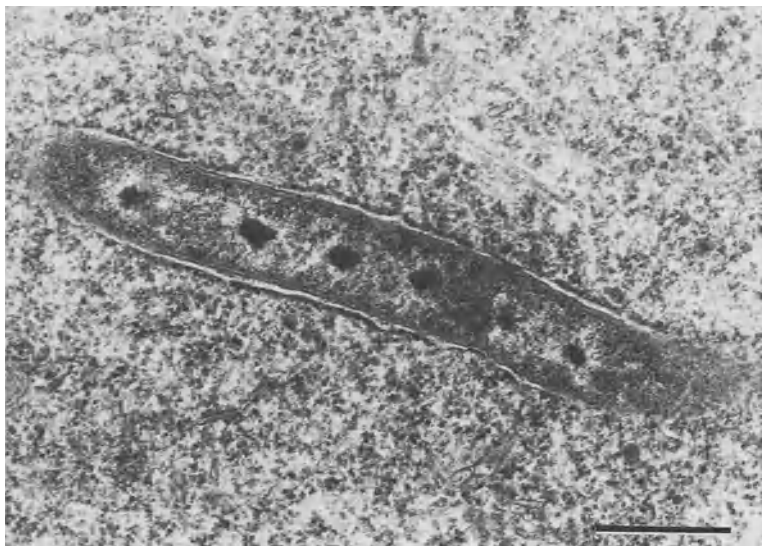

Fig. 10. Electron micrograph of *Polynucleobacter necessarius.* Longitudinal section. The ultrastructure of this symbiont resembles that of Gram-negative bacteria. Bar = 0.5 μm. (From Heckmann, 1975.)

the DNA of *P. necessarius* was 48 mol% by thermal denaturation. A value that was 2.8 mol% lower was found when the GC content was calculated from the buoyant density, which was 1.7036 g/cm^3 (Schmidt, 1982). The differences could be caused by rare bases; however, no DNA chemistry has been done for *P. necessarius.* The average DNA content of the symbiont was determined to be 5.8×10^{-3} pg. Taking into account the average number of nucleoids, a DNA content of 0.5×10^9 daltons per nucleoid was calculated. This value is in close agreement with the value of the kinetic complexity of the DNA, which was determined to be 0.57×10^9 daltons when corrected for the GC content (Schmidt, 1982). Equally small genomes have been reported for *Lyticum flagellatum, Pseudocaedibacter conjugatus,* and *P. falsus,* endosymbionts of the *P. aurelia* species complex (Soldo and Godoy, 1973b), for xenosomes of *Parauronema acutum* (Figueroa-de Soto and Soldo, 1977), and for chlamydiae, rickettsiae, and mycoplasmas (Bak et al., 1969). The genomes of these organisms are the smallest known for cells. They code for only about 700 to 900 proteins.

Heckmann (1975) has shown that it is possible to remove *P. necessarius* from *E. aediculatus* by treating a rapidly growing culture with 100 to 500 units/ml of penicillin for 5 to 6 days. Aposymbiotic hosts may undergo one or two fissions but then stop multiplying and die about 15 to 20 days after the last fission. The same results were obtained with several other antibiotics or with sufficiently high doses of X rays.

Reinfection and rescue of *E. aediculatus* have been achieved either by adding a cell homogenate from symbiont bearers or by injecting symbiont-containing cytoplasm (Heckmann, 1975; Fujishima and Heckmann, 1984). Type strain: in ATCC strain 30859 (clone 15 of *E. aediculatus;* see Heckmann and Schmidt, 1987).

THE *OMIKRON*-LIKE ENDOSYMBIONTS OF *EUPLOTES* These symbionts are very similar in appearance to *P. necessarius.* They were found in six freshwater *Euplotes* species (*E. eurystomus, E. plumipes, E. octocarinatus, E. patella,* and *E. woodruffi*). These species have a 9 type 1 fronto-ventral cirrus pattern like *E. aediculatus,* the bearer of *omikron,* and are considered to be closely related. The symbionts may differ from *P. necessarius* in size, shape, and other features, but they always share with *P. necessarius* the characteristic of multiple nucleoids (Heckmann et al., 1983). Symbionts of this type, but about twice as large as *P. necessarius,* were first noticed by Fauré-Fremiet (1952) in stocks of *E. patella* and *E. eurystomus.* He also observed at that time that small doses of penicillin led to a loss of symbionts and to death of the host ciliates. He therefore suggested that the symbionts might be essential for survival of the ciliate. This was later confirmed when Heckmann et al. (1983) subjected a large number of stocks of *Euplotes* species with a 9 type 1 cirrus pattern to a penicillin treatment of the kind that had earlier been found to remove *P. necessarius.* They found that all the ciliates stopped dividing and eventually died when their symbionts were removed. Heckmann et al. (1986) suggest that all *Euplotes* species with a 9 type 1 cirrus pattern suffer from a common deficiency that arose in a common ancestor of this group of organisms. This ancestor must have lived in symbiosis with a prokaryote that compensated for the acquired deficiency. *P. necessarius* and the *omikron*-like symbionts are considered to be progeny of this prokaryote.

THE *EPSILON* SYMBIONTS OF *EUPLOTES.* The *epsilon* symbionts from killer strains K_1, K_3, and K_7 of *E. minuta,* collected from the Mediterranean Sea at Villefranche-sur-Mer (France), were described by Heckmann et al. (1967). They are small rods, about 0.4 μm in diameter and 0.8–2.5 μm long, when observed in freshly crushed cells with bright phase optics, and appear somewhat darker than free-living bacteria. When the killer strain K_3 was fixed in Schaudinn's fluid, hydrolyzed in 1 N HCl, and stained with basic fuchsin as described by Dippell and Chao (in Sonneborn, 1950), several dozen darkly stained bodies were found scattered in the cytoplasm. Their staining properties, size, shape, and cellular distribution resembled that of *Caedibacter* species and other endosymbionts of *Paramecium.* Since *epsilon* particles were found only in killer strains, it is assumed that they are responsible for the killer phenotype of *E. minuta.*

Siegel and Heckmann (1966) noticed that certain strains of *E. minuta* killed certain other strains of this species when conjugation occurred. It was found that the sensitive cells formed vacuoles, ceased their normal swimming movements, settled to the bottom of the culture vessel, and finally lysed. These changes occurred within 1 to 4 days after the strains had been mixed. No evidence for killing was observed when cells of the three killer strains were mixed together.

A good example of the difficulties encountered in the identification of endosymbionts is provided by the killer particles of stock VF_{17} of *E. minuta.* Heckmann et al. (1967) had noticed that this strain caused symptoms in sensitives slightly different from those observed in mixtures with the other *E. minuta* killers. Here, vacuole coalescence generally proceeded to the point where only one large vacuole was present in the posterior region of the sensitive, giving the whole affected organism a pear-shaped form. Nevertheless, no morphological differences between these symbionts and *epsilon* particles could be detected. Later, when stock VF_{17} was employed for cross-breeding experiments in a study of the genetic control of cortical pattern in *E. minuta* (Heckmann and Frankel, 1968), it was found that this stock not only killed sensitive strains via particles liberated into the medium, but that it also acted as a mate-killer. From a pair of conjugants, one generally developed into a healthy looking exconjugant, whereas the other one failed to develop a large macronuclear anlage, became quiescent, and finally died. The surviving exconjugant clones had the same cortical pattern as stock VF_{17} and were all found to act as killers. They were therefore cytoplasmic descendents of the mate-killer parent. That they were true hybrids, i.e., that they had received a gametic nucleus from the sensitive partner, was shown from presence of certain genetic markers followed in these crosses. Whether VF_{17} was host to a mixed population of symbionts—with one type responsible for the killer trait and the other one for the mate-killer trait, both types being so similar that they could not be distinguished morphologically from each other, or whether a single class of particles present in VF_{17} determined both traits—cannot be decided. Both the killer trait

and the mate-killer trait were lost concurrently with aging of the stock (Frankel, 1973).

THE *ETA* SYMBIONT OF *EUPLOTES*. The *eta* symbiont, which can be observed only by electron microscopy, is round or oval shaped with an average diameter of 0.9 μm. It is bound by three juxtaposed membranes. The outermost membrane has ribosomes attached to it. The interior of the symbiont is granular with a few scattered fibrous strands (Rosati and Verni, 1977). The symbiont was found in strains of *E. crassus* collected by Luporini (1974) from a site on the coast of Somalia on the Indian Ocean. It was named *eta* by Nobili et al. (1976), who investigated the killer trait conferred on its host by this symbiont. Sensitive testers, when exposed to the culture fluid of killer strains or to a homogenate prepared from cells of these lines, develop a large vacuole in the posterior part of the body within 6 to 24 hours. Affected cells are gradually transformed into transparent spheres that eventually "explode."

THE B_1 SYMBIONT OF *EUPLOTES*. A symbiont very similar in morphology to *eta* appears to be responsible for the mate-killer properties of strain C_8 of *E. crassus* (Dini and Luporini, 1976); it was named B_1. When cells of this strain were treated with penicillin, both the mate-killer trait and the symbiont disappeared. Dini and Luporini (1982) provided evidence for the existence of specific host genes required for maintenance of the B_1 particles.

INCONSPICUOUS SYMBIONTS OF *EUPLOTES*. The other symbionts of *Euplotes* listed in Table 1 (A, B_3, C, D, and the unnamed ones) have been discovered by chance during electron microscopic investigations of certain strains. No special functions of these symbionts are known, nor have any effects of the symbionts on their hosts been reported.

The Xenosomes of *Parauronema acutum*

The term xenosome was coined by Soldo to denote the infectious particles that he found in the cytoplasm of the marine ciliate *Parauronema acutum* (Soldo et al., 1974). They were later shown to be small bacteria that possess multicopy genomes and resemble *Caedibacter taeniospiralis (kappa)* and other cytoplasmic symbionts of *Paramecium* in many respects. Two types of xenosomes are distinguished at the present time: killer xenosomes, which inhibit growth when taken up by susceptible ciliates, especially those of the genus *Uronema* (Soldo and Brickson, 1978); and non-killer xenosomes (Soldo et al., 1987). The xenosomes have not yet received binomial names.

Habitat

Parauronema acutum is a small hymenostome marine ciliate that can be maintained axenically. The culture medium is basically that developed for species of the *Paramecium aurelia* complex by Soldo and Van Wagtendonk (1969), distilled water being replaced by seawater (density 1.015–1.026 g/ml) and modified to contain 500 μg/ml asolectin as the sole source of lipid (Soldo et al., 1974). The association with xenosomes is stable. Symbiont-bearing strains have now been maintained for more than 15 years.

Xenosomes released from host cells are capable of infecting symbiont-free strains of *P. acutum.* A single xenosome is capable of infecting a susceptible animal. However, a "threshold" of 100–200 xenosomes appears to be required before a single xenosome can infect a potential host (Soldo, 1983)

Soldo and co-workers measured the oxygen consumption of purified xenosome preparations and reported a rate of oxygen uptake of 1.3 nmoles O_2/min/mg protein, which is higher than the oxygen uptake of *Bdellovibrio* and of the same order of magnitude as that of rickettsiae and *Caedibacter taeniospiralis.* It is about 20 times lower than that of *E. coli.* The rate of oxygen consumption was found to be stimulated by various fatty acids, by intermediates of the glycolytic pathway, and by intermediates of the citrate cycle with the exception of citrate itself, which had no effect. Cyanide was found to be a potent inhibitor of oxygen consumption of xenosomes (Soldo, 1983).

Isolation

Xenosomes can be isolated from *Parouronema acutum* by the same procedures as those used for the isolation of *Paramecium*-symbionts (Soldo and Godoy, 1974). It has been shown that killer xenosomes isolated in this way and purified with the help of Percoll gradients retain their ability to infect *P. acutum* and remain capable of killing sensitive *Uronema* strains (Soldo et al., 1986a). Results obtained from experiments in which isolated killer xenosomes lost their capacity to kill after they had been treated with various enzymes or had been coated with antibodies directed against the xenosomes, indicate that the toxic principles of

the xenosomes is a protein present at or near the surface (Soldo, 1987).

Identification

Rod-shaped, Gram-negative bacteria, 0.3 μm in diameter and 0.8 μm long. The GC content is 33.9 mol%. The symbionts occur in the cytoplasm of the marine ciliate *Parauronema acutum* in numbers ranging from 50 to 300 per cell. Negative staining reveals the presence of flagella, which provide the symbionts with a spinning and darting motility when released from the host (Soldo, 1987). The xenosomes were found to contain inclusions in the form of helical arrays. These structures (called H bodies) are about 0.6 μm long and 0.026 μm wide. They occur singly and in multiples and extend almost the entire length of the symbiont. H bodies were found in over 50% of killer- and nonkiller xenosomes (Soldo et al., 1987).

The genome size of xenosomes was found to be only 515 kbp, which is much smaller than that of free-living bacteria. Analytical measurements and data from sedimentation-rate analyses led to the conclusion that the chromosomal DNA exists in the form of nine circularly permuted double-stranded DNA molecules, each about 515 kbp in length (Soldo et al., 1983). Both the small size and the multicopy nature of the genome are typical of bacterial symbionts rather than for freeliving bacteria (Soldo and Godoy, 1973b; Soldo, 1987).

Killer and nonkiller xenosomes both contain plasmids (Soldo et al., 1986b; Soldo, 1987). The nonkiller plasmids consist of two circular DNA duplexes, each 63 kbp in length. The killer plasmid consists of four circular 63-kbp DNA duplexes. When a ciliate which previously harbored killer xenosomes but had been freed of them, is infected with nonkiller xenosomes, it becomes a killer. Soldo et al. (1986b) report that together with this transformation the restriction pattern of the extrachromosomal DNA is altered. The mechanism by which this transformation takes place is unknown.

Prokaryotic Symbionts of Ciliates from Anaerobic Environments

Ciliates living in an anaerobic habitat, such as the rumen or sewage sludge rich in hydrogen sulfide, show special adaptations. They usually lack mitochondria, bear hydrogenosomes, and are often associated with methanogenic bacteria (Stumm and Vogels, 1989). It has been shown that anaerobic ciliates generate their energy by converting carbohydrates to lactate, acetate, and butyrate and that they can remove reducing equivalents in the form of H_2 (Müller, 1988). Production of H_2 by proton reduction involves the enzyme hydrogenase. However, this enzyme functions well only if the concentration of H_2 is kept low ($<10^{-5}$ atm). This requirement is apparently achieved by methanogenic bacteria, which consume H_2 and tend to be abundant in these habitats.

Habitat

An episymbiotic association with methanogenic bacteria was described for 11 species of rumen ciliates of the family Ophryoscolicidae (Vogels et al., 1980). The attached bacteria were rods 0.9–3.8 μm long and 0.6–0.7 μm wide that occurred as clusters or long chains. They were identified as methanogens (probably *Methanobrevibacter ruminantium*) on the basis of specific fluorescent coenzymes (F_{350} and F_{420}). Experiments with a fistulated sheep revealed a decrease of the association frequency of methanogenic bacteria with rumen ciliates when the hydrogen concentration in the rumen fluid increased and the reverse when hydrogen became scarce (Stumm et al., 1982). This is interpreted in favor of an interspecies transfer of hydrogen. The finding that rumen ciliates have hydrogenosomes, showing strong hydrogenase activity, supports this view (Yarlett et al., 1981). Stumm and Vogels (1989) propose that the attachment of hydrogen-consuming methanogens to rumen ciliates facilitates hydrogen removal, which is advantageous to both the ciliates and to their episymbionts.

Episymbiotic bacteria have been known from sand-dwelling ciliates for many years (Sauerbrey, 1928; Kahl, 1933, 1935; Fauré-Fremiet, 1950a, 1951). They are firmly attached to the cell surface and appear to differ in size, shape, pigmentation, and wall structure from species to species (Fenchel et al., 1977). Fauré-Fremiet (1950b) carried out a unique study of the symbionts of two species of the genus *Kentrophoros* (formerly *Centrophorella*). He investigated their symbionts and found them to be attached to the nonciliated dorsal side of these ribbon-shaped ciliates. The oblong symbionts were densely packed and protruded perpendicularly, so that they appeared like bristles of a brush. They were Gram-negative, nonmotile rods, and were observed to divide by longitudinal fission. Besides containing rather large quantities of polysaccharides, indicated by iodine treatment, they contained dark-refractive sulfur globules, so that the host appeared black. The dark pigmentation is a strong indication that the symbionts are purple sulfur bacteria (Chroma-

tiaceae). Fauré-Fremiet, who found the symbionts exclusively on the ciliates and neither on accompanying sand grains nor on glass slides that had been in the sand in which these ciliates live for several days, considered the symbionts as obligatorily epizoic. Electron microscope studies by Raikov (1971, 1974) confirmed Fauré-Fremiet's observations and led to the discovery that the epizoic bacteria are phagocytized. He studied *Kentrophoros fistulosum* and *K. latum* and found that these ciliates take up the epizoic bacteria by pseudopodia-like cytoplasmic protrusions and enclose them in food vacuoles. This may occur at any place on the nonciliated body side of these ciliates, which have no special mouth structures. The unique form of phagocytosis discovered in these species has been named "random phagocytosis." Based on the content of the food vacuole of these ciliates, their epizoic bacteria appear to be their main nutrition source. 14 *Kentrophoros* species are now known. They all live in the interstices of sandy marine sediments.

Fenchel et al. (1977) examined marine-sediment-dwelling ciliates for cytochrome oxidase activity and for fine-structural details. They found that many of the ciliates of this habitat lacked cytochrome oxidase activity and mitochondria but contained microbodies (membrane-bound organelles, spherical or irregular in shape, 1–2 μm in length, with a homogeneous granular matrix). In addition, these ciliates harbored a species-specific flora of epi- and endosymbiotic bacteria. Large numbers of symbionts per cell were observed, ranging from about 1,000 bacteria per ciliate, corresponding to less than 1% of the host's biomass, to about 100,000 bacteria per ciliate, corresponding to about 20% of the ciliate's biomass. Some of these anaerobic ciliates were found to contain both epi- and endosymbionts, and often more than one type of episymbiont was recognized. Fenchel et al. (1977) hypothesized that the bacteria and the ciliates interact metabolically. This, however, has not yet been investigated. Anaerobic conditions also exist in sediments that are rich in decaying plant material, such as those of freshwater ponds, lakes, ditches, and swamps. This habitat was named "die sapropelische Lebewelt" (life in the sapropel) by Lauterborn (1901). Endosymbiotic bacteria in sapropelic ciliates were first described by Fauré-Fremiet (1909). Later, Liebmann (1937, 1938) noted that all the sapropelic ciliates that he investigated contained rod-like bacteria in their cytoplasm. In recent years, this habitat was thoroughly investigated by a group of Dutch microbiologists (Stumm and Vogels, 1989), and it is now, next to the rumen, the best-studied anaerobic habitat. It is inhabited by large numbers of anaerobic protozoa and methanogenic bacteria. A survey of sapropelic ciliates by means of fluorescent microscopy revealed the presence of methanogenic bacteria inside the cells; they were spread throughout the cytoplasm in considerable quantities (Van Bruggen et al., 1983).

Electron microscopic investigations of sapropelic ciliates revealed the absence of mitochondria and the presence of microbodies. In *Metopus striatus,* a Gram-positive rod-shaped bacterium was regularly found to be in close association with a microbody consisting of a granular matrix surrounded by a membrane (Van Bruggen et al., 1984). The bacterium was isolated and identified as *Methanobacterium formicicum.* A similar or even closer association of microbodies and methanogenic bacteria is reported for *Metopus contortus* (Van Bruggen et al., 1986) and for *Plagiopyla nasuta* (Goosen et al., 1988). Because the methanogens isolated from sapropelic ciliates were found to consume hydrogen it has been hypothesized that the symbiont-associated microbodies are hydrogenosomes (Van Bruggen et al., 1986). A direct proof was recently provided by Zwart et al. (1988) who demonstrated hydrogenase activity in microbodies of *Plagiopyla nasuta* and *Trimyema compressum.*

Isolation

For enrichment and culture of sapropelic ciliates, samples from anoxic natural sediments are introduced into mineral media under reducing conditions. Two media which have successfully been used for this purpose are given by Wagener and Pfennig (1987). They also report the first monoxenic large-scale culture of an anaerobic ciliate. They enriched *Trimyema compressum* from anoxic mud samples and then established a pure culture. The ciliate was fed with a bacterial strain isolated from the enrichment culture that proved capable of serving as food. During continued cultivation, *T. compressum* gradually lost its endosymbionts.

An isolation method for methanogenic bacteria from sapropelic ciliates has been described by Van Bruggen et al. (1986): a small number of ciliates is collected with a pipette and is washed free of potential contaminants in an isolation medium under a dissection microscope. The microscope is covered with a plastic hood flushed with nitrogen. The ciliates are then homogenized in an anaerobic glove box. The homogenate with the symbionts is plated on solid isolation medium containing penicillin G or lysozyme, which do not effect methanogenic bacteria. The homogenate is incubated at 22 to

37°C under an atmosphere of H_2/CO_2 (80:20). In liquid media, growth can be followed by measuring the methane production.

Identification

The symbionts of several sapropelic ciliates have been identified as methanogenic bacteria. The endosymbionts of species of the ciliate *Metopus* (Fig. 11) were first recognized to be methanogens by their autofluorescence when irradiated with short-wavelength blue light (Van Bruggen et al., 1983; 1986). According to Doddema and Vogels (1978), epifluorescence microscopy can detect the presence of the deazaflavin coenzyme F_{420} and the pterin compound F_{342} both of which are specific for methanogens. The methanogenic character of the endosymbionts has subsequently been proven by studies of the isolated symbionts and measurements of their methane production in situ. The symbionts were finally identified as *Methanobacterium formicicum* (Van Bruggen et al., 1984). The methanogenic symbionts of *Plagiopyla nasuta* were also identified as *M. formicicum* (Goosen et al., 1988). This is a bacterium that often occurs in sapropelic habitats; it is a slender, nonmotile rod, with a diameter of 0.4 μm and a length of 2–7 μm. It was identified by colony form, cell morphology, temperature and pH optimum, substrate specificity, DNA base composition, and type of coenzyme F_{420}. It appears likely that *M. formicicum* is preadapted for endosymbiosis, because symbiont-free lines of the ciliate *Trimyema compressum* could also successfully be infected with this bacterium (Wagener et al., 1990).

Methanoplanus endosymbiosus was isolated from the marine ciliate *Metopus contortus* (Van Bruggen et al., 1986). In liquid media the isolated bacteria were irregular, nonmotile, nonsporeforming discs with a diameter of 1.6–3.4 μm. In a side view, they appeared as rods that were sometimes branched. The symbionts were osmotically fragile and lysed immediately when suspended in water. Growth and methanogenesis were observed with H_2/CO_2 or formate as substrates, with generation times of 7 or 12 h, respectively. The temperature range from growth was between 16 and 36°C with an optimum at 32°C. The optimal pH range for growth was 6.8–7.3. Tungsten and NaCl at a concentration of 0.25 M were required for optimal growth. The GC content of the DNA is 38.7 mol%.

For detecting methanogenic endosymbionts, epifluorescence microscopy proved to be a pow-

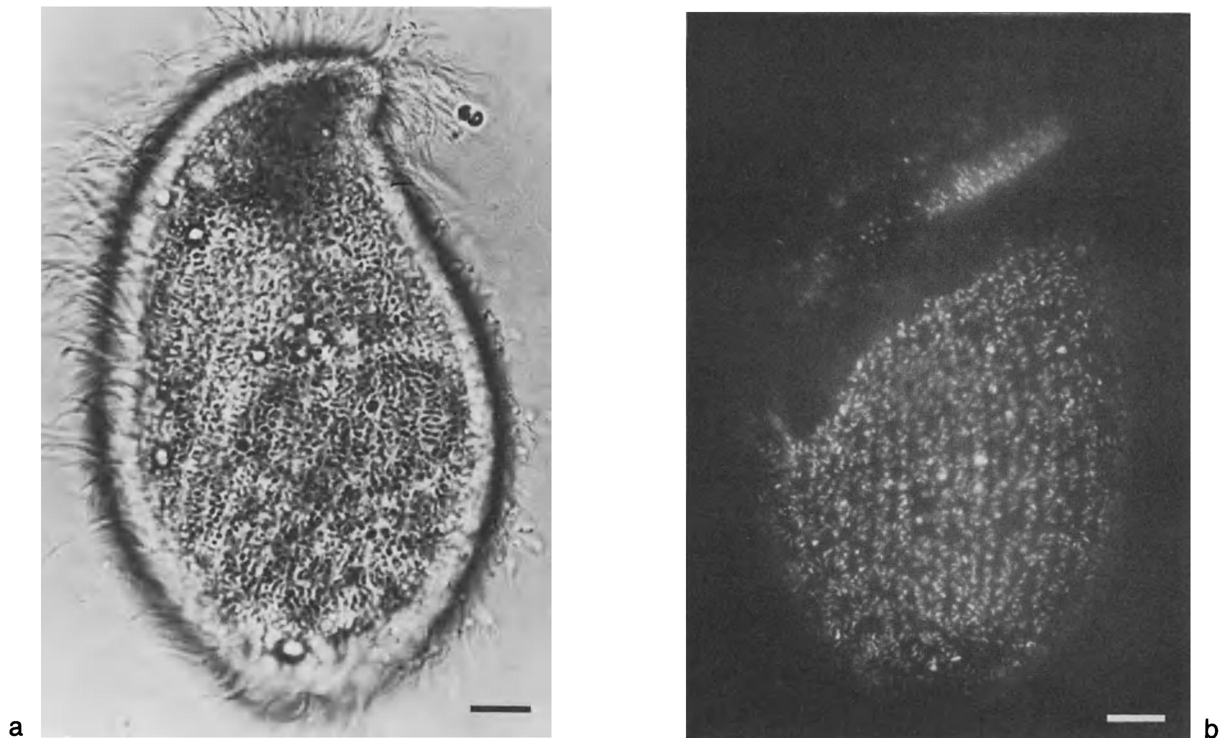

Fig. 11. *Metopus contortus* containing methanogenic endosymbionts. The methanogenic bacteria are located parallel to the kineties (ciliary rows) or the inner side of the cell. Cell fixed with 1.2% formaldehyde and 0.3% glutaraldehyde. (a) Bright field micrograph. (b) Epifluorescence micrograph. Bars = 10 μm. (From Van Bruggen et al., 1986.)

erful method. Even when symbionts are inside cells their blue autofluorescence may be visible. Endosymbionts that fluresce have been observed in the sapropelic ciliates *Bachonella spiralis, Caenomorpha medusula, C. universalis, Lacrymaria cucumis, Metopus es,* and *M. laminarius* (Van Bruggen et al., 1983). They have not been found in ciliates from aerobic habitats.

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft for support of those portions of our work which are reported in this article. The constructive comments of Drs. G. Beale, H.-W. Kuhlmann, K. Müller, L. B. Preer, and H. J. Schmidt are gratefully acknowledged.

CHAPTER 215

Prokaryotic Symbionts of Marine Invertebrates

HORST FELBECK and DANIEL L. DISTEL

The symbiosis of prokaryotic organisms with eukaryotic taxa is a widespread phenomenon that has had profound impact on the physiology, ecology, and evolution of the host organisms. Although these symbioses range from relatively loose coexistence to highly interdependent intracellular associations, in this chapter we will mainly discuss symbionts and symbioses of the latter type, as exemplified by the symbiotic associations of chemoautotrophic bacteria with marine invertebrates. We will also discuss the symbioses of methane-oxidizing bacteria with marine invertebrates and the symbioses of cellulolytic/nitrogen-fixing bacteria with wood-boring marine bivalves (shipworms).

Little is yet known about these symbionts, largely because, except for the symbionts of the shipworms, it has not yet been possible to grow these organisms in pure culture. Therefore, much of what is known about these symbionts comes from studies of the physiology of the intact symbioses. In the following pages we will review what is known about these symbionts based on these studies and on studies of purified symbionts and of purified symbiont macromolecules.

The discovery of the symbiosis between chemoautotrophic bacteria and marine invertebrates was made in conjunction with the discovery of the deep-sea hydrothermal vents (Cavanaugh et al., 1981; Felbeck, 1981). The hydrothermal vents are underwater hot springs that occur near zones of sea floor spreading (Jannasch and Mottl, 1985). In these geologically active zones, the earth's crust is relatively thin. Seawater seeps into the thin crust, is heated by magma beneath the ocean floor, and is ejected again through cracks and fissures in the bottom. During its contact with the hot rocks, the chemical composition of the seawater is radically changed; the water absorbs many minerals and some of its sulfate is reduced to sulfide.

Unlike most deep-sea environments, which are only sparsely populated, some hydrothermal vents are surrounded by large and densely populated animal communities. These communities contain a large variety of invertebrates, including vestimentiferan tubeworms, clams, and mussels. The presence of these large animal populations was extremely puzzling at first because of the absence of any obvious food source for these communities. Soon, however, it was found that bacteria play a primary role in supporting these animal populations (Cavanaugh et al., 1981; Felbeck, 1981). Unlike all previously described communities that obtain their energy directly or indirectly from the sun via photosynthesis, the vent communities are based on bacterial chemosynthesis fueled by sulfide arising from the geothermal reduction of sulfate (Jannasch, 1985). Sulfide from the vent effluent serves as a rich source of energy and reducing power, making possible an abundant growth of free-living chemoautotrophic bacteria. In addition to these free-living chemoautotrophic bacteria, it has also been found that many of the animals in these communities contain chemoautotrophs as endosymbionts within their tissues. These endosymbionts form a potentially important food source for the invertebrate hosts. The complete absence of a digestive tract in the adult vestimentiferans and the greatly reduced digestive systems of the vent bivalves are strong indications that these eukaryotic hosts rely heavily on their endosymbionts to provide them with the energy and nutrients that they require for growth. Therefore, both in terms of ecology and physiology, these vent communities represent a significant departure from previously described environments.

Similar symbioses have also been found in many other animal species, including annelids, pogonophorans, bivalves, and gastropods. The morphology of these symbioses varies widely, as might be expected from the divergent phylogenetic origins of these hosts. A common characteristic, however, is that in these hosts the digestive system is typically absent or reduced in function. The environments that support

these symbioses are also quite varied, both in terms of their geographic location and ecological features. All these environments seem to share some common features, however, including the presence of a redox boundary where a source of reduced sulfur compounds may be found in close proximity to a source of oxygen. Sewage outfalls, eelgrass beds, mangrove swamps, and hypoxic ocean basins are some of the environments that support these symbioses (Felbeck and Somero, 1983; Jannasch and Nelson, 1984; Southward, 1987).

In addition to the sulfur-based chemoautotrophic (thiotrophic) symbioses discussed above, two additional types of symbioses with marine invertebrates have been recently described. The first are the symbioses involving methylotrophic bacteria. These resemble the thiotrophic symbioses, except that the source of energy is a reduced single-carbon compound. This type of symbiosis has been found primarily in areas such as marine hydrocarbon or hypersaline seeps (Cavanaugh et al., 1987; Childress et al., 1986; Fisher et al., 1987). The third type of symbiosis that we will discuss is the symbiosis with cellulolytic/nitrogen-fixing bacteria found in the wood-boring clams of the family Teredinidae. These symbionts allow their hosts to subsist on a diet of wood, using cellulose as their sole carbon source (Gallager et al., 1981; Waterbury et al., 1983). The common feature connecting these symbioses is that, in each case, the eukaryotic host is able to utilize new energy and carbon sources by harnessing the remarkable metabolic flexibility of prokaryotic cells.

Few generalizations can be made concerning these symbionts themselves, partly because these symbionts are diverse in function, and partly because we know very little about these organisms. In the same way as the host organisms have been classified according to their differing modes of nutrition, the symbionts themselves can also be crudely categorized by nutritional modes. These are the thiotrophic, methylotrophic, and cellulolytic/nitrogen-fixing modes. All of the "trophic" endosymbionts so far examined have cell wall structures typical of Gram-negative bacteria. These symbionts range in size and shape from 0.3–0.75μm spheres in *Bathymodiolus thermophilus* (Fiala-Medioni et al., 1986) to extremely large pleomorphic rods of greater than 5 μm in width and 10 μm in length in *Lucinoma annulata* (Distel and Felbeck, 1987). Membrane-bound sulfur inclusions in the periplasmic space, similar in structure and appearance to those seen in *Beggiatoa* and *Thiovulum* species, are frequently observed in the thiotrophic symbionts (Vetter, 1985). The cytoplasm of the sulfur-oxidizing symbionts is typically described as granular in appearance. This granular nature has been ascribed by various authors to the presence of either carboxysomes, ribosomes, or glycogen granules, but the true nature of these granules is yet to be resolved. The methylotrophic symbionts range from cocci of 0.75–2.0 μm in diameter in Florida escarpment mytilids (Cavanaugh et al., 1987) to rods of approximately 1×2 μm in *Siboglinum poseidoni* (Schmaljohann and Flügel, 1987). Stacked internal membranes similar to those seen in type I methylotrophic bacteria (see Chapter 118) are a typical distinguishing feature of the methylotrophic symbionts (Childress et al., 1986; Schmaljohann and Flügel, 1987). A proposed second symbiont lacking these internal membranes has been reported in the Florida escarpment mytilid by Cavanaugh et al. (1987). The cellulolytic/nitrogen-fixing symbionts of the teredinid bivalves are vibrioid rods approximately 0.4–0.6 $\times$ 3–6 μm (Waterbury et al., 1983), typically containing phase-dark material at the apical regions. These symbionts have no flagella when observed in tissue, but when grown in liquid culture they are motile by a single polar unsheathed flagellum. Those symbionts whose phylogeny has been examined (some sulfur oxidizers and the cellulolytic/nitrogen fixer) fall into the gamma subdivision of the protebacteria (see "Characterization Without Pure Culture" in this chapter). The phylogenetic position of the methane oxidizers remains to be elucidated. Only one of these symbionts (the cellulolytic/nitrogen fixer) has been grown in pure culture and has been characterized in considerable detail. Other symbionts have been characterized primarily by their presumed function in the intact symbiotic systems as evidenced by the presence of unique enzyme activities, by examination of symbiont cells purified from host tissue by mechanical means, and by light and electron microscopy of sectioned host tissue.

Because so much of what we know about these symbionts comes from studying the environment where the symbionts live, i.e., the host organisms, we will begin our detailed discussion by describing the intact symbioses. With this as a foundation, we will then move on to discuss the studies of the symbionts themselves.

Morphology of the Symbioses

In the vestimentiferans and pogonophorans, symbionts are a characteristic feature of all members of the phyla. They are embedded

within cells of a specialized tissue called the trophosome, which is the main tissue found in the trunk of the vestimentiferans (Jones, 1985). In vestimentiferans, the trophosome accounts for up to 16% of the animals' wet weight while the percentage is much lower in the pogonophorans, which have a very similar organ (Arp and Childress, 1983; Southward, 1982). The trophosome tissue of the vestimentiferans, which is taken as representative here, is composed of many lobules which are each about 0.15 mm in diameter and are heavily vascularized by the closed circulatory system typical for both of these phyla (Bosch and Grasse, 1984; Hand, 1987). Located in their center are the bacteriocytes containing the symbionts. These bacteria make up 15% to 35% of the volume of the entire trophosome (Powell and Somero, 1986). Within the lobules, as well as from the posterior to anterior end of the trophosome, the phenotype of the bacteria changes (de Burgh et al., 1989): the symbionts in the Vestimentifera range in size from 1 μm to 10 μm (de Burgh et al., 1989) and are very pleomorphic, while those in Pogonophora are typically rods 0.15 μm–0.3 μm thick and 2 μm–4.8 μm long (Southward, 1982). In both cases, they are usually surrounded by a host membrane including one or more bacteria. DeBurgh et al. (1989) describe numerous cytoplasmic inclusions inside of the symbionts of several vestimentiferan species, tubular membrane systems, glycogen-like particles, and poly-β-hydroxybutyrate (PHB) or sulfur bodies. One pogonophoran species, *Sclerolinum brattstromi,* has been described as containing symbionts that are not enclosed in a host membrane but are free in the cytoplasm.

The symbionts in several bivalve and a gastropod species can be found inside of specialized gill cells where they are in close contact with the surrounding seawater. The most detailed description is available for lucinid clams (see Figs. 1 and 2). Here, the bacteriocytes, or bacteria-containing cells, are arranged in tubular stacks whose centers form open cylinders that allow water to flow freely between the mantle cavity and the interlamellar space (Distel and Felbeck, 1987). The symbionts are found in vesicles completely surrounded by a host membrane. They are typically rod- to oval-shaped and rather large (2–5 μm wide and up to 10 μm long) but very pleomorphic. They have numerous inclusions of elemental sulfur in their periplasmic space. These sulfur granules account for up to 2.1% of the dry weight of the gill tissue. Between the bacteriocytes, intercalary cells are located whose thin extensions cover the surface of the bacteriocytes, thus forming the inner lining of the open cylinders

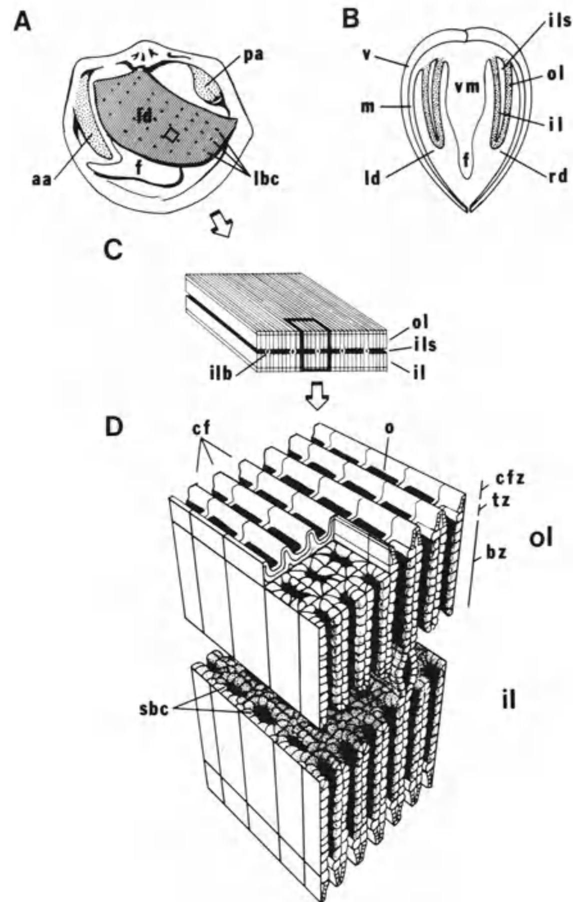

Fig. 1. Structure of the symbiont-containing tissue within the gill of a lucinid clam. (A) A clam (*Lucinoma aequizonata*) with the left valve removed. (B) A transverse section through the entire clam at the median point of the anterior-posterior axis. (From Distel and Felbeck, 1987.)

described above. The micromorphology of the gastropod gill is similar (Okutani and Ohta, 1988; Stein et al., 1988).

In the bivalve family Thyasiridae, the symbionts are apparently located between gill cells below the cuticle (Southward et al., 1986). However, other authors describe them as being intracellularly located inside of a large vacuole (Herry et al., 1989; Reid and Brand, 1986). Several different sizes of rod-shaped symbionts have been observed of 0.2–0.5 μm in diameter

and 0.5–2 μm in length, but usually there is only one phenotype in any host species. In two undescribed host species, two distinct and morphologically different symbionts could be detected, which may indicate that these associations are less selective than the intracellular symbioses described above.

Morphologically, the symbioses described in annelids are fundamentally different from the ones described so far. The bacteria are never intracellular but occur either between cells in many oligochaetes or attached to the outside epidermis as a bacterial lawn in some polychaetes. Oligochaetes with symbiotic bacteria have been described mainly in the tubificid subfamily Phallodrilinae. All of the species in two genera, *Inanidrilus* and *Olavius*, are described as having symbionts and being gutless (Erseus, 1984). The bacteria are located underneath the cuticle between irregular and long extensions of the epidermis cells. In *Inanidrilus* (formerly *Phallodrilus*) *leukodermatus*, the best-described oligochaete showing symbiosis, two different shapes of bacteria have been observed, an oval one measuring about 3.5 μm × 2.3 μm with a very "delicate" outer membrane, and a rod-shaped one of about 0.5 μm × 1.7 μm which has a multi-layered thick cell envelope. Both contain inclusions of elemental sulfur and PHB (Giere, 1985; Giere and Langheld, 1987).

Two polychaetes with external bacterial symbionts have been found at hydrothermal vents; both species, *Alvinella pompejana* and *A. caudata* are of the same genus. They usually are found on the outside walls of the chimneys formed by zinc sulfide precipitations from the vent waters in temperatures of up to about 40°C. The bacteria are associated in both cases with the polychaete epidermis. In both species, cluster-like bacterial/associations are located in intersegmentary spaces. The bacteria are rod-shaped, coccoid, or filamentous. In addition, individual bacteria (rod-shaped, prosthecate, spiral, curved, or unsheathed filamentous in appearance) are distributed over the entire animal tegument. In *A. pompejana*, filamentous bacteria are also associated with epidermic expansions, while in *A. caudata* similarly shaped bacteria can be found inserted on the posterior parapods (Desbruyeres et al., 1985; Gaill et al., 1988).

Ecophysiology of the Symbioses

When symbioses of chemoautotrophic bacteria with marine invertebrates were first discovered, all information about the physiology of the bacteria was limited to the activities of a few enzymes that were found in the tissues containing the bacteria: ribulose-bisphosphate carboxylase and ribulose 5-phosphate kinase (both characteristic enzymes of the Calvin cycle), and ATP sulfurylase, and adenosine phosphosulfate (APS) reductase (indicative of sulfur oxidation) (Felbeck, 1981; Felbeck et al., 1981; Southward et al., 1981). These enzymes are normally absent in animal tissues or are found in very small amounts only. Their presence was a strong indication that the bacteria were able to fix CO_2 through the Calvin cycle using energy from the metabolism of sulfur compounds. The abundance of sulfide and oxygen in the environment suggested that the major pathway for energy production was the oxidation of reduced sulfur. Aside from these enzymes involved in carbon and sulfur metabolism, nitrate reductase was detected in some symbiont-containing tissues.

Since then, these initial observations of symbiont physiology have been supported by many more results, such as the measurement of stable isotope ratios, incorporation studies with radiolabelled tracers, and physiological studies of the mechanisms of sulfur and carbon transport and metabolism.

Stable Isotope Ratios

Carbon, nitrogen, and sulfur exist in two or more stable isotopes in significant quantities in the natural environment. Their isotopic ratios are used to determine the source of an element in a biological system. The most widely used ratio is that of carbon ($^{13}C/^{12}C$). The natural abundance of the heavier carbon isotope is approximately 1.11%. When carbon dioxide is first incorporated into organic molecules by autotrophic organisms, the enzymes responsible for this action use the lighter carbon isotope preferentially. Ruby et al. (1987) clearly showed isotope fractionation in two cultures of sulfur-oxidizing bacteria. The degree of preference can provide information about the character of the initial carbon-fixation step. The carbon isotope ratio established in this step then changes only slightly during the further transfer of organic carbon within a food chain.

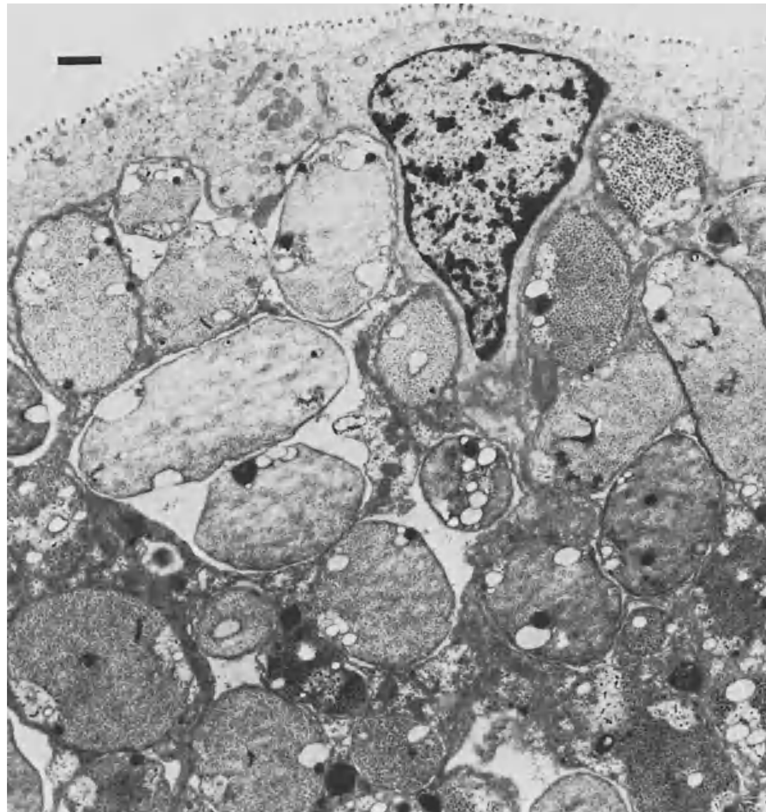
The carbon isotope ratio is usually expressed as a function of the ratio found in the fossil PeeDee belemnite (PDB) standard:

$$\delta^{13}C = \{[(^{13}C/^{12}C)\text{sample}/(^{13}C/^{12}C)\text{ standard}] - 1\} \times 10^3 \text{ (‰)}$$

A sample with a negative number, therefore, is enriched in ^{12}C relative to the PDB standard.

Generally, it has been suggested that an isotope ratio between about −12 to −24‰ indi-

Fig. 2. An electron micrograph of the bacteriocyte tissue in *Lucinoma aequizonata*. A microvilli-covered intercalary cell is visible at the top of the figure, with prominent nucleus and mitochondria. Beneath this cell, a portion of two bacteriocyte cells containing large oval- to rod-shaped symbionts is seen. Bar = 1.0 μm.



cates a photoautotrophic food source, while a value below this to approximately − 45‰ signals a chemoautotrophic source of carbon. When carbon isotope ratios even lower than − 45‰ are found, they are considered to indicate methanotrophy. All of these generalizations, however, have to be viewed carefully because there are many possible sources of error, e.g., if a carbon source is unusually enriched or depleted in one of the isotopes or if an organism is carbon limited the resulting carbon isotope ratios in an organism can be greatly altered.

Stable isotope ratios did, however, provide important clues about the nutritional strategies of the hosts of chemoautotrophic bacteria. The fact that the bacteria-containing tissues and host tissues had similar isotope ratios that were unlike any possible food source nearby indicated the dependence of the host on the symbionts (Rau, 1981a; Rau, 1981b; Rau, 1985). In addition, using carbon isotope ratios, one can also estimate what percentage of the body carbon is from each of two carbon sources whose isotope ratios are known. This calculation is important for those symbioses where the host animal still maintains a functional gut and can, therefore, supplement the carbon supplied by the symbionts by externally obtained food. This calculation has been done for the mud-dwelling clam *Lucinoma aequizonata:* it was assumed that the isotope ratio of carbon supplied by the bacteria stays the same after transfer to the clam and that the only other possible food source is dissolved organic matter in the surrounding mud. Using the measured isotope ratios of these two sources it was calculated that about 70% of the clam's carbon is provided by the symbionts (Cary et al., 1989). Similar studies have been done for the protobranch clam *Solemya velum,* where a bacterial contribution of 98% was estimated (Conway et al., 1989).

Similar investigations and arguments can also be made based on sulfur or nitrogen isotope ratios. In both cases, however, even larger errors than for carbon can arise during the interpretation of an isotope ratio in an animal, because the nitrogen ratio does not stay constant during heterotrophic processes, and the sulfur ratio can change widely due to a wide variability of the isotope ratios of the original sulfur sources for the symbioses. These facts make detailed predictions based on these ratios almost impossible.

Radioactive Tracer Studies

As mentioned earlier, it is generally assumed that the bacteria provide all or part of the host's

nutritional needs. There are two ways this could be accomplished, either as a result of continuous growth followed by digestion of the bacteria by the host, somewhat like an internal chemostat culture, or as a result of excretion of reduced carbon compounds by the bacterial symbionts, followed by incorporation into the host's metabolism.

Several ultrastructural studies have demonstrated that bacteria are indeed digested by their hosts. Bosch and Grasse (1984), deBurgh et al. (1985), and Hand (1987) found a series of degenerative stages of bacteria within the trophosome of the tubeworm *Riftia pachyptila* where, in a gradient from the periphery of the trophosome lobules towards their center, the symbionts degenerate progressively and form myelin-like bodies in the centers of the lobules. Similar observations of lysosomal digestion have been reported for the hydrothermal vent mussel *Bathymodiolus thermophilus* (Fiala-Medioni et al., 1986) and the vent clam *Calyptogena magnifica* (Fiala-Medioni et al., 1990). The quantitative significance of these observations is however unclear. If the bacterial contribution made by this process were significant, one would expect to see large numbers of dividing bacteria to replenish their stock. This, however, has not been observed to date, suggesting that the digestion of the symbionts may simply be due to "housekeeping", as has been proposed by deBurgh (1985) or it may be a way to provide some essential nutrients that cannot be synthesized solely from the excreted products of bacterial metabolism.

The most straightforward way to investigate possible transfer of metabolites between symbiotic partners is to observe the movement of labeled tracers between the partners. This technique has been used in case of the symbiosis with chemoautotrophic bacteria in a variety of studies. Initial studies with the gutless clam *Solemya reidi* and the tubeworm *Riftia pachyptila* (Felbeck, 1983; Felbeck and Somero, 1983) suffered from the lack of a suitable technique to separate the bacteria from host tissue. It was, therefore, difficult to separate the radioactive labeling patterns for metabolic pathways from host or symbiont. Since then, however, a technique has been developed by Distel and Felbeck (1988a) to purify the symbionts quickly from host tissue and to incubate them individually or to separate them quickly after an experiment before further processing of the tissues. This method could be used successfully for sulfur-oxidizing symbionts because these symbionts contain inclusions composed of elemental sulfur (sp. gr. 2.05–2.09), which increase their buoyant density. Thus, sulfur-oxidizing symbiont cells typically exceed 1.1 g/ml in density and can be separated from the less-dense host cells and cell constituents. Symbiont cells purified by this method remain physiologically active for several hours. Distel and Felbeck (1988b) found that purified bacteria from the clam *Lucinoma aequizonata* can incorporate radioactivity from external CO_2 into reduced organic compounds, mainly aspartate and malate.

Fisher and Childress (1986) demonstrated, using autoradiographic techniques, that the initially very high fraction of the fixed radioactivity incorporated into symbiont-containing tissues of the clam *Solemya reidi* decreased substantially after extended chase periods of up to 5 days. Concomitant to this decrease, an increase in labeling of symbiont-free tissues was noted, e.g., in mantle or foot tissue. Their results showed clearly that a translocation of fixed carbon takes place between the bacteria and the host but they cannot distinguish between a translocation through transfer of low-molecular-weight organic material or a lysis of the bacteria. Again, however, it is very difficult to estimate the quantitative importance from these data. Their published value of 45% of the carbon originating from the bacteria can at best be viewed as a rough estimate, because of the large margins of error in the data used for the calculation. Recently, however, it was shown by Anderson et al. (1987) that *Solemya reidi* has the ability for net CO_2 uptake from the environment. Under certain environmental conditions, the concentration of CO_2 in the environment decreased, proving that the clams fixed more carbon from CO_2 than was released due to the sum of all other metabolic processes. This result again supports the conclusion that symbiotic bacteria enable this gutless clam to live by fixing inorganic carbon from the surrounding seawater.

Data on the metabolic interactions of annelid symbioses are relatively scarce. Studies with the symbiont-containing oligochaetes were hampered by the small size of the animals (150 μm thick and about 1 cm long) because they had to be collected individually. Felbeck et al. (1982) demonstrated that this animal/bacteria symbiosis was probably chemoautotrophic and sulfur oxidizing. Results of experiments using radiolabeled CO_2 showed an incorporation of label into organic acids and sugar phosphates. Also, Giere et al. (1988) found an increase in the CO_2 fixation rate of these animals when thiosulfate was added to the incubation medium, suggesting that this sulfur species may be a substrate for the bacteria.

The main problem with experiments using the two polychaete *Alvinella* species is that no method has yet been found to keep them alive after they are removed from their habitat at 2,500 m depth. Thus, experimentation has been restricted to in situ studies and observations on tissues. The characteristic enzyme of the Calvin cycle, ribulose-bisphosphate carboxylase, has been detected in extracts of the episymbiotic bacteria, and incubations with radiolabeled CO_2 showed a significant incorporation in some of the bacterial species. Aside from this indication of autotrophy, however, studies on the uptake of labeled thymidine suggested the existence of facultative heterotrophy (Alayse-Danet et al., 1987). The nature of this symbiosis is not yet clearly understood. Some morphological features of the host appear to be specializations for metabolic interactions between the symbiotic partners, but comparisons of labeling patterns in the *Alvinella* species with a closely related species without symbionts showed no differences (Alayse-Danet et al., 1987).

Physiological Studies

Physiological studies can be used to demonstrate how the intracellular symbionts obtain nutrients and how their metabolism is stimulated by the condition of the external environment. Reduced sulfur compounds and oxygen must be transported to the bacteriocytes, and the symbionts' habitat must be tightly controlled to prevent excessive growth of this bacterial "culture." The bacterial symbionts of the various marine invertebrates are "housed" in several distinctive ways, and different mechanisms are utilized to create environments suitable for the bacteria. We will, therefore, discuss the various symbioses according to the host involved.

VESTIMENTIFERA AND POGONOPHORA. The symbioses in these tubeworms are fairly similar; in both cases, the bacteria are housed in a tissue inside of the worm's body, i.e., everything has to be transported to this organ via the closed circulatory system and the blood (Jones, 1988; Southward, 1982). This fact made the blood of these animals an early subject for investigation of transport mechanisms, especially for a way to carry sulfide from the environment to the "trophosome" (Arp and Childress, 1983). A complication of this transport is that sulfide is extremely poisonous to aerobic eukaryotic organisms because of the inhibition of cytochrome *c* oxidase, the terminal enzyme of the respiratory chain and due to the conversion of hemoglobin to sulfhemoglobin, which is unable to carry oxygen. Oxygen therefore, cannot simply be carried to the tissues in solution but has to be bound or otherwise detoxified to allow its transport through and contact with the host tissues. These animals are unique in that their hemoglobin is able to bind sulfide tightly without undergoing an irreversible chemical reaction, thus preventing its release into the host tissue (Arp and Childress, 1983). This binding is reversible, thus allowing transport from the outside medium to the symbionts. In addition, the blood is able to concentrate sulfide from nanomolar concentrations in the environment to millimolar levels (sum of bound and free sulfide) within the blood. The sulfide is very stable when bound to the freely dissolved hemoglobin in the blood, in contrast to the unbound form of sulfide, which is extremely reactive and is readily oxidized by oxygen. The binding site on the hemoglobin is on the nonheme portion of the molecule. It is not yet understood how the hemoglobin is triggered to release the sulfide again in the symbiont-containing organ, but it has been shown that sulfide is released in the presence of symbiotic bacteria.

This binding and transport mechanism also has several advantages for the bacterial symbionts. Fisher et al. (1988) demonstrated an inhibition of CO_2 fixation in crude symbiont preparations by sulfide concentrations of more than 100 μM, while lower concentrations increased the fixation rate. In the presence of blood, no inhibition of the fixation was observed until the blood-binding capacity was saturated with sulfide. At higher concentrations sulfide was again highly inhibitory. These results suggest that the blood acts as a buffer for sulfide providing a relatively constant controlled level in the immediate environment of the bacteria. The pool of sulfide is high due to the total bound sulfide in the blood but the concentration of free sulfide is in a favorable range for the bacteria.

BIVALVES. Only three bivalve species have been investigated for mechanisms by which suitable environments for their bacterial symbionts are maintained, *Calyptogena magnifica, Lucinoma aequizonata,* and the gutless clam *Solemya reidi.* All three differ from each other in important ways as to how they ensure sulfide, oxygen, and carbon dioxide supplies to the bacteria.

Calyptogena magnifica is found at hydrothermal vents, usually at greater distances from the vents than *Riftia pachyptila.* Frequently, these clams can be observed wedged into cracks in the sea floor where warm water with sulfide is emitted. It has been suggested that the animals concentrate sulfide through their foot,

which they extend deep into the fissures. This behavior enables them to gain direct access to the outflowing sulfide-laden water rather than having to concentrate sulfide from the surrounding water where much lower sulfide concentrations are present. A large fraction of the body weight of the bivalves is formed by blood containing hemoglobin within erythrocytes for oxygen transport. In addition, a large nonheme serum protein is present which is able to bind sulfide and may function as its transport protein. Unlike that of *Riftia pachyptila,* the hemoglobin of *C. magnifica* is easily poisoned by sulfide resulting in the formation of sulfhemoglobin and inability to bind oxygen. Due to the presence of the sulfide-binding protein a high affinity for sulfide, the clam's blood shows no indication of sulfhemoglobin in vivo. Since the bacteria in the gill cells live in close proximity to the environment, no elaborate transport mechanisms for any other substances appear to be necessary.

The bivalve *Lucinoma aequizonata* is collected in the Santa Barbara (CA) channel at a depth close to the interface of a hypoxic basin with the overlying oxygen rich waters. The habitat is unusual because the local oxygen concentrations are very low (<20μM) and almost no sulfide, either bound as metal sulfide or free, is detectable. The bacteria, however, appear to be sulfur oxidizers because they accumulate elemental sulfur in high concentrations. In addition, the clams have no apparent mechanism to concentrate sulfide. This puzzling situation may be explained by the presence of pockets of sulfidic mud in the proximity of the animal; the pockets may be accessible through the clam's long extendable foot (Cary et al., 1989). Sulfide toxicity is avoided in this case through the action of a sulfide oxidase capable of transforming sulfide to the much less toxic form of thiosulfate after sulfide enters the body. Thiosulfate levels in the blood have been observed to be two orders of magnitude higher than the environmental sulfide concentration, suggesting that this compound rather than sulfide may be an energy source for the bacteria rather than sulfide (Cary et al., 1989).

A similar mechanism to maintain a suitable environment for the symbiotic bacteria is used by the protobranch clam *Solemya reidi,* which has only been collected so far from areas around sewage outfalls and at the outflow of a paper mill. In contrast to the previous example, however, both environments are characterized by extremely high concentrations of sulfide (several millimolar). No sulfide-binding protein has been found in the animal. In parallel to the case of *Lucinoma aequizonata,* the sulfide is oxidized to thiosulfate by a sulfide oxidase in the host tissue and then used by the symbionts. Another unusual aspect of this symbiosis is that, in addition to the action of this enzyme, intact host mitochondria are able to oxidize sulfide to thiosulfate, thus producing ATP.

Solemya reidi is the bivalve that has been best investigated for the uptake of substances from the environment. Anderson et al. (1987) have studied in detail the net flux of sulfide, CO_2, and oxygen by live *Solemya reidi* under a variety of conditions. The presence of relatively low levels of sulfide (50–100 μM) or thiosulfate (250–350 μM) stimulated the net uptake of CO_2 from the incubation water, while higher concentrations of sulfide (250–500 μM) inhibited aerobic respiration and halted net CO_2 uptake. This latter phenomenon is most likely due to a partial poisoning of the aerobic metabolism of the host caused by a shortage of oxygen for sulfide detoxification.

Symbioses with Methane-Oxidizing and Cellulolytic Bacteria

Much less is known of the two other kinds of bacterial symbiosis found to date in the deep sea. Two bivalve species (closely related to the hydrothermal vent mussel *Bathymodiolus thermophilus* that has sulfur-oxidizing bacteria) and a pogonophoran species have been shown to contain methane-oxidizing bacteria.

As with the sulfur-oxidizing types, the methane-oxidizing symbionts of the bivalve species are incorporated in the gill cells and have a similar morphology, i.e., they are surrounded by a host membrane and are located in bacteriocyte cells at the surface of the gills. Fisher et al. (1987) describe one type of bacterium seen in the seep mussel, which is spherical and approximately 0.7 to 2.0 μm in diameter. It is characterized by many stacked intracellular membranes like those found in Type I methanotrophs. Cavanaugh et al. (1987) describe two different types of bacteria in a mussel from the Florida escarpment seeps, large coccoid-shaped or rod-shaped cells about 1.6 μm in diameter containing intracellular membrane stacks, and a small coccoid or rod-shaped type without internal membranes.

That these bacteria indeed oxidize methane in situ is shown by the presence of methanol dehydrogenase in cell extracts, a characteristic enzyme of the methylotrophic pathway, and by the incorporation and consumption of labeled CH_4. Cary et al. (1988) could also demonstrate that this mussel species from the Louisiana

coast was able to grow with methane as sole carbon and energy source. In addition, the stable isotope ratios found in both of the mussels were indicative of methane as a carbon source. The methane used in situ originates from several possible sources, and these sources differ in the two sites where the mussels have been found. In the oil fields off the coast of Louisiana, the methane originates mainly from thermogenic processes ($C^{13}/C^{12} > -45‰$), i.e., generated by geological processes, and biogenic sources ($C^{13}/C^{12} < -60‰$), i.e., generated by bacterial sources. For most of the specimens tested the value of C^{13}/C^{12} varied from −40 to −58‰, showing origin from both sources, but thermogenic origin predominated (see "Stable Isotope Ratios," this chapter) (Brooks et al., 1987). In contrast, the mussel found at the Florida escarpment site where brine seeps out of the sea floor uses mostly biogenic methane generated by bacteria in the surrounding muds (Cary et al., 1989).

Since methane is nontoxic, mechanisms like that in the sulfide-oxidizing symbioses to avoid poisoning are not necessary.

One species of pogonophoran tubeworm, *Siboglinum poseidoni* from the central Skagerak close to Denmark, has been shown to have methane-oxidizing symbionts in "trophosome" cells. The Gram-negative rod-shaped bacteria are 1–1.5 μm wide and 2.0–4.0 μm long. They contain numerous membrane stacks and lipid-like storage products. Methylotrophy could be demonstrated by the uptake, metabolism, and incorporation of radiolabeled methane (Schmaljohann, 1987; Schmaljohann and Flügel, 1987).

The third type of bacterial symbiosis with invertebrates covered in this chapter is the one found in several wood-boring bivalve species (shipworms) of the family Teredinidae. Using electron microscopy, Popham and Dickson (1973) observed bacteria in a region of the gills of these species referred to as the gland of Deshayes. The bacteria are Gram-negative vibrioid rods of about 0.4–0.6 μm × 3–6 μm and typically contain phase-dark material at the apical regions. These bacteria provide the enzyme for cellulose digestion, cellulase, and also the nitrogen-fixing enzyme, nitrogenase (Waterbury et al., 1983). In addition, Trytek and Allen (1980) demonstrated, using labeled glucose, that the bacteria synthesize some amino acids that may be essential for the host. These characteristics of the symbionts enable the shipworms to survive on a pure wood diet without any additional carbon or nitrogen source (Gallager et al., 1981).

Culture and Isolation of Bacterial Endosymbionts

To date, the bacteria involved in the symbioses described above have been identified primarily only by their association with the respective eukaryotic host species in which they are found, e.g., the symbionts of the tubeworm *Riftia pachyptila* have been known only as "Riftia symbionts." However, progress is being made toward identifying and studying these symbionts as organisms in their own right.

Before a prokaryotic endosymbiont species can be adequately identified and characterized, the symbiont cells (or informational macromolecules from the symbionts) must be separated from host cells. Two approaches have been successfully applied: the first is pure culture of the symbionts in vitro and the second is characterization of the symbionts or the symbiont's nucleic acid from the host cells and cell constituents after purification by mechanical means.

Pure culture of endosymbiotic bacteria is notoriously difficult. Lack of information relating to the intracellular environment of the symbionts, the evolutionary loss of functions essential for free-living existence, and insufficient knowledge of effective selection factors are some of the obstacles that hinder pure culture of endosymbionts. The most formidable difficulty, however, is the problem of demonstrating the authenticity of the putative symbiont strains once they have been isolated. Traditionally, serial dilution and the presence of diagnostic phenotypic traits have been the best lines of evidence available. Symbionts, which are typically present in the bacteriocyte tissues at densities of about 10^8 to 10^9 cells per gram (Cavanaugh, 1985), should be expected to be isolated consistently from dilutions of 10^{-6} or greater (assuming one symbiont cell in 100–1,000 remains viable after host cell disruption). Furthermore, the same strains would not be expected to be isolated from similar dilutions made from host tissues that do not contain symbionts or from water or sediment samples from the environment surrounding the host organism. The presence of the same phenotypic determinants in both the symbiont-containing tissues and in the cells of the putative symbiont isolates has also been presented as evidence to authenticate putative symbiont isolates. These include unique morphological traits and enzymes diagnostic of specific metabolic pathways. As we will point out below, each of these types of evidence has proven individually unreliable. Therefore, both types of data in concert should be considered

the minimum supportive evidence to demonstrate the authenticity of a putative symbiont isolate. More recently, direct lines of evidence have been employed to determine whether putative symbiont strains are genuine. The most successful of these has been the comparison of molecular sequences of rRNA and, still more recently, the hybridization of specific oligonucleotide probes to rRNA. Such direct evidence, when presented in concordance with traditional data, provides the most comprehensive means of determining if a given isolate is indeed a genuine symbiont species.

A number of bacterial strains have been isolated from homogenates of host bacteriocyte tissues. These hosts include *Riftia pachyptila* (Jannasch and Nelson, 1984), *Lucinoma borealis, Myrtea spinifera, Thyasira flexuosa, T. sarsi* (Wood and Kelly, 1989), *Siboglinum poseidoni* (Schmaljohann and Flügel, 1987), and several wood-boring clams from the family Teredinidae (Waterbury et al., 1983). Of these, only the latter isolates meet the minimum criteria for authenticity previously described.

In the case of *Riftia pachyptila,* Jannasch and Nelson (1984) report isolating from trophosome tissue five bacterial strains at dilutions greater than 10^{-5}. Of these strains, two showed growth enhancement with addition of sulfide, two with addition of thiosulfate, and one (the only isolate with similar morphology to the *R. pachyptila* trophosome symbiont) proved to be a hydrogen oxidizer. However, analysis of the 5S rRNA sequences of the *R. pachyptila* trophosome symbionts and these putative symbiont isolates has demonstrated that none of these isolates are closely related to the authentic trophosome symbiont (Jannasch and Nelson, 1984). Wood and Kelly (1989) have reported isolation of seven bacterial strains from the gills of four bivalve species including: *L. borealis* (family: Lucinidae), *T. flexuosa, T. sarsi,* and *M. spinifera* (family: Thyasiridae). Of the seven isolates, only one (from *L. borealis*) was autotrophic and capable of oxidizing thiosulfate, while the remaining six were methylotrophic. All four of these host species have been shown to contain ribulose-bisphosphate carboxylase (an enzyme diagnostic of autotrophic carbon fixation via the calvin cycle) in their gills. APS reductase has also been detected in all four hosts, and ATP sulfurylase has been found in all but *L. borealis.* This combination of enzymes is strongly indicative of sulfur-based chemoautotrophy. None of these host species have been shown to contain enzymes typical of methylotrophic metabolism in their bacteriocyte tissues.

Methylotrophic symbionts described to date have contained complex arrays of stacked internal membranes. Such membranes are lacking in the symbionts of these four species. Furthermore, serial dilution data are lacking for the isolates from these hosts. No evidence has been provided that these same strains could be consistently isolated from more than a single specimen at a given dilution or that these strains were *not* isolated from symbiont-free host tissues. In fact, a number of different bacterial strains were isolated from one host species when specimens were taken from different locations. Thus, although it is likely that these bacterial strains are associated with the host species in some way, there is currently no evidence to suggest that these isolates are actually the symbionts observed in the gills of these host species. In fact, enzymatic and morphological evidence suggests that they are not. Schmaljohann and Flügel (1987) have reported the isolation of a methylotrophic isolate from the small pogonophoran, *Siboglinum poseidoni.* Again, serial dilution evidence is lacking, but the authors have demonstrated that the host bacteriocyte tissue and intact host animals are capable of incorporating CH_4 and that both the isolate and the bacteria in the host tissue have similar complex membrane stacks and lipid storage deposits. Waterbury et al. (1983) have reported isolation of a single species of cellulolytic/nitrogen-fixing bacteria from gill homogenates from six species of teredinid bivalves. This bacterium could be repeatedly isolated from dilutions in excess of 10^{-7} from a number of different specimens of each species, and it has been shown that cellulase and nitrogenase activities coexist in both the host tissue and in the putative symbiont isolates. These enzyme activities are not known to occur in animal cells and have only rarely been seen to coexist in bacteria. Analysis of 16S rRNA sequences from four species from four morphologically diverse teredinid genera showed that these isolates were identical with respect to this molecular sequence, although the host specimens were taxonomically widely divergent and were collected from the coasts of Massachusetts, Florida, California, and Australia respectively (Distel, 1990). Specific oligonucleotide probes based on the 16S rRNA sequence determined from these putative symbiont isolates were demonstrated by dot-blot assay to hybridize with bulk rRNA purified from intact shipworm gills but not with rRNA purified from three bacterial species known by 16S rRNA sequence to be closely related to the shipworm isolate. Finally, this same oligonucleotide probe was shown to hybridize in situ with the ribosomal RNA of the symbionts within thin sections of host tissue but not with other tissues of the host animal (Distel, 1990).

The teredinid symbiont isolates are the only putative symbiont isolates discussed which we consider to be authenticated.

The shipworm symbiont has been placed in the new genus and species *Teredinibacter turnerae* (Waterbury et al., in preparation), and isolates have been characterized extensively in terms of substrate utilization and growth characteristics. Optimum conditions for growth of the symbionts in pure culture are between 30–35°C, pH 8.5, and NaCl concentrations of 0.3–0.4 M. The isolates are able to grow with cellulose as the sole source of reduced carbon, and with dinitrogen as the sole nitrogen source. The symbionts are microaerophilic. Growth does not occur in vigorously shaken cultures if combined nitrogen is not provided, apparently due to the poisoning of the nitrogenase by oxygen. Growth in liquid cultures is accompanied by a decline in the pH of the medium due to the excretion of substantial quantities of organic acids, including succinate and formic acid (Green and Freer, 1986).

Teredinibacter turnerae cells are Gram-negative curved rods that are motile by virtue of a single polar unsheathed flagellum. Flagella are expressed only in the cultured symbionts and are seen whether these cells are grown in liquid or on solid media. Flagella are apparently not expressed by cells within the host tissue. Analysis of 16S rRNA sequences places *Teredinibacter turnerae* in the gamma subdivision of the proteo bacteria. *Oceanospirillum linum* is among the species most closely related to *T. turnerae* although this relationship is relatively distant (Distel, 1990).

Characterization Without Pure Culture

A variety of methods have been used to attempt to identify and to characterize endosymbionts of marine invertebrates without growing them in pure culture. A prerequisite for these methods was the ability to concentrate or purify symbiont cells or symbiont nucleic acids from homogenates of symbiont-containing host tissues.

Belkin and Nelson (1985) used differential centrifugation to achieve a "partial fractionation" of the gills of *Bathymodiolus thermophilus.* A low-speed (3,000 × g) centrifugation was performed to remove large cellular debris from gill homogenates, followed by a high-speed centrifugation (15,000 × g) to pellet the symbiont cells. This resulted in a preparation that was enriched in symbiont cells. This was determined by the relative enrichment for rapidly renaturing DNA that was higher in GC content than was the genomic DNA from host tissues containing no symbionts. Gross incorporation of ^{14}C-labeled bicarbonate was also increased three-fold in this fraction in comparison to total gill homogenate. Gross incorporation of ^{14}C-labeled bicarbonate by these "bacterial" preparations occurred at a maximum rate at temperatures between 12–15°C. On this basis, the authors suggest that the symbionts of *B. thermophilus* are psychrophilic. Incorporation of ^{14}C-labeled bicarbonate occurred only under aerobic conditions in the symbiont-enriched preparations and ceased when samples were stripped of oxygen. Rates of carbon incorporation were not sensitive to pressures up to 250 atm. Thiosulfate but not sulfide was shown to stimulate carbon fixation in gill homogenate from *B. thermophilus.* No data, however, were presented for the "purified" symbiont preparation. These "purified" symbiont preparations were not examined for physical integrity of the symbiont cells nor for contamination by host cells and cell constituents. Also, the compounds, into which labeled carbon was incorporated, were not identified. Therefore, it cannot be concluded from these results that the incorporation observed was due to a pathway capable of net carbon fixation. In *Lucinoma aequizonata,* a considerable amount of labeled carbon is incorporated by both the host and symbiont cells via equilibrium exchange through pathways that are not capable of net carbon fixation (Distel and Felbeck, 1988b). Such pathways could easily account for all of the label uptake reported here. Finally, it should be noted that the thiosulfate stimulation reported here is based on a single data point. If this single measurement were erroneous, no trend would be seen in the data.

Distel and Felbeck (1988a) purified and separated the symbiont cells from host tissue by means of centrifugation through density gradients. This method is successful for sulfur-oxidizing symbionts because these symbionts contain inclusions composed of elemental sulfur (sp. gr. 2.05–2.09), which increase their buoyant density. Symbiont cells purified by this method were shown by light and electron microscopy, as well as by enzymatic and biochemical criteria, to be intact and largely free of host cell contamination, and to remain physiologically active for several hours. This preparation was used to examine the pathway of carbon fixation in the symbiont cells from *Lucinoma aequizonata* and to determine the individual contributions of host tissue and symbiont tissue to the carbon metabolism of the intact symbiosis (Distel and Felbeck, 1988b).

The compounds into which carbon from ^{14}C-labeled bicarbonate were incorporated by pur-

ified symbionts were aspartate, 3-phosphoglycerate, malate, and citrate, in an approximate ratio of 80:15:5:2. When the symbionts were exposed to labeled bicarbonate while still within the host tissues and then were subsequently purified, they incorporated labeled carbon into the same compounds in approximately the same ratios. The appearance of labeled carbon in 3-phosphoglycerate and the analysis of the position of label incorporation in citrate confirmed that some of the observed carbon fixation occurred via ribulose-bisphosphate carboxylase. This indicates that at least a portion of the observed carbon fixation occurred via Calvin cycle reactions that are capable of net carbon fixation. However, the majority of the carbon fixation detected (carbon fixation into the 4-carbon position in aspartate) occurred via other pathways. Pulse-chase experiments suggest that some of the carbon initially incorporated into aspartate may subsequently enter the Calvin cycle in a manner analogous to that of aspartate/C-4-photosynthetic carbon fixation in plants.

Wilmot and Vetter (1990) have used purified symbiont preparations to demonstrate that the symbionts of *Riftia pachyptila* are unusual among sulfur-oxidizing bacteria in being "sulfide specialists," i.e., these bacteria are capable of metabolizing sulfide but not thiosulfate or sulfite as their sole energy source. The bacteria can utilize sulfide over a broad range of concentrations (55 μM–2 mM), but maximum stimulation of respiratory rate occurred at concentrations above 1.0 mM. The symbionts, which appeared to be microaerophilic, showed no inhibition of oxygen consumption even in relatively high concentrations of sulfide (up to 2.0 mM), which would be inhibitory to most sulfur bacteria. *R. pachyptila* symbionts can oxidize sulfide completely to sulfate, although in short incubations the majority of sulfide is oxidized only to elemental sulfur.

Still another approach to the characterization of as-yet-unculturable symbionts has been the analysis of symbiont nucleic acids. Stahl et al. (1984) characterized the symbionts of three sulfur-oxidizing symbioses by comparing the molecular sequences of the symbiont 5S ribosomal RNA with sequences of known free-living bacteria. The host and symbiont 5S rRNAs were extracted from intact symbiont-containing host tissue and then were separated by electrophoresis on polyacrylamide gels. The symbiont 5S rRNAs were then sequenced by enzymatic and chemical digestion from both termini. Symbionts from *R. pachyptila, Calyptogena magnifica* (from the Galapagos hydrothermal vents), and *Solemya velum* (from tidal flats in Bourne, MA) were examined. These symbionts proved to be members of the gamma subdivision of the proteobacteria. Two-dimensional gel electrophoresis of ^{32}P end-labeled symbiont 5S rRNAs gave evidence of only a single symbiont type in each host species.

Distel et al. (1988) purified 16S ribosomal RNAs from the symbionts of six sulfur-oxidizing symbiotic hosts and used the RNAs to characterize the symbionts phylogenetically (Distel et al., 1988). These hosts included *Riftia pachyptila, Calyptogena magnifica,* and *Bathymodiolus thermophilus* (from the Galapagos hydrothermal vent site), as well as *Lucinoma aequizonata, L. annulata* (from the coast of California), and *Codakia orbicularis* (from the Bahamas). The results of this study are in general agreement with the results of Stahl et al. (1984) based on analysis of 5S rRNA sequences. However, the 16S rRNA molecule (1,500 nucleotides) is considerably larger and has more information than the 5S rRNA (120 nucleotides). Therefore, analyses of 16S rRNAs allow finer resolution of phylogenetic relationships. Also, the scope of the investigation was broadened to include several additional symbionts, and multiple samples of each specimen were examined. This allowed comparison of symbiont populations within individual host species as well as among different host species. A summary of the results is given in Fig. 3. All of the sulfur-oxidizing symbionts examined fall into a restricted cluster within the gamma subdivision of the proteobacteria (Wilmot and Vetter, 1990). No free-living bacterial species are yet known that clearly fall within this symbiont cluster. The closest free-living relative known is *Thiomicrospira* species *L-12* (Ruby and Jannasch, 1982), a sulfur-oxidizing obligate chemolithotroph that was isolated from the Galapagos deep-sea hydrothermal vent site. There is considerable diversity among the symbionts examined. Two distinct subgroups have been identified, one containing the symbionts of the lucinid clams and of *Riftia pachyptila* and a second containing the symbionts of *Bathymodiolus thermophilus* and *Calyptogena magnifica* (see Fig. 3). Each of the sulfur-oxidizing symbiotic hosts examined to date has its own unique symbiont species. When separate specimens of the same host species were examined, they were found to contain symbionts identical with respect to 16S rRNA sequence. These results are in agreement with previous examination of the 5S rRNA sequences of *R. pachyptila, C. magnifica,* and *Solemya reidi,* where only a single symbiont sequence was detected in each host.

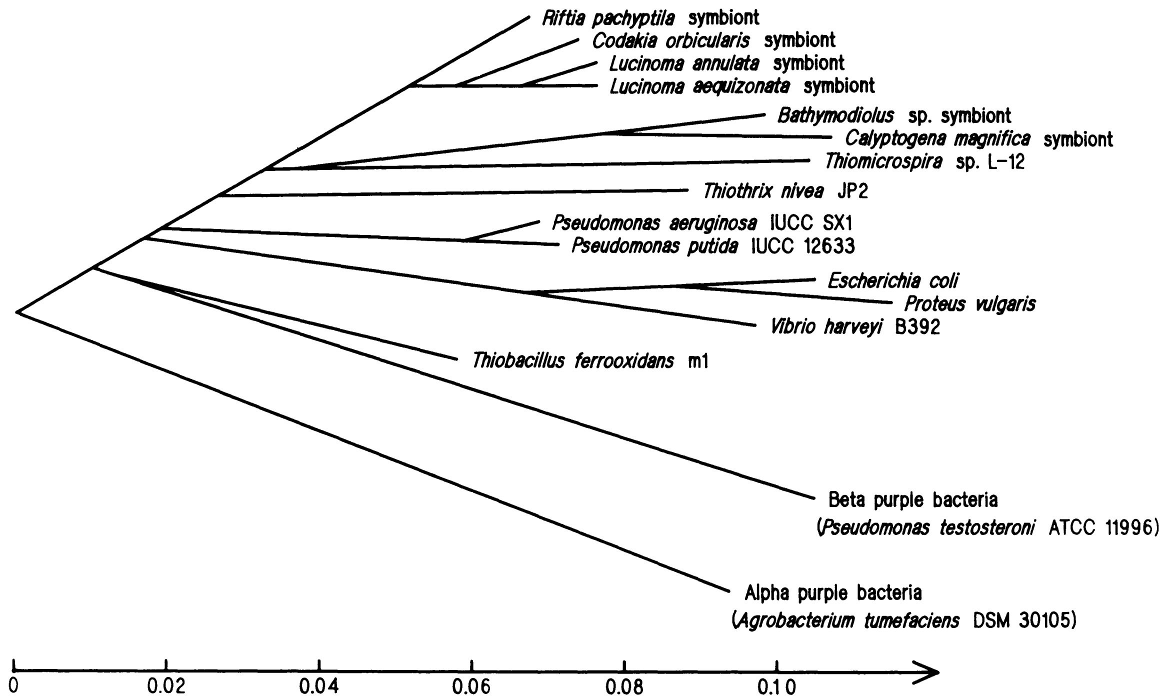


Fig. 3. The 16S rRNA-based phylogeny of invertebrate-associated symbiotic bacteria. All of the bacteria belong to the proteobacteria. This tree is a simplified version of a larger one that included additional, unpublished sequences. The horizontal components of the tree branches represent the estimated number of nucleotide substitutions per sequence position (see the scale on the horizontal axis). (From Distel et al., 1988.)

The symbionts of *R. pachyptila* have been examined by analysis of thermal denaturation kinetics (Nelson et al., 1984) and by DNA-DNA hybridization (Edwards, 1989) of total genomic DNA extracted from trophosome tissue. Thermal denaturation kinetics are consistent with a symbiont population in the trophosome of *R. pachyptila* that is homogeneous and composed of a single type of prokaryotic cell. The symbiont DNA was estimated to have a GC content of about 58 mol% and a genome size of about 2.1×10^9 Daltons (Nelson et al., 1984). Edwards (1989) used CsCl gradients to separate the genomic DNA of the symbionts of *R. pachyptila* from that of the host cells. This was possible because of the large difference in GC content between the symbionts (58 mol%) and the host (34 mol%). DNA-DNA hybridization experiments indicated that there was little variation between the symbionts of *R. pachyptila* specimens from a given site. Estimates of sequence relatedness were based on relative binding ratios (RBR) of total genomic DNA. The RBR was defined by comparison to the degree of binding of the reference DNA to itself, which was considered to be 100%. RBRs for specimens collected within each vent site were from 91–102%. These values are well within the range typically associated with a single prokaryotic species indicating that only a single symbiont species was present in all specimens. *R. pachyptila* symbiont DNA from specimens from distantly separated sites showed a degree of sequence similarity that was not significantly different from that found in specimens from within any single site. The sites examined were the Galapagos, 13°N, and Guaymas Basin hydrothermal vent fields. Each site is separated by at least several hundred miles. Thus, in agreement with rRNA-based analyses (Distel et al., 1988; Stahl et al., 1984), the symbionts of *R. pachyptila* appear to represent a single species that is specifically associated with this host regardless of local environment.

The symbionts of two other vestimentiferans, *Tevnia* species and *Lamellibrachia* species were also compared to *R. pachyptila* symbionts in this study. The *Tevnia* symbionts appear to be very closely related to the *R. pachyptila* symbionts, differing at a level (RBR = 76%) high enough to be attributed to strain differences within a single species. *Lamellibrachia* symbionts, on the other hand, had RBR values considerably lower than this (RBR = 11%) indicating that this symbiont is not closely related to those of *Ternia.*

CHAPTER 216

Prokaryotic Symbionts of the Aphid

DAVID L. GUTNICK

All aphids have an intimate association with prokaryotic symbionts (Buchner, 1965; Houk, 1987). These symbionts are housed in specialized cells termed mycetocytes, which aggregate to form a subcellular organelle, the mycetome (Houk and Griffiths, 1980). While mycetocytes generally contain only one type of symbiont, the entire mycetomal population may consist of two or at most, three different symbionts (Houk, 1987). For example, the pea aphid (*Acyrthosiphon pisum* Harris) contains two endosymbionts designated the primary (P) symbiont and secondary (S) symbiont (Griffiths and Beck, 1973; McLean and Houk, 1973; Fig. 1). The P symbiont is the predominant organism and is located in the mycetocyte while the S symbiont, when present, is located in the sheath cells surrounding the mycetome. Within the mycetocyte, the P symbionts are found exclusively in vacuoles (Houk and Griffiths, 1980).

Evidence as to the prokaryotic nature of the endosymbiont population stems from morphological (Buchner, 1965; McLean and Houk, 1973; Griffiths and Beck, 1973), chemical (Houk and Griffiths, 1980; Houk, 1974a; Houk et al., 1977), nutritional (Dadd et. al., 1967; Dadd and Mittler, 1966), biochemical (Houk et al., 1976; Ishikawa, 1982a, 1982b, 1982c), and molecular biological studies (Houk et al., 1980; Ishikawa, 1982a, 1984a, 1987; Unterman et al., 1989).

Almost all types of aphid symbionts have two peripheral membranes. In addition, they all appear to reproduce by binary fission. The outer membrane is a fluid structure (Hinde, 1971b) capable of forming the characteristic blebs observed on the cell surface of typical Gram-negative eubacteria. Moreover, when pea aphids were fed an artificial diet supplemented with penicillin, this led to alternations in the outer envelope of both P and S symbionts, resulting in the accumulation of an electron-opaque material in the putative periplasm (the space between the two membranes) (Griffiths and Beck, 1973). Finally, peptidoglycan constituents were demonstrated both microscopically and by chemical analysis (Houk et al., 1977). In addition to the two membranes, both P and S symbionts frequently exhibit an outermost membrane, which is an extension of the host-cell endoplasmic reticulum (Griffiths and Beck, 1973).

One fascinating feature of the microbial symbiotic relationship within aphids is the transmission of the symbiont transovarially into the developing eggs/embryos from the mycetocyte (Buchner, 1965; Lanham, 1968). The precise mechanism of this transmission from generation to generation is unknown. Microscopic studies have indicated that as the embryo reaches the blastula stage the symbionts are released from mycetocytes and enter the blastula via the blastopore (Buchner, 1965). These symbionts are devoid of the host membrane during and immediately after entry. In addition, during this process both the P and S symbionts mix together and are extracellular (Hinde, 1971c). The actual infection process itself has not been visualized microscopically, suggesting that it must occur rather quickly (Hinde, 1971c).

Aphids can be grown on artificial diets that lack required nutrients such as sulfur-containing amino acids, B-type vitamins, and sterols. (Dadd et al., 1967; Dadd and Mittler, 1966; Henry, 1962; Hinde, 1971a; Krieger, 1971; Tokumitsu and Maramorosch, 1966; Turner, 1971, 1977). Since these materials are not normally produced by the aphid, the inference is that they are produced by an endosymbiont. The administration of antibiotics to aphids growing on such artificial diets generate aposymbiotic aphids which become nutritionally deficient very quickly, lose their fecundity, and eventually die off (Griffiths and Beck, 1974). Among the antibiotics that have been used are the tetracyclines (Koch, 1968); penicillin (Ehrhardt, 1968a; Ehrhardt and Schmutterer, 1966; Mittler, 1971; Srivastava and Auclair, 1976); streptomycin (Ehrhardt and Schmutterer, 1966; Ehrhardt, 1968a; Mittler, 1971; Srivastava and Auclair, 1976); chloramphenicol (Ehrhardt, 1968a; Mittler, 1971a, 1971b; Srivastava and

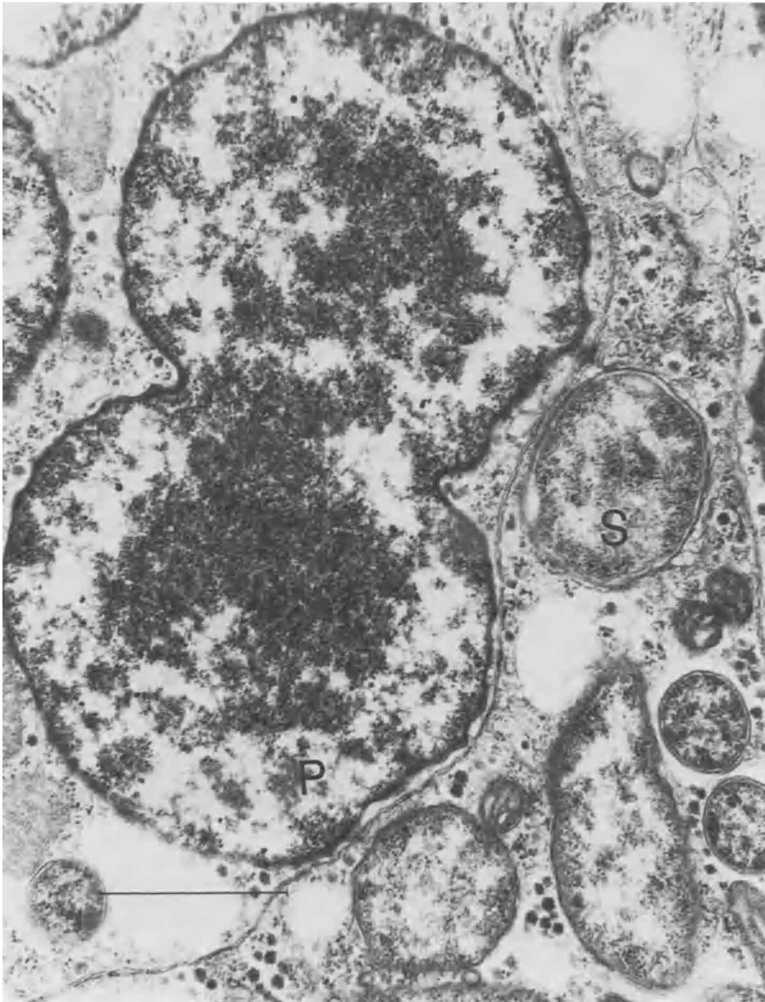

Fig. 1. Primary (P) and secondary (S) endosymbionts from the pea aphid *Acyrthosiphon pisum*. Bar = 1 μm. (Courtesy of E. J. Houk.)

Auclair, 1976); neomycin (Srivastava and Auclair, 1976); and erythromycin (Ehrhardt, 1968a; Mittler, 1971a, 1971b).

Once techniques for the isolation of endosymbionts were developed (see "Isolation," this chapter) the capacity of the endosymbionts to synthesize marcromolecules was shown to be sensitive to such antibiotics as nalidixic acid (Ishikawa, 1982a), rifampicin (Ishikawa, 1982a, 1982b), and chloramphenicol (Ishikawa, 1982a, 1982b). The RNA synthesized in the endosymbiont was shown to consist primarily of tRNA, 5S RNA, and 16S and 23S RNA (Ishikawa, 1982b). In addition, Houk et al. (1980) reported the GC content of the DNA of pea aphid endosymbionts to be as low as 31mol% and concluded that this low GC composition was a reflection of its intracellular habitat. Similar results were obtained by Ishikawa (1987) and by Unterman and Baumann (in press). However, it has recently been shown by the last authors that this GC composition is identical to the GC content of the aphid DNA itself. Thus, determination of the GC composition of isolated DNA is insufficient to establish proof of purity, and more sensitive molecular biological techniques, such as probing with suitable probes, may be required to identify the isolated DNA (see "Isolation," this chapter).

Isolation

Method of Houk and McLean (1974).

The isolation of the pea aphid symbionts was achieved by Houk and McLean (1974). Mycetocytes were isolated from homogenized adult pea aphids in a hypertonic medium and disrupted in a lysis medium (Bruening et al., 1971) by gently bubbling air through them. The medium was supplemented with 1% polyvinyl pyrrolidone (PVP-40) to prevent cross-linking of proteins due to oxidation of any polyphenolic materials. Aphids were wrapped in cheesecloth and ground in a mortar and pestle containing 3 volumes of isolation buffer per unit weight of aphids. The filtrate was collected, passed through Miracloth, and homogenized in a Teflon homogenizer. The suspension was then centrifuged at 5,000 g for 15 min.

The pellet was redissolved in isolation medium (diluted 1:1000). The suspension medium was added at a ratio of 3:2 (v/w) of the original aphid mass. The symbionts were isolated from the suspension by density gradient centrifugation using a preformed, discontinuous Ficoll gradient (2 to 10%). The gradients were formed by layering four different concentrations of 2, 4, 6, and 10% Ficoll respectively in 0.01M phosphate buffer (pH 7.2) in the bottom of 50-ml tubes (Houk and McLean, 1974). Three ml of suspension medium were used for every 2 g of aphids and layered carefully on top of the Ficoll gradients and centrifuged at 400 g for 10 min. The amount of material layered on the gradient was typically equivalent to 2 g of aphids. The region of the gradient containing the symbiont fraction was readily detected as a sharp opaque band that could be isolated by aspiration of a 3-ml aliquot with a no. 20 hypodermic needle into a sterile syringe. The primary symbiont population was found to sediment with a relative mobility (R_m) of 0.60 (calculated as the distance from the meniscus travelled by the microbial population divided by the distance from the meniscus to the bottom of the tube). By comparison, *Escherichia coli* was found to sediment at an R_m of 0.36 while *Streptococcus faecalis* was even smaller and travelled with an R_m of 0.20. The gradient fractions were sedimented by centrifugation (15,000 g) and examined by electron microscopy. Houk and McLean (1974) observed that the symbiont fractions prepared as above were contaminated to some extent (between 4.5–6.5% contamination as judged microscopically) with secondary symbionts, mitochondria, and membrane fragments. This contamination was dependent to some extent on the volume of sample removed from the Ficoll gradient. It was therefore recommended that the maximum sample size be no more than 3–4 ml from such a gradient.

Method of Ishikawa (1982a)

This is a modified version of the original symbiont isolation procedure described above. Aphids were lightly homogenized in buffer A (.035M Tris-HC1, pH 7.6; 0.25M sucrose, 0.025M KCl, 0.01 M $MgCl_2$, 1 mM dithiothreitol, 5mM phenylthiourea). The homogenate was passed through cheesecloth and centrifuged at 2,500 rpm for 25 min in a swinging bucket. The pellet was resuspended in buffer A, layered over a solution of buffer A containing 2.2 M sucrose, and centrifuged at 160,000 g for 30 min. The pellet containing the isolated mycetocytes was then homogenized in a minimal volume of buffer A containing 0.3% (v/v) Nonidet P-40 (BDH).

Aliquots of the homogenate were layered over a linear Percoll gradient (10–90%) and centrifuged for 15 min at 7,000. The Percoll mixture contained 5 g polyethylene glycol 6000 (Sigma), 1 g bovine serum albumin, 1 g Ficoll 400 (Pharmacia) and 8.6 g sucrose in 100 ml Percoll (Pharmacia). The Percoll mixture was diluted in Buffer A before the gradient was formed. In this system, the band of symbionts was readily observed in the gradient (Ishikawa, 1982a). However, cells of *E. coli* were found to move only slightly slower than the isolated symbionts in the Percoll gradient, as opposed to the results with the Ficoll gradient in which the cells of *E. coli* were much smaller and showed a considerably lower R_m (Houk and McLean, 1974). In this method, unbroken mycetocytes pelleted at the bottom of the gradient while mitochondria and membrane fragments were found scattered above the symbiont band.

Cultivation

It is commonly accepted that the prokaryotic symbionts of aphids cannot be cultivated outside the insect (Houk, 1987). However, conditions for the maintenance of isolated symbionts for periods of up to 12 hours have been described (Houk, 1974a). An optimal temperature for protein and nucleic acid synthesis was found to be 28–30°C. The only medium tested for these experiments was Grace's insect tissue culture medium (Tokumitsu and Maramorosch 1966; Houk, 1974b). Under these conditions there was no detectable dependence on supplementation with fetal calf serum. It should be noted, however, that no other systematic approaches to cultivating the symbionts in vitro on more "classical" media have been reported.

Identification

A number of aphid hosts have been examined for their symbiont populations (for references, see Houk and Griffiths, 1980). In the majority of cases the symbiont populations were found to be Gram negative (see Fig. 1).

Unterman et al. (1989) analyzed the sequence of genes in the 16S rRNAs of both primary and secondary symbionts of pea aphids. In these experiments, DNA was isolated from both the intact insect and an isolated mycetomal preparation. Although identical restriction fragments were obtained with either preparation, the DNA from the whole aphid was used since the mycetomal preparation was more readily susceptible to nuclease digestion. The identification of P (primary) symbiont DNA and S (secondary) DNA was on the basis of the relative intensities of restriction endonuclease fragments using a cloned gene for 16S RNA from *E. coli* as a probe. For example, EcoR1 digestion of aphid DNA yielded two fragments of 10 kb and 2 kb, respectively. After hybridization the 10 kb fragment was much more intense than the 2 kb band. Since the P symbiont is present in much larger numbers than the S symbiont in the pea aphid (McLean and Houk, 1973), the 10 kb fragment was assumed to code for the rDNA sequence of the P symbiont. However, the authors did not include controls using DNA from aposymbiotic aphids prepared after growth in the presence of antibiotics (Mittler, 1971b). When the sequences of the two 16S RNA genes

were compared with the sequences of selected prokaryotes and analyzed for evolutionary relatedness (Ristel et al., 1988; Olsen et al., 1986; Woese, 1987) with selected eubacteria, Unterman et al. (1989) were able to place both the primary and the secondary symbionts within the γ-subdivision of the proteobacteria (Stackebrandt et al., 1988; Woese, 1987). The analysis showed the S symbiont to be a member of the Enterobacteriaceae. The P symbiont, which is closely related to the Enterobacteriaceae apparently diverged from *E. coli* about 420 million years ago, while the S symbiont diverged from same organism some 250 million years ago. It is interesting to note that both the P and the S symbionts are clearly distinct from the obligate intracellular parasites, the chlamydiae, and the mycoplasmas. The chlamydia and mycoplasmas belong to the Gram-positive branch of the eubacteria. Unterman et al., (1989) speculate that the initial divergence of the P and S symbionts may have been the result of adaptation of the P symbiont to the intracellular environment followed by a later infection of the of the aphid host by the S symbiont. One interesting observation from this work is that the pea aphid symbionts contain only a single copy of the rRNA operon (Unterman et al., 1989). Similar results (Unterman and Baumann, in press) were obtained with the symbionts from the peach aphid *Myzus persicae* and the sorghum aphid *Schizaphis graminum* as well as with one member of the family Coccoidae *(Peudococcus citri)*. It is interesting to note the comparison with *E. coli* which has seven rRNA operons (Boros et al., 1979), and *B. subtilis* which appears to have ten (Rudner et al., 1988). Since the presence of a single copy of rRNA operons has been correlated with a very slow growth rate (Neumann et al., 1983; Razin, 1985), it is not surprising that attempts at in vitro cultivation have failed. If the growth of the endosymbiont is correlated with the growth of the host, the expected doubling time ould be about two days (Srivastava et al., 1980).

Biochemical Activities

Two general approaches have been used to study metabolic processes by aphid symbionts. In the first approach, the ability of the whole aphid to incorporate a radioactive precursor into product subsequently detected by autoradiography is compared with the activity in aposymbiotic aphids prepared by treatment with antibiotics. This approach has been used to study such processes as: 1) incorporation of sulfur into amino acids (Ehrhardt, 1968a, 1968b.); 2) the synthesis and incorporation of lipids Houk, 1974b); and 3) the incorporation of [^{14}C] acetate into sterols (Ehrhardt, 1968b) and other classes of lipids. In sharp contrast, it was shown (Campbell and Nes, 1983) that aphids of *Schizaphis graminum* could not incorporate [2-^{14}C] mevalonic acid into either sterols or into sterol intermediates, such as squalene and 2,3-oxidosqualene, when reared on an artificial diet. It is possible that the family Aphididae could be divided into two groups, one that is capable of de novo synthesis of sterols via their endosymbionts, and one that is not.

The second approach involves similar types of labelling experiments except that isolated symbionts are used. Houk et al. (1976) showed that isolated symbionts of the pea aphid incorporated [^{14}C] acetate into most of the common classes of lipids. The same radioactive precursor, as well as [^{3}H] mevalonate, were also incorporated into sterols, with cholesterol being the major product.

DNA, RNA, and protein synthesis have been extensively studied in isolated symbionts of pea aphids (Ishikawa, 1982a, 1982b, 1984a, 1984b 1985, 1987) using [methyl-^{3}H]thymidine, [5-^{3}H]uridine, or L-[^{35}S]methionine respectively. DNA synthesis was inhibited by nalidixic acid, RNA synthesis by rifampicin, and protein synthesis by both rifampicin and chloramphenicol. This analysis led to results indicating that the proteins synthesized by the isolated symbionts in vitro are apparently quite different from those associated with the symbionts inside the insect. In fact, it has been asserted that the synthesis of only a single symbiotic protein species, symbionin (MW 63,000), is sensitive to chloramphenicol in the intact insect (Ishikawa et al., 1985). This protein was not synthesized by the isolated symbionts in vitro, suggesting that either the gene or the messenger RNA encoding this protein do not reside in the symbiont itself, but are imported! In support of this conclusion was the finding that symbionin (identified by two-dimensional gel electrophoresis) was the only protein isolated from the whole insect whose synthesis was apparently resistant to cycloheximide and sensitive to chloramphenicol (Ishikawa, 1982b). Evidence has been presented suggesting that symbionin is present in much higher amounts in the symbionts from nymphal tissue than in those of adult aphids (Ishikawa et al., 1985). While no direct evidence for enhanced turnover was presented, a number of low molecular-weight molecules have been isolated that actually inhibit protein synthesis in symbionts (Ishikawa, 1984). One intriguing possibility is that the aphids produce some materials during their development which turn off

macromolecule synthesis as the insects age. The hypothesis was advanced that symbionin was required for embryonic development following fertilization. The interpretation of the results are complicated by the possibility of contamination with bacteria, mitochondria, or membrane fragments during the isolation of the symbionts. Controls using aposymbiotic hosts and specific immunological probes would be useful in linking a particular biochemical reaction to a specific isolate.

The Basis of Symbiosis

The function of the symbionts in aphid survival has remained a subject of some controversy. The various hypotheses can be grouped as follows: biosynthesis—for sulfur-containing amino acids, tryptophan, vitamins, and sterols, and other lipids (Buchner, 1965; Houk and Griffiths, 1980); energy production (Lanham, 1968); osmoregulation (Houk and Griffiths, 1980); and the production of polysaccharide-degrading enzymes (Campbell and Dreyer, 1985; Dreyer and Campbell, 1987). Evidence for nutritional and biosynthetic activities stems from the ability of different aphid populations to survive for many generations on artificial diets in the absence of specific nutrients that are not normally synthesized by insects. In the presence of antibiotics, such diets are inadequate and the aphids lose their fecundity and subsequently die off. Sterol synthesis has received the most attention, since as a group, insects do not synthesize these compounds de novo. Both biochemical (Houk et al., 1976) and morphological evidence supporting the notion that the symbionts provide the host with endogenous sterols (Griffiths and Beck, 1977a, 1977b) have been presented. Moreover, the fact that the aphids can be reared on an artificial diet without sterol supplementation provides additional support (Akey and Beck, 1972; Dadd and Mittler, 1966). However, the possibility of fungal contamination during feeding experiments cannot be ruled out as a source of sterols in the diet. In addition, Campbell and Nes (1983) pointed out that the specific sterols or other essential nutrients provided by the symbionts may be specific for only one class of aphids but not for all classes.

Recently, the hypothesis was advanced that the prokaryotic symbionts furnish the aphid host with polysaccharide-degrading enzymes such as pectinases, cellulase, and hemicellulases (Campbell and Dreyer, 1985). Such enzymes could be used by the aphids for plant tissue penetration and phloem feeding. In this regard, it has been shown that the more susceptible a particular sorghum variety is to the aphid *Schizaphis graminum* (the greenbug), the greater the rate of pectin hydrolysis. Moreover, aphid biotypes that can overcome resistant species of sorghum appear to have a different array of polysaccharidases from aphids that cannot overcome resistant species. Substantial activities for these enzymes were found in aphid homogenates (Campbell and Dreyer, 1985), even though such enzymes are generally only associated with microorganisms, either bacteria or plant-pathogenic fungi (Bateman and Basham, 1976). Different regulatory patterns for enzyme synthesis coupled with associated mutations could explain the ability of the aphid to overcome the resistance to aphid infection of specific plant varieties. Thus far, no direct evidence has been forthcoming suggesting that symbionts in fact either produce these enzymes or contribute to their production in the insect host. However, it has recently been shown (Eisenbach and Mittler, 1987), by crossing resistant strains of greenbugs *(Schizaphis graminum)* with sensitive strains, that the ability to overcome the resistance of a particular sorghum biotype was maternally inherited. This non-Mendelian pattern of inheritance may result from symbiotic transfer and subsequent expression of the resistance characteristics by the prokaryote (Eisenbach and Mittler, 1987). Ideally, one should be able to probe symbiotic DNA with genetic probes for the degradative enzymes. The use of specific monoclonal antibodies for this purpose should also prove useful.

Applications

Aphids are among the most important agricultural pests in modern agriculture (Minks and Harreweijn, 1987). This stems not only from the damage they cause through sap-sucking, but also as a result of their ability to serve as vectors in transmitting viral diseases (Raccah, 1986). A better understanding of the basis of aphid symbiosis should lead to new experimental models for the manipulation of the symbiont population, which in turn may lead to a unique approach to the biological control of these important agricultural pests.

Acknowledgments

We thank Dr. Ralph Baumann for kindly supplying a preprint of his review and Dr. E. J. Houk for supplying the photomicrographs of the endosymbiotes.

PART VI

Phylogenetically Unaffiliated Bacteria

CHAPTER 217

Thermophilic, Aerobic, Hydrogen-Oxidizing (Knallgas) Bacteria

MICHEL ARAGNO

Introduction

Geothermal fluids and gases often contain significant concentrations of molecular hydrogen ($\geqslant 1$ % v/v). This suggests that hot springs and other geothermal manifestations might harbor thermophilic, aerobic, hydrogen-oxidizing (Knallgas) bacteria. It is therefore surprising how few attempts were made before 1980 to isolate thermophilic hydrogen bacteria from these environments (Goto et al., 1977), although they were found in cold nongeothermal habitats (McGee et al., 1967; Emnova and Romanova, 1977; Aragno, 1978; Schenk and Aragno, 1979).

The discovery of strains of the highly thermophilic, obligately chemolithoautotrophic *Hydrogenobacter* (Kawasumi et al., 1984; Kryukov et al., 1983), of *Bacillus tusciae* (Bonjour and Aragno, 1984), and of the geothermal habitat of *B. schlegelii* (Bonjour et al., 1988) recently confirmed that geothermal sites were the source of several new, highly thermophilic, hydrogen-oxidizing aerobes, and that these could play a role in the primary production of organic matter in such environments. Moreover, these organisms, which often have a high growth rate and produce large numbers of cells, certainly present an interesting potential for biotechnological applications.

Ecology

Origin of Geothermal Manifestations

The total heat flux of internal origin on earth amounts to about 3×10^{10} kW, corresponding to about 0.2% of the heat flux reaching the earth as solar energy. The internal heat probably is composed partly of a residue of the initial energy (due to the impact and the early decomposition of short-lived radioactive elements), and partly from the decomposition of still-present long-lived radioactive elements.

In normal conditions, this flux generates a temperature gradient under the surface (starting 10 m below ground level, where solar energy becomes insignificant), of about 3°C/100 m. Anomalies in this gradient generally occur near the limit of lithospheric plates, where fluid magmatic masses come close to the surface. In regions where the Earth crust is fractured by active tectonism, convective circulation of warm fluids is more probable and thus may generate hot springs or fumarolic fields. Water, the main fluid present in this case, in liquid or gaseous form, is almost exclusively of superficial origin: the deuterium/hydrogen (D/H) ratio of geothermal waters is identical to that of cold interstitial waters of the same region (Panichi and Gonfiantini, 1978); the increased $^{18}O/^{16}O$ ratio of these waters is due to isotopic exchange between waters and rocks in the deep reservoir (Panichi et al., 1974; Panichi and Gonfiantini, 1978).

Consequently, hot springs and other geothermal manifestations are present mainly in volcanic zones, even where there has been no volcanic activity for a long time. Rain water penetrating geothermal fields is heated by contact with hot rocks. Ions and gases dissolved in geothermal fluids occur mainly by the reaction, at high temperature (>800°C), of water and hot rocks or magma. During their climb along fissures, geothermal fluids lose heat by adiabatic expansion and conduction of the neighboring rocks. Finally these fluids may reach the surface, giving rise to hot springs, solfataras, or fumaroles.

Submarine hot springs are perhaps more abundant on earth than terrestrial ones. Some are situated in shallow waters near volcanic islands like Vulcano (Eolian Islands, Sicily), Santorini (Aegean arc, Greece), and S. Miguel (Açores) where the mixing of sea water with hydrothermal fluid probably occurs. A borderline case would be seaside hot springs, such as in Porto di Levante (Vulcano Island, Sicily) or the Izu Peninsula (Japan).

Other hydrothermal vents are situated in the mid-oceanic ridges, where continental plates separate, at a depth of 2,000 to 3,000 m (Jan-

nasch and Mottl, 1985). Two main types are recognized: the so-called "black smokers", or hot vents, where pure hydrothermal fluid reaches the crust surface at 350 ± 2°C at a flow rate of about 1 to 2 $m \cdot sec^{-1}$; and "warm vents," which typically open through submarine basaltic pillow-lavas, at a temperature of 2 to 20°C over ambient and a flow rate of 0.5 to 2 $cm \cdot sec^{-1}$; in these, the hydrothermal fluid mixes with normal seawater at a depth of 10 to 200 m.

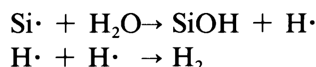
The neighborhood of deep-sea vents is known for harboring a rich animal community, mainly worms, mussels, and crustaceans, as well as a rich bacterial biomass. Some of these chemolithoautotrophic prokaryotes are the primary producers of the whole nutrient chain in these ecosystems. H_2S appears to be the main primary source of energy and electrons, but H_2 and other reduced compounds might also play a significant role (Jannasch and Mottl, 1985). Although hydrogen is present in fairly high concentrations in the hot vents, its concentration in the low-temperature, warm vents appears to be very low.

Very little is known so far about the mechanisms of aerobic oxidation of hydrogen in marine springs. Jannasch and Nelson (1984) have reported the isolation of an aerobic, hydrogen-oxidizing bacterium from a *Riftia* trophosome, whereas Nishihara et al. (1990) have isolated an organism related to *Hydrogenobacter* from a seaside saline hot spring in Japan. Further research on the occurrence of hydrogen-oxidizing bacteria in marine hydrothermal vents is therefore necessary and seems promising.

Origin of Molecular Hydrogen and of CO_2 in Geothermal Manifestations

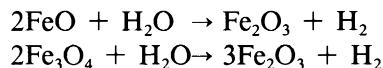
Molecular hydrogen occurs frequently in the gas phase of geothermal manifestations. It can reach concentrations of the order of several percent v/v of the total dry gas, for example 4.6–4.8% in S. Federigo solfatara, in Tuscany, Italy (Bonjour and Aragno, 1984; Conrad et al., 1985).

Several mechanisms have been suggested to explain the occurrence of H_2 in geothermal gases. The following reaction may be possible at high temperature between water and silicon (Si) radicals (Kita et al., 1982):



$$Si\cdot + H_2O \rightarrow SiOH + H\cdot$$
$$H\cdot + H\cdot \rightarrow H_2$$

The following reactions for the reduction of water by hot (>800°C) ferrous rocks (d'Amore and Nuti, 1977) have also been proposed:



$$2FeO + H_2O \rightarrow Fe_2O_3 + H_2$$
$$2Fe_3O_4 + H_2O \rightarrow 3Fe_2O_3 + H_2$$

CO_2 is generally the most abundant gas in the uncondensable fraction of geothermal gas. In S. Federigo (Bonjour and Aragno, 1984; Conrad et al., 1985), it makes up 80–90% (v/v) of the total. It can originate from metamorphic reactions between silicic and carbonate rocks, the simplest equation being:

$$SiO_2 + CaCO_3 \rightleftharpoons CaSiO_3 + CO_2$$

A small part of the CO_2 could also originate from the atmospheric CO_2 and from that produced by the decomposition of organic matter that is transported by water (Gunter and Musgrave, 1966).

The gases directly sampled from melted magma at 1,050 to 1,150°C were CO_2, H_2, CH_4, NH_3, SO_2, and some H_2S.

Ecological Factors Governing Bacterial Growth in Terrestrial Geothermal Habitats

The ecology and evolution of bacteria of superficial geothermal habitats are governed by several factors unique to these environments. The most important are listed below:

1. The very small area of these habitats and the often-considerable distances between one geothermal region and another (≈ thousands of km).
2. The temperature varies between the ambient temperature and the boiling point of water.
3. The pH, even in a given geothermal region, may vary considerably from one manifestation to another. Values from pH 1.5 to 10.5 have been reported (Brock, 1978; Aragno, 1981)
4. Potential electron donors present in the geothermal gases often include significant concentrations of H_2, H_2S, S, NH_3, or CH_4 (Tables 1 and 2), all of which may serve as electron donors for chemolithotrophs.
5. Presence of CO_2 in the geothermal gases.
6. Oxygen is limiting, since most of the oxygen reaching these waters simply diffuses from the air. The oxygen concentration in geothermal waters is generally very low; not only does oxygen solubility decrease with increasing temperature, but the waters are contin-

Table 1. Composition of the uncondensable fraction of endogenous gases in S. Federigo solfatara.

Gas	Percentage (v/v)
H_2	3.5–5
N_2	5.5–14
CH_4	0.7–1.8
CO_2	79–88
H_2S	0.2–4.3

From Bonjour (1988).

uously bubbling with oxygen-free geothermal gases, and there is a high concentration of compounds with a high reducing power, such as H_2S.

7. Scarcity of organic matter is common. With the exception of airborne allochthonous material (insect and plant fragments), the only organic matter in geothermal environments above 70°C is that produced by chemolithoautotrophs, as photosynthesis does not occur above that limit.
8. Mineral salts are generally present in geothermal waters at relatively high concentrations, often up to 2,000 mg/l of total dissolved solutes or more. The composition of the principal salts varies considerably from one site to another. Table 2 gives examples of the mineral composition of waters from six geothermal sites. Among the compounds present, some can have exceptionally high local concentrations, such as boric acid in the geothermal fields of Tuscany.

It should be noted that in some hot pools or hot springs, the above physicochemical characteristics may vary strongly and suddenly for several reasons. Some variations are caused by the influence of surface rain waters. Other may be ascribed to changes in the underground channels due to clogging by salt deposits or to microseisms, frequent in these regions.

Consumption of Hydrogen in Geothermal Waters

Hydrogen consumption in natural environments is a widespread phenomenon (Conrad, 1988). In fresh water and in soils, nevertheless, H_2 uptake cannot be explained by the activity of the "classical" aerobic, hydrogen-oxidizing bacteria, because their apparent K_m for H_2 is much higher than that measured in water and soil samples (Conrad and Seiler, 1979, 1981; Conrad et al., 1983a), and because they are unable to utilize H_2 at the concentrations usually encountered in these environments (Conrad et al., 1983b).

The situation is different in geothermal manifestations. The first-order kinetics reported for H_2 consumption in two geothermal samples from the S. Federigo solfatara in Tuscany (Conrad et al., 1985) showed an apparent K_m greater than 1 μM H_2, which is of the same order as the kinetics of H_2 consumption by aerobic, sulfidogenic, acetogenic, or methanogenic hydrogen-oxidizing bacteria.

Whether aerobic or anaerobic bacteria are involved in H_2 consumption seems to depend on the temperature of the sampling site. Even though consumption occurred under both conditions in all the samples tested, Conrad et al. (1985) showed that anaerobic H_2 consumption was much higher in the sample taken at 95°C,

Table 2. Concentrations of chemicals in waters from six superficial geothermal sites.

Table 3. Temperature, pH, and rate constants of H_2 consumption activities in geothermal spring water incubated at 60°C under aerobic and anaerobic conditions.

Site	Original water temperature	pH	Rate constant of H_2 consumption (h^{-1})	
			Aerobic	Anaerobic
Number 1	95°C	6.2	1.9	11.5
Number 2	79°C	3.2	9.7	1.7

From Conrad et al. (1985).

while aerobic consumption dominated in the sample taken at 79°C (Table 3). This fits well with the decrease of oxygen solubility with temperature. Most environments above 90°C are almost totally anaerobic; they are indeed the habitat of the strictly anaerobic, sulfur-reducing, and methanogenic, hyperthermophilic archaebacteria (see Chapters 28 and 33)

The above considerations suggest the following picture: geothermal habitats are likely to harbor aerobic, hydrogen-oxidizing bacteria, provided molecular hydrogen is present in the geothermal gases at a significant concentration. The most severe limitation is oxygen concentration, which in turn depends on the temperature. The ecological extreme for aerobes is about 85 to 90°C. This agrees with the upper limits for growth of the most extreme thermophilic aerobes, such as *Sulfolobus* (Brock, 1978) and *Hydrogenobacter* spp. (see below).

Habitats of Thermophilic, Hydrogen-Oxidizing Bacteria

These bacteria have been found in many different habitats, both geothermal and nongeothermal.

GEOTHERMAL HABITATS. These include water from hot and warm springs (≥50°C), sediments from hot and warm pools and creeks, and moist fumarolic soils (≤100°C). Temperature and pH appear to be the major ecological factors determining the presence or absence and the type of knallgas bacteria in a given spring. Fig. 1 shows the distribution of different types of thermophilic knallgas bacteria from Tuscany (Italy) and S. Miguel (Azores) in a pH versus temperature plot. *Hydrogenobacter* spp. and *Bacillus schlegelii* were found in neutral to slightly acidic sources (pH ≥ 5.0). Both genospecies from Tuscany are distinctly adapted to different temperature ranges. *Bacillus tusciae* was isolated from moderately acidic ponds (pH 2.5–5.5) at temperatures below 60°C. Schink et al. (1983) reported the isolation of strongly acidophilic knallgas bacteria from Lemonade Pool (Yellowstone) at pH 2.5 and 40°C. The isolate grew well at pH 2.5, but not at pH 5.5. Unfortunately, this strain (Gram-negative, nonsporeforming rod) was then lost. Obviously, more attempts to isolate strongly acidophilic knallgas bacteria are necessary. No acidophilic knallgas bacteria were isolated from muds that were both hot and acidic (T>60°C, pH<4, see Fig. 1).

NONGEOTHERMAL HABITATS. Surprisingly, several strains of thermophilic knallgas bacteria have been isolated from cold, nongeothermal habitats. This is the case for the moderately thermophilic *"Pseudomonas thermophila,"* isolated from soil (McGee et al., 1967) and from drainage (Emnova and Zavarzin, 1977), and for *Bacillus schlegelii* (Aragno, 1978; Schenk and Aragno, 1979; Bonjour et al., 1988). Although *B. schlegelii* is a strict thermophile, with a minimum temperature of approximately 45°C and an optimum at 70°C, it was originally isolated from a freshwater sediment where the maximum temperature in summer was about 8°C. Relatively high most-probable-number (MPN) counts (10–100 per g dry sediment) were obtained from various lakes and canals. The organism was later also isolated from glacier ice (Bonjour et al., 1988) and from the air in Switzerland. This clearly indicates the allochthonous origin of this sporeformer in low-temperature environments, as well as its relative abundance as air-borne endospores. Thus, if moderately thermophilic, nonsporeforming knallgas bacteria are likely to be found in nongeothermal environments, the presence of strict thermophiles is clearly associated with the requirement for the possession of endospores allowing transport by air. In contrast to *B. schlegelii, Hydrogenobacter spp.* and *Bacillus tusciae* have never been isolated from nongeothermal habitats.

Warm, nongeothermal habitats, such as compost piles or waste masses during the transient phase between aerobic and anaerobic decomposition, are likely to harbor thermophilic knallgas bacteria because significant concentrations of hydrogen are produced via fermentation reactions (Dugnani et al., 1986). So far, few attempts have been made to isolate thermophilic knallgas bacteria from these environments, and in cases where a positive enrichment culture was obtained, only *B. schlegelii* was isolated (M. Marchiani, T. Beffa, and M. Aragno, unpublished observations).

Sampling, Enrichment, Isolation, and Cultural Methods

General methods for isolating and cultivating aerobic, hydrogen-oxidizing bacteria, as well as the indispensable precautions that are essential

for handling explosive gas mixtures are described in Chapter 15. The following considerations are specific to the thermophilic hydrogen-oxidizing bacteria.

Sampling

The minimal equipment for sampling in geothermal areas for knallgas bacteria consists of sterile tubes or flasks that close hermetically, a holder for the sampling tube or bottle, an electrical thermometer (or thermistor) with a range of at least 0–100°C, and a portable pH meter. No special precautions are required for conditioning the samples, which are not harmed by exposure to air. If the samples cannot be tested the same day, it is preferable to keep them refrigerated.

Gas Analysis

Semi-quantitative determinations of the H_2 content of the geothermal gases can be made using Draeger tubes for 0.5% H_2 (Draegerwerk AG, Lübeck, FRG). This allows direct field detection and estimation of concentrations above 0.5% H_2 v/v. Gases bubbling through small pools are best suited for such analyses. The procedure is as follows:

Field Measurement of H_2 Concentration

A funnel (minimum volume, 600 ml) fitted with a tube of sufficient length is dipped into the pool water beside the bubbling zone. The tube should be made of natural rubber, polyvinyl chloride (PVC), or neoprene, but not of silicone, which is highly permeable to gases. 25% of the funnel volume should be filled with air: the reaction in the tube is the oxyhydrogen reaction, and the gas analyzed must contain at least 5% O_2. Then, the funnel must be transferred to the bubbling zone and filled with gas. The gas will then be pumped through the tube. The length of the pink zone indicates the H_2 concentration. *Follow the manufacturer's instructions exactly.*

Gas for laboratory analysis may be sampled using the procedure described below, which is diagrammed in Fig. 2.

Gas Collection Procedure

A 100-ml serum bottle is filled with CO_2-saturated water, and 1–2 ml of the carrier gas to be utilized for the gas chromatographic (GC) analysis is added to avoid an explosion due to expansion. The tube from the funnel is first completely purged with bubbling gas. It is then connected to the serum bottle through a syringe needle while another needle connects the bottle to a syringe with two valves. While the bottle neck is held down, the syringe is pumped slowly until the gas has almost completely replaced the water in the bottle, after which the needles are withdrawn.

Enrichment Procedures

The general procedures described in Chapter 15 are applicable, with the following modifications and precautions.

ENRICHMENT MEDIA. Schlegel's basal mineral medium (Chapter 15) was used with success for enrichment of thermophilic knallgas bacteria from geothermal sources. Used without modification, it permitted the isolation of several genospecies of *Hydrogenobacter* and *Bacillus schlegelii.* As its phosphate content is high compared to most natural habitats, a medium of similar composition, but with only 10 mM phosphate, can also be used.

Other basal mineral media were used by Goto et al. (1977) Kawasumi et al. (1980), Kristjansson et al. (1985), and Kryukov et al. (1983) for enrichment of several types of thermophilic, neutrophilic knallgas bacteria.

Enrichment of *Bacillus tusciae* (Bonjour and Aragno, 1984) was achieved on Schlegel's basal mineral medium modified as follows: phosphate concentration was lowered to 10 mM, and HC1 was added to lower the pH to about 3.5. Note that after good growth occurred, the pH increased to 5.5–6.0.

For enrichment of halophilic *Hydrogenobacter* (Nishihara et al., 1990), the same basal medium can be used as for mesophilic, halophilic, hydrogen bacteria (Nishihara et al., 1989; see also chapter 14)

GASSING AND INCUBATION CONDITIONS. The composition of the gas phase used is different depending on the author. In general, thermophilic, hydrogen-oxidizing bacteria are microaerophilic. In our experience, the best enrichments are obtained using shallow, unshaken cultures (e.g., 10 ml in 50-ml bottles, or 20 ml in 100-ml bottles) placed in desiccators or Witt's vessels, filled with 5 KPa O_2, 10 KPa CO_2, and 30–40 KPa H_2 (partial pressures measured at normal laboratory temperature). This underpressure of 45–55 KPa is necessary to avoid overpressure when the vessel is warmed to an incubation temperature over 60°C.

Other authors (Goto et al., 1977; Nishihara et al., 1990) used bottles gassed with a H_2:O_2:CO_2 mixture in volumetric proportions of 7:1:1 and placed on a shaker at the desired temperature.

Incubation temperature depends on the type of organism to be isolated. *Hydrogenobacter* spp. and *Bacillus schlegelii* grow well at 65°C. However, the latter tends to predominate at this

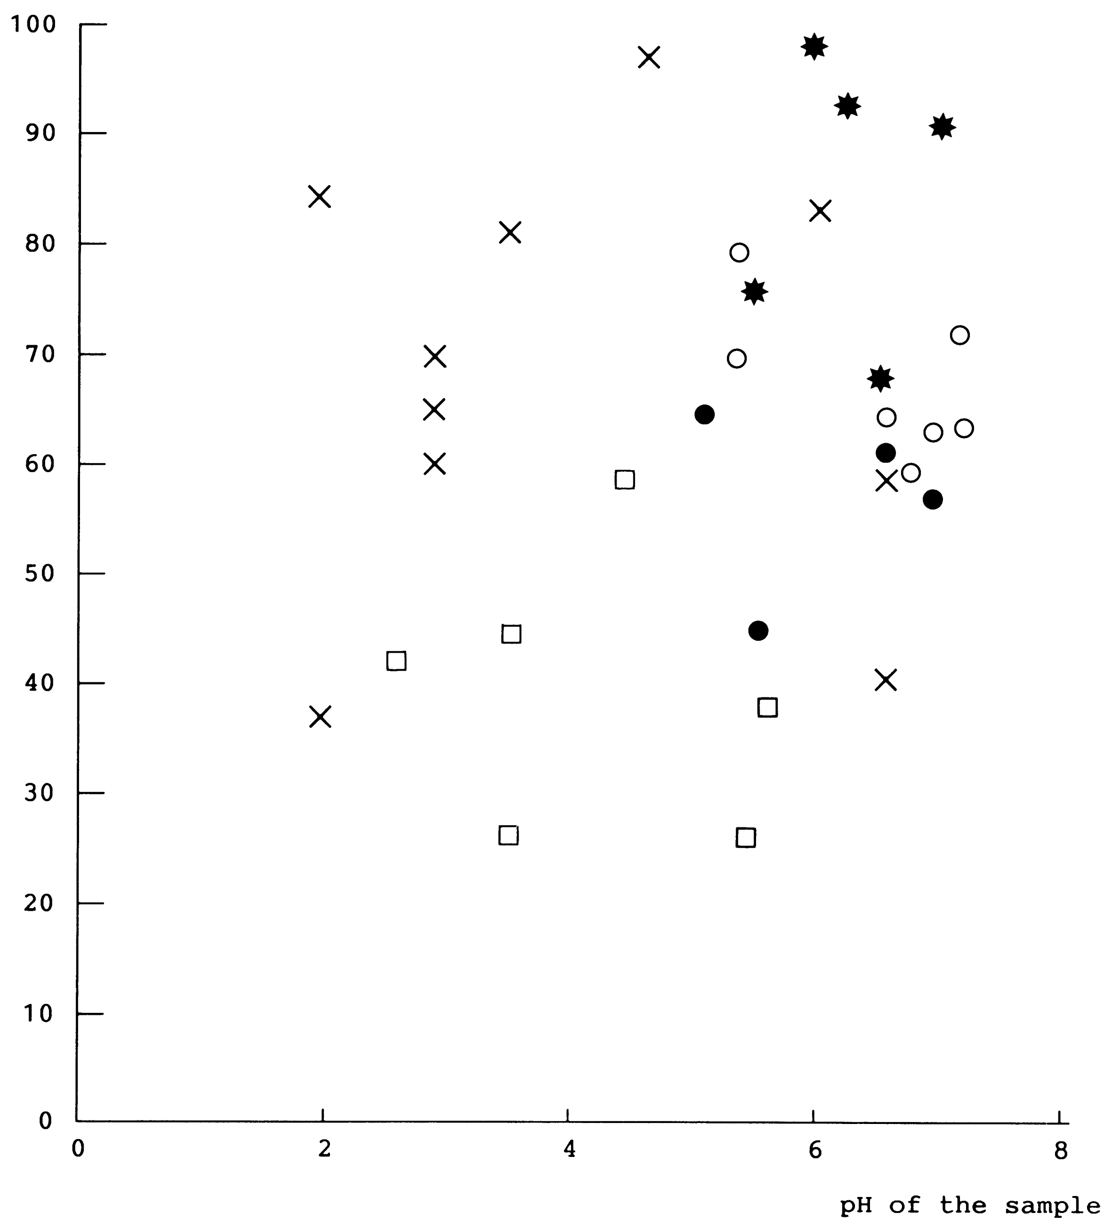

Fig. 1. Distribution of different types of thermophilic, hydrogen-oxidizing bacteria from Tuscany (Italy) and S. Miguel (Açores) in a pH versus temperature plot. Each point represents a single sample. ✸ *Hydrogenobacter*, homology group 1; ● *Hydrogenobacter*, homology group 2; ○ *Bacillus schlegelii;* □ *B. tusciae;* × no bacteria found.

temperature but incubation at 73–75°C should favor the specific enrichment of *Hydrogenobacter* spp. Incubation at 80°C will permit enrichment specifically of the most thermophilic *Hydrogenobacter* spp. (e.g., genospecies 1, see below). In that case, it is preferable to preincubate the culture overnight at 75°C before increasing the temperature to 80°C, as this temperature is over-optimal for this genospecies as well. Halophilic *Hydrogenobacter* were obtained after enrichment at 70°C (Nishihara et al., 1990).

Normally, it is preferable to repeat the enrichment procedure once or twice, each time using one loopful of the culture as inoculum. This increases the proportion of knallgas bacteria and prevents nonautotrophic growth at the expense of compounds present in the original inoculum. Cultures showing a good growth after the third enrichment (a control can also be run,

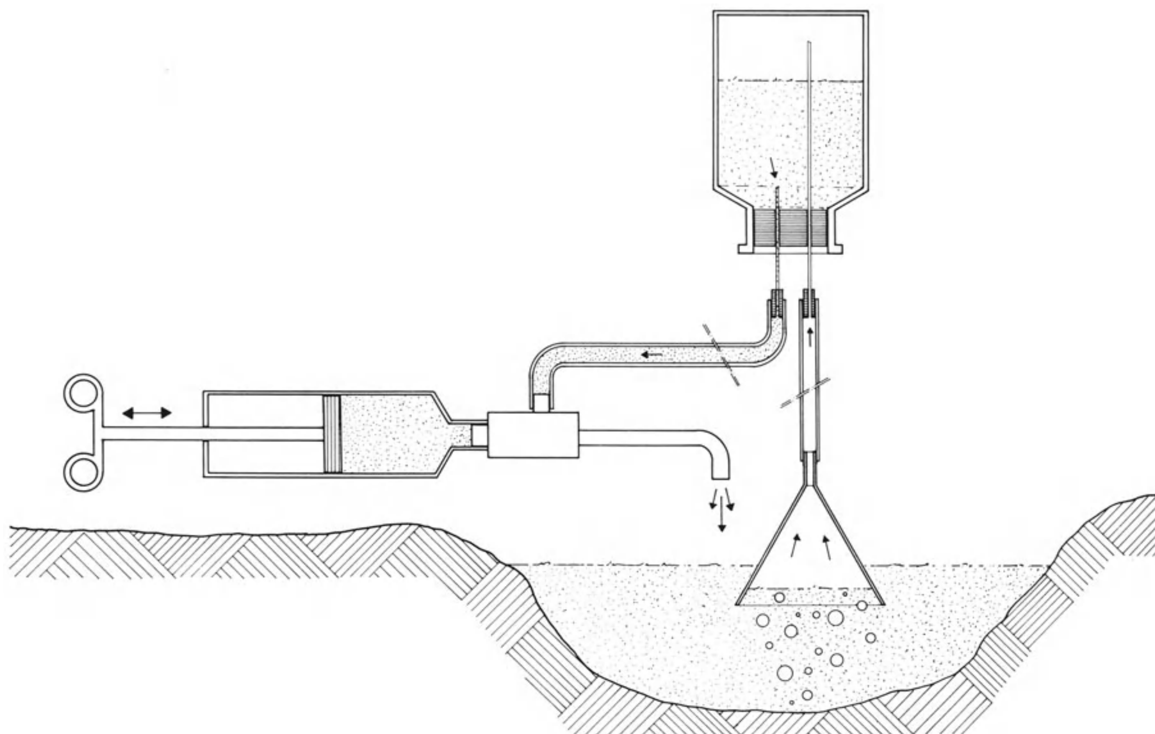

Fig. 2. Sampling system for collecting underground gases from geothermal sources.

incubated under air or N_2:O_2:CO_2 mixture) can then be subjected to the isolation procedure.

Isolation Procedures

When isolating thermophilic knallgas bacteria, it is often difficult to obtain well-separated single colonies on solidified media. One often observes a spreading of the cultures on the entire medium surface, or no growth at all. This generally happened when *Hydrogenobacter* spp. has been cultivated autotrophically with H_2 as the sole electron and energy source.

Increasing the agar concentration and air drying the surface of the plate prior to incubation often helps the formation of single colonies. Several other methods have also been proposed: Alfredsson et al. (1986) found that Icelandic *Hydrogenobacter* strains grew well on an agar medium supplemented with thiosulfate (3.92 g/l $Na_2S_2O_3 \cdot 5H_2O$) under air plus 10KPa CO_2, and even better under air with 10KPa H_2 and 10 KPa CO_2, but not with H_2 as the only electron and energy source.

Ishii et al. (1987b) achieved colony formation by *Hydrogenobacter thermophilus* on media solidified with Gelrite, an agar-like bacterial polysaccharide (Merck & Co, Darmstadt, FRG). The composition of the culture medium was as follows:

Isolation Medium for *H. thermophilus*

Component	Amount
$(NH_4)_2SO_4$	3 g
KH_2PO_4	1 g
K_2HPO_4	2 g
$MgSO_4 \cdot 7H_2O$	0.5 g
NaCl	0.25 g
$CaCl_2$	0.03 g
$FeSO_4 \cdot 7H_2O$	0.014 g
$CuSO_4 \cdot 5H_2O$	0.010 g
Trace mineral solution	0.5 ml
Gelrite	10 g
Water	1 liter
Trace mineral solution:	
MoO_3	4 mg
$ZnSO_4 \cdot 7H_2O$	28 mg
H_3BO_3	4 mg
$MnSO_4 \cdot 5H_2O$	4 mg
$CoCl_2 \cdot 6H_2O$	4 mg
Water	1 liter

The addition of 10 mg/l $CuSO_4$ as shown above, was necessary for colony formation by *H. thermophilus.* At that concentration, the copper salt inhibited colony formation by the halophilic *Hydrogenobacter* (Nishihara et al., 1989b), which requires copper at a much lower concentration (2 mg/l $CuSO_4 \cdot 5H_2O$ in the trace mineral solution).

If it is not possible to isolate single colonies by streaking on solidified media, it is possible to proceed by serial dilution of the last enrich-

ment culture. This should be repeated several times, using the last positive tube, in order to obtain pure cultures. Incubating the cultures at about 75°C rather than at 70°C or below would favor *Hydrogenobacter* spp. over *B. schlegelii.*

Purity can be checked by microscopical observation, confirming morphological homogeneity and the absence of *B. schlegelii* spores (the most probable contaminant), and by the presence of a single inflexion point in the DNA denaturation curves.

Culture Procedures

CULTURE MEDIA. Schlegel's basal mineral medium (see Chapter 15) is well suited for the cultivation of most of the neutrophilic strains isolated so far. To prevent inhibition by phosphate, the concentration of this anion can be decreased to 10 mM. For halophilic *Hydrogenobacter,* the medium described by Nishihara et al. (1990) has been used. For *Bacillus tusciae,* rather than using the enrichment medium proposed above, it is preferable to use a low phosphate ($\leq$ 10 mM) medium, using as buffer a compound with good buffering capacities around pH 4.5. For the type strain, L(+)-tartrate at a concentration of 50 mM was added successfully as a buffer at pH 4.5. For other strains, the buffer compound must be checked for both nonutilization and nontoxicity.

GAS MIXTURE COMPOSITION. The composition of the gas mixture may vary according to the experimental conditions. Oxygen concentration is often critical because of the pronounced microaerophily of many strains. The culture should be started with a very low partial pressure of oxygen (1–5 KPa). Due to respiratory protection, actively growing cells are more oxygen resistant: this makes it possible to increase the O_2 concentration progressively during growth. Bonjour and Aragno (1986) have shown that in *Hydrogenobacter* spp., the level of microaerophily depends on the electron source. It is more pronounced when thiosulfate is used than under H_2. The mixolithotrophic cultures (H_2 + thiosulfate) are the most resistant to oxygen. See Chapter 15 for safety precautions when using gas mixtures containing H_2.

CULTURE CONDITIONS. Most strains of *Bacillus schlegelii* do not grow well under agitation. Good cell yields may be achieved in shallow, static cultures—for example, in Fernbach vessels placed in desiccators filled with the proper gas mixture. Fermenter cultures of *Hydrogenobacter* and of *B. tusciae* are also possible, provided the desired temperature can be reached.

Identification of Thermophilic Knallgas Bacteria

Key to the Identification of Thermophilic knallgas Bacteria

The following organisms are all able to grow chemolitho-autotrophically under a $H_2/O_2/CO_2$ mixture. Organisms belonging to the same species, but lacking the ability to oxidize H_2 (though they may be able to grow either autotrophically with reduced sulfur compounds or heterotrophically) could exist in nature, although none have been isolated so far. As is the case for several mesophilic knallgas bacteria (see Chapter 15), H_2-chemolithoautotrophy is not necessarily an important taxonomic marker at the species or genus level.

1. Sporeformers, Gram positive to variable 2
   Nonsporeformers, Gram negative 3
2. Growth at pH 7.0, no growth at pH 4.0. Endospores terminal, spherical, deforming the sporangium. GC 66–68 mol% .... *Bacillus schlegelii*
   Growth at pH 4.0, no growth at pH 7.0. Endospores subterminal to terminal, oval, deforming the sporangium. GC 57–58 mol% .... *B. tusciae*
3. Growth at 70°C. GC 37–46 mol% 4
   No growth at 70°C. Growth at 50°C 5
   Growth only below 50°C: see Chapter 15: key to the mesophilic, knallgas bacteria
4. Halophilic, growth with 0.5 M NaCl .... Halophilic *Hydrogenobacter* spp.
   Not halophilic, no growth with 0.5 M NaCl .... *H. thermophilus,* as well as several genospecies almost undistinguishable phenotypically, but showing low DNA homology with *H. thermophilus. Calderobacterium hydrogenophilum* should be included among these genospecies of *Hydrogenobacter.*
5. Three species of facultative knallgas bacteria, all moderate thermophiles, were described on the basis of 1–2 strains isolated. So far they have not been validly described:
   No carotenoid pigment formed; colonies light brown .... *"Pseudomonas thermophila"*
   Presence of carotenoid pigment; colonies dull yellow:
   Motile .... *"P. hydrogenothermophila"*
   Nonmotile .... *"Flavobacterium autothermophilum"*

These organisms need further characterization (see below).

The Thermophilic, Sporeforming Knallgas Bacteria

Table 4 lists the characteristics of *Bacillus schlegelii* and *B. tusciae.* Both species of thermophilic, sporeforming knallgas bacteria have a relatively high GC content, compared to most other members of the genus *Bacillus.* Other

thermophilic *Bacillus,* among which are *B. acidocaldarius, B. thermoruber,* and *B. thermocatenulatus* (Schenk and Aragno, 1979; Aragno, 1981), have a GC content > 60 mol%. Nevertheless, this property is probably not related to thermophily, since the even more thermophilic *Hydrogenobacter* spp. have a low GC content, whereas most of the mesophilic Knallgas bacteria (so Chapter 15) have a GC content of 60 mol% or higher. Phylogenetically, Gram-positive bacteria, including the sporeformers, are separated in two groups, one comprising the low GC organisms (including the genus *Bacillus*), the other the high-GC organisms. The phylogenetical position of the thermophilic bacilli with high-GC content is still unclear (Woose, 1987).

SHORT DESCRIPTION OF *BACILLUS SCHLEGELII* SCHENK AND ARAGNO (1979). This species has long straight rods, 0.6 × 2.5–5 μm, with peritrichous flagella. Spherical, terminal endospores, 0.8–1 μm in diameter, distinctly distend the sporangium. It is Gram variable, and the cell wall is covered by a regular array of protein units (Schenk and Aragno, 1979; Krüger and Meyer, 1984).

It has a strictly respiratory metabolism, with oxygen as the final acceptor. It cannot grow anaerobically with nitrate although nitrate is reduced to nitrite. Either chemolithoautotrophic growth (using H_2, CO, or reduced sulfur compounds as the electron donor and CO_2 as the carbon source), or chemoorganoheterotrophic growth occurs. Hydrogenase is constitutive, membrane-bound, and does not reduce NAD(P). The optimum temperature for hydrogenase is above 90°C (Pinkwart et al., 1983). Phenol, 1-propanol, and a small number of amino and organic acids can serve as sole carbon source. Sugars are not metabolized.

Its optimum temperature for growth is 70°C, with no growth at 37 or 80°C. Optimum pH for growth: 6 to 7. It is widespread as air-borne spores, originally isolated from a freshwater sediment, later also from other nongeothermal and geothermal habitats (Bonjour et al., 1988; see "Habitats of Thermophilic, Hydrogen-Oxidizing Bacteria"). The type strain is DSM 2000.

FURTHER STUDIES OF *B. SCHLEGELII*. *Bacillus schlegelii* is able to grow chemolithoautotrophically with thiosulfate (Hudson et al., 1988) as electron donor. The organism named *"Thiobacillus thermophilica"* (Egorova and Deryugina, 1963), a sulfur-oxidizing, thermophilic sporeformer, may have been identical to *B. schlegelii,* but apparently the original strain was lost. Krüger and Meyer (1984) isolated several sporeformers after enrichment under thermophilic conditions, using a mineral medium under 5% CO_2 + 35% CO + 60% air. These isolates were identified as *Bacillus schlegelii,* except strain OMT2 (see below). The type strain of *B. schlegelii* was then shown to share with the new isolates the ability to grow even faster with CO as the electron and energy source than with H_2. There was no immunological cross-reaction detected between the CO oxidase (CO dehydrogenase) from *B. schlegelii* and from *Pseudomonas carboxydovorans.* Other strains of *B. schlegelii* have not been tested so far for the utilization of CO as an electron source.

Hudson et al. (1988) isolated a strain of *B. schlegelii* from geothermally heated Antarctic soils by enrichment under air in a thiosulfate-containing mineral medium. The assignment of their isolate to *B. schlegelii* was later confirmed by the high DNA homology with the type strain (F. Bonjour, unpublished observation).

All strains tested but one (Bonjour et al., 1988; Krüger and Meyer, 1984) share a DNA-DNA homology of 78% or higher, regardless of their ecological or geographical origin and the mode of enrichment followed. Strain OMT2 (Krüger and Meyer, 1984) resembled *B. schlegelii* strongly (spherical spores, thermophily, ability to grow chemolithoautotrophically with H_2 or CO), but had a somewhat higher GC content of its DNA, a lower DNA homology with the type strain (59%), and differed in a few phenotypical characteristics.

The hydrogenase of *B. schlegelii* was compared to those of mesophilic, Gram-negative knallgas bacteria by Pinkwart et al. (1983). The *B. schlegelii* enzyme was more oxygen-sensitive and more stable under H_2 and in the presence of thioglycolate. Its molecular weight is about 100 kDa (110–125 kDa according to Krüger and Meyer, 1984, with possible dimers of 220–250 kDa). No immunological cross-reaction was detected with the hydrogenases from other Gram-negative, mesophilic knallgas bacteria.

SHORT DESCRIPTION OF *BACILLUS TUSCIAE* BONJOUR AND ARAGNO (1984). The cells of this species are straight rods, 0.8 × 4–5 μm, with a single lateral flagellum (see table 4). Oval, subterminal endospores, 1.2 × 1.8 μm, distinctly swell the sporangium. They are Gram positive in young cultures. No protein coat is outside the cell wall. PHA inclusions were observed in cells grown autotrophically under nitrogen starvation. Colonies on agar are spreading, white to cream, with a chalky surface. A white pellicle forms on the surface of liquid cultures at the end of the growth phase.

B. tusciae has a strictly respiratory metabolism, with oxygen as the final acceptor. It cannot grow anaerobically with nitrate but nitrate is reduced to nitrite. It is either chemolithoautotrophic, using H_2 as electron donor and CO_2 as carbon source, or chemoorganoheterotrophic; hydrogenase inducible, non-NAD-reducing, found in the soluble fraction after ultracentrifugation of the crude extract. CO_2 is fixed via the reductive, ribulose-1,5-bisphosphate cycle. A few amino acids and organic acids and several alcohols can serve as sole carbon source. Sugars are not metabolized.

The optimum temperature for growth is 55°C, with no growth at 35 or 65°C. The optimum pH for growth is 4.2 to 4.8. Growth is weak at pH 3.5 and at pH 6.0. *B. tusciae* has been isolated so far only from acidic geothermal pools, subject to short-term variations in temperature and pH.

Unlike *B. schlegelii, B. tusciae* has never been isolated from nongeothermal habitats, despite repeated attempts with freshwater sediments. Although authentic *B. tusciae* has so far been isolated only from Tuscany, similar strains have been isolated from the Furnas hot springs in S. Miguel (Azores) (M. Marchiani, personal communication). The presence of a soluble, non-NAD-reducing hydrogenase is unusual among knallgas bacteria and deserves further investigation.

The Highly Thermophilic, Nonsporeforming Knallgas Bacteria

From geothermal regions all over the world, various research groups have isolated several knallgas bacterial strains sharing the following basic properties:

Gram negative
Strict thermophiles (optimum temperature ≥70°C)
Habitat, exclusively geothermal
Strictly aerobic, although more or less microaerophilic
Autotrophic
Lithotrophic, using molecular hydrogen, elemental sulfur, or thiosulfate as electron and energy sources
Nonsporeforming
Low GC content (37–46 mol%)

Most strains isolated have been obligate autotrophs, although at least two strains, strain Z-809 (Savel'eva et al., 1982) and strain MF3 (Bonjour, 1988), were able to grow heterotrophically with a limited number of organic compounds (see below).

TAXONOMY OF EXTREME THERMOPHILES. Two genera and species were described almost simultaneously and independently by Japanese and Russian authors: *Hydrogenobacter thermophilus* (Kawasumi et al., 1984) and *Calderobacterium hydrogenophilum* (Kryukov et al., 1983). These organisms resemble each other strikingly, so they should be assigned at least to the same genus. In that case, the genus name *Hydrogenobacter* must have priority over *Calderobacterium,* since the Japanese authors published the original description in issue no. 1 of vol. 34 of the *International Journal of Systematic Bacteriology,* whereas the validation of the publication by the Russian authors appeared in the next issue.

Later, organisms similar to *Hydrogenobacter* and *Calderobacterium* have been isolated in other parts of the world: Iceland (Kristjansson et al., 1985) and Italy (Bonjour and Aragno, 1986; Bonjour, 1988). A halophilic strain clearly belonging to *Hydrogenobacter* was described by

Nishihara et al. (1990). Further isolates from the Azores, the USA, and New Zealand are at present under study in our laboratory. The phenotypical characteristics of all these organisms are very similar and allow a precise definition of the genus *Hydrogenobacter*.The cells are: long, straight to slightly curved rods, 0.3–0.5 × 2–4 (−8) μm; filaments are sometimes formed at supra-optimal temperatures; nonmotile; flagella, endospores, PHB granules, carboxysomes, or intracellular membranes have never been observed; Gram negative (by staining and cell wall ultrastructure), although the peptidoglycan layer appears to be relatively thick (Kristjansson et al., 1985).

Isolates of *Hydrogenobacter* are all: strictly respiratory, with oxygen as the terminal acceptor; microaerophilic; cannot grow anaerobically with nitrate; nitrate is not reduced; chemolithoautotrophic, using H_2 or reduced sulfur compounds as electron donors and CO_2 as carbon source; CO_2 is fixed via the reductive TCA cycle (Shiba et al., 1985). Most strains are unable to grow heterotrophically with any of a variety of organic compounds (organic and amino acids, alcohols, sugars) tested. Hydrogenase is membrane-bound and does not reduce NAD(P). Ammonium salts and/or asparagine can serve as sole nitrogen sources. Dinitrogen is not fixed.

These strains are: sensitive to penicillin and other eubacteria-specific antibiotics; have a GC content of 37–46 mol%; are oxidase positive and catalase negative; contain cytochromes *b, c,* and *o,* but no cytochrome a/a_3 (Kawasumi et al., 1984; Pusheva et al., 1988). The optimum temperature for growth is 70–75°C and no growth occurs at 45°C or at 90°C. Optimum pH for growth is 6–7 and the pH limits are 4.0 and 7.5. So far, they have been isolated exclusively from geothermal environments.

Several characteristics have only been studied in strains from one geographical origin: they should be tested on the other strains. They include: 1) an unusual profile of cellular lipids in the Japanese strains, with linear $C_{18:0}$ and $C_{20:1}$ as the major lipids (Kawasumi et al, 1984); 2) a unique quinone, 2-methylthio-1, 4-naphthoquinone, as the main quinonic component, in the type strain of *H. thermophilus* and in the halophilic *Hydrogenobacter* (Ishii et al., 1983; Nishihara et al., 1990); 3) a carotenoid pigment reported only in the Icelandic strains (Kristjansson et al., 1985); 4) an external coat consisting of regular arrays of proteic subunits in Icelandic strains (Kristjansson et al., 1985); and 5) the genome size of the Russian strains is very small (1.4–1.6 × 10^9 Dalton) compared to that of other eubacteria. The kinetics of DNA renaturation is similar for all strains examined, but differs from other bacteria tested (Lysenko et al., 1985)

So far, it has been very difficult to establish clear phenotypical distinctions among the organisms described. This is due in part to their striking similarity to each other, but also to the absence of most of the "classical" phenotypical characteristics (carbon substrate utilization spectra, many catabolic enzymatic activities) since they are obligate autotrophs.

A comparison by DNA-DNA homology analysis of strains of Hydrogenobacter from various parts of the world has yielded interesting results (Bonjour, 1988; Lysenko et al., 1985). The results shown in Table 5 indicate that there are five very clear-cut homology groups. Groups 1 and 2 were isolated from Italian sources. While all the organisms belonging to group 1 were isolated from the S. Federigo solfatara (Tuscany), two of the strains from group 2 originate from regions distant from Tuscany: strain 102 from Agnano Terme (near Naples, 250 km SE of S. Federigo) and strain MF3 from a fumarole on the Etna volcano (Sicily, 250 km SE of Naples). Group 3 comprises two strains isolated in Iceland by Kristjansson et al. (1985), and group 4 comprises two Japanese strains described by Kawasumi et al. (1984); strain TK-6 is the type strain of *H. thermophilus.* The strains in group 5, from the USSR, were studied by Kryukov et al. (1983) and by Lysenko et al. (1985). Among them, strain Z-829 is the type strain of *Calderobacterium hydrogenophilum.* DNA homology measurements between the halophilic *Hydrogenobacter* (Nishihara et al., 1990) and the other homology groups are still lacking.

Due to their very low intergroup homology, these five groups should be considered as different genospecies. However, following the recommendation by the "Ad hoc committee on reconciliation of approaches to bacterial systematics" (Wayne et al., 1987), we will not propose new species names for these genospecies unless clear-cut phenotypic properties can be associated with the DNA homology groups.

It appears from these results that DNA homology grouping partially reflects the geographical distribution of the organisms. The two groups isolated from Tuscany and other Italian sources differ by their maximum temperature, group 1 being more thermophilic (maximum, 86°C) than group 2 (maximum 80°C). Although strains of both groups were isolated from the same geothermal field (S. Federigo), they appear to be thermally diverse (see Fig. 1).

Surprisingly, strain MF3, which is facultatively autotrophic, clearly belongs to group 2, whereas all the other strains are obligate auto-

trophs. The other facultative autotroph described (strain Z-809, Savel'eva et al., 1982) has been lost, and did not appear in the paper by Lysenko et al. (1985).

In short, at least five genospecies of *Hydrogenobacter* exist, reflecting wide geographic and temperature distributions. Contrasting with clear-cut genomic separation, they show striking morphological and metabolic similarities that so far do not permit distinction on a phenotypical basis. Thus, specific names cannot be given at this time. Rare in the group, facultative heterotrophy is only a strain-specific property without taxonomic significance.

FURTHER STUDIES OF THE EXTREME THERMOPHILES. *Hydrogenobacter* spp. are able to grow chemolithoautotrophically with thiosulfate and elemental sulfur (Bonjour and Aragno, 1986; Alfredsson et al., 1986) as well as with H_2 as electron donor. When thiosulfate and H_2 are given simultaneously, both are utilized concomitantly (mixolithotrophy), allowing a higher growth rate than with only one electron donor. Growth with thiosulfate only is very sensitive to oxygen, whereas mixolithotrophic growth is the least sensitive to oxygen. During growth on thiosulfate, elemental sulfur accumulates transiently.

Although obligately lithotrophic, *H. thermophilus* TK-6 could incorporate limited amounts of organic compounds, like acetate, pyruvate, and glucose, but only when $H_2 + O_2$ were present (Shiba et al., 1984). The addition of small amounts of pyruvate, acetate, or malate stimulated the autotrophic growth of this organism.

The respiratory chain was investigated by several authors. The hydrogenase activity of strain Z-809 was studied by Pusheva and Savel'eva (1982), who noted the thermophily of the enzyme, as well as its resistence to O_2. The hydrogenase of *C. hydrogenophilum* Z-1215 was purified (Pusheva et al., 1987) and its kinetic parameters determined. The hydrogen uptake activity by whole cells of strain Z-829 showed no measurable H_2-concentration threshold ($\leq$0.01 ppmv) whereas a distinct threshold was observed with cell-free extracts of the same organism (10–100 ppmv) (Kryukov and Bodnar, 1987). Cytochrome c_{552} from *H. thermophilus* TK-6 was purified and characterized (Ishii et al., 1987a). It reacted directly with the purified hydrogenase from the same organism (Ishii et al., 1987c). These authors propose a model for the respiratory chain of this organism, including 2-methylthio-1,4-naphthoquinone in the reverse electron transport pathway to NAD. The cytochromes of *C. hydrogenophilum* Z-829 were investigated and its cytochrome c_{552} was purified (Pusheva et al., 1988). It reacted with bovine cytochrome oxidase.

The elongation factor EF-Tu from *C. hydrogenophilum* was isolated and purified (Mikulik et al., 1988). In contrast to EF-Tu from *Thermus thermophilus,* it cross-reacted with antibodies against EF-Tu from *Escherichia coli.* In spite of this similarity, the temperature relationships of EF-Tu from *C. hydrogenophilum* and from *E. coli* were quite different: optimal at 40°C and complete loss after 5 min at 60°C for the latter, optimal at 70°C and complete loss after 5 min at 95°C for the former.

The Moderately Thermophilic, knallgas Bacteria

Three species of moderately thermophilic knallgas bacteria have been described, although at present they are not recognized as validly published. Surprisingly, they were the first thermophilic knallgas bacteria isolated. All have an optimum growth temperature of about 50°C, whereas their minimal temperature extends into the mesobiotic range.

"PSEUDOMONAS THERMOPHILA." McGee et al. (1967) described a moderately thermophilic knallgas bacterium as *"Hydrogenomonas thermophilus"* (sic). Further studies on this organism described conditions for colony formation (Tischer et al., 1975) and the ultrastructure of the cell wall (Wang and Tischer, 1975). The strain was not deposited in an official culture collection and apparently was lost. Krasilya et al. (1973) isolated an organism (strain K-2) they attributed to *H. thermophilus.* After the rejection of *Hydrogenomonas* by Davis et al. (1969), Emnova and Zavarzin (1977) transferred this organism to *Pseudomonas,* as *"P. thermophila."* However, neither the latter nor the former description was acknowledged as valid (Skerman et al., 1980). As the description by McGee et al. (1967) is rudimentary, the following description is based, unless otherwise stated, on the paper by Emnova and Zavarzin (1977) for strain K-2.

The cells of this organism are: short rods, 1.3–1.75 × 0.5–0.6 μm; motile by means of one polar flagellum; Gram-negative (Gram reaction and cell wall structure); neither endospores nor capsules are formed; PHB inclusions are present (Kostrikina et al., 1981). Strain K-2 contains carboxysomes and extensive intracellular membranes (Kostrikina et al., 1981; Romanova et al., 1982). Colonies are light brown. No carotenoid pigment is formed.

This organism has a strictly respiratory metabolism, with oxygen as the terminal acceptor. It cannot grow anaerobically with nitrate, al-

though nitrate is reduced to nitrite. It is a facultative chemolithoautotroph, using H_2 as electron donor and CO_2 as carbon source. Hydrogenase is membrane-bound and not NAD-reducing. Cytochromes *a, b, c,* and *o* are present (Emnova and Zavarzin, 1979). CO_2 is fixed via the ribulose-bisphosphate cycle (Romanova et al., 1980). It grows under air on a variety of organic and amino acids. Sugars and alcohols are not utilized, and it is neither proteolytic (on gelatin) nor lipolytic (on Tween 80). Ammonium salts, nitrates, and several amino acids can serve as N sources, but nitrites and urea cannot. Dinitrogen is not fixed. The optimum temperature for growth is 50°C, with slow growth at 36 and 56°C. Strain K-2 was isolated from a drainage ditch.

The presence of carboxysomes and intracellular membranes is unusual in knallgas bacteria (Walther-Mauruschat et al., 1977), indicating a possible relationship of *P. thermophila* with thiobacilli or nitrifying bacteria. Its aptitude to utilize other electron donors (reduced sulfur or nitrogen compounds) has not been tested so far. Wang and Tischer (1975) noted the presence, in the original strain, of a proteinaceous coat consisting of a hexagonal array of subunits. This was not observed in strain K-2 (Kostrikina et al., 1981).

Strain K-2 has been extensively studied by Russian microbiologists as a potential biomass producer (Emnova and Romanova, 1982). The published papers deal mainly with the activity and localization of the hydrogenase (Emnova and Romanova, 1977; Emnova et al., 1979), the respiratory chain and membrane function (Emnova and Zavarzin, 1979; Romanova and Emnova, 1980; Kuznetsov et al., 1984), the temperature and pH dependence of the ribulose-bisphosphate carboxylase (Romanova et al., 1980), the ultrastructure (Kostrikina et al., 1981; Romanova et al., 1982), enzyme production (Emnova et al., 1982), and the pattern of RNA extraction from cell biomass (Emnova, 1978).

"PSEUDOMONAS HYDROGENOTHERMOPHILA" AND "FLAVOBACTERIUM AUTOTHERMOPHILUM." These two species were described on the basis of four strains isolated from soils around hot springs in Japan (Goto et al., 1978). In fact, they appear to be very similar to each other, differing only by the motility of the former and the occasional observation of round "cysts" in cultures of *F. autothermophilum.* Genomic relationships between both types and a deeper taxonomic approach are thus needed before these organisms can be accepted as valid species. The following description fits both "species":

The cells are: long, straight rods; 2–6 × 0.6 µm; motile by means of one polar flagellum *(P. h.)* or non-motile *(F. a.);* Gram-negative; endospores are not formed; colonies dull yellow, due to the presence of a carotenoid pigment.

Both species display a strictly respiratory metabolism, with oxygen as the terminal acceptor. They are either chemolithoautotrophic, using H_2 as electron donor and CO_2 as carbon source, or chemoorganoheterotrophic. A few organic acids, but neither sugars nor alcohols, are utilized. Ammonium salts, nitrate and urea, but not nitrite, can serve as N source. Dinitrogen is not fixed. They are catalase and urease positive. Their GC content is 63.5 mol% *(P. h.)* and 64.9 mol% *(F. a.).*

The optimum temperature for growth is 50–52°C, with extremes of 30 and 55°C. The pH optimum is 7.0; ranging from pH 5–8. They were isolated from soil around hot springs in Japan. (The paper by Goto et al. (1977) deals mainly with the optimization of the culture medium.)

Biotechnological Potential of Thermophilic Knallgas Bacteria

The thermophilic knallgas bacteria present a number of advantages for utilization in biotechnological applications: they combine the characteristics of knallgas bacteria discussed in Chapter 15 (lithoautotrophy, use of H_2, a potentially important energy converter, high growth yields) with those of thermophiles. Among these, one could mention the lower risk of spontaneous contamination and the production of structures, particularly enzymes, that are more resistant, not only to heat, but also to other external factors, and that are often more stable. Thermophiles do not normally require cooling of the culture. An other advantage of thermophilic knallgas bacteria over other types of thermophiles is their high growth rates and the high cell densities they reach in fermenter cultures. For these reasons, *Hydrogenobacter* spp. appear particularly promising for biotechnological applications.

A deeper knowledge of the biochemistry and the genetics of these organisms is thus urgently needed, particularly regarding the possibility of using them as recipients of genes from other thermophiles, or of using enzymes and/or genes from these organisms as tools for a variety of applications.

Morphologically Conspicuous Sulfur-Oxidizing Eubacteria

JAN W. M. LA RIVIÈRE and KARIN SCHMIDT

This chapter deals with the genera *Achromatium, Macromonas, Thiobacterium, Thiospira,* and *Thiovulum* (see Fig. 1). They all belong to chemotrophic microbial populations generally encountered in natural habitats that are characterized by the simultaneous presence of H_2S and O_2, i.e., at the border between aerobic and anaerobic zones in surface waters and in the outflows of H_2S-bearing springs. It will be useful to introduce this discussion with some general remarks on the special nature of this ecological niche to help explain the embarassing paucity of knowledge we possess about its inhabitants.

In nature, the coexistence of H_2S and O_2 can only be sustained in systems subject to continuous inputs of both substances, because H_2S is not stable in the presence of O_2. H_2S can be rapidly oxidized without the intervention of living organisms, the rate of oxidation depending on pH, temperature, and the presence of catalysts and/or inhibitors (Chen and Morris, 1972a, 1972b); reaction products range from sulfur and polysulfides to thiosulfate, sulfite, and sulfate. Thus, this habitat contains an array of reduced sulfur compounds that are all potential substrates for chemolithotrophic oxidation but that differ greatly in their stability in the presence of O_2.

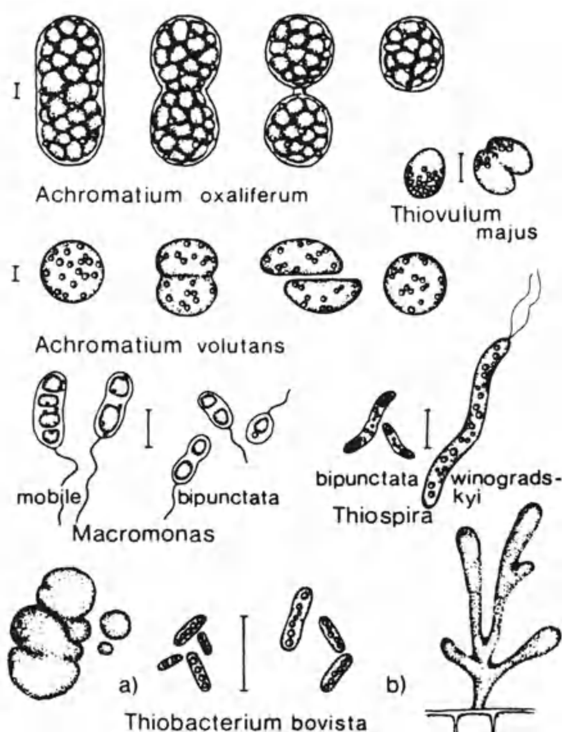

Fig. 1. Composite drawing of the described organisms, redrawn from the original literature. Bars = 10 μm—except for the typical colonies of the *Thiobacterium* species: (a) "puffball" shape, (b) dendroid shape.

The chemotrophic segment of the microbial population occupying this special niche includes—in addition to accidental "interlopers" such as H_2S-tolerant microaerophilic heterotrophs—a group of organisms called *colorless sulfur bacteria,* which appear to interact directly with the reduced-sulfur compounds characterizing this habitat.

These colorless sulfur bacteria include in the first place *Sulfolobus, Thiobacillus,* and *Thiomicrospira* (see Chapters 28 and 138), which have been shown to possess the capacity to chemolithotrophically oxidize reduced-sulfur compounds. Secondly, the group includes the five genera to be discussed here—*Achromatium, Macromonas, Thiobacterium, Thiospira,* and *Thiovulum*—as well as *Beggiatoa, Thiothrix,* and *Thioploca* (see Chapter 16 and 166). These eight genera are included among the colorless sulfur bacteria because the observed appearance and disappearance of sulfur inclusions suggest the possession of at least the capacity to oxidize sulfide and sulfur. The nutritional status of these genera is by no means certain and their relationship to reduced-sulfur compounds may range from obligate chemolithotrophy to protective, detoxifying sulfide oxidation, or to merely gratuitous sulfide oxidation. Another argument for inclusion of this group is the observed absence of these genera in habitats devoid of H_2S. Finally, there are an indefinite number of colorless sulfur bacteria that are not recognized in the eighth edition of *Bergey's*

Manual of Determinative Bacteriology (Buchanan and Gibbons, 1974) or discussed in this Handbook because they have been described poorly or no more than once. The works of the old masters, such as Gicklhorn, Hinze, Kolkwitz, Lauterborn, Molisch, Nadson, Warming, and Winogradsky, offer clear indications that several genera and even more species of colorless sulfur bacteria exist that cannot now be recognized usefully.

Thus the 11 genera discussed in this book represent only the most accessible part of the inhabitants of this ecological niche; even so, only five of them exist at the moment in pure culture: *Thiobacillus, Sulfolobus,* and *Thiomicrospira,* which can be cultivated with the stable compounds thiosulfate and/or sulfur as oxidizable substrates, *Macromonas,* of which only heterotrophic strains exist in pure culture, and *Beggiatoa,* from marine and freshwater habitats. Only the marine *Beggiatoa* strains seem to be facultative autotrophs (Nelson, 1989). The other six genera have not yielded pure cultures most probably because they are obligate sulfide-oxidizers, which, in view of the autoxidizability of H_2S, renders the use of solid media impossible and that of liquid media extremely cumbersome, since continuous inputs of H_2S and O_2 have to be maintained. Thus, for the moment, these six genera exist only by virtue of their morphological recognizability. The morphological characteristics are the only basis for the division into different genera.

In nature, quite often the predominance of one or a few colorless sulfur bacteria can be observed. Knowledge of the factors determining such predominance would obviously be of great help in isolation studies, but so far we have no clue as to the determinants of competition and survival of these diverse organisms, which have to compete not only among one another, but very likely also against the chemical oxidation of H_2S.

Thus we are faced with a vicious circle: lack of knowledge of the physiology of these organisms impedes the design of effective isolation procedures, which, in turn, are the very requirement for obtaining such physiological knowledge through pure culture study. The riddle they pose is further complicated by the complexity of their natural habitat. In addition to natural aeration, when exposed to light, the medium also receives O_2 from photosynthesis, subject to diurnal fluctuations. Furthermore, H_2S can originate from groundwaters poor in organic matter, as well as from sulfate reduction in mud layers, in which case it is invariably accompanied by organic compounds. The mineral contents of the water also appear to play an important role. A relatively high Ca^{2+} concentration or the presence of solid $CaCO_3$ characterizes many of the habitats in which the organisms are found; the relationship is most obvious for *Achromatium* and *Macromonas,* which both can have $CaCO_3$ inclusions.

Enrichment and Cultivation Methods

Imitation of the natural conditions in the laboratory appears to be the best approach to enrichment, cultivation, and isolation of *Achromatium, Macromonas, Thiobacterium, Thiospira,* and *Thiovulum,* the five genera under discussion in this chapter. The enrichment methods consist essentially of using Winogradsky columns (Winogradsky, 1888) that are kept in the dark and that contain sediments in which H_2S is generated through sulfate reduction. Hence, adequate, i.e., slowly decaying, organic material—and in the case of freshwater enrichments, $CaSO_4$—has to be included in the sediment; in seawater enrichments, a considerable amount of sulfate is already present in the water phase. Besides stationary columns, flow-through variations have been used in which the water phase is continuously and slowly replenished, which provides a means of controlling the position of the H_2S/O_2 border zone and of eliminating contaminants. This method has led to reproducible enrichment procedures for *Thiovulum,* while a more classical enrichment method could be used for the heterotrophic *Macromonas bipunctata.* For the other three genera, enrichment is still extremely difficult and at best capricious.

In the design of effective enrichment and cultivation methods, some guidelines can be further derived from specific ecological attributes of the organisms themselves:

1. The presence of elemental sulfur inclusions, a stored energy source, implies that the culture can survive periods of absence of H_2S but not of O_2 (all genera).
2. Possession of strong chemotactic properties introduces the possibility of exerting selection through water flow *(Thiovulum, Thiospira).*
3. Limited motility, or its absence in some genera, calls for stability of the position of the H_2S/O_2 border zone in the place where the organism is expected to accumulate (*Achromatium:* at the bottom; *Thiobacterium:* at the surface).
4. Capacity for attachment to solid surfaces permits selection by water flow, provided the

water contains the proper mix of H_2S and O_2 *(Thiobacterium, Thiothrix).*
5. The organism permitting, application of low temperatures (10–17°C) appears favorable, as this slows down chemical H_2S oxidation and thus leads to greater stability.

In conjunction with these methods, purification of cell material has been undertaken by taking advantage of chemotaxis *(Thiovulum)* and of selective sedimentation based on high specific gravity *(Achromatium).* Suspending the cells in sterile solutions followed by transfer to fresh sterile solution after separation had taken place could be carried out repeatedly, the "washing efficiency" depending on the initial degree of contamination and the endurance of the cells to repeated washings.

Such purified material, derived from nature or enrichment cultures, can then be subjected to cultivation in aseptic, controlled systems in which constant inputs of H_2S and O_2 are maintained. A great deal of ingenuity has gone into the design of such systems, based, for instance, upon the use of gas mixtures, semipermeable membranes, controlled pumping of sterile nutrient solutions, and solid/liquid phase systems in which the solid phase provides H_2S. So far, the use of sulfide-charged ion-exchangers or badly soluble sulfides as a constant source of H_2S has not been found practicable, nor has the use of inhibitors of chemical H_2S oxidation. Important examples of devices successfully used in specific instances are presented by Devidé (1954), Keil (1912), la Rivière (1963, 1965), and Perfil'ev and Gabe (1961). Wirsen and Jannasch (1978) described a variety of cultivation systems for *Thiovulum* (see below) in which full advantage was taken of modern materials and equipment. It is likely that these systems are also suitable for cultivation of other recalcitrant sulfur bacteria.

Presently, however, our knowledge is still restricted to such data as can be obtained from observations on natural populations and on enrichment cultures in the laboratory, both macro- and microscopically. In addition, laboratory cultures have in several cases produced sufficient quantities of cell material, sufficiently free from contamination, to make electron microscopy of whole cells and thin sections possible. Similarly, such cell material has permitted the determination of sometimes important physiological data. The main target of studies in complex culture systems remains, however, the acquirement of knowledge about the organism that will lead to the design of simpler cultivation methods. After all, one should keep in mind that one successful petri dish culture offers more promise for isolation and subsequent work than any of the culture systems mentioned above.

Significance of the Colorless Sulfur Bacteria

This group of organisms poses the question of how such a great morphological diversity has evolved in a very specialized and restricted niche in competition with chemical sulfide oxidation. One might well speculate that this niche must have been much larger at the time when, during the evolution of the present biosphere, the first oxygen appeared on an initially anaerobic stage and that, for a long time since, a much smaller O_2 concentration prevailed in the atmosphere than at present. However this may be, it is certain that microbial activity, including that of colorless sulfur bacteria, has played and is still playing an important role in the biogeochemical cycle of sulfur (Jørgensen, 1989; Kuenen, 1975; SCOPE 19, 1983; SCOPE 39, 1989; Kuenen and Bos, 1989; la Rivière, 1966). It is, for instance, generally accepted that the sulfur deposits that are mined today are biogenic and have been formed by sulfate reduction followed by an oxidation step that may have involved colorless sulfur bacteria. The well-known *sulfuretum,* in which sulfur is still accumulating today, offers an opportunity for determining the additional contributions of chemical and photosynthetic sulfide oxidation. Furthermore, sulfide oxidation to sulfate is an important step in the regeneration of oxidizing power within water bodies where sulfate plays a role in anaerobic mineralization. Also, the release of H_2S into the atmosphere from oceanic, marshy, and estuarine areas is at the moment a matter of concern on a global scale in judging the impact of artificial SO_2 emissions that are superimposed on it (Svensson and Söderlund, 1976). The magnitude of the biogenic H_2S emissions is presently not well known, but it is certain that the colorless sulfur bacteria codetermine it to a large extent. Finally, biological sulfide oxidation is responsible for the generation of certain types of acid soils and the formation of acid mine effluents. In the mining industry, so-called microbial leaching is presently being practiced for improving the yield of various metals from sulfide ores. For this purpose, *Thiobacillus* species are frequently being used (see Chapter 32). Furthermore, the microbiological methods for removing sulfur from coal, and removing hydrogen sulfide from biogas, generated by anaerobic digestion, are growing in industrial importance.

In the situation as outlined in this introduction, more detailed presentation of available information that follows can offer no more than some springboards and roadsigns for those who want to penetrate further into a fascinating and as yet unconquered territory of the microbial kingdom. Such endeavors also offer the rare sensation of reading the works of the old masters as valuable guidebooks of undiminished contemporary relevance. In order to facilitate such reading, pertinent references as well as earlier used names of organisms have been included.

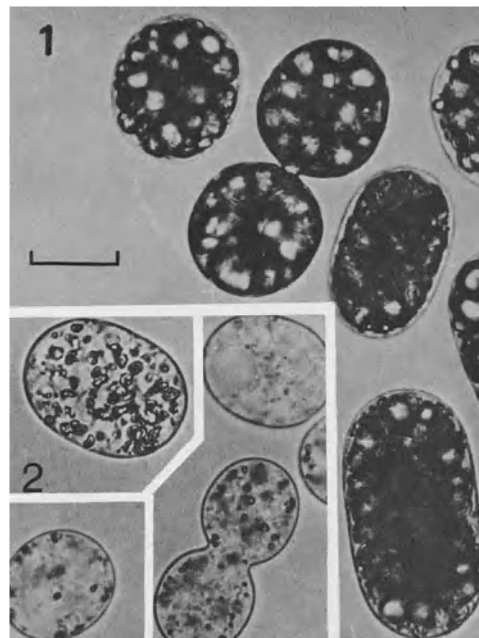
The Genus *Achromatium*

Two species of Achromatium are known (La Rivière and Schmidt, 1989): *Achromatium oxaliferum,* which occurs in fresh waters and marine environments, and *Achromatium volutans,* which is less well known and has been found in marine muds only.

Achromatium oxaliferum

Achromatium oxaliferum (Figs. 1 and 2) was described for the first time by Schewiakoff (1893). Since then the organism has temporarily also carried the names *Hillhousia mirabilis* (West and Griffiths, 1909), *Hillhousia palustris* (West and Griffiths, 1913), and *Achromatium gigas* (Nadson, 1913). Its cells are conspicuous because of their massive $CaCO_3$ inclusions occurring together with much smaller sulfur globules. In addition, their large size immediately attracts attention: the cells are spherical, ovoid, or cylindrical with a minimum length of the small axis of 5 μm and a maximum length of the long axis of 100 μm. Division is by constriction. The cells are slowly motile on solid surfaces only. It is, therefore, not surprising that the organism has tantalized numerous observers, none of whom, however, has so far succeeded in developing an effective enrichment method.

ECOLOGY. In all cases, the cells were encountered in or on the bottom mud of fresh and saline waters, as is to be expected from the high specific weight of these organisms which prevents them from moving vertically in the water. Since they are not at all commonly found among the macroscopically recognizable white masses that usually guide the investigator most effectively to natural populations of colorless sulfur bacteria, it appears useful to list here some of the habitats in which the organism was found, all the more so because no useful common characteristic of these habitats has as yet emerged.



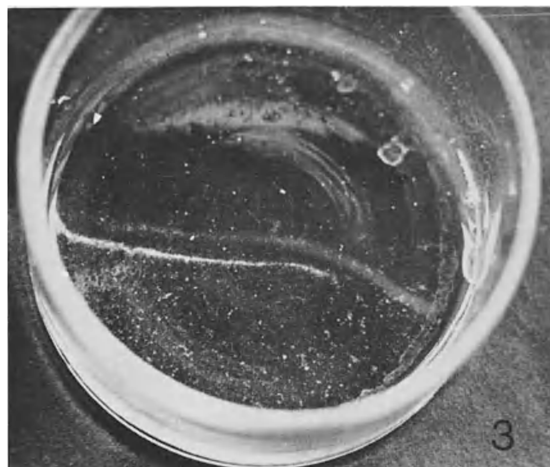


Fig. 2. *Achromatium oxaliferum* (from a garden pond near The Hague, The Netherlands). (1) Cells filled with $CaCO_3$ crystals. Bar = 20 μm. (2) Cells after treatment with 0.05 N acetic acid; sulfur globules can be clearly seen. (3) Topside view of a beaker with a band of "enriched" *Achromatium* cells.

Gicklhorn (1920), Bersa (1920), and Bavendamm (1924) found *Achromatium* in ponds in the botanical garden in Graz where the alga *Chara* also occurred in large numbers. The bottom mud of Swedish lakes was the source for Skuja (1948), and that of Lake Windermere for Skerman (Starr and Skerman, 1965). Lackey and Lackey (1961) found the organism in fresh and brackish waters in Florida as well as in salt marshes at Woods Hole. It was also found in a small concrete garden pond in Pacific Grove, California, and in 2 out of 14 garden ponds examined near The Hague (J. la Rivière, unpublished). These were made of concrete, had

a depth of 40 cm, and contained very loosely packed mud with much organic matter as well as cells of algae and cyanobacteria. Nadson and Visloukh (1923) found *Achromatium* in marine muds. Some of these waters were high, others low, in Ca^{2+} concentration.

Since all authors agree that the organism is an obligate aerobe and the high weight of its cells restricts it to the bottom habitat, it seems obvious that in all of the above-mentioned locations the borderzone between H_2S and O_2 must have resided in the mud or on top of it, indicating that the H_2S generation in the sediment must have been relatively weak, or, alternatively, aeration consistently strong. This appears to make *Achromatium oxaliferum* the counterpart to *Thiobacterium* which (as a "puffball" type) floats at the surface. There is, however, one important difference in that *Achromatium* possesses some means of locomotion while *Thiobacterium* does not. This motility is very slow and restricted to jerky rolling movements on solid surfaces, most probably effected by means of peritrichous filaments moving about in the slime layer that surrounds the cells (de Boer et al., 1971). In this way, the cells are capable of migrating chemotactically through the mud, where, depending on the distribution of localized microsources of H_2S, concentration gradients exist over short distances that are manageable by the organisms.

Lauterborn (1915) noted that cells were packed with $CaCO_3$ and had few sulfur inclusions when encountered on top of the mud, while cells below the surface contained little or no $CaCO_3$ and much more sulfur. This suggests that the restricted capacity for chemotaxis is somewhat complemented by the storage of sulfur but does not explain the significance that $CaCO_3$ storage could have for the organism beyond keeping it in the bottom layers by sheer weight. In this respect, any possible interaction with surrounding photosynthetic organisms appears important, as these exert a considerable influence not only on the O_2 concentration but also on the $CO_2/CaCO_3$ equilibrium, which are both subject to diurnal changes. In addition, $CaCO_3$ might exert a buffering effect with respect to H_2SO_4 formed by sulfur oxidation.

ENRICHMENT AND CULTIVATION. Most observations on the organism have been done on material taken directly from nature. No effective laboratory enrichment culture methods are available; at best the natural populations can be kept alive in the laboratory for 6–10 months. Schewiakoff (1893) used a watch glass containing mud, *Achromatium* cells, and some supernatant water from the natural habitat. After placing it in sunlight he observed "energetic multiplication" (perhaps chemotactic accumulation?) and formation of white agglomerations of 50–100 cells each. West and Griffiths (1913) placed the mud with overlaying tap water in small cylinders (15 cm wide, 5 cm high) and stirred the mud from time to time; in this way they kept the organisms alive for 9 months. They stated that the cells had a doubling time of 24–48 h under these conditions and that death resulting from O_2 deficiency was accompanied by the loss of the $CaCO_3$ inclusions. De Boer et al., (1971) maintained natural populations for 10 months by placing the loosely packed mud from a pond in closed plastic bottles at 5°C. The overlaying pond water column was about four times higher than the mud layer. The same authors used a very simple method, suggested to them by C. B. van Niel, for concentrating the cells in such a mud-water system. It is based on the heavy weight and white color of the *Achromatium* cells:

Collecting and Concentrating *Achromatium* Cells Found in Nature (de Boer et al., 1971)

Material from the upper part of the sediment was collected. Lightweight particles were removed by repeated decanting in tap water. Layers of heavier mud particles, approximately 0.5 cm thick, were subjected to gentle swirling in a tilted beaker that at the same time was rotated slowly along its vertical axis (Fig. 2). This treatment led to further fractionation of the particles according to their specific gravity and the heavy *Achromatium* cells soon became visible as a narrow white band very close to that of the sand-particle fraction. The cells were pipetted off and transferred to a smaller beaker and further purified by the same method. This procedure was repeated several times until a dense mass of *Achromatium* cells was obtained. This no longer contained cells of algae, protozoa, or sand particles, and the number of smaller bacteria present had been reduced to a very small minority, as shown by microscopic examination.

The method was obviously only successful for *Achromatium* cells that actually contained appreciable quantities of $CaCO_3$ inclusions.

At least 50% of the cells obtained in this way were viable, as shown by their motility observed under the microscope. They proved to be quite suitable for electron microscopy and some elementary physiological tests.

FURTHER CHARACTERISTICS. The organism is very easy to identify by the morphological characteristics already mentioned. Healthy cells are almost completely filled with highly refractile $CaCO_3$ crystals, which makes it difficult to observe the sulfur globules. These are best seen after selective removal of the $CaCO_3$ by treating

the cells with 0.05 N acetic acid (de Boer et al., 1971) (Fig. 2).

Cells collected by the method described above remained contaminated by heterotrophs even after repeated washings with sterile water. Nevertheless, indications were obtained that the cells moved and multiplied more actively in the presence of organic acids, casamino acids, or both. The experiments, however, could not be pursued further because of overgrowth by more rapidly multiplying heterotrophs (K. Schmidt, unpublished). The cells could be lysed by lysozyme and proved to be Gram-negative and catalase-negative.

Achromatium volutans

Achromatium volutans (Fig. 1 and 3) was first described by Hinze (1903) under the name of *Thiophysa volutans* and later by Nadson (1913, 1914) under the name of *Thiophysa macrophysa*. The organism was found in saline waters only: in association with mud and decaying seaweeds from the Bay of Naples (Hinze, 1903, 1913), in the saline sulfur spring "Solgraben von Artern" (Kolkwitz, 1918), and in a saline spring in Florida (Lackey and Lackey, 1961). The best description is probably that of Hinze (1903), who obtained his cell material from marine mud placed in a flat dish; within 1 h, many cells were found at the mud surface, concentrated through chemotaxis into a thin white layer.

The organism was very similar to *Achromatium oxaliferum* with respect to cell shape, motility, and mode of division. A striking difference was the total lack of $CaCO_3$ inclusions and the presence of far more and larger sulfur globules. Also the cells were consistently smaller, ranging from spheres with a diameter of 5 μm, when young, to ovals up to 40 μm in length. Right after division cells were flat at one end, which was never observed in *Achromatium oxaliferum* (Fig. 1).

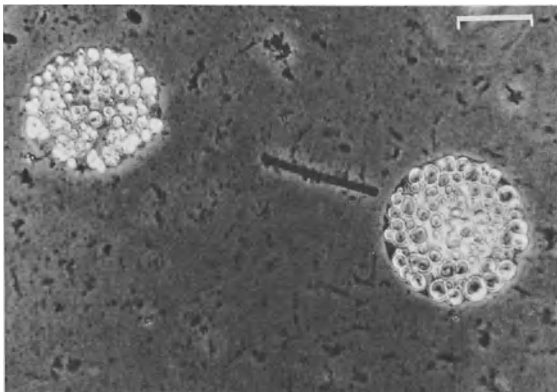

Fig. 3. *Achromatium* (=*Thiophysa*) *volutans* (from Solgraben in Artern, Germany). Bar = 20 μm.

The observations of Hinze (1903) suggest that this organism is more sensitive to environmental conditions like H_2S and O_2 concentrations than is *Achromatium oxaliferum*. This appears plausible because its lower specific gravity is likely to permit more rapid chemotactic response.

The Genus *Macromonas*

Cells of *Macromonas* are often found in habitats where *Achromatium oxaliferum* also occurs (Bavendamm, 1924; Gicklhorn, 1920; Lauterborn, 1915; Skuja, 1956). To the knowledge of the authors, only one attempt at enrichment of these organisms has been described (Dubinina and Grabovich, 1984). Hence, most available data originate from observations on material directly taken from natural sources.

The cells are colorless, cylindrical or bean shaped, and sluggishly motile with one polar flagellum. Since flagellation was observed in the light microscope, presence of a tuft of flagella is more likely. Their typical characteristic is the presence of several large refractile spherules, which have been thought to consist of $CaCO_3$; definite proof for this is lacking, however. In addition, small sulfur globules may be present.

Two species have been recognized (la Rivière and Dubinina, 1989).

Of the two species *Macromonas mobilis* (Fig. 1) was first described by Lauterborn (1915) under the name *Achromatium mobile* and later by Gicklhorn (1920) as *Microspira vacillans*. The cells are ellipsoidal or cylindrical and slightly curved, measuring usually 9 by 20 μm. Smaller cells are often present and are believed to be daughter cells (Gicklhorn, 1920). The single polar locomotor organ (tuft of flagella?) measures 20–40 μm and can be observed by light microscopy. It provides for motility at a rate of 800 μm/min. Besides small sulfur inclusions, usually between 5 and 15, one to four large refractile bodies occur, which closely resemble the $CaCO_3$ inclusions of *Achromatium oxaliferum* and, therefore, are provisionally considered to consist of $CaCO_3$. No methods for isolation are known.

Macromonas bipunctata (Fig. 1) was first described by Gicklhorn (1920) as *Pseudomonas bipunctata* and renamed *Macromonas bipunctata* by Utermöhl and Koppe (Koppe, 1923). Dubinina and Grabovich (1984) reported the isolation of heterotrophic bacteria answering the description of *Macromonas bipunctata* by these authors. The cells are single or in pairs,

pear-shaped, cylindrical or curved; they measure 2.2–4×3.3–6.5 μm. They are motile by a polar tuft of flagella, Gram-negative, strictly aerobic and catalase-positive. Sulfur inclusions are produced when the cells are grown in media containing sulfide, which is oxidized by hydrogen peroxide and thus offers no useful energy to the cell.

While recognizing the valid description of *Macromonas bipunctata* by Dubinina and Grabovich, la Rivière and Dubinina (1989) still maintain *Macromonas mobilis* as type species because " . . . now that the way has been paved, it is felt that isolation of *Macromonas mobilis* may take place in the near future and thus complete the taxonomy of the genus with a minimum of alterations."

Enrichment and Isolation of *Macromonas bipunctata* (Dubinina and Grabovich, 1984)

The white mat found on the surface of bottom sediments in a sewage treatment plant was used for inoculating 10 ml portions of the following semisolid medium contained in test tubes:

Sodium acetate	1 g/l
Calcium chloride	0.1 g/l
Casein hydrolysate (Difco)	0.1 g/l
Yeast extract (Difco)	0.1 g/l
Agar (Difco)	1 g/l

After sterilization, a mixture of vitamins and of trace-elements (Pfennig and Lippert, 1966) was added, as well as 0.2 mg freshly prepared FeS per 10 ml medium as source of sulfide. The pH was adjusted to 7.2–7.4.

After two to three days at 28°C, a white surface film appeared, which contained a large number of typical *Macromonas* cells. Streaks were made from a suspension of this film on agar plates containing the medium described above solidified with 1 g agar/l. After two to three days flat *Macromonas* colonies appeared with a diameter of 1 to 4 mm and a finegrained structure. These colonies were used for subsequent purification by restreaking on solid medium.

The Genus *Thiobacterium*

The organisms of this genus are nonmotile rods that form sulfur inclusions. The cells are embedded in gelatinous masses that are either "puffball"-shaped or dendroid. Spherical, "puffball"-shaped gelatinous masses may be found freely floating in stagnant, H_2S-bearing waters (Fig. 1; *Thiobacterium* a). Dendroid gelatinous masses may be found attached to solid surfaces that are exposed to flowing, H_2S-containing waters (Fig. 1; *Thiobacterium* b).

Their lack of motility prevents these organisms from following chemotactically the spatial fluctuations of the zone of optimal H_2S and O_2 concentrations. This suggests that they are either capable of growing under a wider range of H_2S and O_2 concentrations than acceptable to most of the motile colorless sulfur bacteria, or, alternatively, that they are confined to growth in locations where their optimal conditions more or less continuously prevail. The latter alternative appears to be supported by the fact that they are found floating at water-air interfaces or attached to solid surfaces. The first case is likely to occur when H_2S generation is consistently so high that the zone of optimal conditions is kept automatically at the top of the anaerobic water column. The second case arises when a water stream with more or less constant H_2S and O_2 concentrations is maintained for longer periods of time; this is the situation one finds in certain sections of the outflows of sulfur springs.

In *Bergey's Manual* (Buchanan and Gibbons, 1974; la Rivière and Kuenen, 1989a), only one species, *Thiobacterium bovista,* was recognized. It comprised the bacteria embedded in spherical, gelatinous masses, first described by Molisch (1912) under the name of *Bacterium bovista,* as well as those embedded in dendroid structures, first described by Lackey and Lackey (1961) under the name of *Thiodendron mucosum.* Observations in nature of *Thiobacterium bovista* have been reported by Scheminsky, et al. (1972), and by Caldwell and Caldwell (1974).

Molisch obtained the spherical colony type (Fig. 1) of *Thiobacterium* at the surface of Winogradsky column enrichments prepared with seawater plus a sediment consisting of black mud mixed with decaying algae, all ingredients originating from the harbor of Trieste, in which the organism was also directly observed. The diameter of the spherical structures ranged from microscopic dimensions to about 4 mm and the structures were sometimes clustered together. The lengths of the cells were between 2 and 5μm, their width between 0.6 and 1.5μm. They usually contained four sulfur globules per cell. These cells were embedded in the gelatinous skin of the spherical masses, the inside of which was filled with water. The nature of the mucoid matrix was not elucidated.

The dendroid forms (Fig. 1) were found by Lackey and Lackey (1961) in saline, H_2S-bearing waters in Florida at temperatures between 13 and 30°C. The dendroid matrix, of as yet unidentified material, had the shape of branching filaments with a varying thickness of up to 20μm, individual branches sometimes being clubshaped. Thus, the colonies acquired treelike structures, reaching a width of up to 3 mm. Most of the colonies were found attached to algal and cyanobacterial cells, (generally of the

genus *Lyngbya*) which raises the question of a possible interaction involving O_2.

The cells were randomly arranged throughout the branches and consisted of rods, normally 3–5 μm long and 1.5 μm wide; in the swollen ends of the branches, however, cells three times that size were found. Most cells contained three to eight sulfur globules arranged on a longitudinal axis.

The organism could not be grown in enrichments in the laboratory but was kept alive for 3 months in jars with water of the original habitat at 20°C.

The Genus *Thiospira*

Thiospira cells consist of typical colorless spirilla with sulfur inclusions. Their polar flagella are in some cases united in a tuft, visible in the light microscope. The cells are chemotactic with respect to O_2 and H_2S. They can arrange themselves in characteristic agglomerations located in regions of optimal H_2S and O_2 concentrations, forming "Bakterienplatten" in liquid columns and "Atmungsfiguren" in covered slide preparations (Fig. 4). The members of the genus have been found in fresh waters and marine environments in which H_2S was present.

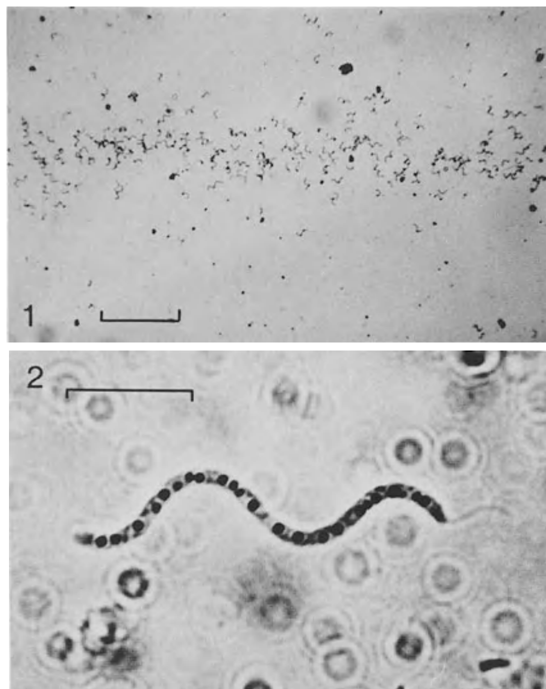

Fig. 4. *Thiospira* sp. (from upwelling groundwater near Delft, The Netherlands). (Courtesy of J. Klein, IHE, Delft.) (1) Cells accumulating at the optimum O_2/H_2S-zone. Bar = 100 μm. (2) Dividing cell with a flagellum. Bar = 10 μm.

At the moment, two species are recognized (la Rivière and Kuenen, 1989b).

Thiospira bipunctata (Fig. 1) was first described by Molisch (1912) and at that time named *Spirillum bipunctatum.* Its cells are slightly twisted rods forming short spirilla with a width of 1.7–2.4 μm and a length of 6.6–14 μm. They are most probably polarly flagellated. Each end of the cell typically contains a large granule of some storage material, described as volutin, leaving a clear space in the middle normally filled with two or three sulfur globules. The latter are sometimes also found at the ends.

Thiospira winogradskyi (Fig. 1) was first described by Omelianski (1905) and at that time named *Thiospirillum winogradskii.* It is a colorless spirillum containing numerous sulfur globules that may disappear when the H_2S in the medium is exhausted. It is 2–2.5 μm wide and can reach a length of 50 μm. "Volutin" bodies are absent. The cells have polar flagella and are strongly chemotactic.

Dubinina and Grabovich (1983) reported the isolation of heterotrophic spirilla under the name of *Thiospira bipunctata.* These were morphologically similar to *Thiospira bipunctata* as described by Molisch since they formed sulfur inclusions when grown in media containing sulfide. The sulfur was formed by nonspecific sulfide oxidation by metabolically produced hydrogen peroxide. Since other heterotrophs have also been found to form sulfur inclusions in sulfide-containing media (Skerman et al., 1957), further study is required for determining the proper taxonomic status of these isolates, which may well prove to be identical to existing *Spirillum* species.

Enrichment Procedures

All enrichments for *Thiospira* have been carried out in Winogradsky columns (Winogradsky, 1888) in which H_2S was released from a sediment.

Molisch (1912) enriched *Thiospira bipunctata* from mud from a Black Sea estuary (a liman) in cylinders (5–15 × 10–30 cm), filled with seawater and a sediment of mud mixed with dying or dried algae. The columns were kept for several weeks at room temperature in the dark or under dim light.

Omelianski (1905) enriched *Thiospira winogradskyi* using tap water and a mixture of liman mud, $CaSO_4$, and fragmented rhizomes in cylinders 7 cm wide and 40 cm high. After some months' incubation at room temperature in the dark, "Bakterienplatten" appeared in the lower part of the columns, which moved up and down with the prevailing H_2S concentration. When

the cells had settled to the bottom, the sediment was stirred up, which apparently led to renewed H_2S production and prolongation of the lifetime of the culture, which in this way could be kept for 2 years. The present authors had occasion to observe a *Thiospira* species among the colorless sulfur bacteria at 7°C in the outflow of an upwelling, H_2S-bearing groundwater near Delft, The Netherlands (Fig. 4). The cells formed "Atmungsfiguren" in slide preparations and could be kept viable for at least 6 weeks at 4°C in the dark, in cylinders containing groundwater and some mud from the location of origin.

The Genus *Thiovulum*

The cells of this spectacular genus (Figs. 1 and 5) are ovoid and measure 5–25 μm in length. They normally contain sulfur inclusions, often concentrated at one end. The cells multiply by longitudinal fission preceded by constriction. The cells have peritrichous flagella that provide strong chemotactic motility, the cells rotating around an axis coinciding with the path of travel; they never reverse direction and concentrate at places of optimum O_2 and H_2S concentrations in sharply defined characteristic veils or webs consisting of separate, ever moving, individual cells, to some extent held together by a very loose slime matrix (Fig. 5).

Because of this strong chemotaxis, the development of methods for enrichment and cultivation has been more successful for *Thiovulum* than for the other genera discussed in this chapter.

Only one species, *Thiovulum majus,* is recognized (la Rivière and Kuenen, 1989c). This includes the former species *Thiovulum minus* (Hinze, 1913). Other obsolete names are *Monas muelleri* (Warming, 1875) and *Thiovulum muelleri* (Lauterborn, 1915).

Ecology

Thiovulum has been observed in marine environments and saline springs by Warming (1875), Hinze (1903, 1913), Molisch (1912), Bavendamm (1924), Fauré-Fremiet and Rouiller (1958), Lackey and Lackey (1961), and la Rivière (1963). Freshwater forms were reported by Lauterborn (1915) and Lackey and Lackey (1961). In all instances, *Thiovulum* is found in very sharply localized white masses in situations where H_2S meets with O_2. Since it appears restricted to low concentrations of each substance for optimal growth, the patterns it forms provide a macroscopic visualization of this borderline, even in slowly flowing waters,

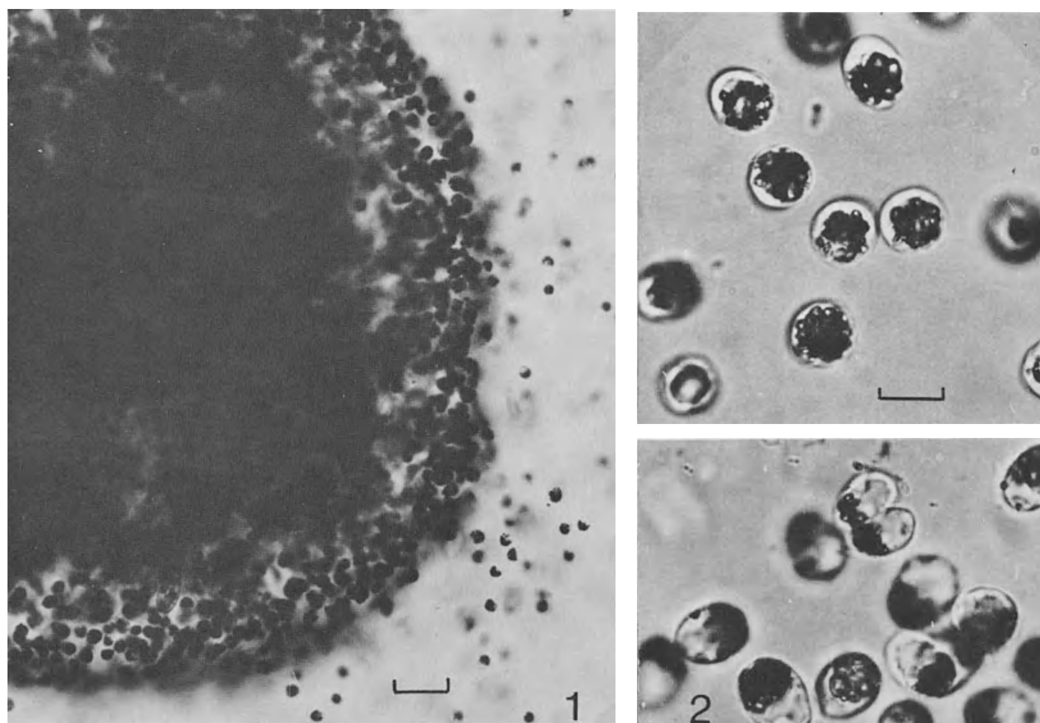

Fig. 5. *Thiovulum majus* (from Bergen op Zoom, The Netherlands). (1) Periphery of a veil of *Thiovulum majus.* Bar = 50 μm. (2) Swarming cells. Bar = 20 μm. (From Schlegel, 1976.)

as the cells rapidly follow changes of the concentration gradient. This makes it sometimes possible to identify *Thiovulum* accumulations in nature by their characteristic white patterns observed above black, sulfide-releasing muds in otherwise clear water. Similarly, such veils may be observed over decaying organic matter in flowthrough marine aquaria.

Measurements with microelectrodes in natural and laboratory systems (Jørgensen and Revsbech, 1983) have established that these veils are about 100 μm thick and are formed at the interface of the oxygen and sulfide zones. The veils create an unstirred boundary layer preventing mixing of oxygen and sulfide and thus also preventing chemical sulfide oxidation. The veils thus create a situation in which the *Thiovulum* cells are fed by diffusion of both substrates, which each penetrate over a distance of 50 μm into the veil. In oxygen-rich water the veils take the shape of small spheres which are made anaerobic in the center by the rapid oxygen utilization of the cells, which thus create the gradient required for optimum growth. Jørgensen and Revsbech (1983) provide further fascinating evidence showing that the chemotactic behavior of *Thiovulum* is extremely sensitive to environmental influences and is an important instrument, by "concerted action" of many cells, in the creation of the precarious niche in which *Thiovulum* lives.

Enrichment

Unpublished work by van Niel, Wijler, and Lascelles (van Niel, 1955) led to the development of a simple enrichment method, described by la Rivière (1963, 1965). The method has been successfully used in Pacific Grove (California), Delft (The Netherlands), and also in Woods Hole (Massachusetts) (Wirsen and Jannasch, 1978).

Enrichment of *Thiovulum* (Wirsen and Jannasch, 1978)

A layer of decaying seaweed *(Ulva)* mixed with some marine mud is placed on the bottom of a jar of 1–10 liters filled with seawater, the thickness of the compressed algal layer is kept to less than half the height of the jar (Fig. 6A). A continuous, slow flow of seawater is introduced near the surface of the sediment, and the jar is allowed to overflow. The layer of *Ulva* via sulfate reduction as a source of H_2S while the flowing seawater provides a continuous supply of O_2. By means of chemotaxis, the cells of *Thiovulum* seek out the regions of optimal concentration, where growth takes place in characteristic veils. The flow of seawater has also the essential functions of supplying the sediment with SO_4^{2-} as a source of H_2S, and of flushing out contaminating organisms that are not chemotactic; as a rule the *Thiovulum* veils are surrounded by clear water.

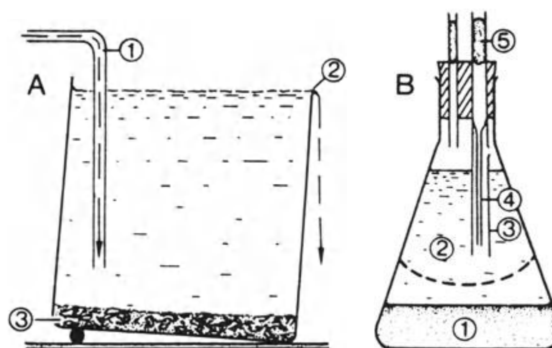

Fig. 6. Culture vessels for enrichment of *Thiovulum:* (A) by Wijler's method and (B) for stationary cultivation of *Thiovulum.* (A): 1, inflow of seawater; 2, overflow; and 3, layer of decaying *Ulva.* (B): 1, sulfide-containing agar layer; 2, seawater; 3, protective tube for localized aeration; 4, Pasteur pipette; and 5, cotton plug. The broken line indicates the zone of growth of *Thiovulum.*

When fresh *Ulva* is used, one should wait ca. 2 weeks before starting the seawater flow; a thick film of bacteria usually has developed at the surface at that time. After the flow of seawater is started, growth of *Beggiatoa* and/or *Thiothrix* may be observed in the upper part of the jar. In that case, the flow rate should be increased somewhat; the filamentous bacteria move to lower regions and eventually to the bottom while *Thiovulum* appears in the top layer usually 2–3 weeks after the start of the experiment. This indicates that the optimum sulfide concentration for *Thiovulum* is definitely lower than that for *Beggiatoa* and *Thiotrix.* When the flow rate is further increased, the veils of *Thiovulum* move further downwards.

At all times the culture should be kept in the dark, and relatively low temperatures (15°C) appear to be favorable. The layer of *Ulva* can be replaced by decaying marine animals like starfishes and sea urchins; a layer of fishmeal has also given positive results.

Wirsen and Jannasch (1978) found that an initial addition of neutralized Na_2S led to an earlier appearance of *Thiovulum* veils and to larger enriched populations.

Enrichment cultures of *Thiovulum* can be used as a source of crude cell material for several weeks until the H_2S-generating power of the sediment is exhausted. Lateral illumination with a flashlight greatly facilitates observation and harvesting of the *Thiovulum* veils.

Purification of Crude Cell Material

Besides filtration, methods based upon the chemotaxis of *Thiovulum* have been used, singly or in combination. la Rivière (1963, 1965) used the following method:

Purification of *Thiovulum* (la Rivière, 1963, 1965)

A total of 50–100 ml of a cell suspension carefully harvested by pipetting from an enrichment culture is rapidly filtered through a thin layer of cotton or of cheese-

cloth into a 100-ml glass cylinder. After 5–10 min, the cells settle chemotactically near the bottom, from where they are transferred by means of a pipette in as small a volume as possible into a test tube containing 15 ml sterile, aerobic seawater, cooled to about 15°C, in which they again form a veil near the bottom in 5–15 min. Repeated transfers in a similar manner to fresh tubes with sterile seawater lead to highly purified cell suspensions, as the initial filtration removes debris, protozoa, and other larger organisms while subsequent "washings" decrease the number of smaller contaminants. Plating on media for *Thiobacillus* and for heterotrophs permits following the effectiveness of the purification steps.

The success of the method depends entirely on the degree of initial contamination of the raw material and the capacity of the cells to survive successive purification steps. In experiments in Pacific Grove, "washing" could be performed 6–10 times in succession, leading to suspensions that were consistently free from contaminants. However, similar pure suspensions were not obtained in experiments in The Netherlands (la Rivière, 1965) or in Woods Hole (Wirsen and Jannsch, 1978), which is probably caused by differences in vigor between the enriched populations and in properties of the seawater used, such as temperature, degree of pollution, and microbial contamination.

Wirsen and Jannasch (1978) used the following modifications of the method described above:

1. Repeated chemotactic "washing" by pipetting or decantation in sterile aerobic seawater without an initial filtration step; this could be done only when freshly formed veils, relatively free from larger organisms, were available in the enrichments.
2. Chemotactic "washing" in deoxygenated sterile seawater, in which case the cells migrate to the top layer.
3. Concentration and washing of the cells by means of a membrane filter with a porosity of 8μm. Initial cell suspensions are concentrated to about 2 ml by suction, whereupon fresh sterile seawater is added, followed again by concentration by suction, *Thiovulum* cells being retained by the filter while contaminants are passed through it. Three to five such "washings" are possible.

Application of these methods combined with subsequent cultivation procedures provided Wirsen and Jannasch (1978) with highly purified cell suspensions suitable for electron microscopy and for the performance of some important physiological experiments. The various treatments, however, could not be repeated a sufficient number of times to obtain suspensions that were entirely free from contaminants.

Cultivation of Purified *Thiovulum* Populations

STATIONARY CULTIVATION OF THIOVULUM SUSPENSIONS FREE FROM CONTAMINANTS (LA RIVIÈRE, 1963, 1965). In a 500-ml Erlenmeyer flask, 250 ml of the following sterile agar medium is sterilized at 120°C for 10 min: 250 ml seawater, 2% agar (Difco), 0.01% NH_4Cl, 0.01% KH_2PO_4. Just prior to solidification of the agar, 2.5 ml of a separately heat-sterilized solution of 1% Na_2CO_3 in seawater is added, followed by 8 ml of sterile seawater previously saturated by gaseous H_2S. The pH does not need adjustment; it should be around 8.0. After setting of the agar, 250 ml of seawater are added and the flask is closed with a steam-sterilized stopper allowing for local aeration by means of a Pasteur pipette surrounded by a vertical glass tube which is open at the lower end (Fig. 6B). In this way, aeration is restricted to the inside of the protective glass tube, the dissolved oxygen slowly diffusing downwards to the bulk of the seawater layer. Thus, a gradient between the tube and the agar block is established which can be easily demonstrated with a redox dye; e.g., thionine. Without aeration, the dye is in its reduced form throughout the liquid; with conventional aeration without protection tube, the turbulence distributes the oxygen uniformly and the dye is in its oxidized form throughout the liquid. With localized aeration we obtain a sharp boundary between a "reduced" and an "oxidized" zone, which can be maintained for weeks.

The flask is placed at a temperature of 10–15°C and kept under constant aeration with cotton-filtered air. After equilibration overnight, the flask is ready for inoculation with purified cell material, and soon the individual cells of the inoculum can be seen to settle in one plane somewhere between the agar surface and the aeration tube.

Within days, the cells increase in number until a sharply defined web is formed at about 1 cm above the agar surface in an otherwise clear liquid. On prolonged incubation, the web rises slowly because of increasing O_2 demand; later on the web moves downward as H_2S becomes exhausted. By this time, signs of decay become apparent: White strands consisting of dead cells adhering to each other hang down from the sides of the flask. The life of the culture lasts for about 3 weeks.

This procedure has been successfully used only in Pacific Grove, where purification of the inoculum could be pursued to the point where

all contamination had been eliminated. It was also used—with some modification—by Pringsheim and Kowallik (1964) in their study of H_2S oxidation by *Beggiatoa.*

It should be pointed out that the method is unsuitable when impurities are present, as *Thiovulum* is rapidly overgrown in any closed stationary system. It should further be realized that even when successful the method yields only very small amounts of cell material.

CULTIVATION IN OPEN, FLOW-THROUGH SYSTEMS. Such systems are based upon the same principle that underlies the enrichment culture method. Besides the use of sterilized, aerated seawater fed into the culture vessel by controlled pumping, different sources for input of H_2S have been applied. These include periodical addition of H_2S or portions of saturated solutions of H_2S once or twice daily (la Rivière, 1963, 1965). Wirsen and Jannasch (1978) developed several reliable devices in which continuous H_2S provision was assured from different sources:

1. Decaying *Ulva* kept separately from the culture vessel by a nylon membrane of 0.45-μm porosity.
2. A pure culture of *Desulfovibrio aestuarii* separated from the culture vessel in the same way, H_2S generation being kept up by periodic addition (every 2–4 weeks) of fresh sodium sulfate/lactate medium. This system (Fig. 7) provided the best results permitting the maintenance of active *Thiovulum* populations for 220 days without reinoculation; during this time cells were frequently harvested, leading to rejuvenation of the veils.
3. A neutralized solution of Na_2S in sterile seawater separated from the culture vessel by a dialysis membrane.
4. A coil of silicone tubing, permeable to H_2S, through which a gas mixture of N_2 and H_2S (1%) was kept circulating. The coil was placed on the bottom of the culture vessel.

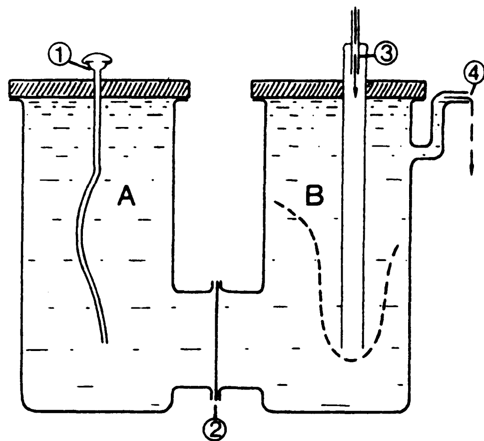

Fig. 7. Double culture vessel for the maintenance of purified cell suspensions of *Thiovulum* sp. (after Jannasch and Mateles, 1974; and Wirsen and Jannasch, 1978). (A) Culture vessel with *Desulfovibrio estuarii.* (B) Culture vessel for *Thiovulum.* 1, lactate supply; 2, semipermeable membrane; 3, inflow of air-saturated seawater; 4, overflow. The broken line indicates the zone of growth of *Thiovulum.*

The same authors, furthermore, used closed-flow systems based upon recirculation rather than open systems with overflow. In the closed system, no *Thiovulum* cells are lost, but contaminants are not flushed away; hence they are only useful for specific short-term experiments.

Finally, it should be pointed out that none of the authors who studied *Thiovulum* has been successful in using solid media. Also H_2S could not be replaced by thiosulfate, nor could nitrate be substituted for O_2.

State of Present Knowledge on *Thiovulum*

Besides the properties mentioned earlier, further characteristics of the organism have been determined by study of cell material derived from enrichments and from mass cultivation of purified material.

Thiovulum is Gram-negative and catalase-negative (la Rivière, 1965); the cells die quickly at high O_2 concentrations, as can be easily seen when they are trapped at the edges of a slide preparation. They are also immediately killed by anaerobic conditions. Its internal structure has been studied by electron microscopy by Fauré-Fremiet and Rouiller (1958), de Boer et al. (1961), Remsen and Watson (1972), and Wirsen and Jannasch (1978). Among its most striking features are Fauré-Fremiet's polar fibrillar organelle, the thin cell wall, and the slime excretion, which plays a role in structuring and maintaining the veils in which, nevertheless, the cells are in continuous motion. A discussion of the earlier results is presented by Starr and Skerman (1965).

Wirsen and Jannasch (1978) performed uptake experiments with CO_2 and some organic compounds labeled with $^{14}CO_2$ on highly purified cell suspensions, which permitted correction for uptake by contaminants. They showed substantial CO_2 uptake in *Thiovulum* which was optimal at H_2S concentrations of 1 mM in initially air-saturated seawater. No significant carbon uptake was registered for casamino acids, acetate, glutamate, mannitol, and some vitamins. These results provide strong evidence for the chemolithotrophic nature of the *Thiovulum* strains examined.

CHAPTER 219

The Genus *Propionigenium*

BERNHARD SCHINK

The genus *Propionigenium* consists so far of one single species that comprises four strains of physiologically and morphologically similar isolates from various origins (Schink and Pfennig, 1982). This genus was created to house strictly anaerobic bacteria that are able to grow by decarboxylation of succinate to propionate. Enrichment cultures, which were set up originally to enrich for syntrophic succinate degraders from marine and freshwater sediments, developed unexpectedly fast growth of small, coccoid bacteria that did not depend on cooperation with hydrogen-scavenging partners and formed propionate as the sole fermentation product. Pure cultures could only be obtained with enrichment cultures from marine sources; the freshwater enrichments grew much slower, and pure cultures were finally isolated when the sodium chloride concentration of the medium was enhanced to 100–150 mM. This finding gave the first hint on a sodium dependence of this new type of energy conservation.

Succinate is formed in large amounts in the rumen of cows and sheep, but the animal host cannot take up this valuable fermentation product (Wolin, 1979). Conversion of succinate to propionate is therefore an important function of the rumen microflora, and succinate decarboxylation appears to be a rather common capacity of several propionate-forming fermenting bacteria, e.g., *Selenomonas* (Scheifinger and Wolin, 1973), *Veillonella* (Yousten and Delwiche, 1961), or certain *Propionibacterium* spp. (Yousten and Delwiche, 1961). Initially these conversions were regarded as "cometabolic" activities, which did not provide any advantage to the bacteria. Many years later, it was shown that the methylmalomyl-CoA decarboxylase of *Veillonella alcalescens* was a membrane-bound enzyme that coupled the decarboxylation reaction with the transfer of sodium ions across the cytoplasmic membrane (Hilpert and Dimroth, 1982). The sodium gradient thus established helps to provide energy for transport of dicarboxylic acids across the membranes, but it cannot supply energy for growth of these bacteria. It was quite a surprise, therefore, when a bacterium was isolated from sediments that can run its entire energy metabolism for growth on this decarboxylation reaction. This unusual capacity explains why these isolates were placed in a new taxonomic unit, apart from other propionate-forming bacteria.

Today we know of several other bacteria able to grow by conversion of succinate to propionate. Among these are Gram-negative mesophiles and also thermophiles (C. Guangsheng and A. Stams, unpublished observations). The coupling between sodium-extruding decarboxylation and ATP synthesis varies to some extent between these isolates, and the direct sodium coupling between a methylmalonyl CoA decarboxylase and a sodium-dependent ATPase as found in *Propionigenium modestum* (see below) is not the only solution to this problem. Further research in this area will discover whether *P. modestum* should be maintained in a genus of its own, or whether it should be associated with the genus *Veillonella* (Mays et al., 1982; Delwiche et al., 1985), with which it shares many morphological and physiological properties.

Habitats

P. modestum was originally isolated from a black, anoxic, marine sediment sample taken from the Grand Canal in Venice, Italy, where it occurred in numbers of 100 cells/ml sediment (Schink and Pfennig, 1982). Similar strains were isolated later from many other marine habitats and also from human saliva. Enrichments from freshwater sediments sometimes produced cells of similar morphology as the type strain GraSucc2, and could be cultivated only in media with enhanced (100–150 mM) sodium chloride concentrations. Later enrichment experiments with freshwater sediments from many different sites in Germany, Italy, and the USA yielded different, vibrioid, Gram-negative bacteria (Denger and Schink, 1990). No isolates able to grow with succinate as the sole energy

source have yet been obtained from rumen ecosystems.

It has to be assumed that anoxic marine sediments are the typical habitats of *P. modestum.* Its energy metabolism is based entirely on sodium ions as coupling ions in energy conservation. With this ability, it is well adapted to a marine environment. Many marine bacteria have recently been found to use sodium ions as energy couplers in various functions, e.g., respiration (Skulachev, 1985; Dibrov et al., 1986a) or motility (Brown et al., 1983; Dibrov et al., 1986b).

Isolation

Medium for Isolation and Cultivation

A strictly anoxic, sulfide-reduced mineral medium with 20-mM succinate as the sole organic carbon and energy source, and incubation at 27–30°C has proved to be highly selective for the enrichment of *P. modestum* if marine sediment samples of about 5-ml volume are used as the inoculum. The carbonate-buffered standard medium used for enrichment and isolation is described below in detail (after Widdel and Pfennig, 1981; Schink and Pfennig, 1982).

Carbonate-Buffered Standard Medium

Dissolve in 1 l of distilled water:

KH_2PO_4	0.2 g
NH_4Cl	0.5 g
NaCl	20.0 g
$MgCl_2 \cdot 6H_2O$	3.0 g
KCl	0.5 g
$CaCl_2 \cdot 2H_2O$	0.15 g

Autoclave the complete mineral medium in a vessel equipped with a filter inlet to allow flushing of the headspace with sterile oxygen-free gas and use screw cap inlets for addition of thermally unstable additives after autoclaving. Connect a silicon tubing from the bottom of the vessel to a dispensing tap (if possible with a protecting bell) for sterile dispensing of the medium (do not use latex tubing; it releases compounds that are highly toxic to many anaerobes). A stirring bar is also required.

After autoclaving, connect the vessel with the still hot medium to a line of oxygen-free nitrogen: carbon dioxide mixture (90% N_2:10% CO_2) at low pressure (<100 mbar), flush the headspace and cool it under this atmosphere to room temperature, perhaps with the help of a cooling water bath.

The mineral medium is amended with the following additions from stock solutions that have been sterilized separately (amounts per liter of medium): 30 ml of 1 M $NaHCO_3$ solution (autoclaved in a *tightly closed* screw cap bottle with about 30% headspace. The bottle should be autoclaved in a further protecting vessel, e.g., a polypropylene beaker, to avoid spills of carbonates if the bottle breaks in the autoclave); b) 2 ml of 0.5 M $Na_2S \cdot 9H_2O$ solution (autoclaved separately under oxygen-free gas atmosphere as above); c) 1 ml of trace element solution, e.g., SL 10 (Widdel et al., 1983); d) 0.5 ml of 10–fold concentrated, filter sterilized vitamin solution (Pfennig, 1978); and e) adequate amounts of sterile 1 M HCl or 1 M Na_2CO_3 to adjust the pH to 7.1–7.3.

The complete medium is dispensed into either screw-cap bottles or screw-cap tubes which are filled to the top, leaving a lentil-sized air bubble for pressure equilibration. Enrichment cultures usually produce gas in the first enrichment stages and are better cultivated in half-filled serum bottles (50–100 ml volume) under a headspace of nitrogen: carbon dioxide mixture (90% N_2:10% CO_2). The vitamin mixture is not needed by all strains.

For mass cultivation of *P. modestum* strain GraSucc2 in fermenters, a phosphate-buffered medium is easier to handle. The following medium has been applied successfully (Hilpert et al., 1984).

Phosphate-Buffered Medium

Distilled water	940 ml
KH_2PO_4 (= 30 mM)	4.2 g
NH_4Cl	0.5 g
NaCl	20.0 g
$MgCl_2 \cdot 6H_2O$	3.0 g
$CaCl_2 \cdot 2H_2O$	0.15 g

Add sulfide, trace elements, and vitamins as above, as well as 60 ml of a neutralized 1 M sodium succinate solution, and adjust the pH to 7.0 before inoculation.

Isolation of Pure Cultures

After two to three transfers in liquid medium, gas should no longer be formed by the enrichment cultures, and a dominant population of short, coccoid rods should be established. These bacteria can be isolated easily in anoxic agar deep dilution series (Pfennig, 1978) or in roll tubes (Balch et al., 1979). Streaking on petri dishes in an anoxic glove box has not yet been tried with these bacteria, but there is no reason why this method should not be applicable as well. Preparation of pure cultures requires two subsequent dilution series; purity should be checked after growth in selective mineral medium as well in complex medium, e.g., AC medium (Difco Laboratories, Ann Arbor, MI, USA). AC medium prepared according to the original recipe appears to inhibit several sediment bacteria. Therefore, a 1:10 or 1:5 diluted variation (in sea water as well as in freshwater medium, with corrected agar concentration) of this medium should also be used to ensure that the cultures are pure.

Identification and Further Properties

In phase contrast microscopy, cells of *P. modestum* appear as short, coccoid rods with a diameter of 0.5–0.6 μm and a length of 0.5–2.0 μm, often in short chains (Fig. 1). They are Gram negative and do not form spores. The GC content of the DNA is in the range of 32–36 mol%.

P. modestum is strictly anaerobic and does not stand increased oxygen tensions. The optimum temperature for growth is 30–33°C and under these conditions, doubling times of 2.5–4.5/h are obtained, depending on whether yeast extract (0.1% wt/vol) is provided as source for assimilatory metabolism. Yeast extract is not required and does not support the energy metabolism, but it enhances the growth yields by about 35%.

In addition to succinate, fumarate and pyruvate also support growth and are fermented stoichiometrically to acetate and propionate. No sugars, alcohols, or any other organic substrates are utilized. No cytochromes have been detected, which is consistent with the absence of electron transport phosphorylation. The growth yields with fumarate and pyruvate are small (3.8 and 6.2 g/mol on fumarate and pyruvate, respectively.

The biochemical basis of energy conservation with succinate as sole substrate has been studied in detail (Hilpert et al., 1984). Succinate exchanges in the cell with propionyl-CoA to form succinyl-CoA and free propionate, which leaves the cell. Succinyl-CoA is rearranged to methylmalonyl-CoA and decarboxylated by a membrane-bound decarboxylase that couples this reaction with the transport of sodium ions across the cytoplasmic membrane. The sodium ion gradient thus established, drives ATP synthesis via a membrane-bound, sodium-dependent ATP synthase. The latter enzyme has been characterized thoroughly (Laubinger and Dimroth, 1987; Laubinger and Dimroth, 1988). It is composed of an F_1 and an F_0 moiety, both of which have subunits comparable to those of a "classical" bacterial proton ATPase. The enzyme of *P. modestum* can also pump protons across the membrane, but only if the sodium concentration is very low (< 1 nM). Under physiological conditions, ATP synthesis is driven entirely by sodium ions.

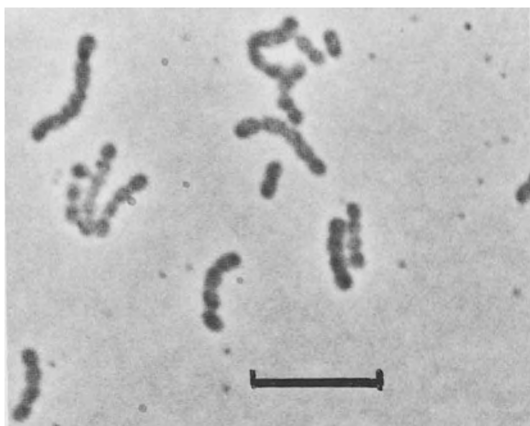

Fig. 1. Phase contrast photomicrograph of cells of *Propionigenium modestum* GraSucc2 (type strain) after growth with 20 mM of succinate. Bar = 5 μm.

This unusual coupling of decarboxylation and ATP synthesis was the first case of an energy metabolism found that was based entirely on sodium as coupling ions, and which did not involve classical substrate-linked phosphorylation or electron transport phosphorylation steps. Today we know of several more cases of bacteria that can base their total energy metabolism on such decarboxylation reactions. The biochemical basis for energy conservation may be quite different in each case: e.g., anaerobic bacteria that ferment oxalate to formate and carbon dioxide employ a decarboxylase enzyme which is soluble in the cytoplasm, and energy conservation occurs via substrate import and product export by an antiporter system (Anantharam et al., 1989).

Conservation of decarboxylation energy is of special interest because the free energy change of such reactions is small and yields only about 20–25 kJ/mol. If such reactions drive ATP synthesis (free energy expense 70–75 kJ/mol ATP; Thauer et al., 1977), several decarboxylation reactions have to be coupled with one ATP synthesis reaction. Although the exact stoichiometries of sodium ion translocation by the methylmalonyl-CoA decarboxylase and the ATP synthase have not yet been determined, it is obvious from the free energy calculations that at least three decarboxylations are necessary to allow synthesis of one ATP. This calculation agrees well with the cell yield obtained with *P. modestum* GraSucc2 (2.0–2.5 g/mol succinate). Bacteria that base their whole energy metabolism on a decarboxylation reaction represent the most "modest" ways of energy conservation, i.e., they operate with the lowest amount of energy a living cell can convert into ATP (Thauer and Morris, 1984).

Applications

So far there is no commercial application for *P. modestum*. The fact that its unique energy conservation mechanism can also be reversed and

allows carboxylation reactions without the expense of ATP (Dimroth and Hilpert, 1984), can possibly render such systems as interesting for new ways of biochemical syntheses.

CHAPTER 220

The Genus *Zoogloea*

PATRICK R. DUGAN, DAPHNE L. STONER, and HARVEY M. PICKRUM

Bacteria of the genus *Zoogloea* have historically been considered members of the family Pseudomonadaceae but have been differentiated from other obligately aerobic, Gram-negative, nonsporeforming, rod-shaped bacteria that grow in aquatic habitats on the basis of their production of a characteristic gelatinous matrix. The "zoogloeal matrix" surrounds clumps of cells found in natural aquatic habitats or when grown in unshaken liquid culture in the laboratory (Butterfield, 1935; Butterfield et al., 1937; Wattie, 1943). The name *Zoogloea,* which was derived from the Greek word meaning animal glue, refers to the primary trait, the zoogloeal matrix, that is used to distinguish *Zoogloea* from other metabolically similar bacteria.

The two species of *Zoogloea, Z. ramigera* and *Z. filipendula,* have been isolated from sewage or from sewage-treatment systems that employ oxidative methods, i.e., activated sludge systems, trickling filters, or oxidation ponds (Butterfield et al., 1937; Butterfield and Wattie, 1941; McKinney and Horwood, 1952; McKinney and Weichlein, 1953). Both species produce branched, finger-like projections or outgrowths from the floc (i.e., clumps of cells that grow in an aggregated form that settles or "flocs" from aqueous suspension) when grown under quiescent culture conditions but have been differentiated from each other on the basis of cell size, biochemical reactions, and appearance of the zoogloeal matrix.

Characteristics of the Zoogloeal Matrix

The zoogloeal matrix is a capsular envelopment that surrounds several cells and commonly results in a flocculent growth habit in liquid media. That is, cell flocs settle from suspension, leaving a relatively clear supernatant. Unz and coworkers (Unz, 1974; Farrah and Unz, 1975; Unz and Farrah, 1976a) have convincingly demonstrated that floc formers of the *Zoogloea* type grow in an aggregated state and that the individual cells are entrapped within the zoogloeal matrix while cell division occurs. Floc formation of the zoogloeal type implies cell growth in an aggregated form (Friedman and Dugan, 1968b), whereas the term "flocculation" (Peter and Wuhrmann, 1971) has been defined as the aggregation of suspended bacterial cells after growth of cells has occurred, i.e., the "flocculation" of colloidal material. Biologically, the two processes are considerably different although the same physical and chemical laws apply to both.

Although there can be confusion relative to the distinction between zoogloea formation and flocculent growth, there is a consensus that microbial floc formation results from the presence of adherent extracellular fibrils (Busch and Stumm, 1968; Deinema and Zevenhuizen, 1971; Finstein, 1967; Friedman and Dugan, 1968b; Friedman et al., 1968, 1969; Tago and Aida, 1977). The presence of polysaccharide and the ability to flocculate has been demonstrated with mutants lacking polysaccharide and which do not exhibit flocculent growth; recombinant bacteria with restored polysaccharide production also simultaneously show restored floc formation (Easson et al., 1987a, 1987b). All floc-forming bacteria appear to posses extracellular fibrillar strands, but not all Gram-negative floc-forming bacteria produce the characteristic zoogloeal matrix, such as that for *Zoogloea ramigera* strain 115 seen in Figs. 1 and 2.

The polysaccharide of *Zoogloea* may remain as a loose slime layer in the vicinity of the cells, a well-defined capsule, or a zoogloeal matrix around the cells which synthesized it or it may be dispersed in the medium as a colloidal suspension or in solution. Increased viscosity of the surrounding medium may result from extensive polymer synthesis by the cells. The key feature in bioflocculation appears to be the synthesis of relatively insoluble extracellular polymer strands that remain within the vicinity of cells and do not disperse. The photographs

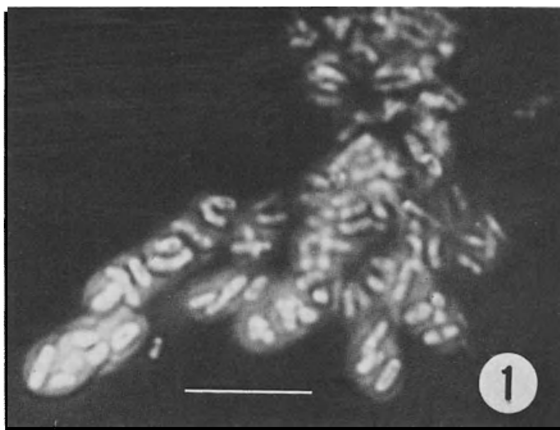

Fig. 1. Photomicrograph of *Zoogloea ramigera* strain 115 floc negatively stained by the Maneval method and photographed through the light microscope. The cells are shown embedded within the zoogleal matrix and with the characteristic finger-link projections. Bar = 10 μm.

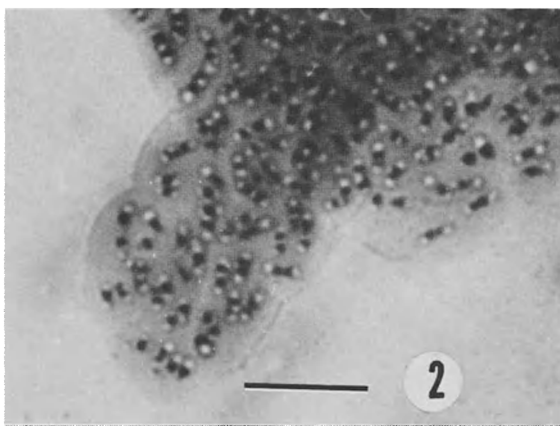

Fig. 2. Photomicrograph of *Zoogloea ramigera* 115 floc stained with 1% aqueous crystal violet. The gelatinous zoogloeal matrix in which cells are embedded is shown. The variable staining appearance is due to polybetahydroxy butyric acid (PHB) granules that accumulate in the cells. Bar = 10 μm.

shown in Figs. 3, 4, 5, 6, and 7 show the insoluble polysaccharide strands found around flocs of these bacteria. The polymer strands shown in Fig. 6 were photographed under ultraviolet illumination after the flocs were stained with the fluorescent dye Paper White-BP as previously reported (Dugan and Pickrum, 1973; Friedman et al., 1969).

The chemical composition and structure of the extracellular polysaccharides determine its physical and chemical properties. Polysaccharides in solution or suspension vary in water solubility, rheological properties (e.g., viscosity, viscoelasticity), chemical and thermal stability, surfactant properties, the ability to bind water, etc. *Zoogloea* strains vary in the composition of the in polysaccharide (Table 1), but information concerning the structure of some isolates is limited.

The polysaccharide of *Z. ramigera* 115 has been examined in detail. This weakly acidic polysaccharide is slightly soluble in water, stable in a pH range of 3 to 10, and is not precipitated in the presence of salt (Stauffer et al., 1980). Stauffer et al. (1980) reported that the polysacchride of *Z. ramigera* 115 is stable to temperature cycling from $-15°$ to 90°C. However, Norberg and Enfors (1982) reported that the first temperature cycle from 25° to 90°C did increase the viscosity of the polymer at the lower temperature. The polysaccharide of *Z. ramigera* 115 is highly viscous and lowers the surface tension of water. The polysaccharide exhibits Newtonian flow at lower concentrations and, as the concentration increases, the polymer becomes increasingly pseudoplastic and viscoelastic (Stauffer et al., 1980). Similar flow behavior was observed in relation to growth and polysaccharide production in a fermentor (Norberg and Enfors, 1982).

The polysaccharide of *Z. ramigera* 115 contains glucose, galactose, and pyruvic acid, the ratios of which may vary with culture conditions and growth phase of the culture (Norberg and Enfors 1982; Franzen and Norberg, 1984; Ikeda et al., 1982). Growth on different sugar substrates did not alter the composition of sugars in the polymers (Parsons and Dugan, 1971). A ratio of glucose:galactose of 2:1 with trace amounts of terminal pyruvylated glucose (Franzen and Norberg, 1984; Friedman et al., 1969; Parsons and Dugan, 1971; Sinskey et al., 1986) as well as a ratio of 11.0:3.1:1.5 for glucose:galactose:pyruvic acid (Ikeda et al., 1982) has been determined. Uronic acids, pentose, or amino sugars have not been detected in the polysaccharide of *Z. ramigera* 115 (Franzen and Norberg, 1984; Friedman, et al. 1969; Ikeda et al., 1982). The polysaccharide of *Z. ramigera* 115 is a highly branched structure with β-1-4-linkages and a molecular weight of approximately 10^5 (Friedman et al., 1968, 1969; Ikeda et al., 1982;). A structure with repeating units has been proposed (Ikeda et al., 1982), although there is conflicting evidence that the polysaccharide of *Z. ramigera* 115 has an irregular structure (Franzen and Norberg, 1984).

A variety of sugars have been identified as components of the polysaccharides of *Zoogloea* cultures (Table 1). Polymer from *Z. ramigera* MP6 contains the amino sugars, glucosamine, and possibly methyl-pentose amine, hexose

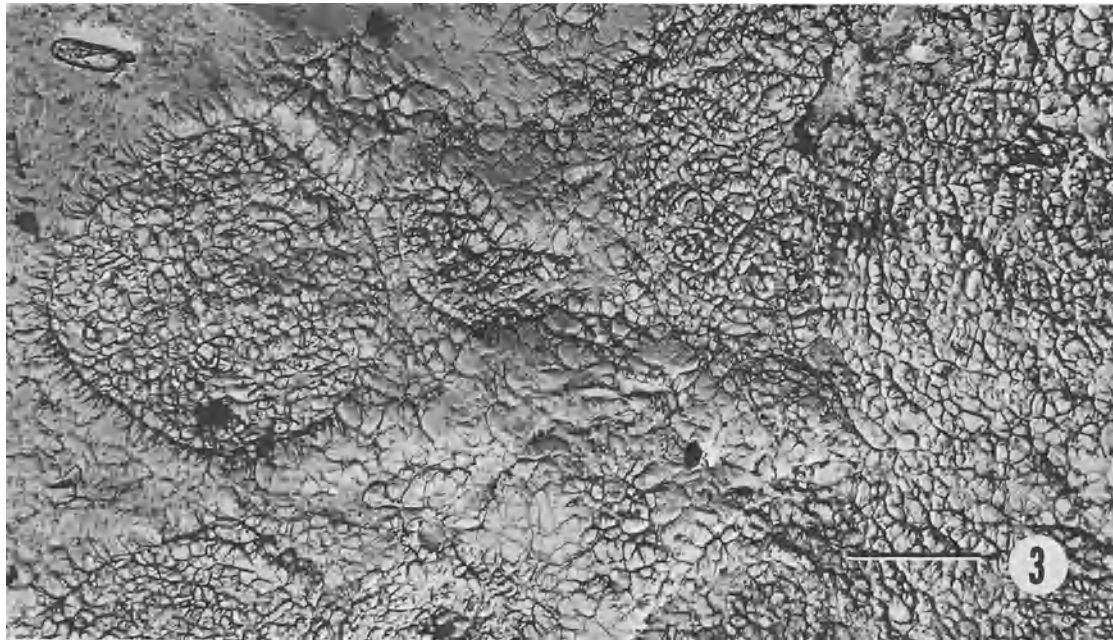

Fig. 3. Electron micrograph of a freeze-fractured specimen of *Zoogloea ramigera* 115. The fibrillar network of extracellular polysaccharide strands from which the zoogloeal matrix is formed is shown. In the living specimen, water is bound in the interstices of the network, which resembles a ball of chicken wire. Bar = 10 μm.

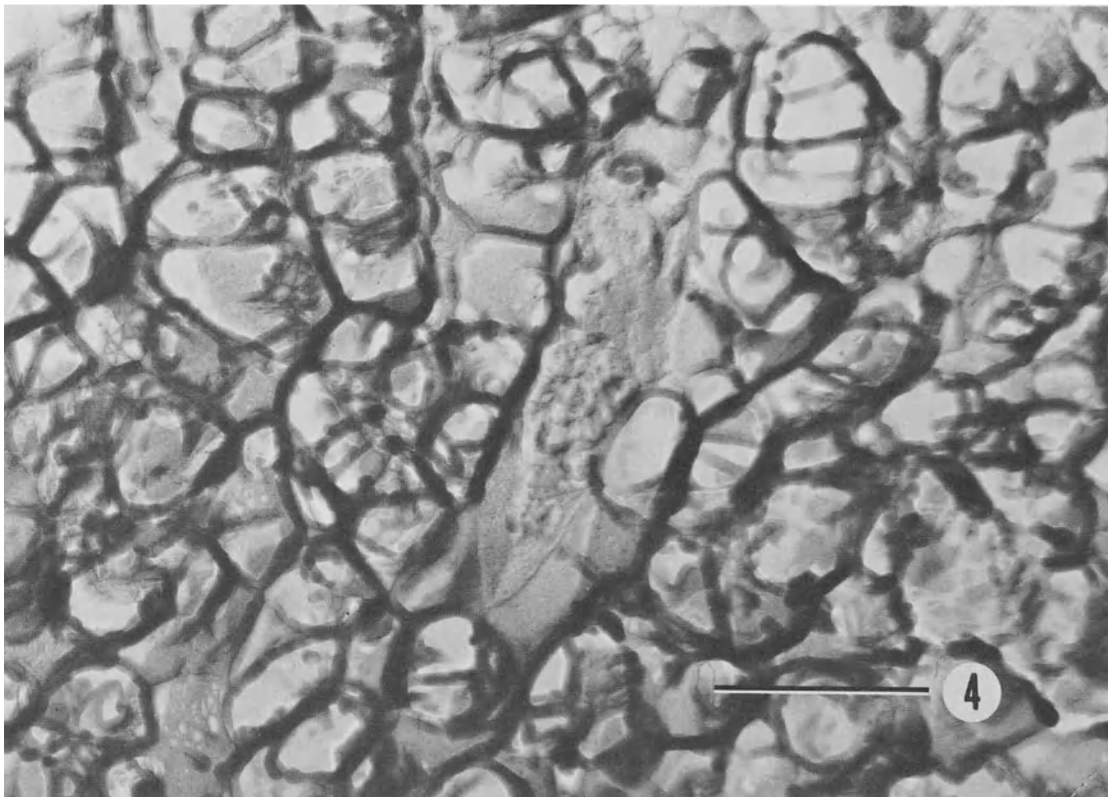

Fig. 4. Enlargement of the floc shown in Fig. 3. A cell embedded within the zoogloeal matrix is shown. Bar = 10 μm.

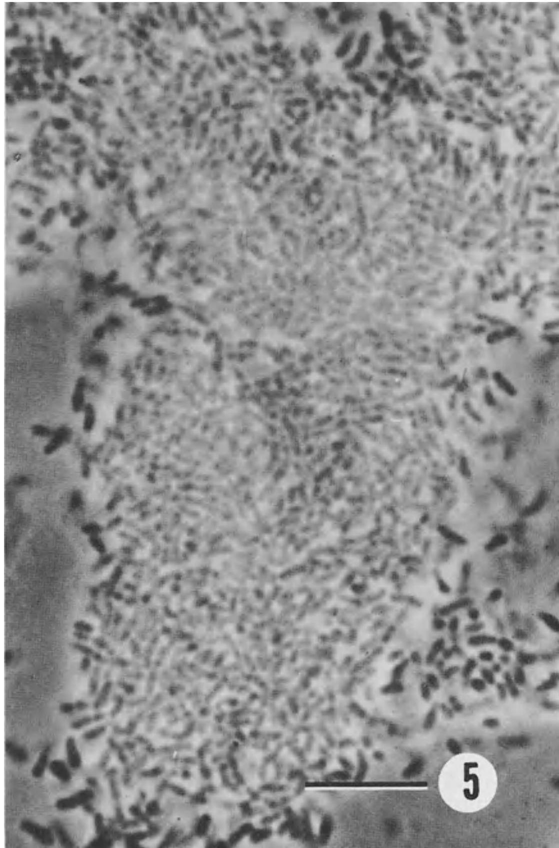

Fig. 5. Photomicrograph of a floc of the *Zoogloea* isolate designated CT-2 originally isolated by K. Crabtree. The floc was stained by a water-clear solution of the fluorescent dye Paper White-BP, and photographed under phase-contrast optics. Some of the bacteria are in the focal plane whereas others are not. Bar = 10 μm.

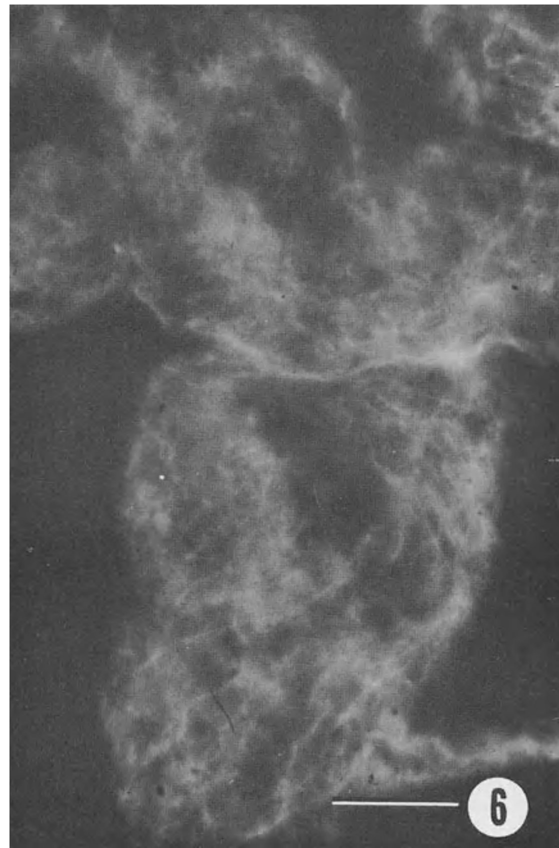

Fig. 6. Photomicrograph taken under ultraviolet (UV) illumination of the identical field shown in Fig. 5. Only material stained by the polysaccharide-specific fluorescent stain Paper White-BP can be seen under UV illumination. This procedure demonstrates that the cell floc shown in Fig. 5 was interspersed by a network of fibrous polysaccharide strands analogous to a "cobweb" which appears to hold the floc intact. Bar = 10 μm.

sugars, and uronic acid (Farrah and Unz, 1976). Tezuka (1973) identified glucosamine and possibly fucosamine as components of the polymer of a *Zoogloea* culture isolated from activated sludge, but did not detect neutral sugars or uronic acids. Polymer of *Z. ramigera* NRRL B-3669M contains glucose, mannose, and galactose, while isolate NRRL B-3793 contained rhamnose, mannose, and possibly galactose (Wallen and Davis, 1972). *Z. filipendula* P-8-4 and *Z. ramigera* contain glucose, galactose, and mannose in the polysaccharide, while an unidentified *Zoogloea* species designated C-1 contained glucose, galactose, mannose, arabinose, and rhamnose (Pickrum, 1972). It is possible that those isolates that have been shown to produce extracellular polysaccharides with only glucose, galactose, and mannose are more closely related to *Pseudomonas dentrificans* than to the *Z. ramigera* 115 isolate (see Table 1). Research on *Zoogloea* isolates has increased significantly because of its potential use in applications for removal of hazardous metal contaminants from waste streams.

Habitats

Zoogloea species have been isolated from organically enriched oxygenated water, particularly domestic sewage and aerobic sewage-treatment systems, such as trickling filters, activated sludge tanks, or oxidation ponds (Amin and Ganapati, 1967; Dugan and Lundgren, 1960; Unz and Farrah, 1972). These are all continuous-flow systems that are rich in dissolved or particulate oxidizable organic materials, which provide for the enrichment of *Zoogloea* and closely related bacteria. Zoogloeal masses may also be found adhering to solid objects suspended or floating in lakes and ponds. For example, 19 of 36 Gram-negative bacteria isolated

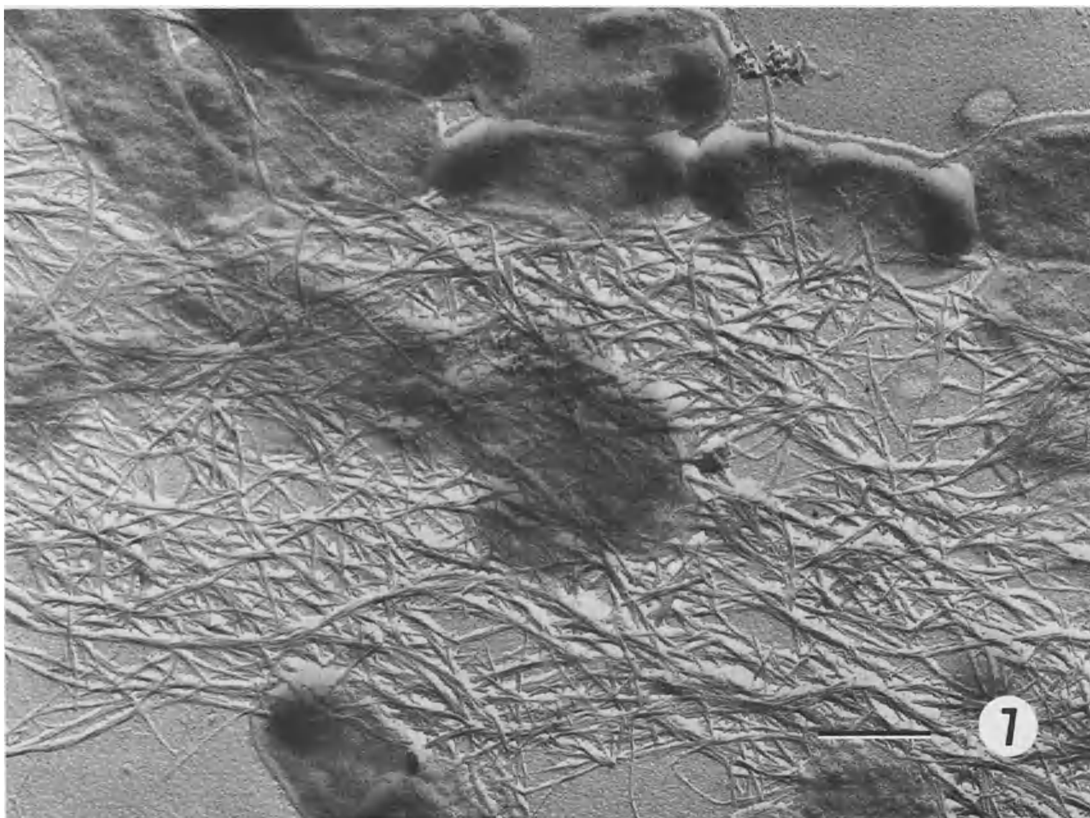

Fig. 7. Shadow-cast electron micrograph of *Zoogloea ramigera* isolate I-16-M after treatment with 1 N NaOH for 24 h at 28°C. Extracellular fibrillar strands and cell ghosts are shown. I-16-M produces flocs but no observable gelatinous zoogloeal matrix. Bar = 10 μm.

from Lake Erie formed flocs in the laboratory, and they all clustered with previously identified isolates of *Zoogloea* when subjected to a computer taxonomic program. Therefore, *Zoogloea* appears to be ubiquitous in aquatic environments.

Isolation

Zoogloeal masses obtained from organically rich natural aquatic systems, sewage treatment plants, wastewater, etc., may be used in isolation procedures to obtain pure cultures of *Zoogloea.* These organically rich sources may also be used to inoculate enrichment media from which strains of *Zoogloea* may be isolated. Both the zoogloeal matrix found around the characteristic isolates of *Zoogloea* and the nongelatinous fibrillar strands associated with the nonzoogloeal *Zoogloea* isolates are a deterrent to pure-culture isolation because other bacteria adhere to or become entangled within the floc. Successful isolation of *Zoogloea* has been achieved with methods employing ultrasonic methods to disrupt zoogloeal masses, micromanipulation to manually separate individual cells from the zooglea matrix, the inclusion of inhibitory agents in culture media to prevent the growth of unwanted microorganism and the use of carbon growth substrates which may enrich for *Zoogloea.* These methods are used in conjunction with conventional isolation precedures to obtain isolates of *Zoogloea.*

Enrichment

Several methods can be used to establish enrichments of zoogloeal bacteria. The simplest method is the incubation of raw sewage, sewage sludge, treated sewage effluent etc., in containers at room temperature until a surface film or pellicle is formed (Amin and Ganapati, 1967). Alternatively, mineral salts solution overlaying a nutritive agar plug may be inoculated and incubated until a surface pellicle develops (Unz, 1984).

Mineral Salts Solution

The overlay medium is prepared from stock solutions and adjusted to pH 8.5 with 0.5 N NaOH. The mineral salts solution contains:

Table 1. Composition of purified extracellular polysaccharides of *Zoogloea*.

Strain	Composition	Reference
Z. ramigera 115	Glucose, galactose, pyruvic acid	Ikeda et al., 1982; Franzen and Norberg, 1984
Z. ramigera I-16-M	Glucose, galactose, mannose	Pickrum, 1972
Z. ramigera MP6	Glucosamine, methylpentose amine, hexose sugars, uronic acids	Farrah and Unz, 1976
Z. ramigera NRRL B-3669M	Glucose, galactose, mannose	Wallen and Davis, 1972
Zoogloea species NRRL B-3793	Rhamnose, mannose, galactose	Wallen and Davis, 1972
Zoogloea species C-1	Glucose, galactose, mannose, arabinose, rhamnose	Pickrum, 1972
Zoogloea species	Glucosamine, fucosamine	Tezuka, 1973
Z. filipendula P-8-4	Glucose, galactose, mannose	Pickrum, 1972
Zoogloea isolate P-95-5[a]	Glucose, galactose, mannose	Crabtree et al., 1965; Crabtree and McCoy, 1967

[a]The isolate is probably actually *Pseudomonas denitrificans*.

$(NH_4)_2SO_4$	0.3 g
NaCl	5.85 g
$CaCl_2 \cdot 2H_2O$	0.2 g
K_2HPO_4	0.1 g
$MgSO_4 \cdot 7H_2O$	0.14 g
$FeSO_4 \cdot 7H_2O$	0.3 mg
$MnCl_2 \cdot 4H_2O$	6.3 mg
$CoSO_4 \cdot 7H_2O$	0.11 mg
H_3BO_4	0.6 mg
$ZnCl_2$	0.22 mg
$CuSO_4 \cdot 5H_2O$	0.08 mg
Distilled water	1 liter

Nutrient-Enriched Agar

The nutritive agar contains 20 g agar per liter of mineral salts solution. The carbon source is any *one* of the following added per liter of mineral salts.

Starch	2.4 g
m-Toluic acid	1.35 g (neutralized)
n-butanol	1.5 ml
Lactic acid (85%)	1.35 g
Ethanol (95%)	1.5 ml
Glucose	2.4 g

After the addition of the carbon source, the pH is adjusted to 8.5 with 0.5 N NaOH.

Isolation

Isolations may be made from surfaces covered with zoogloeal masses and/or effluents taken from organically polluted water. Material on surfaces is scraped off and placed into 0.05% proteose peptone-yeast extract broth (PPYE). The gelatinous material is disrupted by ultrasound (20 kc output, Branson) in sterile PPYE, samples serially diluted and incubated in PPYE (28°C). After incubation for 3 days, the highest dilutions showing growth (10^{-7} to 10^{-10}) are streaked onto PPYE agar and tryptone-glucose extract agar (TGE, Difco). When sufficient growth has occurred, colonies of different morphological types are transferred to duplicate tubes of PPYE broth. Tubes are incubated with and without agitation. After incubation, tubes containing a pellicle (stationary) or a floc (shaken) are selected, and the entire isolation procedure is repeated until pure cultures are obtained. In general, isolations can be most readily achieved with the use of organically dilute media.

Micromanipulation may be used to separate bacterial cells from zoogloeal matrices in order to obtain pure cultures of *Zoogloea* (Unz and Dondero, 1967a). In this method, flocs or slimes from enrichment cultures are dispersed in liquid medium and observed at 100× magnification. To remove debris and microorganisms, fingered zoogloeal projections are transferred individually by micropipettes through successive drops of medium. Washed zoogloea are placed upon nutritive agar films coated on the underside of coverslips and individual cells dissected away from the zoogloeal matrix with microneedles. Slides are incubated and the developed microcolonies transferred with sterile micropipettes to broth medium. Alternatively, washed zoogloea may be collected and briefly sonicated prior to streaking on growth medium (Unz, 1984). Media appropriate for the above methods are casitone-yeast (CY) broth (see below), nutrient broth, and the respective agar media (Unz, 1984; Unz and Dondero, 1967a).

CY Medium

CY medium contains per liter of distilled water:

Casitone	5.0 g
Yeast autolysate	1.0 g

The addition of 0.001% crystal violet to isolation media, either broth or agar, has also been used successfully to inhibit many undesirable bacteria that tend to adhere to the flocs. Agar

plates that contain crystal violet in the growth medium also have differential value. On these plates, the isolates listed in Table 1 can be identified as follows: *Z. ramigera* 115 decolorizes and degrades crystal violet and forms straw-colored colonies; isolate C-1 fails to develop colonies; and isolates I-16-M, P-8-4, and P-95-5 absorb the dye and produce violet colonies. Since isolate C-1 is different from the known *Zoogloea* isolates, the use of the crystal violet is considered to have value in the identification of *Zoogloea* species, but such use has not been well studied (Friedman and Dugan, 1968b; Dugan, 1975).

Aromatic compounds utilized for growth may be used for the isolation of some *Zoogloea* from environmental samples (Unz and Farrah, 1972). *Zooglea* isolates may be obtained from activated sludge using solid basal medium with 1% *m*-toluate as the carbon source by streaking sludge or other inocula directly on the media and incubating. Solid samples, i.e., soils and feces, may be suspended with equal volumes of sterile distilled water then streaked onto media. Developed colonies are transferred to CY medium (see above) disrupted by agitation, and streaked for isolation on *m*-toluate medium. *Zoogloea* grown on *m*-toluate medium form large colonies with yellow-green coloration indicative of *meta* cleavage products. Colonies are usually difficult to remove from the surface of the plates. This procedure will not isolate *Zoogloea* that do not utilize *m*-toluate as a growth substrate.

Zoogloea colonies on agar plates have a glistening, viscous appearance (Fig. 8). Colonies are straw-colored on media containing yeast extract or protcose-peptone and white on mineral salts media supplemented with alanine and argenine as the carbon source. The color differences are also observed in liquid media. Colonies have a leathery consistency, and the entire colony can frequently be removed with an inoculating loop (Dugan and Lundgren, 1960; Friedman and Dugan, 1968b). This distinctive characteristic is probably related to the formation of extracellular polysaccharide. Growth of *Zoogloea* in shaken liquid culture is often flocculent but flocs are tight and do not have a typical zoogloeal matrix.

Identification

As the name of the genus implies, *Zoogloea* species have been identified primarily on the basis of the presence of the characteristic extracellular, capsular, or zoogloeal, matrix. However, matrix formation and its morphological appearance may be controlled nutritionally by the carbon and nitrogen sources, as well as by the carbon to nitrogen ratio, and by the turbulence of the growth medium (Parsons and Dugan, 1971; Unz and Farrah, 1976b). Therefore, the presence or absence of a zoogloeal matrix is not a trait upon which identification can be reliably made. Although the presence of finger-like projections and a zoogloeal matrix is distinctive and a positive indicator, the absence of the zoogloeal matrix does not necessarily indicate that the isolate is not a *Zoogloea* species.

Isolates of *Zoogloea* are Gram-negative, polarly flagellated, rod-shaped bacteria that flocculate and accumulate poly-β-hydroxybutyrate (PHB) or polyalkanoic granules when cultivated in media that are rich in carbon. Cell size ranges from 0.5 to 1.3 μm in diameter and 1.0 to 3.6 μm in length. *Zoogloea* species are oxidative in metabolism and are able to utilize a variety of sugars, sugar alcohols, alcohols, amino acids, and proteins for growth. The inclusion of B vitamins, purines, pyrimidines, and nucleotides in culture media, although not required for growth, decreases the growth lag and increases biomass formation of cultures (Dugan and Lundgren, 1960; Friedman and Dugan, 1968b). The metabolic characteristics of the organisms are not sufficiently distinct to be the basis of identification for the genus *Zoogloea* (Crabtree and McCoy, 1967; Crabtree et al., 1965; Dugan, 1975; Dugan and Lundgren, 1960; Friedman and Dugan, 1968b; Ganapati et al., 1967; Unz, 1974; Unz and Dondero, 1967a, 1967b). However, the overall ability of *Zoogloea* species to oxidatively metabolize many sugars, sugar alcohols, and alcohols, with the formation of esters that often result in the typical fruity odor of esters in culture media, can be of use in restricting the options in identification (Joyce and Dugan, 1972). The strong capability of *Z. ramigera* 115 to form esters from a variety of organic acids and alcohols may be responsible for the addition of pyruvic acid to alcoholic groups on the extracellular zooglocal polymer and may explain why some investigators were unable to observe pyruvate (Friedman et. al., 1969), whereas others observed traces (Norberg, 1984) and others identified a significant amount (Ikeda et al. 1982).

The taxonomy of the genus *Zoogloea* is uncertain with respect to differentiation from other genera within the family Pseudomonadaceae. Also uncertain is whether *Z. filipendula,* a species historically considered as a member of the genus *Zoogloea* validly fits in the genus. The designation of the neotype strain of *Zoogloea ramigera* has also been questionable (Unz, 1984). Some *Zoogloea* isolates re-

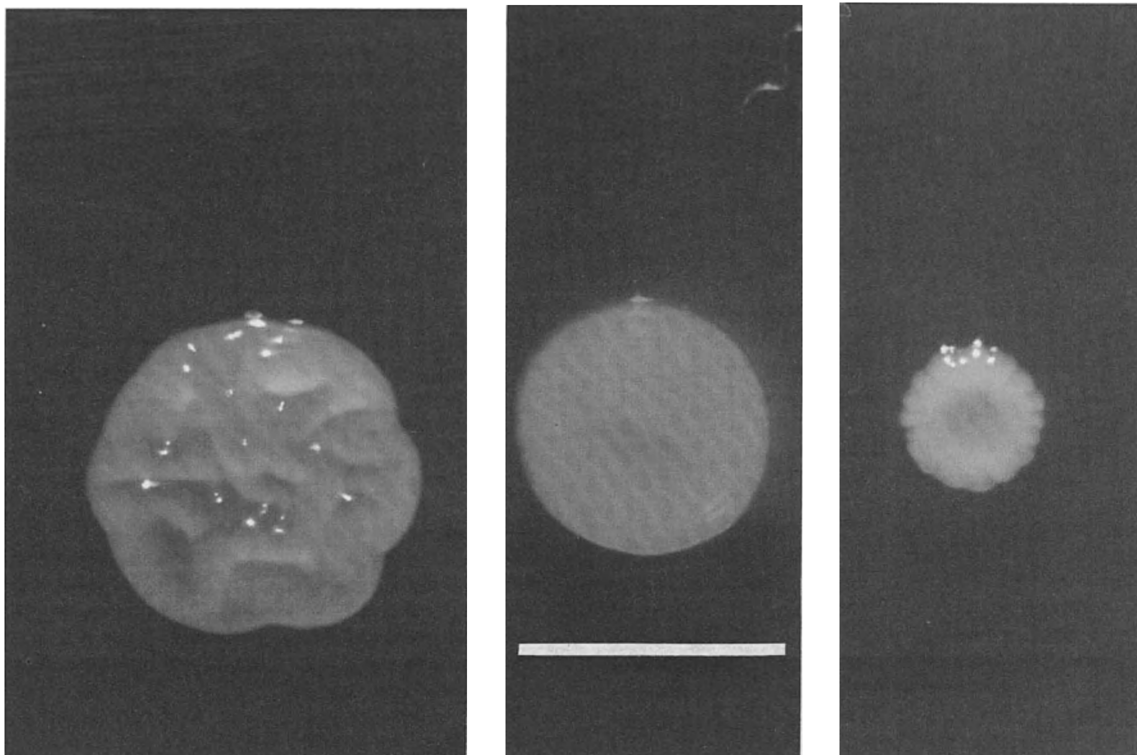

Fig. 8. Colonies of *Zoogloea ramigera* 115 vary in overall appearance and size. Variation is due to culture conditions and age of culture. Bar = 5 mm.

semble species of the genera *Pseudomonas* (particularly *P. denitrificans*) *Gluconobacter*, and *Acetobacter*. *Zoogloea* differ from *Gluconobacter* and *Acetobacter* in the inability to grow at pH 4.5.

Antigenic relationships among some of the *Zoogloea* have been reported (Chorpenning et al., 1978). *Z. ramigera* 115 and I-16-M did not closely relate to *Z. filipendula* P-8-4 on a serologic basis. *Z. ramigera* 115 had greater antigenic relatedness to *Gluconobacter oxydans* subspecies *suboxydans* (ATCC 621) than to either *Z. ramigera* I-16-M or *Z. filipendula* P-8-4. These data indicated that *Z. ramigera* 115 and I-16-M are distinctly different serovars, an observation which is also supported by the difference in composition of their extracellular polysaccharides.

The GC content of the DNA of *Zoogloea* ranged from 60.1 to 64.8 mol% (Pickrum, 1972; Unz, 1984). The data, although not conclusive, reinforce the view that several of the floc-forming isolates are similar organisms that are sufficiently distinctive to allow differentiation from other Gram-negative rods. However, at present there is no definitive description of either the genus *Zoogloea* or its species, other than the gelatinous matrix of finger-like projections, but this matrix is not always present.

Genetics

Because of the potential application of *Zoogloea* in several microbially based technologies, there is a need to isolate and identify genes for polysaccharide and PHB production, determine the biosynthetic pathways, and examine the enzymatic and genetic control mechanisms.

The exopolysaccharides of *Zoogloea* are involved with flocculation (Easson et al., 1987a, 1987b; Friedman et al., 1969) and adsorption of heavy metals (Dugan, 1987; Dugan and Pickrum, 1972; Ikeda et al., 1982). As with other polymers, the structure and physical and chemical properties of polysaccharides define its flocculation and adsorption characteristics. Therefore, manipulation of the structure of the polysaccharide is of importance in developing flocculants and bioadsorbents with desired characteristics that may be applicable to microbially based technologies for waste water treatment or metal reclamation. Genetic control of the biosynthesis of polysaccharides by microorganisms is a means by which the structure of the polymers may be manipulated and production of the polysaccharides increased.

Mutants generated by the insertion of the Tn5 transposon were used to examine the genetics

of polysaccharide production in *Z. ramigera* I-16-M (Easson et al., 1987a, 1987b). There is an inherent instability in the chromosome in which DNA sequences spontaneously delete within the polysaccharide gene region, and this results in the loss of polysaccharide production. The frequency of chromosomal deletions within this gene region was enhanced by the presence of Tn*5* transposon. Polysaccharide production was restored in the mutants by complementation with a gene library constructed with a broad-host-range cosmid vector. The restoration of polysaccharide production in a number of mutants by a single plasmid vector suggests that the genes for polysaccharide production may be clustered on the chromosome.

The genetics involved with PHB synthesis is of interest because of the potential use of PHB and other polydroxyalkanoates in the plastics industry. PHB metabolism in *Z. ramigera* I-16-Mis a cyclic process (Tomita et al., 1983). The biosynthesis of PHB involves the condensation and reduction of acetyl CoA to form D(−)-3-hydroxybutyryl CoA followed by incorporation into PHB granules. Degradation of PHB granules proceeds via the production of D(−)-3-hydroxybutyrate oligomers and hydrolysis and oxidation to acetoacetate. The cycle is completed with the activation of acetoacetate to acetoacetyl CoA.

Studies examining the structure and function of enzymes in PHB synthesis (Davis et al., 1987a, 1987b; Fukui et al., 1976; Nishimura et al., 1978; Saito et al., 1977) and genetic experiments to determine the sequence and location of genes (Peoples et al., 1987) have focused on the enzyme β-ketothiolase, which mediates the first step in the biosynthesis of PHB, the condensation of two acetyl CoA units to form acetoacetyl CoA. A recombinant DNA clone designated LDBK1 expresses the complete thiolase gene sequence in *Escherichia coli* (Peoples et al., 1987). The encoded protein has thiolase enzyme activity and co-migrates with native enzyme in Western blotting and immunodetection experiments. The expression of thiolase-coding sequences is under transcriptional control of the *lac* promoter region contained in the λgtll expression vector that was used to generate the recombinant library of *Z. ramigera* DNA. The structural gene for the thiolase enzyme is 1,173 nucleotides long and codes for a protein of 391 amino acids. The calculated molecular weight and the predicted amino acid sequence of the gene product are in agreement with the molecular weight and amino acid sequence determined experimentally for the native thiolase. The high 6c content of the complete sequence (66.2 mol%) is in agreement with values obtained for the *Z. ramigera* genome (64.5 mol%). The position of the active site peptide, a potential ribosome binding site, and start codons within the DNA sequence have all been identified.

The major DNA-dependent deoxyribonucleic acid polymerase from *Z. ramigera* isolate I-16-Mhas been partially purified and biochemically characterized (Pickrum, 1975). The polymerase activity was eluted as a single peak at 0.1 M potassium phosphate from a DEAE-cellulose column. The partially purified enzyme showed one major, one intermediate, and five minor protein bands after polyacrylamide gel electrophoresis. The DNA polymerase activity was detected in the acrylamide gels by an in situ assay and coincided with the major protein band. Nuclease activity could not be detected in the preparation after electrophoresis.

The DNA polymerase resembles the *Micrococcus luteus* enzyme in many characteristics, and its properties seem to place it as an intermediate between the polymerase I and polymerase II of *Escherichia coli* and *Bacillus subtilus* (Pickrum, 1975). It appears that the enzyme requires all four deoxynucleoside-5′-triphosphates, a divalent cation, 2-mercaptoethanol, and denatured DNA as a template-primer for maximal activity. Dithiothreitol is capable of replacing 2-mercaptoethanol in the reaction. The enzyme replicated, with varying efficiencies, the DNAs isolated from *Bacillus subtilus, Escherichia coli,* calf thymus, salmon, and soft fish roe. Treatment of DNA with pancreatic deoxyribonuclease improved its priming ability, the effectiveness of which depended on the extent of treatment with deoxyribonuclease.

The divalent metal ion requirement of the polymerase could be satisfied with either Mg^{2+} or Mn^{2+}. A slight but observable synthesis was obtained in the presence of 20 mM Co^{2+} or 10 mM Cd^{2+}. The enzyme was unstable in solutions of ionic strength below 0.2 M potassium phosphate or protein concentrations below 1 mg/ml. Enzyme solutions could be stabilized by the addition of glycerol or by increasing the salt or protein concentrations and storing at −20°C.

A synthesis-dependent exonuccease activity, interpreted as a 5′ to 3′ exonuclease, was found, at a low level, with the most purified DNA polymerase preparation; however, this activity was not characterized. Rates were stimulated in the presence of deoxynucleoside triphosphates. The most purified fraction contained no detectable endonuclease activity.

The polymerase enzyme is sensitive to the sulfhydryl-blocking reagents N-ethyl-maleimide, *para*-(chloro)mercuribenzoate, and *para*-

(chloro) mercuriphenylsulfonic acid. Of these, *para*-(chloro) mercuribenzoate is the most effective sulfhydryl reagent.

Applications

Z. ramigera is important in inducing flocculation (Unz, 1974) and reducing biological oxygen demand (BOD) in sewage-waste water treatment (Butterfield, 1935; Joyce and Dugan, 1970). The metal-adsorbing characteristic of *Z. ramigera* has been investigated with application to the treatment of heavy metals and transuranic waste streams (Dugan, 1970, 1987; Dugan and Pickrum, 1973; Friedman and Dugan, 1986a; Kuhn and Pfister, 1989; Norberg and Persson, 1984). Production of PHB or other polyhydroxyalkanoates by *Zoogloea* may be useful for the development of copolymers for commercially useful biodegradable plastics.

Waste Water Treatment

An early and continued use of *Zoogloea* in a treatment process has been in the area of domestic waste water treatment. Although zoogloeal bacteria are not the only microorganisms responsible for a successful waste water treatment process, they are important for the degradation of organic carbon and for the flocculation required for settling. *Zoogloea* bacteria are highly active oxidizers of organic compounds which significantly reduce the biological oxygen demand (BOD) in waste water. Butterfield et al. (1937) reported that 50% of the BOD from sewage could be removed in 5 hours by the aerobic, Gram-negative, floc-forming bacteria indigenous to aerobic waste water system, and 68% could be removed in 3 hr by a natural mixed population of bacteria. *Zoogloea ramigera* converts excess carbon to PHB, extracellular polysaccharide, and esterified organic acids (Joyce and Dugan, 1970). It is the interaction of extracellular microbial polymer by adsorption and bridging that aggregates microorganisms and produces flocs (Busch and Stumm, 1968).

Poly-β-hydroxybutyrate Production

A potential use of *Zoogloea* involves the production of PHB, a highly polymerized lipid reserve material, that is usually synthesized by the bacteria in response to nitrogen limitation in the presence of excess carbon source. The production, enzymology, and genetic control of PHB metabolism in *Zoogloea* is of interest because of the application of PHB and other polyhydroxyalkanoates in the biodegradable plastics industry. PHB produced by some *Alcaligenes* species is currently being marketed as a biodegradable plastic under the trade name Biopol (Holmes, 1985).

Biosorption of Metals

A developing technology is the use of *Zoogloea* to adsorb and concentrate metals and transuranic elements from contaminated waste streams. The significance of extracellular microbial polymers as agents for relatively nonspecific adsorption of dissolved or suspended organic, particulate, and ionic substances has been established with polysaccharides produced by Gram-negative floc-forming bacteria. (Dugan, 1970; Dugan et al., 1971; Friedman and Dugan, 1968a). The adsorptive characteristics of the whole cell or purified polymer can be exploited for commercial waste water treatment to remove heavy metal and transuranic ions and also may be useful in mineral separation processes, where the use of other flocculating agents of biological origin are currently being investigated.

Zoogloea biomass can remove a variety of metallic cations from solution (Dugan and Pickrum, 1973; Friedman and Dugan, 1968a; Norberg and Persson, 1984; Norberg and Rydin, 1984; Sag and Kutsai, 1989a, 1989b). The removal of aluminum, calcium, cobalt, iron, magnesium, manganese, nickel, and silicon from acidic mine water samples demonstrates the effective metal binding characteristic of *Zooglea* and *Zoogloea*-derived polymer that is applicable to the treatment of complex, relatively undefined aqueous metal containing systems (Dugan, 1987; Dugan and Pickrum, 1973). Presumably, microorganisms are partially responsible for the accumulation of metals within the solids generated by sewage treatment and the reduction in metal concentration in effluent supernatant as compared to the metal concentration of the influent and the supernatant from primary settling (Dugan et al., 1971).

Chemically, the purified polysaccharide isolated from *Z. ramigera* 115 interacts with monovalent cations to form soluble salts, binds but does not appear to form cross-linkages with divalent cations, and forms insoluble precipitates with trivalent cations (Ikeda et al., 1982; Stauffer et al., 1980). Successive removal of uranium, copper, and cadmium from solution by *Zoogloea* biomass indicates selective binding among cations in mixed solutions (Norberg and Persson, 1984).

With the potential use of *Zoogloea* for the treatment of metal-bearing waste waters demonstrated, a microbially based technology for

the treatment of these wastes appears to be developing. *Z. ramigera* 115 cells, immobilized in calcium alginate beads, have been used in air-bubbled column reactors to remove mixtures of cadmium, copper, lead, manganese, strontium, and zinc from aqueous solutions (Kuhn and Pfister, 1989, 1990). Although calcium alginate alone sorbed metals, the use of immobilized *Z. ramigera* 115 enhanced metal binding significantly. A batch method was used to study the removal of cadmium, copper, and uranium from solution using biomass of *Z. ramigera* 115 (Norberg and Persson, 1984). A bench-scale continuous process was demonstrated with *Zoogloea* biomass to adsorb copper from solution (Norberg and Rydin, 1984). Affecting adsorption was the concentration of biomass and copper in solution and the operating pH.

Important to the costs of a treatment process, is the ability to recycle biomass for multiple treatment cycles. Acid treatment releases cadmium, copper, and uranium adsorbed to *Zoogloea* biomass, thus enabling multiple cycling for the complete removal of metals from solution (Norberg and Persson, 1984). In experiments with cadmium it was shown that the sorbed cadmium could be eluted by exposing the beads to nutrient solutions whereupon more cadmium could be sorbed (Kuhn and Pfister, 1989, 1990). Alternatively, the release of cadmium from calcium alginate immobilized *Z. ramigera* 115 was achieved by use of a 0.04% aqueous nitrilotriacetate solution (Kuhn and Pfister, 1989, 1990).

CHAPTER 221

Large Symbiotic Spirochetes: *Clevelandina, Cristispira, Diplocalyx, Hollandina,* and *Pillotina*

LYNN MARGULIS and GREGORY HINKLE

The genera *Cristispira, Clevelandina, Diplocalyx, Hollandina,* and *Pillotina* are morphologically complex, Gram-negative, motile, spirochetes (helical bacteria) in which the flagella are always entirely periplasmic (i.e., located between the inner [plasma] and the outer membrane typical of Gram-negative bacteria) (Fig. 1). (For a general discussion of the morphology of spirochetes, see Chapter 191.) All are obligate symbionts in the digestive system of mollusks or arthropods. These morphologically complex spirochetes have greater than 10 and sometimes as many as 300 flagella inserted at both ends of the cell and overlapping in the middle. If n is the number of flagella at one end of the cell and 2n the number of overlapping flagella in the middle of the cell, then the characteristic array is n:2n:n (e.g., 10:20:10 or 300:600:300). The coated membranes, distinctive cytoplasmic structures (including the sillon, a cell-length invagination or groove of the outer membrane in contact with the inner membrane), and relative proportions that distinguish these genera are depicted in Fig. 2, based on the morphometric analyses summarized in Table 1.

The habitats of these organisms are predictable (e.g., the crystalline style of bivalve mollusks for *Cristispira,* and the intestine of dry wood-eating cockroaches and termites for the others). None has been grown axenically. As molecular biological data are not yet available, species have been determined morphologically. Five species of large, symbiotic spirochetes have been described in the modern bacteriological literature and reverified, revised, or named as: *Clevelandina reticulitermitidis, Cristispira pectinis, Diplocalyx calotermitidis, Hollandina pterotermitidis,* and *Pillotina calotermitidis.* (For genera description, including an explanation of the morphometric analysis of spirochetes, see Bermudes et al., 1988.)

Although often classified on the basis of size and light microscopic morphology in the family. Spirochaetaceae (e.g., Bermudes et al., 1988), these spirochetes are ultrastructurally distinct from all other members of the Spirochaetaceae (see Chapter 191). Therefore, we classify the large symbiotic spirochetes in the family Pillotinaceae. (This family was first suggested by Hollande and Gharagozlou, 1967, who used the incorrect Latin derivative "Pillotaceae.") The spirochetes most similar morphologically to any member of the Pillotinaceae are the tick-borne symbionts, e.g., *Borrelia persica,* (flagella formula 25:50:25) (Karimi et al., 1979); the free-living microbial mat spirochete *Mobilifilum chasei* (10:20:10) (Margulis et al., 1990a); and the pectinolytic rumen spirochete *Treponema saccharophilum* strain PB, which is reported to have approximately 32 flagella (whether 32:64:32 or 16:32:16 is not clear) (Paster and Canale-Parola, 1985). All these spirochetes are significantly smaller than any member of the Pillotinaceae. No free-living *Pillotina*-like spirochete has ever been reported none at least, larger than 0.5 μm in diameter bearing at least 30 flagella.

A summary of the characteristics of the large, symbiotic spirochetes is presented in Table 1. Although only five genera are in the formal taxonomic literature, hundreds of symbiotic spirochetes from a large number of animals have been reported. For a more extensive discourse on *Cristispira* species in a variety of mollusks, see Kuhn (1981) and Breznak (1984a). Large spirochetes in the hindguts of termites and wood-eating cockroaches are more thoroughly described by To et al. (1980).

Cristispira pectinis (Gross) was first described as the trypanosome *Trypanosoma balbiani* (a eukaryote) by Certes (1882). Thought to have a multicellular, chambered body, *Cristispira* was renamed by Gross (1910), the name *Cristispira* being derived from the unusually prominent flagellar bundle or "crest." The modern understanding of the organism comes from Noguchi (1921), who, detecting them in oysters *(Crassostrea),* clams *(Venus),* and mussels *(Modiola),* recognized *Cristispira* as a spirochete bacterium. This identification was confirmed when the crest was shown to be a flagellar bundle by Ryter and Pillot (1965).

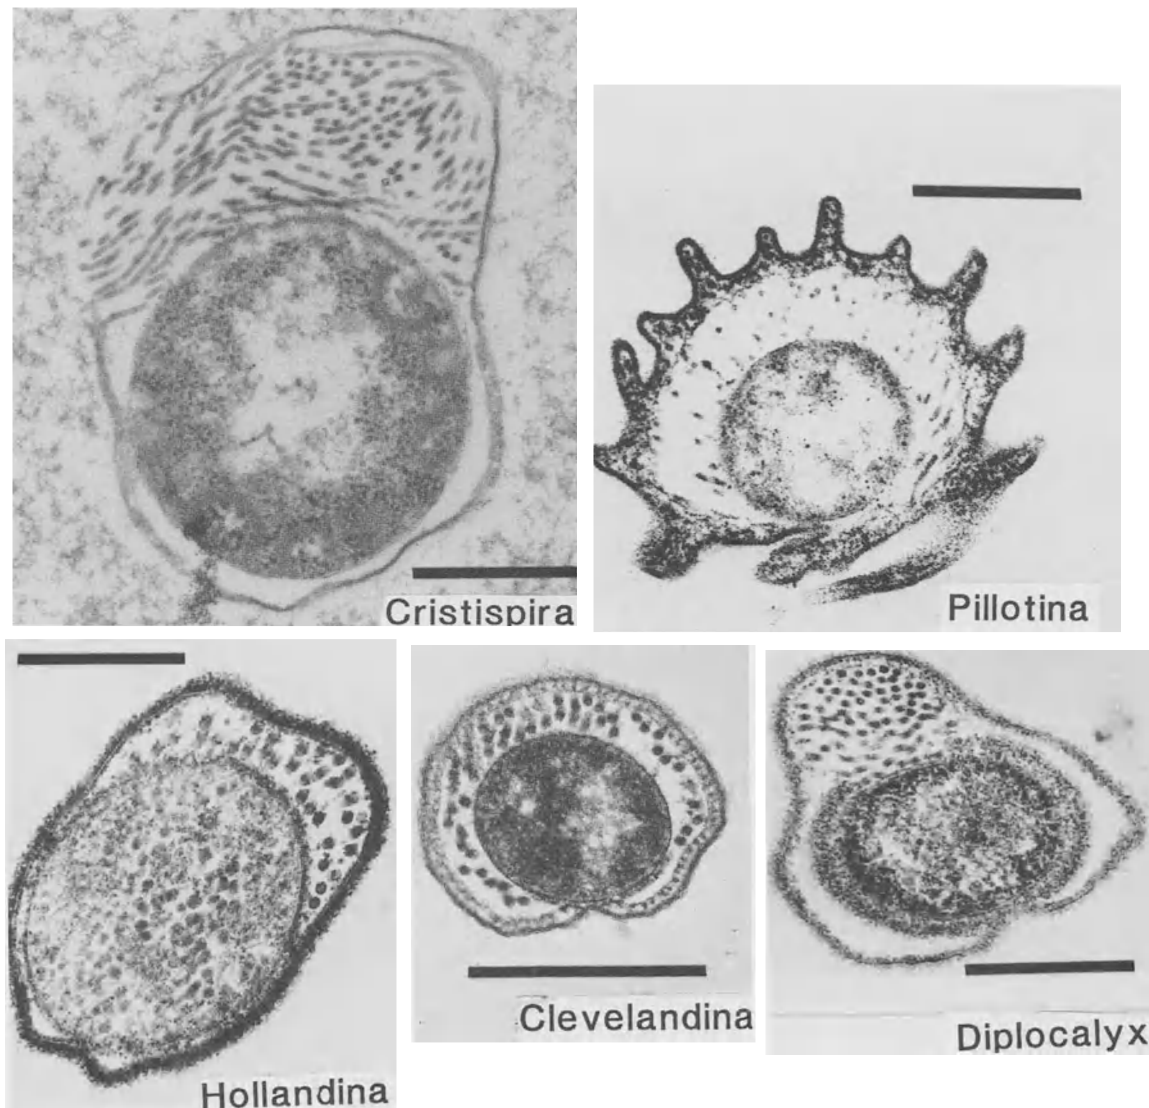

Fig. 1. Large symbiotic spirochetes as shown in transverse electron microscopic sections: *Cristispira* from the East Coast oyster. (Courtesy of J. M. Sieburth.) *Pillotina* from *Reticulitermes flavipes.* (Courtesy of R. Bloodgood.) *Hollandina* from the Sonoran desert termite. (Courtesy of L. P. To.) *Clevelandina* from *Zootermopsis.* (Courtesy of J. Breznak and H. Pankratz.) *Diplocalyx* from the Madeiran termite. Numerous flagella are seen in cross-section in the region between the outer and the plasma membrane. (Bars = 0.5 μm)

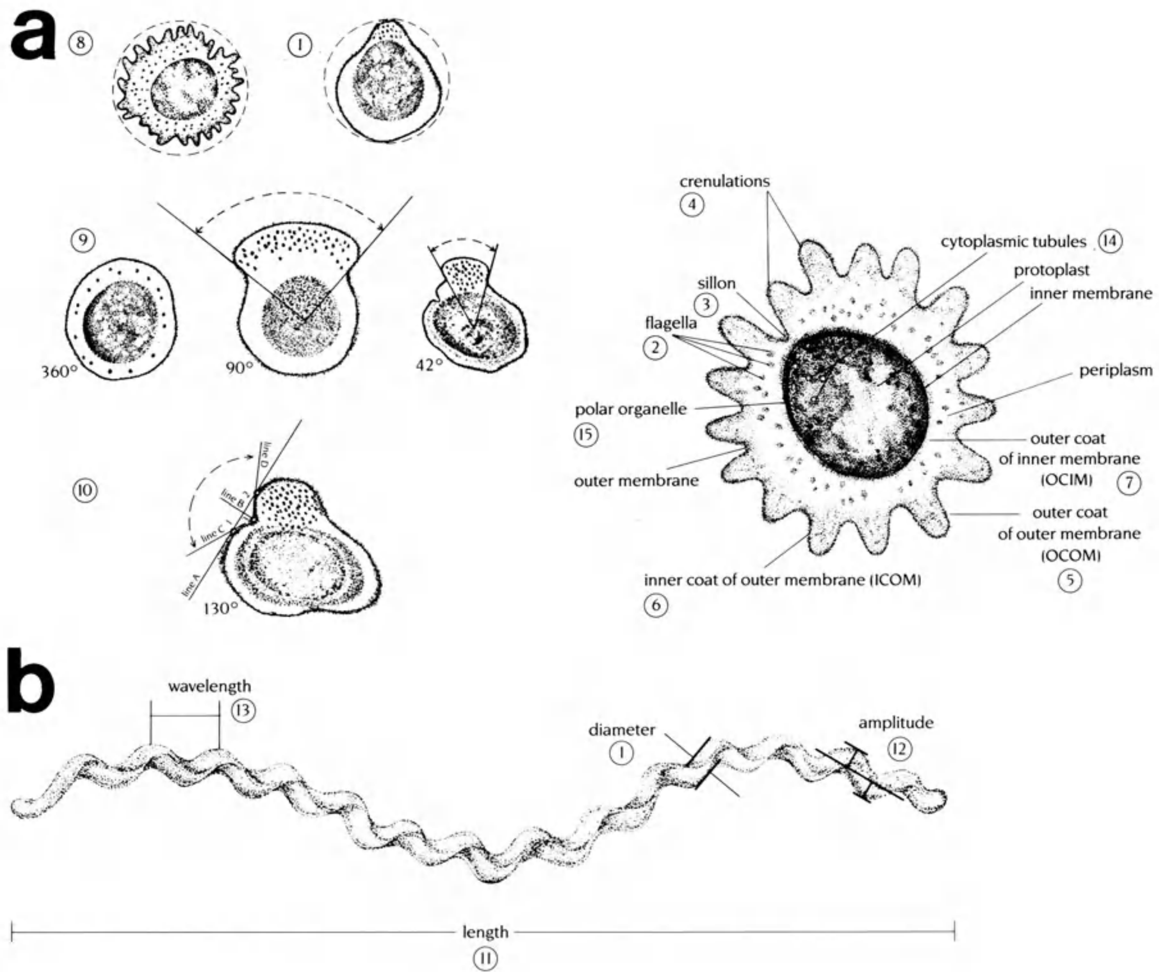
Leidy (1850) first described spiral-shaped microbes from termite intestines and called them *Spirillum undula* later renaming them *Vibrio termites* (Leidy, 1881). Dobell (1912) recognized these organisms as spirochetes; he called the larger ones *Treponema termites* and the smaller ones *Treponema minor.* The larger spirochetes were transferred to the genus *Cristipira* by Hollande (1922). They were further described by Damon (1925), Duboscq and Grassé (1929), and Kirby (1941). In an early electron microscopic study, Grimstone (1967) described a large unnamed spirochete from the wood-eating cockroach *Cryptocercus punctulatus.* Electron microscopy and the use of glutaraldehyde as a fixative reinvigorated the study of the termite hindgut microbiota by providing a means of distinguishing morphologically the uncultivable symbiotic bacteria. After the genus *Pillotina* and the family Pillotinaceae were proposed by Hollande and Gharagozlou (1967) for large spirochetes from the Madeiran termite *Incisitermes praecox,* large insect gut spirochetes were informally called "pillotinas." The discovery of a separate spirochete morphotype from the termite *Incisitermes flavicollis* led Gharagozlou (1968) to establish the genus *Diplocalyx.* To et al. (1978) described a third genus, *Hollandina,*



Encircled number	Morphometric criterion
1	Diameter
2	Number of flagella
3	Presence of sillon
4	Presence of crenulations
5	Ratio of thickness of outer coat of outer membrane to outer membrane thickness
6	Ratio of thickness of inner coat of outer membrane to outer membane thickness
7	Ratio of thickness of outer coat of inner membrane to inner membrane thickness

from the hindgut of the Sonoran desert termite *Pterotermes occidentis.* Known informally from the micrographs of D. G. Chase, *Clevelandina* was fixed in the microbiological literature by Bermudes et al. (1988).

Habitat

Cristispira develops especially dense populations in and on the crystalline style of many marine (and a few freshwater) mollusks. Styles are noncellular, gelatinous, cellulase-containing rods that extend into the stomach of many bivalve mollusks. Their presence, appearance, and consistency differ from species to species and even from individual to individual. In actively feeding animals, the style is rotated by epithelial cilia and, much like a pestle, one end is pushed against the stomach wall. The rotation likely aids in the mixing of food particles and digestive enzymes within the mollusk stomach. Some styles dissolve and reform with a tidal rhythm; when the style dissolves, the *Cristispira* disappear. Other smaller bacteria, including *Spirillum ostrea* (Margulis et al., 1991), an unidentified Gram-negative rod, and a smaller spirochete, have also been found in mollusk styles (Kuhn, 1981). Though they do not have a style, gastropods (single-valve mollusks) have been reported to harbor *Cristispira* as well (Morton, 1952; Orton, 1922; Terasaki, 1960). A partial list of the distribution of *Cristispira* in marine mollusks is given in Table 2.

The four other genera of large spirochetes are insect symbionts; they swim freely in the lumen of the distal portion of the intestine, actually an hypertrophied hindgut or paunch. The paunch, which has less oxygen relative to air (Breznak, 1984b), is easily identified and dissected in any of the wood-eating cockroaches or so-called "lower" termites. The geographical distribution of these spirochetes is listed in Table 3. Their abundance is greatest in insects that attack and ingest dry rather than damp or wet wood. As a rule, Pillotinaceae spirochetes are very abundant in both kalotermitid (dry wood) and rhinotermitid (subterranean) termites. In rhinotermitids they tend to be most abundant just posterior of the midgut/anterior hindgut junction. These spirochetes are apparently absent from the damp-wood-eating nasutitermitids and other "higher" termites. In "higher" termites, a bacterial or bacterial/fungal community rather than a protistan/bacterial community has evolved. (Spirochetes 0.5 μm in diameter with approximately 40–50 flagella have been reported in the hindgut of the higher termite *Nasutitermes exitiosus;* Czolij et al., 1985). The presence of Pillotinaceae spirochetes is easily determined by light microscopy on the basis of habitat, size, flexibility, and motility, but genera and species are not identifiable without ultrastructural analysis.

Table 2. Genera of mollusks harboring *Cristispira*.

Marine bivalve genera	
Cardium papillosum	*Penitella ovoidea*
Chama gryphoides	*Pinna nobilis*
Chama pellucida	*Pinna squamosa*
Chama sinistrorsa	*Platyodon cancellatus*
Chione fluctifraga	*Protothaca staminea*
Chione succincta	*Protothaca tenerrima*
Clinocardium nuttallii	*Saxicava arctica*
Crassostrea gigas	*Saxidomus giganteus*
Cryptomya californica	*Saxidomus nuttalli*
Cuminga californica	*Scrobicularia piperata*
Diplodonta orbella	*Siliqua patula*
Entodesma saxicola	*Solen ensis*
Gastrochaena dubia	*Soletellina acuminata*
Gryphaea angulata	*Sphaerium corneum*
Lampsilis anodontoides	*Strophitus* sp.
Lima hians	*Tapes aureus*
Lima inflata	*Tapes decussatus*
Lyonsia pugetensis	*Tapes laeta*
Macoma secta	*Tapes philippinarum*

Ostrea talienwhaneensis	*Ventricolaria* sp.
Ostrea virginiana	*Venus casta*
Panope generosa	*Venus mercenaria*
Paphia staminea	*Venus verrucosa*
Pecten jacobaeus	*Zirfaea pilsbryi*

From Kuhn (1981).

Morphology

Given ecological information and high resolution ultrastructural analysis, a single transverse thin section suffices to identify one of these large symbiotic spirochetes to genus. Ultrastructural analysis requires morphometrics (Bermudes et al., 1988). Sixteen criteria are useful when sufficient information is available (Fig. 2b). Diameters (criterion 1) in oblong cells are measured at the narrowest and widest points enclosed by the membrane. In crenulated cells, measurements are made at the tips of the crenulations. The number of flagella (criterion 2) is reported as the number inserted at each end. The number of flagella observed ranges from zero (in sections taken beyond the most distal insertion) to twice the number of flagella inserted at one end, where, toward the center, flagella inserted at one end overlap with the flagella from the other end. The sillon or groove (criterion 3) is a contact or pronounced invagination running the length of the cell of the outer membrane toward the inner membrane (Fig. 2). This structure provides a reference point for the description of other structures. Crenulations (criterion 4) are conspicuous folds or ruffles in the outer membrane (Fig. 2); to date they are limited to the genus *Pillotina*. Criteria 5, 6, and 7 deal with the presence of coatings on the inner and outer membranes of the Gram-negative cell walls (i.e., the glycocalyx or sheath). Criterion 8 is the ratio of the diameter of the protoplasmic cylinder to the cell diameter. Criterion 9, the angle subtended by the flagella, is a measurement of the distribution of the flagella in the periplasm. Flagellar bundles (criterion 10) are deemed present if the angle made by lines C and D is less than 180° (Fig. 2a). Criteria 11, 12, and 13 are the length, amplitude, and wavelength of the spirochete (Fig. 2b). Cytoplasmic tubules (criterion 14) are small, hollow structures within the protoplasmic cylinder as observed by negative stain or transmission electron microscopy (Fig. 2 and 6). They vary from 15 to 25 nm in diameter. The polar organelle (synonym, polar membrane; criterion 15) is an electron-dense lamina located on the inside of the inner (plasma) membrane toward the distal ends of the cell (Fig. 2 and 5). Rosettes (criterion 16) are linearly aligned, peripheral structures of the protoplasmic cylinder (Fig. 5); they have only been seen in *Cristispira*.

The largest spirochete in the microbiological literature, *Cristispira* is usually the only spirochete seen in mollusk styles. Healthy termites, however, may contain from one to more than five different morphotypes of pillotina spirochetes difficult to distinguish from each other with a light microscope (Fig. 3, 7, 8, and 9). Length (from 12 to 100 μm), amplitude (from 1.5 to 6.0 μm), and wavelengths (from 6 to 20 μm) can thus only be represented in approximate terms. The combination of large diameter (0.4 to greater than 1.0 μm), great length, and long wavelength distinguish pillotinas from the many other smaller, hindgut spirochetes (Figs. 7 and 8). Idealized drawings based on electron micrographs of transverse sections of all five genera are shown in Fig. 4.

Cristispira

Cristispira cells can be greater than 3 μm in diameter and over 150 μm in length. The enormous number of periplasmic flagella (>100) gives *Cristispira* a figure-eight shape in cross-section, with the flagellar bundle often equal in size to the protoplasmic cylinder (Figs. 1 and 4). In highly motile *Cristispira*, the crest, which is merely the flagellar bundle, is difficult to discern. As the spirochetes lose vitality and speed,

[a]—, There is no ultrastructural information on which identification could be based.
[b]Originally published nomenclature used (*Calotermes* is equivalent to *Kalotermes*).
Adapted from Bermudes et al. (1988).

the crest swells and becomes more obvious. The periplasmic space in *Cristispira* tends to be minimal, but expands to much greater diameter where subtended by the periplasmic flagella.

Rosettes line the periphery of *Cristispira* along its length except where flagella insert (Fig. 5). Although the electron-luminous spheres making up the rosettes generally measure about 100 nm in diameter, the number of component spheres varies from 2 to as many as 9, such that the ultrastructure of the rosettes is not constant. "Chambers" or ovoid inclusions in light micrographs correspond to these rosettes; they have no known function.

The polar organelle, a structure first described in spirilla and subsequently found in other types of flagellated bacteria, is clearly present in *Cristispira* and lies conspicuously beneath the flagellar bundle (Figs. 2 and 5a). The proximity of the polar organelle to flagella insertions suggests a role in motility generation. Nothing is known directly about the reaction of *Cristispira* to gaseous oxygen, though if cytochrome oxidase were present at the polar organelle in

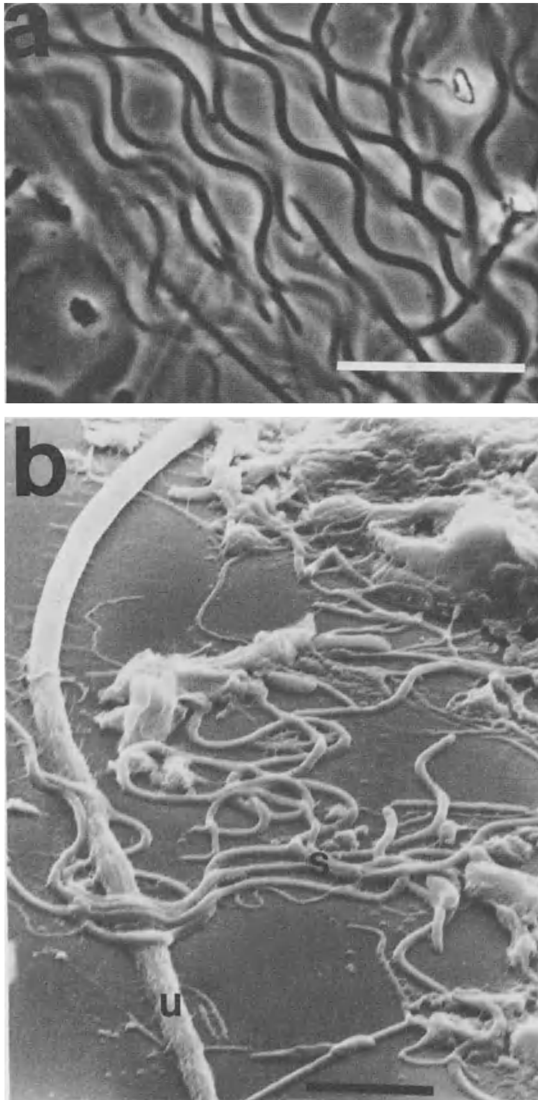

Fig. 3. (a) Live *Hollandina* spirochetes from *Pterotermes occidentis;* light micrograph. (b) *Hollandina pterotermitis* (S) and a huge, unidentified bacterium (U); scanning electron micrograph. (Bar = 5 μm)

Cristispira (as it is in *Sphaerotilus natans;* Tauschel, 1985), this would suggest that the metabolism of this spirochete is aerobic or microaerophilic. The type species for the genus is *Cristispira pectinis* (Gross, 1910).

Clevelandina

Clevelandina spirochetes are symbiotic in the paunch of subterranean termites and therefore may be anaerobes. The cells are generally oblong in cross-section, 0.4 to 0.8 μm in diameter and have 30 to 50 periplasmic flagella (Fig. 1, 4, and 9). The angle subtended by the flagella tends to be greater than 180°, and the inner coat (calyx) is correspondingly reduced. The cells are characterized by a thick inner coat (layer) of the outer membrane which tends to be chambered, and an outer coat of the inner membrane which is present except where the circumference is covered by flagella. A sillon, the contact between the inner and outer membrane that extends longitudinally, is present and crenulations are lacking. The type species is *Clevelandina reticulitermitidis* from the California termite *Reticulitermes tibialis* (Bermudes et al., 1988).

Diplocalyx

The *Diplocalyx* spirochetes are symbionts in hindguts of dry wood-eating termites; they are probably either anaerobes or microaerophiles. The cells are helical and 0.7 to 0.9 μm in diameter. In *Diplocalyx* the 40 to 60 periplasmic flagella are tightly bundled between the inner and outer membranes (Figs. 1 and 4). A prom-

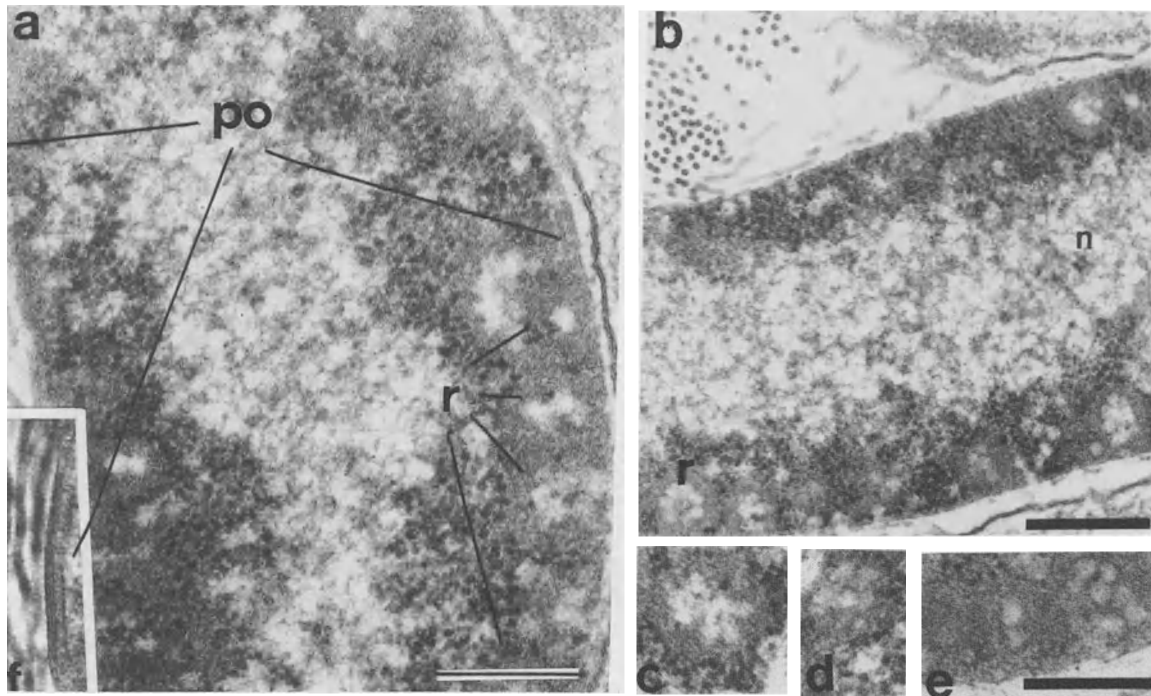

Fig. 5. *Cristispira pectinis* (a) Relationship of rosettes (r) to polar organelles (po); four rosettes and two polar organelles in longitudinal electron microscopic sections. (Bar = 0.2 μm) (b) Peripheral location of rosettes, one with seven-fold symmetry. (Bar = 0.2 μm) (c to e) Rosettes with two to nine spherical components. (Bar = 0.1 μm) (f) Detail of a polar organelle showing quadrilaminar structure. Abbreviations: n, nucleoid. See Margulis et al. (1991) for details.

inent sillon varies in position in different morphotypes relative to the flagellar bundle. A thick outer coat of the inner membrane, forming a calyx (cup), is present except under the flagellar bundle and sillon. Crenulations of the outer membrane are absent. Cytoplasmic tubules, about 21 nm in diameter (Fig. 6b), and polar organelles have been seen in some sections. The type species is *Diplocalyx calotermitidis* from the Mediterranean termite *Incisitermes flavicollis* (Gharagozlou, 1968).

Hollandina

Hollandina spirochetes, found in wood-eating cockroaches and termites, are probably anaerobes or microaerophiles. They are smooth, rounded to oblong, and helical when observed in transverse section; they are 0.4 to 1.0 μm in diameter (Figs. 1 and 4). *Hollandina* spirochetes generally have a thick coating on the outer surface of the outer membrane. Crenulations of the outer membrane are lacking. Cells have from 15 to 70 flagella dispersed in the periplasmic space. A sillon is absent or relatively inconspicuous. Polar organelles and cytoplasmic tubules have been observed in some sections. The type species is *Hollandina pterotermitides* from the Sonoran desert termite *Pterotermes occidentis* (Bermudes et al. 1988).

Pillotina

Pillotina spirochetes are symbionts in the guts of wood-eating cockroaches and termites and are probably anaerobes or microaerophiles. They have helical cells 0.6 to 1.5 μm in diameter with prominent crenulations in the outer membrane (Figs. 1, 4, 6a, 7, 8, and 9). A stellate profile with approximately 30 to 70 flagella distributed throughout the periplasmic space is distinctive for the genus. The inner coat of the outer membrane is consistently prominent; an outer coat of the outer membrane is present in some populations. A deep and narrow crenulation forms the sillon. The type species is *Pillotina calotermitidis* from the Madeiran termite *Incisitermes praecox* (Hollande and Gharagozlou, 1967).

Cytoplasmic Tubules

Hollow tubules, called microtubules by Gharagozlou (1968; Fig. 6a) although they are somewhat smaller in diameter than the standard 25-nm microtubules of eukaryotes (Margulis et al., 1978, 1981; To, 1978), have been seen in the

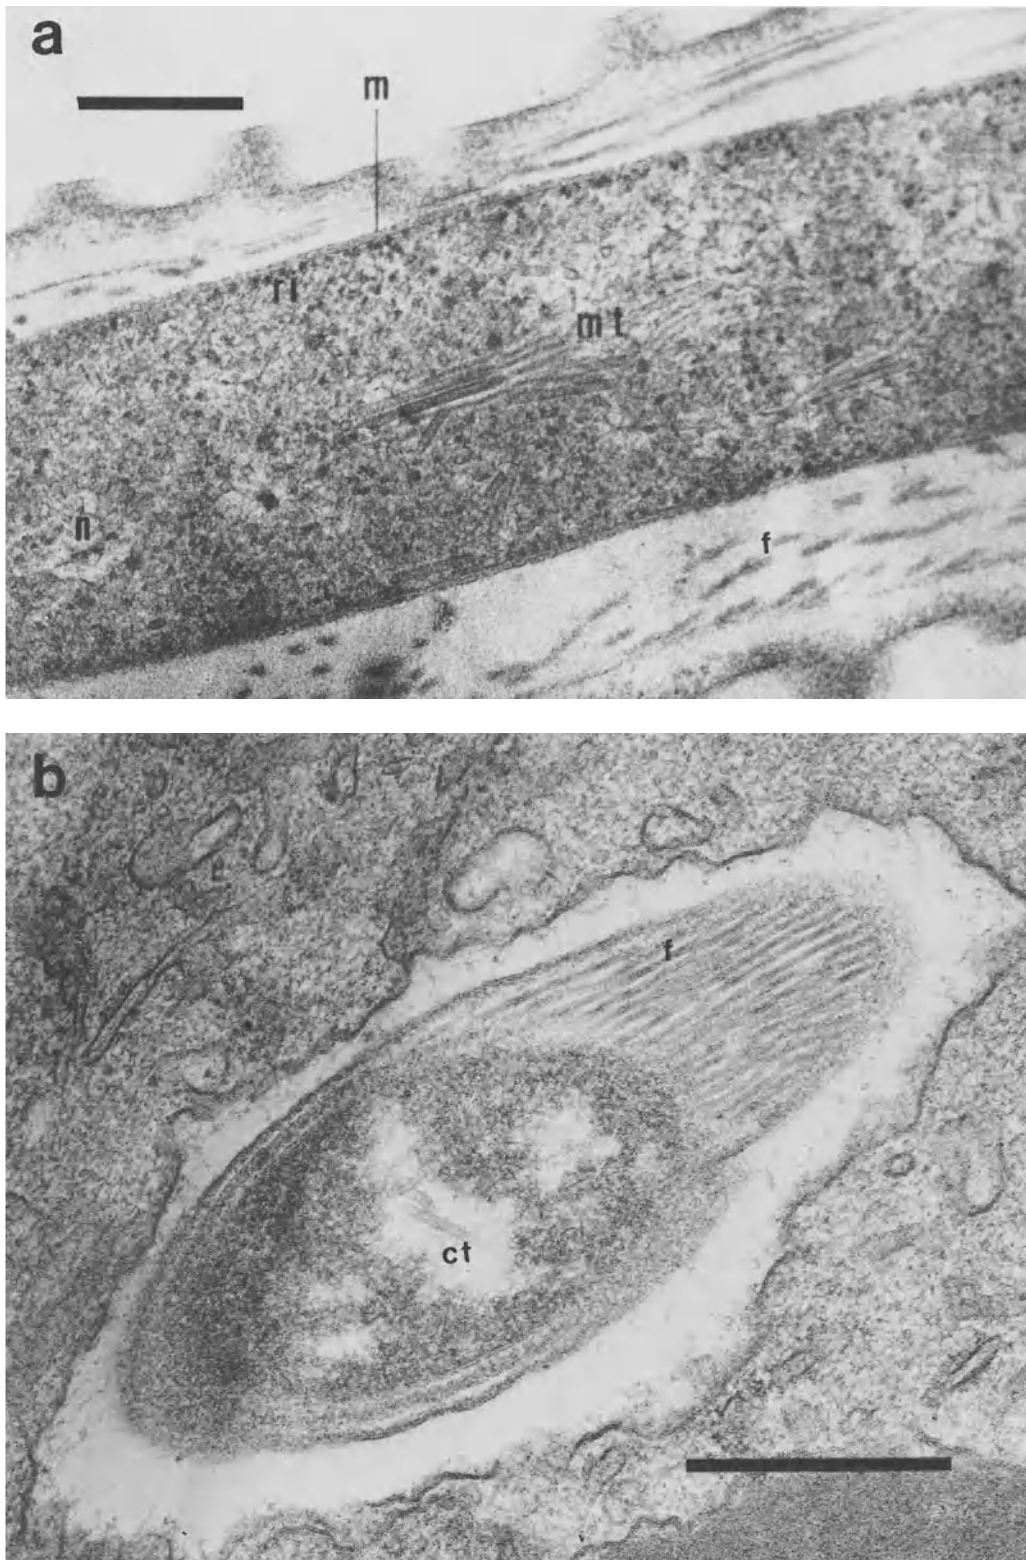

Fig. 6. (a) Cytoplasmic tubules (mt), 24 nm in diameter, in a longitudinal section of the termite *Pillotina calotermitidis* from Madeira. (Bar = 0.5 μm) (b) Cytoplasmic tubules (ct), 21 nm in diameter; and flagella (f), in *Diplocalyx* from *Incisitermes minor* from Newbury Park, California. Fig. 7. Densely populated microbial community from the hindgut of the subterranean termite *Reticulitermes hesperus.* An unidentified protist (Pr), undulipodia (U), and unidentified and large spirochetes (S), including *Pillotina* and *Clevelandina,* are seen in this transmission electron micrograph. Bar = 0.5 μm.

protoplasmic cylinders of many termite spirochete genera, including those listed in Table 1. In large spirochetes of the dry-wood-eating termites *Incisitermes schwarzi* and *Pterotermes occidentis,* the presence of a tubulin-like protein was detected by antitubulin immunofluorescence and by co-migration with authentic brain tubulin in acrylamide gel electrophoresis (Bermudes et al., 1987; Margulis et al., 1978). Tubulin proteins, which comprise eukaryotic cilia,

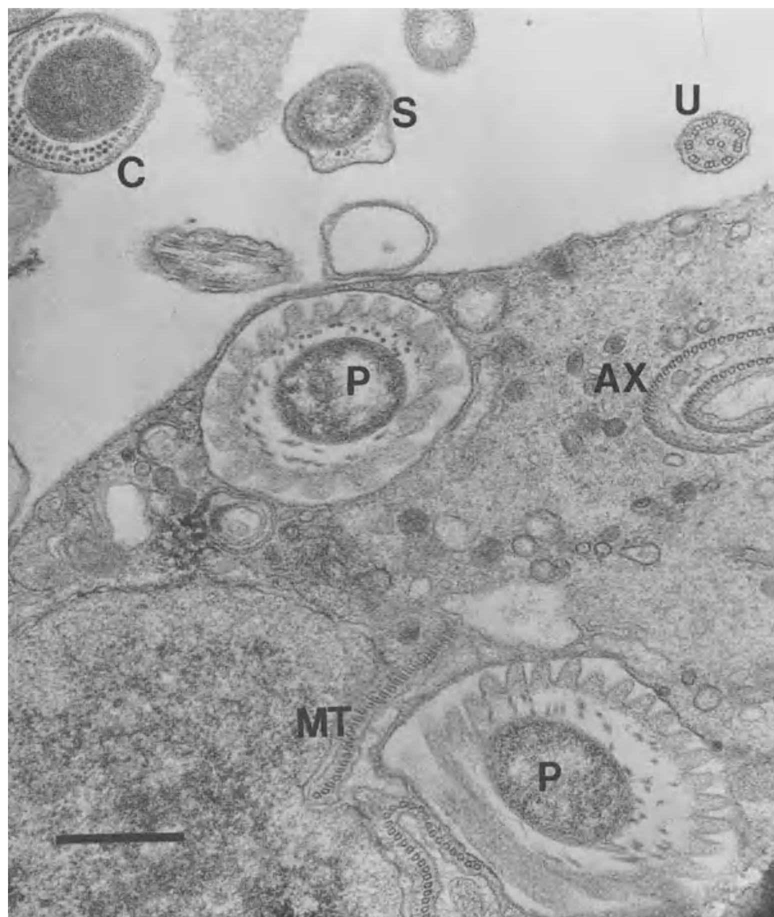

Fig. 8. Two *Pillotina* spirochetes (P) inside an unidentified hindgut protist, associated with host axostyle (AX) and microtubules (MT). Note the *Clevelandina* cell (C) and an unidentified small spirochete (S) at the upper left; U, undulipodium. (Bar = 0.5 μm)

flagella (undulipodia), and the mitotic apparatus, are ubiquitous in eukaryotes. This is the only known evidence of tubulin-like proteins in prokaryotes. An evolutionary relationship between the cytoplasmic tubules of these spirochetes and eukaryotic microtubules has been suggested (Margulis, 1981). Cytoplasmic tubules have not been reported in any *Cristispira* strains.

Distribution of Morphotypes

The geographical distribution of *Cristispira* (Table 2) and of large spirochetes from insect hindguts (Table 3) were summarized earlier. In any given termite, distinctive spirochete morphotypes are consistently and reliably found. Many undescribed spirochete morphotypes, especially smaller ones, are present in termite and cockroach hindguts, often in impressive numbers (Fig. 7). More than 25 species of kalotermitids and rhinotermitids have been examined, and they nearly all harbor some type of pillotina spirochete. Since more than 350 species of drywood termites (Krishna, 1961) and 158 species of subterranean termites are known (Wilson, 1971), and fewer than 30 termite species have been examined with the electron microscope, many more complex spirochetes likely await discovery.

Isolation

Collection and Examination of Symbiotic Spirochetes

Large spirochetes are easily observed live in wet mounts. Styles can be readily dissected from fresh mollusks and crushed with a coverslip for direct observations of *Cristispira.* Intestines are removed with forceps from termites or wood-eating cockroaches. The microorganisms are very densely packed and so are usually diluted with Trager's solution (1934) before observation. They may be maintained for observation for up to 2 hours *(Cristispira)* or 24 hours (some hindgut spirochetes), using petrolatum- or paraffin-sealed microscope slides. The style or gut,

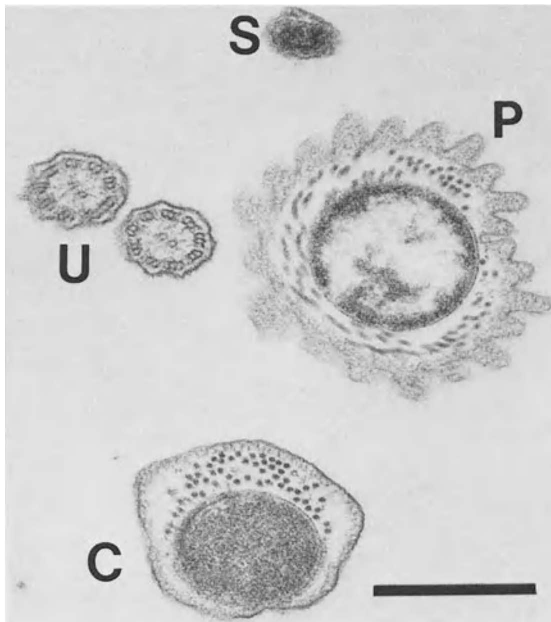

Fig. 9. *Clevelandina* (C), *Pillotina* (P), and an unidentified spirochete (S) coexisting with undulipodia (U) in the hindgut of *Reticulitermes hesperus*. Bar = 0.5 μm.

its microcosm intact, is prepared for electron microscopy by fixation with glutaraldehyde (Margulis et al., 1991; To, 1978) or observed directly.

Collection of *Cristispira*

To observe live *Cristispira*, the host mollusk must be freshly harvested since styles degenerate within a few hours after removal from their natural estuarine habitat. Oysters maintained in the laboratory quickly lose their spirochetes. *Cristispira* tend to be either plentiful or absent in any given style and when present tend to align longitudinally in the style matrix. The environmental conditions indicative of the presence and abundance of *Cristispira* in a mollusk are poorly understood. Mollusks of the same species sharing the same environment will not all contain *Cristispira*. The aeration of the general environment seems to have no correlation with the presence of *Cristispira*. Mollusks in well-aerated surf and mollusks buried deep in black, anaerobic muds both contain *Cristispira*. *Cristispira* can be collected the year round.

Maintenance of Motile *Pillotina* Cells

In spite of many efforts, no medium has yet been devised that permits the in vitro growth of any of these large, symbiotic spirochetes. The following medium, however, did maintain motile termite spirochetes in mixed culture for at least 72 and up to 120 hours:

> Sweet E broth (Holdeman and Moore, 1972) is adjusted to a pH of 6.8, rendered anaerobic by gassing with 80% Ar, 10% CO_2, and 10% H_2, and anaerobically sterilized in Hungate anaerobic tubes containing 1.5% agar. By the syringe method, fetal bovine serum and cocarboxylase are added to a final concentration of 5.0% and 0.05%, respectively. Hindgut contents from a surface-sterilized termite are inoculated into the medium.

The obvious sensitivity of the spirochetes to air bubbles on the slides and in the medium suggests that these organisms are microaerophiles or anaerobes.

Identification

Large symbiotic spirochetes may be identified by light microscopy to at least the family Pillotinaceae and in some cases to genus given identification of their animal hosts. For classification to species, ultrastructural identification is required. The use of molecular sequence analysis, in particular 16S ribosomal RNA sequence comparison, has not been applied to any large symbiotic spirochetes so the phylogenetic relation of these spirochetes with other spirochetes or any bacteria is unknown.

Symbiotic Relationships with Other Organisms

Cristispira

The crystalline styles of oysters digest cellulose in the absence of *Cristispira* symbionts. With respect to cellulose digestion in oysters, styles with spirochetes do not differ from styles without spirochetes (Margulis et al., 1991). Therefore, the role, if any, the spirochete plays in oyster digestion is unknown.

Termite Spirochetes

Termite spirochetes are always found in association with dense populations of hypermastigote and polymastigote protists, as well as with other bacteria. They are present in the hindguts of healthy, dry-wood, and subterranean termite hosts of all insect stages and castes: larvae, pseudergates, alates, and soldiers. The termite communities include some 10^5–10^6 protists per ml of fluid gut: lophomonads, trichonymphids, devescovinids, monocercomonads, and oxymonads. They also regularly contain 10^9–10^{11} bac-

teria per ml of hindgut fluid, including *Arthromitus* (Margulis et al., 1990b) and other Gram-negative rods of many kinds (To and Margulis, 1978; To et al., 1980; Figs. 7, 8, and 9). Live spirochetes are observed in many sorts of relationships with each other and with members of the community: 1) free in the lumen of the intestine (Grimstone, 1967; Margulis et al., 1979; Fig. 3, 7, and 9); 2) attached casually to the surfaces of protists, especially devescovinids and dinenymphids (Bloodgood and Fitzharris, 1976); 3) attached to other bacteria (Margulis and Schaadt, 1976); 4) attached to each other and translating in moving bundles (Margulis and Schaadt, 1976; To et al., 1978); 5) attached to debris and beating in synchrony without translation (Margulis and Schaadt, 1976); 6) attached in regular tufts to the surfaces of mastigotes (these populations of spirochetes may beat in synchrony and thus move their mastigote hosts, thereby forming motility symbioses; Cleveland and Grimstone, 1964; To et al., 1978); or 7) entirely engulfed within the cytoplasm of protists (Margulis et al., 1979, 1981; Fig. 8). Apparently, these spirochetes have sticky surfaces that facilitate attachment to each other and to other microbes. The hindgut spirochetes, along with other members of the hindgut microbial community, are actively transferred to newly hatched larvae and from insect to insect by proctodeal (mouth-to-anus or anus-to-anus) contact. If unprotected or exposed to oxygen, the spirochetes die in a few minutes.

The spirochetes are probably not essential for cellulose digestion because the community and the host can survive their absence, at least for some weeks. The spirochetes appear to depend on the protists in the hindgut community; the spirochetes do not survive more than a few days after the protists are removed by chemical or heat treatment of the termite hosts (Grosovsky and Margulis, 1982). None of the large symbiotic spirochetes seem to have any practical importance.

CHAPTER 222

The Genera *Succinivibrio* and *Succinimonas*

ROBERT B. HESPELL

Introduction

The rumen is a strictly anaerobic ecosystem inhabited mainly by bacteria and ciliated protozoa, plus smaller numbers of fungi. Although several hundred or more species of bacteria can be found in this ecosystem, only about thirty species are usually found at high enough levels to be considered of ecological significance. *Succinivibrio dextrinosolvens* and *Succinimonas amylolytica* are included in this group of major species, but have not been extensively studied. These two species are usually found in animals fed some grain in their diets. In addition to contributing to ruminal starch digestion, both species produce succinate, a fermentation product, which can be decarboxylated by *Selenomonas ruminantium* to form propionate, a major ruminal volatile fatty acid. The cells of both species stain Gram negatively and are motile by means of monotrichous, polar flagella. However, *S. amylolytica* cells are coccoid whereas cells of *S. dextrinosolvens* are curved rods with tapered ends. At present, these organisms have been isolated mainly from ruminants, but it is reasonable to suspect they may be present in the gastrointestinal tract of other animals.

Habitats

Succinivibrio dextrinosolvens and *Succinimonas amylolytica* are inhabitants of the rumen of cattle and sheep. The numbers of these bacteria vary depending on the diet. *S. amylolytica* is found in the rumen of animals fed mixed diets composed of forages and at least some grain (Bryant, et al., 1958), whereas *S. dextrinosolvens* occurs in high numbers with animals fed high levels of starch or other diets containing large amounts of rapidly fermentable carbohydrates (Bryant and Small, 1956; Wozny et al., 1977). Both species are involved in the digestion of starch and its breakdown products in the rumen. The occurrence of both species in ecosystems other than the rumen has not been well documented. However, there have been at least two reports of *Succinivibrio* species occurring in the blood of humans suffering from bacteremia (Porschen and Chan, 1977; Southern, 1975). In both cases, the patients had gastrointestinal tract disorders and thus, the organisms might have been able to enter the blood as a result of loss of gastrointestinal tract integrity. If so, this suggests that *Succinivibrio* species might be normally present in low numbers in the colon of humans.

Isolation

Selective Enrichment and Isolation

Currently, no procedures have been published regarding selective enrichment or isolation of either *S. dextrinosolvens* or *S. amylolytica.* All strains have been isolated on nonspecific, habitat-simulating media used to enumerate total culturable bacteria from ruminal contents. As with other ruminal bacteria, both species are strict anaerobes. However, three strains of *S. dextrinosolvens* isolated under diverse conditions have been shown to grow on a defined medium (Gomez-Alarcon et al. 1982). This medium lacks the volatile fatty acids, peptides, and a number of other components often used in media to cultivate many species of ruminal bacteria. Thus, it might be possible to use this medium to selectively enrich or isolate *S. dextrinosolvens.*

Cultivation Media

Both species can be grown on a variety of complex, rumen fluid-containing media (Bryant and Burkey, 1953; Bryant and Robinson, 1961) or on more defined media in which the rumen fluid has been replaced by Trypticase, yeast extract, hemin, and volatile fatty acids (Caldwell and Bryant, 1966; Hespell and Bryant, 1981). A typical complex medium for both species and a chemically defined medium for *S. dextrino-*

solvens (adapted from Gomez-Alarcon et al., 1982) are shown in Table 1. Since both species produce succinate as a fermentation product, the use of a bicarbonate-carbonic acid system is needed to provide carbon dioxide and a means of buffering. Ammonium ions serve as a major nitrogen source for both species. *S. amylolytica* has a narrow range of fermentable substrates and only glucose, maltose, dextrin, and starch are known to be used. *S. dextinosolvens* also ferments these substrates plus galactose and xylose, but starch is only partially used and is incompletely hydrolyzed. Neither species ferments amino acids or peptides.

Preservation of Cultures

Both species can be maintained for long times by storage of cultures in liquid nitrogen or ultracold freezers (Hespell and Canale-Parola, 1970). Alternatively, short-term storage is possible by placing glycerol cultures in normal (−20°C) freezers (Teather, 1982).

Table 1. Media for *S. amylolytica* and *S. dextrinosolvens*.[a]

Ingredient	Amount per 100 ml of medium	
	Complex	Defined
Carbohydrate (5%)[b]	5.0 ml	5.0 ml
Trypticase	0.5 g	—
Serine	—	30 mg
Leucine	—	40 mg
Methionine	30 mg	30 mg
Yeast extract	0.2 g	—
p-Aminobenzoic acid	—	10 μg
Ammonium chloride (5.3%)	1.0 ml	1.0 ml
Resazurin (0.1%)	0.1 ml	0.1 ml
IVI VFA solution[c]	3.0 ml	—
L-Cysteine·HCl (2.5%)[b]	1.0 ml	1.0 ml
Mineral A[d]	4.0 ml	4.0 ml
Mineral B[e]	4.0 ml	4.0 ml
Ferrous sulfate	0.3 mg	0.3 mg
Trace minerals[f]	0.5 ml	0.5 ml
Hemin plus 1,4-napthoquinone[g]	1.0 ml	1.0 ml
Sodium carbonate (8%)[h]	5.0 ml	5.0 ml
Distilled water	76.0 ml	79.0 ml

[a]Both media are prepared under carbon dioxide; final pH 6.8. The defined medium is for *S. dextrinosolvens* only.
[b]Autoclaved separately; prepared and stored under a nitrogen gas phase.
[c]Prepared by adding 7 ml acetic, 3 ml propionate, 2 ml butyrate, and 0.6 ml each of isobutyrate, 2-methylbutyrate, and isovalerate to 700 ml of 0.2 M NaOH. Adjust to pH 7.0 with NaOH and to final volume of 1 liter.
[d]Mineral A = 0.5% K_2HPO_4.
[e]Mineral B = 1.0% KH_2PO_4, 1.2% NaCl, 0.58% $NaSO_4$, 0.16% $CaCl_2·2H_2O$, and 0.25% $MgSO_4·7H_2O$.
[f]Trace minerals contained 10 mg each of $ZnSO_4·7H_2O$, H_3BO_3, $NaSeO_3$, $Na_2MoO_4·2H_2O$, $NiCl_2·6H_2O$; 5 mg $CuSO_4·5H_2O$, and 2 mg of $Al(SO_4)_2·12H_2O$ made to 100 mlm with distilled water.
[g]Solution made by dissolving 25 mg of 1,4-napthoquinone in 2 ml of 95% ethanol and combining with 10 mg of hemin dissolved in 50 ml of 0.01 M NaOH and 38 ml distilled water.
[h]Autoclaved separately; prepared, equilibrated, and stored under a carbon dioxide gas phase.

Identification

Succinimonas

Succinimonas form surface colonies that are light tan in color, translucent, smooth, and convex. Even after prolonged incubation, the colonies are only 0.6 to 1.5 mm in diameter. Colonies within agar media are lenticular in shape. Typically, the cell morphology is that of a short, oval rod or coccobacillus (1–1.5 μm by 1.2–3.0 μm long). The cells appear singly or in pairs but can form clumps in older cultures. The cells always stain Gram negatively. In wet-mount preparations, most cells show some degree of translational motility which ceases when oxygen is present. Often cells which have become attached to the glass surface display a rotational movement about one cell end. The flagellar arrangement is polar and monotrichous. Some cells may show granules near the cell periphery. The nature of these granules is unknown but they may be composed of glycogen, which is found in a number of species of ruminal bacteria. In liquid media, growth is even and disperse, but generally dense turbidities do not occur.

The major products formed from glucose are acetic and succinic acids, and the formation of these products requires a large uptake of carbon dioxide. No hydrogen gas, formate, lactate, or ethanol is produced, but trace amounts of acetoin and/or propionate may be formed. No strains are known to hydrolyze gelatin and production of hydrogen sulfide, indole, or catalase has not been observed. Growth occurs at 30–39°C but not at 22°C or 45°C. Strain differences are rather minimal and all strains are considered to be isolates of a single species, *Succinimonas amylolytica* (Bryant, 1984a).

Another major ruminal species found in animals that are fed high-grain diets is *Ruminobacter amylophilus* (formerly *Bacteroides amylophilus*). This organism also forms small, tan colonies on the surface of agar media. However, the cell morphology is distinctly different from *S. amylolytica.* The cells are larger (0.9–1.2 by 1-3 μ long), tend to form pleomorphic, swollen shapes, and most importantly, they are nonmotile (Hamlin and Hungate, 1956). In addition, *R. amylophilus* does not grow on glucose. *R. amylophilus* produces acetate, formate, and succinate as major fermentation products and

trace amounts of lactate and ethanol may also be formed. The results of 16S rRNA cataloging show that *R. amylophilus* is remotely related to the purple sulfur group of bacteria (Stackebrandt and Hippe, 1986), but the phylogenetic status of *S. amylolytica* is unknown.

Succinivibrio

Succinivibrio dextrinosolvens forms light tan, entire, translucent surface colonies that are generally only 1–2 mm in diameter. Occasionally, colonies may be irregular, raised, and yellowish. Subsurface colonies are lenticular and equally small. However, in media having low agar concentrations (0.2 to 0.6%), subsurface colonies take on a diffuse, white, furry appearance. The cells appear singly or in pairs of small, curved rods, usually 0.3–0.5 by 2.0–4.0 μm long with pointed ends. With newly isolated strains, helical or twisted filaments of 2–4 coils composed of two or more cells are common. These filaments often show rotational motility. This helical characteristic varies with strains and can be lost during successive subcultures in the laboratory, resulting in single or pairs of slightly curved rods. Under adverse cultural conditions many strains can form pleomorphic shapes—usually large, swollen rods or spherical bodies. Cells invariably stain Gram negatively and are motile. The motility is translational with a vibrating movement. The flagellation arrangement is polar and monotrichous.

A large production of acetic and succinic acids with an uptake of carbon dioxide is the most common fermentation pattern for *Succinivibrio* strains fermenting glucose (Bryant and Small, 1956; Scardovi, 1963). Small, variable amounts of formate and lactate can be made. Hydrogen gas, propionate, and butyrate are not made. Good growth occurs at incubation temperatures of 30 to 40°C, but no growth occurs at 22°C or 45°C. Biochemical tests for nitrate reduction, catalase, and production of indole, acetoin, or hydrogen sulfide are all negative. Presently, all ruminal strains are considered to constitute a single species, *Succinivibrio dextrinosolvens* (Bryant, 1984b). The succinovibrio-like strains isolated from blood samples (Porschen and Chan, 1977; Southern, 1975) appeared to have lophotrichous flagellation and are probably not true isolates of the this species, but further studies are needed to verify this.

Anaerobiospirillum succiniproducens displays motile, helical rods with cell widths of 0.6–0.8 μm and cell lengths of 3.0–8.0 μm. This organism produces acetate and succinate as major fermentation products. *A. succiniproducens* has been isolated from colonic contents of dogs, but not from the rumen. It is easily differentiated from *S. dextrinosolvens* by having bipolar tufts of about 16 flagella and by its ability to ferment lactose but not galactose or xylose (Davis et al., 1976). The phylogenetic relationships of *Succinivibrio dextrinosolvens, Succinimonas amylolytica,* and *Anaerobiospirillum succiniproducens* to one another and to other higher taxa are not known.

Biochemical and Physiological Properties

The carbohydrate fermentation pathways in *S. dextrinosolvens* have been studied by Scardovi (1963). Enzymatic activities of the Embden-Meyerhof pathway were present in cell-free extracts, but enzymes of the hexose monophosphate pathway were absent. Phosphoenolpyruvate was found to undergo carboxylation to form oxaloacetate as the product, with ADP acting as the phosphate acceptor. Presumably, the oxaloacetate mainly undergoes reduction to form succinate and is partially used in biosynthetic transamination reactions to form amino acids. The pathways for assimilation of ammonia by *S. dextrinosolvens* have been elucidated with strain C18 (Patterson and Hespell, 1985). This strain was shown to possess glutamine synthetase, urease, glutamate dehydrogenase, glutamate-oxaloacetate transaminase, and aspartate synthase. When grown in continuous culture under ammonia limitation, cells contained high levels of glutamine synthetase and urease, but glutamate dehydrogenase activity was low. The opposite pattern is observed with growth in the presence of ample ammonia. The glutamate dehydrogenase was NADPH-linked. The glutamine synthetase was regulated by an adenylation-deadenylation mechanism, allowing for rapid enzyme inactivation when high levels of ammonia are present.

CHAPTER 223

The Genus *Leptotrichia*

TOR HOFSTAD

The oral cavity of humans is the natural habitat of several different kinds of filamentous organisms, including the Gram-negative anaerobic bacterium *Leptotrichia buccalis.* This organism, which is the only species of the genus *Leptotrichia,* was among the first microorganisms to be recognizably described and drawn in the letters of Antoni van Leeuwenhoek.

The generic name *Leptotrichia* was used by Trevisan (1879) for filamentous organisms found in the human mouth. The species designation *buccalis* had been used several years earlier by Robin (1853), who used the name *Leptothrix buccalis* for filamentous forms that he had observed in wet mounts of tooth scrapings. Wherry and Oliver (1916) were able to cultivate the organism, which they called *Leptothrix innominata* in accordance with Miller (1889), but the first adequate description of *Leptotrichia buccalis* was given by Thjøtta, Hartmann, and Bøe in 1939. These authors, as well as Bøe (1941) and Bøe and Thjøtta (1944), found that the organism had much in common with the fusobacteria and, consequently, should be classified as a Gram-negative anaerobic bacterial species. Later investigators (Davis and Baird-Parker, 1959; Hamilton and Zahler, 1957; Kasai, 1961, 1965) confirmed and extended the cultural and biochemical findings of Thjøtta et al. (1939), but were of the opinion that *L. buccalis* was a Gram-positive organism. However, the ultrastructure of *L. buccalis* is that of a typical Gram-negative bacterium (Hofstad and Selvig, 1969). *Leptotrichia* is now classified as the third genus in the family Bacteroidaceae. Its capacity to produce lactic acid as the only major acid from glucose clearly distinguishes it from *Bacteroides* and *Fusobacterium. L. buccalis* is identical with *L. innominata* of Prévot et al. (1967). The GC content of the DNA is 28–30 mol% (measured by the thermal melting method).

In the past, *L. buccalis* has frequently been confused with *Fusobacterium* species (Hine and Berry, 1937; Kligler, 1915; Morris, 1954; Spaulding and Rettger, 1937a and 1937b). The name *Leptotrichia* has also been used (Bibby and Berry, 1939; Kligler, 1915; Morris, 1954) for the facultative Gram-positive organism termed *L. dentium* by Davis and Baird-Parker (1959) and now classified as *Corynebacterium matruchotii* (Collins and Cummins, 1986). See Chapter 237 for a discussion of *Fusobacterium.*

Habitats

The oral cavity of humans is the habitat of *L. buccalis,* but the organism has also been found in the female genitourinary tract (Bollgren et al., 1979; Evaldson et al., 1980). Also, the organism has been reported in the oral cavity of dogs (Goldstein et al., 1978) and in guinea pigs fed commercial pellets (T. Hofstad, unpublished observations). The principal source of the organism in the oral cavity is the dental plaque, i.e., the bacterial deposit that forms on the tooth surface and at the gingival margin. The concentration of *L. buccalis* in plaque material is uncertain. Slack and Bowden (1965) found the number of *L. buccalis* organisms in 1-day-old experimental plaque to be less than 0.01% of the total viable count; the number increased to 2.3% in 14-day-old plaque. Hillman et al. (1970) have shown that *L. buccalis* adheres to untreated enamel powder and to enamel powder coated with human saliva. However, the occurrence of the organism in the mouth is not solely dependent on tooth eruption since *L. buccalis* can be isolated from the dorsum of the tongue, and, occasionally, from predentate infants (McCarthy et al. 1965).

L. buccalis has infrequently been associated with infection in humans (Duperval et al., 1984; Kohler et al., 1982; Morgenstein et al., 1980; Reig et al., 1985; Thadepalli and Rao, 1979). Being a highly saccharolytic organism, it may participate in the development of tooth decay. The organism has cell wall lipopolysaccharide with the characteristics of an endotoxin (Gustafson et al., 1966). Antibodies reacting with this lipopolysaccharide are present in normal

human sera (Falkler and Hawley, 1976; Mergenhagen et al., 1965). These are IgM antibodies (Hawley and Falkler, 1976) and may be included among the so-called natural antibodies.

Physiology

Leptotrichia buccalis is anaerobic on first isolation although most strains become aerotolerant upon transfer and grow slowly on the surface of solid media in an ordinary CO_2 incubator. The organism grows on ordinary solid media such as Brucella blood agar, and in fluid and semifluid media based on peptone and yeast extract supplemented with a fermentable carbohydrate. Addition of serum to the medium may enhance growth.

L. buccalis is saccharolytic. Several mono- and disaccharides are fermented with the production of lactic acid alone, or accompanied by trace amounts of acetic and succinic acids. The terminal pH is 5.4 or less. Two separate lactate dehydrogenases have been isolated from cell-free extract of *L. buccalis* (Brown and Gross, 1981). Esculin is hydrolyzed. The inability of *L. buccalis* to form ammonia indicates that organic nitrogenous compounds are not metabolized.

L. buccalis is susceptible to penicillins, cephalosporins, tetracyclines, chloramphenicol, clindamycin, and metronidazole, but resistant to aminoglycosides. The minimum inhibitory concentration of erythromycin ranges from 4–16 μg/ml (Duperval et al., 1984; George et al., 1981).

Isolation

Isolation of *L. buccalis* can be performed under nonselective or selective conditions.

Sampling

Leptotrichia buccalis can be isolated from saliva or centrifuged salivary deposits, dental plaque, and the soft tissues of the mouth. It is best isolated from plaque between adjacent teeth (interstitial plaque) and the crevice or pocket that exists between the gingiva and the surface of the tooth. Sampling from the gingival crevice is best performed by the use of sterile filter paper points that are gently inserted into the crevice.

Centrifuged salivary deposits or plaque material can be inoculated onto the medium either directly or after being suspended and diluted in prereduced anaerobically sterilized (PRAS) one-quarter strength Ringers solution (Sutter et al., 1985) or the serum-containing diluent of Bowden and Hardie (1971). The inoculum on the tapering end of the paper point is streaked over a small area of the surface of the solid medium, and further spreading of the deposited material carried out by a sterile wire loop.

Isolation Under Nonselective Conditions

Because of its characteristic colonial morphology (see below), *L. buccalis* can be isolated from mixed cultures on blood agar or the starch-containing medium of Kasai (1961).

The medium of Kasai has the following composition:

Tryptone	20.0 g
Yeast extract	2.0 g
Soluble starch	20.0 g
K_2HPO_2	5.0 g
Sodium chloride	5.0 g
Cysteine hydrochloride	5.0 g
Distilled water	1 liter

The isolation of *L. buccalis* is indirectly favored by starch, which is an unavailable energy source for many of the other organisms present in the inoculated material. It is advisable to prepare 1:10 dilutions of the saliva or plaque samples and spread 0.01–0.05 ml on each freshly prepared plate. Incubation should be carried out at 37°C for 2 or more days in an anaerobic atmosphere containing 5–10% CO_2.

Selective Isolation

Media selective for *Fusobacterium nucleatum* can be used for isolation of *L. buccalis* from mixed cultures. The fusobacterium egg yolk agar (FEA) of Morgenstein et al. (1981) and the Crystal violet erythromycin agar (CVE) of Walker et al. (1979) (see Chapter 237) are most useful. *L. buccalis* grows on the FEA medium with white, raised, and granular colonies which are larger than the convex, round, and entire colonies of *F. nucleatum.* Large, brain-like or rough colonies of *L. buccalis* on the CVE medium are easily distinguished from the smaller and smooth or slightly irregular *F. nucleatum* colonies. However, strains of *L. buccalis,* susceptible to 8 μg/ml, or less, of erythromycin will not grow on the CVE medium.

Axenic Cultivation and Maintenance

L. buccalis can be maintained by weekly serial subculture on blood agar. Viable cells can be stored at −70°C in Greave's solution.

Table 1. Differentiation of *Leptotrichia buccalis* from *Fusobacterium nucleatum* and *Eubacterium saburreum.*

Characteristic	*L. buccalis*	*F. nucleatum*	*E. saburreum*
Microscopic morphology	Gram-negative,[a] 5–15 μm long, thick fusiform bacilli; filaments common	Gram-negative, 5–15 μm long, slender fusiform bacilli; filaments uncommon	Gram-positive,[b] 5–20 μm long bacilli, rounded or blunt ends; bulbous swellings and filaments common
Colonial morphology (blood agar)	Smooth, shiny, rhizoid, or convoluted	Smooth, convex, "flecked" appearance	Rough, rhizoid, adherent; or smooth, rhizoid or convoluted, nonadherent
Terminal pH from glucose	<5.4	>5.8	<5.4
Production of indole	−	+	+
Production of gas	−	−	+
Foul odor	−	+	−
Predominant fatty acids from glucose (GLC)	Lactic	Butyric	Acetic and butyric

[a]Often Gram-positive in young cultures.
[b]Often Gram-negative in old cultures.

Greave's Solution

Bovine serum albumin	50 g
Sodium glutamate	50 g
Glycerol	100 g
Distilled water	100 ml

Mass cultivation is performed in nutrient broth supplemented with yeast extract (0.3%), glucose (0.5%), cysteine HCl (0.1%), and serum (2%). The use of well-filled, narrow-necked bottles or similar containers makes the use of prereduced anaerobically sterilized (PRAS) media unnecessary.

Identification

A reliable identification of *L. buccalis* can be made from cellular and colonial morphology and, in addition, from a few biochemical tests (Table 1).

In Gram-stained specimens, *L. buccalis* is 0.8- to 1.5-μm-wide and 5- to 15 μm-long fusiform rods, commonly occurring in pairs with the adjacent ends flattened.

Filaments are seen in old cultures. The organism is Gram-negative, often with Gram-positive granules, but may be wholly Gram-positive in very young cultures. In young cultures, therefore, the cells of *L. buccalis* are not unlike those of the Gram-positive oral organism *Eubacterium saburreum.* However, *E. saburreum* never has tapered ends.

Young colonies of *L. buccalis* are colorless, smooth, and often shiny, raised and with a filamentous edge; the colonies are described as "medusa-head" colonies. Following prolonged incubation, the filamentous edge may disappear and the surface becomes convoluted, resembling that of a human brain. The colonies are nonadherent to the medium and after 2 days of incubation on blood agar measure 2–3 mm in diameter. Two- to three-day-old colonies on blood agar of *E. saburreum* may be mistaken for *L. buccalis.*

L. buccalis has been identified in plaque material using the fluorescent-antibody technique (Baboolal, 1968).

CHAPTER 224

The Genus *Francisella*

FRANCIS E. NANO

Introduction

Francisella tularensis was recognized as the causative agent of a febrile illness in three different parts of the world in the early part of the 20th century. McCoy (1911) described a new disease which he found while studying a suspected outbreak of plague in ground squirrels in Tulare County, California. McCoy and Chapin (1912) isolated the etiologic agent of this "plague-like disease" and named the organism *Bacterium tularense* after the county in which it was found. This organism was also recognized as a disease agent of humans at about the same time. Pearse (1911) described what was known as "deer fly fever" in the area around Brigham City, UT, and Wherry and Lamb (1914) identified *B. tularense* as the infectious agent of a diseased meat worker in Cincinnati, OH. Edward Francis carried out an extensive series of experiments on the transmission of this organism and on the pathology of the disease he named *tularemia* (Francis, 1923). Shortly after the description of tularemia in the United States, Ohara (1925) isolated a similar organism (Francis and Moore, 1926) in Japan that caused Yato-byo (hare disease). In 1926, Soviet researchers (Pollitzer, 1967) isolated the same organism from human cases in Siberia. The name of the etiological agent of tularemia has changed over the years from *B. tularense,* to *Pasteurella tularensis,* to what it is called today, *Francisella tularensis,* the latter name in honor of the studies performed with this organism by Francis. In 1950 (Larson et al., 1955), another bacterium was discovered that was eventually placed in the genus *Francisella.* This organism, *F. novicida,* has only been found twice since its original isolation and apparently has a very low infectivity for humans.

F. tularensis is a Gram-negative cocco-bacillus that is 0.2 μm × 0.2–0.7 μm in size; *F. novicida* is larger at 0.7 × 1.7 μm. *F. tularensis* has a loosely associated capsule which is difficult to see with light microscopy and is often stripped away during preparation for electron microscopy. *F. tularensis* cells can appear highly pleomorphic, especially when taken from a stationary growth culture. There are no flagella nor pili associated with this organism but some researchers have observed a long flagellar-like organelle in electron micrographs; it is probable that such structures are electron microscopic artifacts. In the host, *F. tularensis* can be found both intracellularly and extracellularly (see Fig. 1), and there is substantial evidence that *F. tularensis* grows in macrophages.

Initially, researchers from around the world were uncertain of the relationship among the agents causing tularemia-like diseases since the North American cases were clinically much more severe than those found in other parts of the world. After exchanges of convalescent sera and *F. tularensis* strains, it became apparent that the strains from Asia, Europe, and North America were antigenically identical but that the North American strains were considerably more virulent, as demonstrated by both the clinical presentation and the virulence for laboratory animals. Later, it was found that there were two forms of *F. tularensis* in North America: the highly virulent form noted in most clinical descriptions of the disease, and a form that seemed to correspond to the European-Asian isolates.

There are at least three nomenclature systems used to describe the different biovars. Olsufiev et al. (1959) proposed the designation *F. tularensis* var. *tularensis* for the highly virulent North American strain and *F. tularensis* var. *palaearctica* for the less virulent strain found throughout the Northern Hemisphere. More recently Soviet investigators have used *F. tularensis nearctica* Olsufjev and *F. tularensis holarctica* Olsufjev in place of the biovar designations of *tularensis* and *palaearctica,* respectively. Jellison proposed the designations "A" and "B" for the highly virulent and less virulent forms, respectively. I will use these designations since they are simpler and imply nothing about geographical distribution and relatedness, ideas that may change with time. *F.*

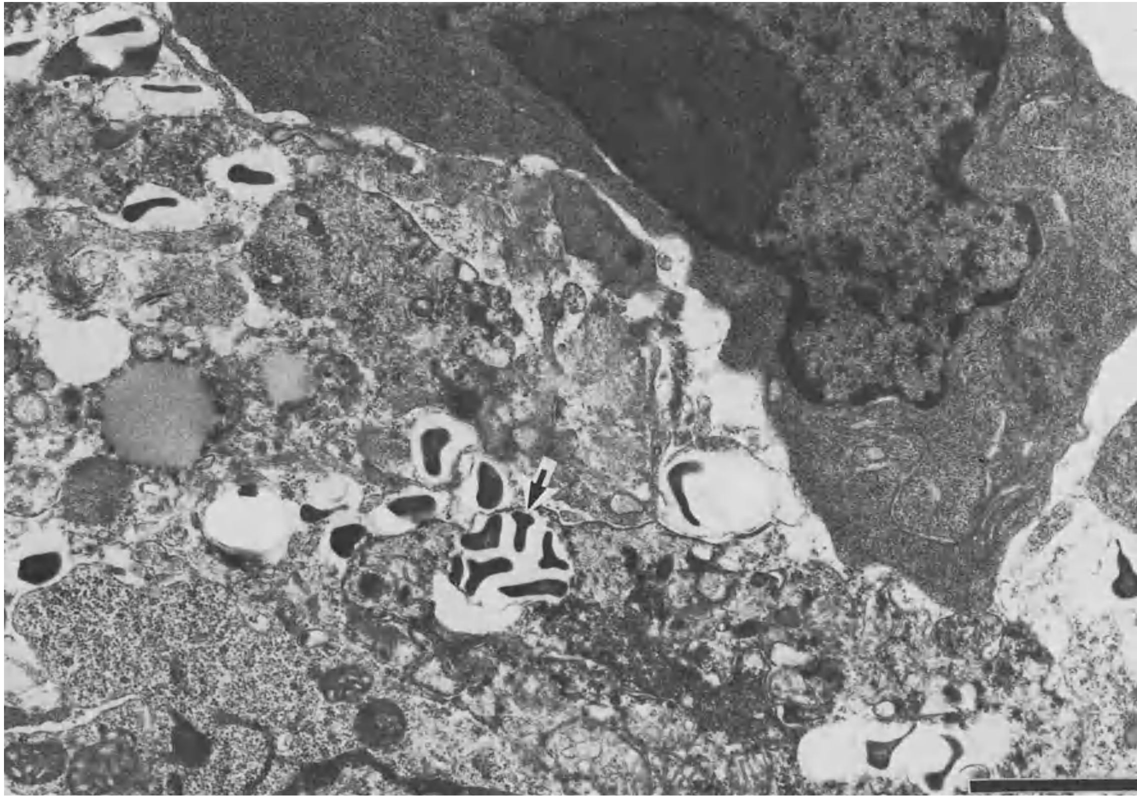

Fig. 1. Intracellular growth of *F. tularensis*. Transmission electron microscope image of a thin-section profile of *F. tularensis*, type A (Schu), in the liver of an RML strain White Swiss mouse. Bacteria are found in both intracellular and extracellular environments. Intracellularly, the organisms appear within endosomes (arrow). Note the pleomorphic forms of *F. tularensis*. Aberrations within the cell, such as mitochondrial swelling, endoplasmic reticular disruption, and lipid droplet formation are indicative of intracellular infection and are considered the result of cytopathic effects. Bar = 1.0 μm. (Courtesy of Stanley F. Hayes.)

novicida has only been isolated from North America.

Distribution and Transmission

F. tularensis has been found on every continent except Australia. Paradoxically, tularemia is not found south of the equator nor in England even though migratory birds have been shown to carry tularemia. It may be that the known foci of tularemia will continue to expand. It was only in 1968 (Young et al., 1969) that Vermont was though to be tularemia-free, only to yield a small epidemic of the disease. Until the 1980s, *F. novicida* had been isolated only once; we now suspect that *F. novicida* is endemic over wide areas of North America (Hollis et al., 1989). Moreover, it is possible that *F. novicida*-like strains are endemic in certain portions of the world, conferring immunity to *F. tularensis* and therefore preventing its establishment. Since *F. novicida* does not infect healthy humans and is not agglutinated by anti-*F. tularensis* antisera, the presence of *F. novicida* may go unnoticed.

Tularemia can be spread in a number of different ways; the prevalent mode of transmission differs from place to place and has been changing since the discovery of tularemia. In North America, during the early part of this century, tularemia was associated with rabbit hunting and the preparation of wild meat; hence, the colloquial names "rabbit fever" and "market men's disease" came about. In the western part of the United States, tularemia is often spread by biting insects and has been referred to as "deer fly fever." With the decline of rabbit hunting, tick bites—and to a lesser extent other insect bites—have become the major mode of transmission. Transmission of the type B form of *F. tularensis* through stream water occasionally causes small outbreaks of tularemia. However, one stream in Montana has been shown to carry *F. tularensis* type B for many years without causing any apparent infections in people using the stream water (Parker et al., 1951). It is likely that many infections with *F. tularensis* type B

occur without being recognized as tularemia and serological evidence suggests that many subclinical or unrecognized cases occur. Although tick-borne tularemia is probably always caused by *F. tularensis* type A and represents "typical" tularemia in North America, the type B forms of *F. tularensis* can also be found in ticks.

In northern Scandinavia and Finland where tularemia is common, tularemia is spread by a number of different routes including insect bites, inhalation of *F. tularensis*-laden agricultural products, and self-inoculation while dressing wild hares. Note that the hare (genus *Lupus*) is susceptible to the type B strain of *F. tularensis,* whereas the rabbit (genus *Sylvilagus*) is resistant to this strain. The similarity of transmission of tularemia by rabbits in North America and hares in Europe and Japan simply reflects close contact of humans with these animals during hunting and subsequent dressing. In Japan, as in Scandinavia, most cases of tularemia are associated with contact with hares.

Most of the world cases of tularemia occur within the Soviet Union, where a large number of hunters and trappers come into contact with infected animals. Also, transmission of *F. tularensis* in water has been responsible for epidemics which involve thousands of people. The reservoir for tularemia in the Soviet Union, as in northern Canada and Scandinavia, is a number of small animals, including rats and lemmings. The public health hazard of tularemia has led to intensive studies of zootic tularemia foci, and large-scale vaccination programs of the Soviet rural populations (Pollitzer, 1967).

Clinical

F. tularensis is an invasive pathogen that is able to cause a wide variety of symptoms which are determined by the route of infection and the immune response of the host. If tularemia is initiated by a self-inflicted cut or an insect bite, an ulcer usually develops at the site of infection, followed by fever, malaise, and swelling of local lymph nodes. This form of tularemia is called ulcero-glandular, and can progress to other forms of disease, depending on the natural immunity of the host and further self-inoculation. In some patients a septicemia can develop which may lead to infection of the lungs and pulmonary involvement; this systemic form of the disease is termed typhoidal tularemia. The typhoidal form of tularemia can also be initiated by ingestion or inhalation (causing pneumonic tularemia) of *F. tularensis.* The ocular-glandular form of tularemia, which is characterized by invasion of the conjunctiva, usually results from individuals unknowingly infecting the eye after touching infected material or an ulcer. However, any site on the body where there is a break in the skin or an exposed mucosal surface can be infected by *F. tularensis;* the terms used to describe the syndromes merely reflect the most common presentations of the disease.

An extensive study of the pathology in tularemia in humans and other animals was carried out by Lillie et al. (1937) and has been extended since then by a number of workers. There is a large variation in the lesions seen in tularemia that vary among the species infected, the virulence of the *F. tularensis* strains, and the route and dose of inoculation. In experimental animals splenomegaly is common and tiny grey focal lesions are seen in both the liver and spleen. In humans, cases of ulcero-glandular forms of tularemia, miliary granulomatous lesions can be found as well as suppurative, ulcerating lymph nodes. The pneumonic form of tularemia is pathologically identical to tuberculosis with caseating granulomatous lesions. An extensive review of tularemia by Bell (1981) includes a section summarizing the pathological lesions seen in human and animal cases.

Streptomycin remains the drug of choice for tularemia despite its toxicity (Anonymous, 1988). Gentamicin, tetracycline, and chloramphenicol have been used clinically and are also effective in treating tularemia. If the infection is not life threatening, tetracycline may be the drug of choice due to its relatively low toxicity. However, as with chloramphenicol, tetracycline treatment often results in relapses. A number of other antibiotics can inhibit *F. tularensis* growth in vitro (Baker et al., 1985) but they have not been tested clinically. Penicillins are not effective in treating tularemia and one study (Baker et al., 1985) showed that of 15 strains tested all had β-lactamase activity.

Identification, Isolation, and Cultivation

Clinically, tularemia can be confused with many other diseases, especially if a cutaneous ulcer is not present. Usually a presumptive diagnosis is made on the basis of a history of a tick bite or contact with diseased rabbits. Conclusive clinical evidence of infection can only be made by a rise in titer of agglutinating antibodies from serum samples taken 10–14 days apart.

F. tularensis is usually suspected when the bacterium is a nonsporeforming, aerobic Gram-negative cocco-bacillus which requires rich media supplemented with cysteine or another reducing agent. Microscopic examination may reveal a tendency to bipolar staining and the presence of a capsule. Definitive identification of *F. tularensis* is accomplished by reaction with antisera, using either agglutination or fluorescent antibody reaction.

Biochemical reactions are not particularly helpful in identifying *F. tularensis* but can be used to a limited extent to separate the biovars of *F. tularensis* and *F. novicida.* The type A biovar is able to ferment glycerol and possesses a citrulline ureidase whereas the type B biovar does not have these characteristics. *F. novicida* can be differentiated by its ability to ferment sucrose. All strains are able to use glucose, mannose, and fructose; *F. novicida* and some strains of *F. tularensis* are unable to ferment maltose.

The most rapid form of laboratory diagnosis can be accomplished by examining the reaction of fluorescence antibody with infected tissue. However, this is not practical for most laboratories which rely on culturing *F. tularensis* and testing for agglutination by specific antisera. Isolation of *F. tularensis* can be done on a number of different types of rich media that are supplemented with cysteine and whole blood. Addition of penicillin (100,000 units/ml) and polymyxin B (100,000 units/ml) will suppress the growth of other bacteria and cycloheximide (0.1 mg/ml) will suppress the growth of fungus. *F. tularensis* appear as grey, viscous colonies surrounded by an area of green discoloration on an agar medium containing blood. When *F. tularensis* needs to be isolated from a dilute source or from a mixture of microorganisms, injection of a mouse can help with the enrichment, although such experiments require Biological Level 3 containment facilities. *F. tularensis* should be easy to isolate from the liver and spleen of moribund animals.

F. tularensis can be cultivated on a number of rich agar media that contain cysteine. In addition, *F. tularensis* can be grown in complex liquid media such as peptone-cysteine broth and trypticase soy broth with cysteine, as well as in defined media. Optimal growth occurs at 37°C with continuous shaking, yielding cultures of up to 4 × 10^{10} cells/ml. *F. novicida* can grow in any of the media used for *F. tularensis.*

Cysteine Heart Agar (Difco) for Growth and Isolation of *F. tularensis*

Beef Heart Infusion	500 gm
Proteose Peptone	10 gm
Sodium Chloride	5 gm
L-cysteine	1 gm
Agar	15 gm
Distilled or deionized water	1000 ml
Final pH 6.8	

After dissolving the medium, autoclave for 15 min at 121°C. Cool to 45–48°C and add 50 ml of defibrinated rabbit or horse blood.

Peptone Cysteine Agar for observing colony morphotypes.

Bacto peptone	20 gm
NaCl	10 gm
Glucose	1 gm
Cysteine-HCl	1 gm
Agar	15 gm

After dissolving all the ingredients (except the agar) adjust the pH to 6.8. Add the agar and autoclave for 15 min at 121°C.

Each lot of media can be tested by growing the avirulent B38 or the live vaccine strain (LVS). The B38 strain normally grows very poorly, so medium that supports its growth should support the growth of virulent strains. *F. tularensis* colonies will reach their maximum size in 3–5 days. *F. novicida* grows considerably faster with colonies appearing within 24 h. *F. novicida* does not require the addition of cysteine but grows faster in its presence.

Francisella strains can be preserved by freezing or lyopholizing log phase cultures that are mixed one- to-one with either skim milk, 2.6% gelatin, or 0.2% agar. Serial passage on solid medium will invariably lead to loss of virulence.

F. tularensis is highly infectious and Biosafety Level 3 facilities should be used when culturing virulent strains or working with infected animals. However, for decades researchers have worked with a number of attenuated *F. tularensis* strains that have proven to be safe; special containment facilities have not been necessary. In particular, the B38 strain and the LVS have been used for antigen preparations and immunological studies, respectively. Personnel who come into contact with highly virulent *F. tularensis* should be vaccinated with the live vaccine strain, which is especially effective in preventing the pneumonic form of tularemia.

Interaction of *F. tularensis* with Its Host

F. tularensis is able to invade and multiply within nonprofessional phagocytes such as L-cells (Merriott et al., 1961) and HeLa cells (Shepard, 1959); the evidence for intracellular growth includes electron microscope observations and intracellular growth in the presence

of streptomycin. The cellular location of *F. tularensis* replication has not been conclusively demonstrated and different authors have suggested that replication takes place inside the cytoplasm (Shepard, 1959) or within a phagolysosome (Lofgren et al., 1988). The significance of in vitro intracellular growth within nonprofessional phagocytes to growth in vivo is unclear. Electron micrographs have demonstrated intracellular growth of *F. tularensis* within liver tissue but the cell type was not identified (J. F. Bell and S. F. Hayes, unpublished observations).

Both in vivo and in vitro experiments reveal that *F. tularensis* grows inside macrophages and monocytes but not within polymorphonuclear lymphocytes (PMN). The growth rate inside macrophages and cultured cell lines correlates with the virulence of the *F. tularensis* strain. *F. tularensis* is not found within PMNs in infected animals presumably due to the antiphagocytic effects of its capsule. In vitro, PMNs cannot phagocytize *F. tularensis* unless immune serum is added. The capsule-minus mutants of the live vaccine strain are readily phagocytized by PMNs whereas the encapsulated strain is not (Sandstrom et al., 1988).

The capsule of *F. tularensis* is clearly a virulence factor. Depending on the parent strain, one can measure one to three logs increase in the LD_{50} in capsule-minus strains (Eigelsbach et al., 1951; Eigelsbach et al., 1952; Hood, 1977; Sandstrom et al., 1988) (much of this information assumes that the "rough" mutants described by different researchers were capsule-minus strains). Hood (1977) was able to dislodge the capsule by incubating *F. tularensis* cells in a solution of 10% saline. Cells treated this way had a large decrease in virulence, but it is impossible to know if this treatment affected other components of the cell besides the capsule. The capsule also seems to protect *F. tularensis* from serum complement; normal serum can kill capsule-minus strains.

Microbiology

Many *F. tularensis* strains generate different colonial morphotypes at a high frequency. Two type A isolates were studied in detail by Eigelsbach et al. (1951) who observed different variants using a dissecting microscope to differentiate the colony types. Wild type *F. tularensis* appear as viscous, rounded colonies; however, when viewed through a dissecting microscope with oblique lighting the colonies appear blue (due to either light interference or selective absorption). The highly virulent Schu strain and the avirulent B38 strain (of biovar type A lineage) both segregate different colony types that had either changes in the blue shade (to "gray" variants) or the shape of the colony. Working with the Schu strain, these workers were able to determine that loss of the blue coloration correlated with the absolute loss of virulence and that some of the colonial shape changes affected virulence to a lesser extent. The European and Asian isolates also segregate gray variants but do not show the extreme variation seen in strain B38. The blue-gray transition is not reversible at detectable frequencies since one blue cell of the Schu strain will kill a mouse whereas $> 10^9$ gray cells will not. Also, the genetic lesions conferring avirulence in strain B38 and the LVS do not revert to wild type at detectable frequencies. Without knowing the molecular basis for the colonial morphotypes, it is difficult to suggest whether the changes reflect point mutations, illegitimate recombination induced by transposons, or the loss of plasmids. Perhaps some of the virulence factors of the North American type A strain of *F. tularensis* are on mobile genetic elements. The plasmid carriage state of most *F. tularensis* strains is unknown; however it is known that the live vaccine strains and *F. novicida* do not have plasmid (F. Nano, unpublished observations).

A large amount of antigenic analysis of *F. tularensis* was done before the 1970s using chemical methods, agglutination reactions, Oucterlony analysis, and delayed and immediate type hypersensitivity reactions. Most of the information from these early studies corresponds well with what has more recently been learned from sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and immunoblots. A capsule covers the *F. tularensis* cell, and antibody against the capsule is agglutinating. The composition of the capsule has not been precisely defined, but the data of Hood (1977) indicates that it was made largely of two saturated fatty acids (16:0 and 1-OH 14:0) and four sugars (mannose, rhamnose, and two unidentified sugars). The data concerning a capsule-minus mutant of the LVS, however, shows no difference in fatty acid composition between the encapsulated strain and the capsule-minus mutant. These two works do not necessarily contradict each other since the "capsule-minus" strain may have a genetic defect that affects assembly of carbohydrate portions of the capsule but not of the lipid portions. *F. novicida* either does not have a capsule or it is different antigenically from that of *F. tularensis,* since no cross agglutination occurs.

The lipid composition of *F. tularensis* is unusual in that it contains hydroxy fatty acids 2-OH-10:0, 3-OH-16:0, and 3-OH-18:0, and fatty acids with long carbon chains (C_{20}–C_{26}). From the published data it is difficult to determine the precise fatty acid composition and the distribution to different cell components. Cumulatively, the data from different publications suggest that the hydroxy fatty acids are not in the inner membrane, but are most likely in the capsule (Anderson and Bhatti, 1986; Hood, 1977; Jantzen et al., 1979).

The capsule blocks the accessibility of outer membrane proteins and lipopolysaccharides to antibody and chemicals, and has thus hindered analysis of the outer membrane. Investigators in Sweden have studied the immunogenic potential of outer membrane components and have described four outer membrane proteins (Sandstrom et al., 1987). Another investigator described a protein, called FopA, and cloned the encoding gene (Nano, 1988). FopA has properties similar to OmpA of *Escherichia coli;* it is an outer membrane protein that appears to have a tight association with LPS. Its mobility in SDS-PAGE is affected by heat, reducing agents, and treatment with organic solvents. FopA is the major protein immunogen in infected humans (Bevanger et al., 1988) and in animals injected with killed cells. The LPS of both *Francisella* species is rough, with no apparent O-side chains visible by silver-staining (F. Nano, unpublished observations).

What are the relationships among the *F. tularensis* strains and *F. novicida* and how is the genus *Francisella* related to other genera of bacteria? Judging by DNA homology, genetic recombination studies and Western immunoblot analysis, the different *F. tularensis* strains and *F. novicida* are closely related. Although attempts have been made to demonstrate a relationship between *F. tularensis* and *Yersinia, Pasteurella,* or *Brucella* species there is no good evidence by modern standards showing a convincing evolutionary relationship. The GC content of the DNA up *Francisella* is 33 to 36 mol%, which is quite different from that of these other bacteria. As 16S RNA sequencing analysis of different bacterial species continues we should learn the correct phylogenetic place of *Francisella.*

Yersinia philomiragia is closely related to *Francisella* species (Hollis et al., 1989), and it has been proposed to encorporate this species into the genus *Francisella.* The origin of the *F. philomiragia* samples that were studied demonstrate that this species is found over wide areas of North America and Europe. Furthermore, the fact that all of the patients (except one) that were the source of the strains had a severe underlying disease or had experienced a near-drowning episode, indicates that these strains have extremely low infectivity for healthy humans. The presence of some of these strains in ocean water suggests that they may be pathogens of fish or marine mammals.

Acknowledgments

I would like to dedicate this review to my predecessors at the Rocky Mountain Laboratories who studied tularemia for many decades (and discovered *F. novicida* and *Y. philomiragia*), especially J. F. Bell, C. R. Owen, and W. L. Jellison.

CHAPTER 225

The Hemotrophic Bacteria: The Families Bartonellaceae and Anaplasmataceae

JULIUS P. KREIER, RAINER GOTHE, GARRET M. IHLER, HEINZ E. KRAMPITZ, GLENDA MERNAUGH, and GUY H. PALMER

The organisms of the genera included in the families Bartonellaceae and Anaplasmataceae are heterogeneous. It is probable that these organisms were first considered to be related because they all parasitized red blood cells and because they produced diseases characterized by anemia. The additional observations that all of these organisms were best demonstrated by light microscopy of red blood cells after treatment with Romanovsky-type stains, and that they were all quite small, reinforced adherence to the grouping based on the common hemotrophism. The small size and the often intracellular site of growth of the organisms and their dependence for transmission on arthropods also suggested a relationship to the Rickettsiales (Kreier and Ristic, 1972, 1973). The attributes of some members of the two families are summarized in Table 1.

The stroma of erythrocytes is a suitable habitat for a variety of organisms but the erythrocyte membrane may be a barrier to infection. Tedeschi et al. (1978), for example, described growth of corynebacteria in human erythrocytes after experimental introduction despite the normal inability of the organisms to enter red blood cells. It is a fact however that organisms capable of entering and growing in erythrocytes belong to systematically quite diverse groups. Plasmodia, piroplasmids, and endotrypanosomes among the protozoa, as well as the bacteria described in this chapter are all able to enter and grow in erythrocytes. The grouping together, largely based on the common hemotrophism of the organisms treated in this chapter, should thus be considered an interim solution followed for reasons of historical continuity until either confirmed or rejected on the basis of new data.

The organisms of the genera *Bartonella* and *Grahamella* of the family Bartonellaceae are typical bacteria with cell walls morphologically comparable to the cell walls of other Gram-negative bacteria (Krampitz and Kleinschmidt, 1960; Takano-Moron, 1970). Despite the fact that in vivo they often grow intracellularly, they can be cultured without difficulty on nonliving culture media. In culture, organisms of the genus *Bartonella* may be flagellated (Peters and Wigand, 1952) but organisms of the genus *Grahamella* are not (Krampitz and Kleinschmidt, 1960). *Bartonella* and *Grahamella* are thus small, facultatively intracellular Gram-negative bacteria. It is apparent then that these organisms do not have the attributes classically ascribed to the rickettsiae: small, obligately intracellular bacteria which cannot be cultured outside of living host cells (see Chapter 121 and Moulder, 1962).

The organisms of the genera *Anaplasma, Aegyptianella, Haemobartonella,* and *Eperythrozoon* of the family Anaplasmataceae differ from typical bacteria since they lack cell walls and cannot be cultured on nonliving media (Aikawa and Nussenzweig, 1972; Peters et al., 1973; Tanaka et al., 1965). All prokaryotic protists which lack cell walls have some similarities, particularly in morphology (Anderson, 1969; Davis et al., 1973). Prokaryotic organisms lacking cell walls are, despite their morphological similarities, a quite heterogeneous group. Some are mycoplasmas and others may be cell wall-defective bacterial variants (L-phase variants). Some L-phase variants may revert to normal vegetative cells while others are stable. Stable L-phase variants are indistinguishable from mycoplasmas morphologically but nucleic-acid-homology studies show that L-phase bacteria and mycoplasmas are not closely related and that L-phase bacteria are themselves heterogeneous (Davis et al., 1973).

Organisms of the family Anaplasmataceae have not been cultured outside of their hosts. Most mycoplasmas are readily cultured and form characteristic colonies on solid culture media (Hayflick, 1969). L-phase organisms, which often resemble mycoplasmas, in general have the cultural requirements of the bacteria from which they are derived except that the tonicity of the culture medium must be increased to prevent lysis of the cell-wall-less organisms.

Organisms of the various genera of the family Anaplasmataceae are all quite similar morpho-

Table 1. Characteristics of the Bartonellaceae and the Anaplasmataceae.

Characteristic	Family Bartonellaceae		Family Anaplasmataceae			
	Bartonella bacilliformis	*Grahamella*	*Anaplasma*	*Aegyptianella*	*Haemobartonella*	*Eperythrozoon*

Symbols: +, positive; −, negative; ND, no data.
Data from Weinman, 1944; Peters and Wigand, 1955; Kreier and Ristic, 1968; Ristic and Kreier, 1984a and 1984b; Gothe and Kreier, 1977.

logically and are also morphologically similar to mycoplasmas and L-phase bacteria (Peters et al., 1973; Tanaka et al., 1965). The lack of a cell wall is the major factor in determining the organism's morphology but it may not be assumed that all organisms lacking cell walls are mycoplasmas (Davis et al., 1973).

The Anaplasmataceae occur in the blood plasma, and in or on red cells. Those which enter red cells do so by an endocytic process. Reproduction then occurs by binary fission of the cells that become established in the parasitophorous vacuole (Ristic, 1968; Ristic and Watrach, 1961; Tanaka et al., 1965). The characteristic morphologies of the organisms of the various genera of the Anaplasmataceae seen in stained blood films are determined more by their relationships to the host erythrocytes, grouping of the parasites at the sites of growth, and accessory structures associated with the parasites, than by the characteristics of the organisms themselves (Kreier and Ristic, 1973).

The occurrence of reproduction by binary fission without morphologically specialized infectious forms clearly differentiates the organisms of the family Anaplasmataceae from the chlamydiae, since the chlamydiae are characterized by a unique obligately intracellular growth cycle. This cycle is characterized by the appearance of an infectious elementary body, which is a small, electron-dense form, and a noninfectious initial body which is larger, less electron-dense, and is the vegetative form (Page, 1974).

The cellular nature of the Bartonellaceae and Anaplasmataceae precludes consideration of viral groups for these parasites (Kreier and Ristic, 1973).

As can be seen from the preceding discussion, the Anaplasmataceae and Bartonellaceae do not readily fit into any of the well-established taxons of prokaryotes. The *Bartonella* and *Grahamella* are true, small, hemotrophic bacteria. The Anaplasmataceae are small, cell-wall-less, obligately parasitic, hemotrophic prokaryotes. Information from systematic antigenic analysis and information on nucleic acid homology, which would aid in determining relatedness among these organisms and between them and other organisms, is not available. The taxons into which these organisms are presently placed are based largely upon morphology, host range, tissue and cellular preference, and established tradition (Ristic and Kreier, 1984a, 1984b; Weinman, 1974).

These organisms clearly do not fit comfortably with the rickettsiae as classically defined, nor is there good reason to assume that the Bartonellaceae and Anaplasmataceae are necessarily closely related. To reduce taxonomic confusion, Moulder (1974) redefined the rickettsiae in a very broad fashion, so that it is possible to allow these organisms to remain together in their customary taxonomic position (Ristic and Kreier, 1984a, 1984b; Weinman, 1974). This course of action would appear to be completely justified in light of the meager information available on the relationships among these organisms at the present time.

There are available a number of fairly thorough reviews of the literature on these organisms (Gothe and Kreier, 1977; Kreier and Ristic, 1968; Ristic, 1960, 1968, 1977; Weinman, 1944, 1968; Weinman and Kreier, 1977).

The Bartonellaceae Family

The Genus *Bartonella*

Bartonella bacilliformis is a hemotrophic bacterium which was first isolated from the blood of infected patients by Albert Barton (1909). In humans, it causes a unique clinical syndrome known as bartonellosis or Carrion's disease. Although the disease has been known for centuries in the South American Andes, it first attracted the attention of the world's medical community in 1871 when an epidemic outbreak caused more than 7,000 deaths among workers constructing a railway between Lima and La Oroya in Peru (Weinman, 1944). Further observations concerning the disease were made by the 1913 Harvard Expedition to Peru (Strong et al., 1915). The clinical spectrum of bartonellosis is quite broad and has been the subject of a number of monographs over the past 100 years (Hurtado et al., 1938; Odriozola, 1898; Ricketts, 1949).

Habitats of *Bartonella*

GEOGRAPHICAL DISTRIBUTION. *Bartonella bacilliformis* and the disease it causes are geographically restricted to the western Andes of the South American countries of Peru, Ecuador, and Colombia, where its arthropod vector is found. Even within these locales, it is confined to elevations between 500 and 3,000 meters (Reynafarje, 1972), where temperature and humidity conditions are favorable for survival of the vector. Although organisms resembling *Bartonella* have been described on other continents (Dooley, 1980; Wernsdorfer, 1969; Whitaker et al., 1966), there are no confirmed reports of the occurrence of *B. bacilliformis* outside the Andes region of South America.

AS SYMBIONTS OF ARTHROPODS. *Bartonella bacilliformis* is transmitted through the bite of *Phlebotomus verrucarum* (Hertig, 1942; Shannon, 1929), a hematophagous sandfly with nocturnal feeding habits and a short flight range. Victims are usually infected during the twilight hours, and a single night in an endemic zone is often sufficient to lead to infection (Dooley, 1976). Other species of sandflies have also been implicated as vectors in regions where typical cases of bartonellosis have been described in the absence of *P. verrucarum* (Herrer and Blancas, 1962; Hertig, 1942; Noguchi and Shannon, 1929; Noguchi et al., 1928). The biological cycle of *Bartonella* in the vector is not known.

AS HUMAN PATHOGENS. *Bartonella bacilliformis* is the only species in the genus *Bartonella* (Ristic and Kreier, 1984a). In humans it causes bartonellosis or Carrion's disease, which is typically described as a biphasic disease with two strikingly distinct clinical forms, Oroya fever (a hemolytic disease) and verruga peruana, (a disease characterized by wart-like growths) which usually occur sequentially and are immunologically linked. That both phases are caused by the same organism was proved in 1885 by Daniel Carrion, a Peruvian medical student, who inoculated himself with blood from a verrugous nodule (the wart-like lesion induced by *B. bacilliformis*) and died several weeks later of Oroya fever (Schultz, 1968).

The symptoms of Oroya fever may develop in a patient 1 to 3 weeks following the bite of an infected sandfly. In its most severe form, Oroya fever is an acute, rapidly evolving, febrile anemia. During the anemic period 90 to 100% of a patient's erythrocytes may be parasitized with bacillary forms of *Bartonella* (Fig. 1). The cause of the progressive and severe anemia is a massive destruction of the parasitized red blood cells in the spleen and other organs of the reticuloendothelial system (Reynafarje and Ramos, 1961). The erythrocyte count may fall to less than 1 million cells per mm^3 in a four- to five-day period (Pinkerton, 1963). Without treatment, mortality rates may be as high as 40% (Weinman, 1944). Secondary salmonellosis is a frequent complication and cause of death during the febrile anemic phase of the disease (Cuadra, 1956). A prolonged asymptomatic period may follow the anemic stage. However, in many patients, a chronic eruptive, or verruga peruana, phase develops. The verruga peruana phase is characterized by hemangiomatous skin eruptions, whose characteristic features are endothelial cell proliferation and pronounced vascularization. These lesions vary in size and number and may occur as either miliary, nodular, or mulaire forms. They exhibit a marked tendency to hemorrhage due to their extensive vascularity. Histological studies have revealed the presence of bartonellae and proliferating endothelial cells, and an infiltration of inflammatory cells in the nodules (Arias-Stella et al., 1986; Recavarren and Lumbreras, 1972). Although the role of the bacteria in the development of the verruga stage is unclear, it is possible that they either possess some angiogenic potential as suggested by Garcia et al. (1988), or that they induce inflammatory cells to release angiogenic factors (Arias-Stella et al., 1986), which stimulate endothelial cell proliferation and capillary growth.

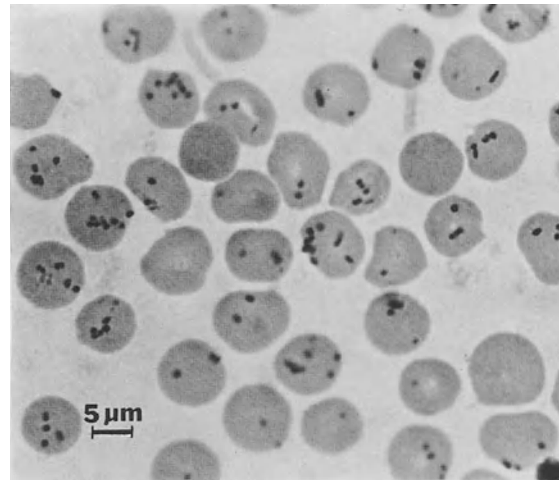

Fig. 1. Wright-stained *Bartonella bacilliformis* in blood of an Oroyo fever-infected human. (From Takano-Moron, 1970, with permission.)

Oroya fever and verruga peruana usually occur sequentially. However, the anemic phase may occur without subsequent development of the eruptive phase and likewise, the eruptive phase may occur without a preceding overt anemic stage (Aldana, 1929; Cuadra, 1957; Hurtado et al., 1938). The fact that the two phases rarely coincide suggests a role for the host's changing immune status.

AS INAPPARENT PARASITES OF HUMANS. Epidemiological studies have shown that in areas endemic for bartonellosis, 5 to 10% of the population with or without a past history of the disease yield blood cultures positive for *B. bacilliformis* (Colichon et al., 1972; Herrer, 1953b; Herrer and Cornejo Ubilluz, 1962; Weinman and Pinkerton, 1937b). Latent infection, during which *Bartonella* can be isolated, may persist in patients for long periods (Ricketts, 1949). These findings strongly support the hypothesis that humans are an important reservoir of *Bar-*

tonella bacilliformis (Weinman and Pinkerton, 1937b). However, other reservoirs may also exist (Herrer, 1953a).

Isolation of *Bartonella*

GENERAL FEATURES. *Bartonella bacilliformis* is a fastidious bacterium whose exact nutritional requirements have not been defined. It can be recovered from a variety of clinical specimens including blood, splenic, lymphoid, and hepatic endothelial cells, and verrugous lesions (Ristic and Kreier, 1984a). Isolation of the organisms is generally easier during the early stages of the disease.

A variety of methods and media for the isolation and cultivation of *Bartonella* have been described (Benson et al., 1986; Geiman, 1941; Jiminez, 1940; Knobloch 1988; Mitchell and Slack, 1966; Noguchi and Battistini, 1926). Although it is an intracellular parasite, it must be considered facultative in this respect since it can be readily grown in culture media provided they are enriched with blood or serum.

The triphasic medium described by Colichon and colleagues (Colichon et al., 1966; Colichon et al., 1971) is particularly useful since it permits good yields of *Bartonella.* The triphasic medium consists of sequential layers of a Bordet blood agar slant, a tryptose agar slant and an overlying layer of tryptose broth prepared according to the following protocol:

Triphasic Medium for Growth of *Bartonella*

Bordet blood agar

Infusion of potato	1 liter
Glycerine	10 ml
Sodium chloride	5.4 g
Proteose peptone	10.0 g
Agar	14.0 g

The components are dissolved by heating and the pH is adjusted to 7.2. After autoclaving (15 min at 15 psi), the medium is cooled to 50°C and 15% sheep blood (v/v)is added. The medium is dispensed into Kolle flasks which are placed in a slanted position until the medium solidifies. When the Bordet blood agar is solidified, add tryptose agar medium whose formula is as follows:

Tryptose agar

Tryptose	15.0 g
Sodium chloride	5.0 g
Disodium phosphate	2.5 g
Distilled water	1 liter
Agar	13.0 g

The components are dissolved by heating and the pH is adjusted to 7.2. After autoclaving, the medium is allowed to stand until the particulate matter settles. Sheep plasma (15% v/v) is then added to the clear supernatant. The tryptose agar is dispensed as a thin layer over the Bordet blood agar layer and allowed to solidify in a slanted position. Finally, flasks are returned to a vertical position and 30 ml of tryptose broth (same composition as tryptose agar but without the agar and plasma) is added to each. As a sterility check, flasks are incubated for 48 h prior to use.

Culture Media for Preservation and Additional Studies of *Bartonella*

In vitro motility of *Bartonella* is easily observed in cultures maintained in liquid overlays of nutrient medium. Brain heart infusion agar containing 10% human serum (v/v) and 10% human red blood cell lysate (v/v) is prepared as the base medium. Phosphate-buffered saline (PBS), pH 7.4, is used as an overlay. Bartonellae grow readily in the overlay as well as at the agar-overlay interface (Benson et al., 1986). Active growth can be maintained by transfer of aliquots of established cultures to fresh cultures every 48 h. For long-term preservation of *Bartonella,* aliquots of the growth in the overlay can be mixed with dimethylsulfoxide (DMSO) (9:1 v/v) (Lee Ann Benson, personal communication) and stored at −70°C.

A transparent culture medium for culture maintenance and growth studies can also be prepared in test tubes by layering Bordet blood agar in the bottom of 16 × 150 mm test tubes and overlaying with tryptose agar to a depth of 2 cm. The medium is inoculated by puncture. With this system, it is possible not only to demonstrate aerobic and microaerobic growth of *Bartonella,* but also to determine metabolic activity of the organism by adding substrates with appropriate indicators to the tryptose agar.

Technique for Isolation of *Bartonella* from Human Clinical Specimens

Clinical specimens can be processed in several ways for the isolation of *Bartonella.* Cultures can be obtained from a high proportion of infected individuals by use of the following protocol: Ten ml of venous blood is mixed with 0.6 ml of 10% sodium citrate and the mixture centrifuged. The cellular sediment is inoculated into a flask of triphasic culture medium, which is then incubated at 28°C and scored for growth after the fifth day of incubation.

Identification of *Bartonella*

The identification of *Bartonella bacilliformis* depends to a great extent on epidemiological and clinical considerations. The occurrence of appropriate symptoms in an individual who has been in areas of known endemicity is a strong basis for making a presumptive diagnosis of bartonellosis. Identification of *Bartonella* in

blood cultures and blood smears is required for a positive diagnosis of Oroya fever. The identification of *Bartonella* in histologic sections of lesions is used to confirm a clinical diagnosis of verruga peruana (Weinman, 1944).

Morphological and growth characteristics are also considered in the identification of *Bartonella bacilliformis.* The organism is a Gram-negative nonsporeforming coccobacillus which exhibits pleomorphism both in vitro and in vivo. It is most easily observed in Giemsa- or Wright-stained blood smears where it appears as intense purple rods or cocci (see Fig. 1). During the early stages of Oroya fever, the predominant forms are bacilli, 1 to 3 μm in length by 0.2 to 0.3 μm in width. Polar enlargement and polar cytoplasmic granules may be seen. As the patient convalesces or as cultures age, cocci, approximately 0.75 μm in diameter, appear (Peters and Wigand, 1955; Weinman, 1944).

Bartonella have a thin cell wall (Fig. 2) (Cuadra and Takano, 1969; Peters and Wigand, 1955) which, in tissue sections, is seen to enclose a double membrane (Recavarren and Lumbreras, 1972). At least 24 protein antigens, 6 of which are probable cell wall antigens, have been identified by immunoblot and immunoprecipitation procedures (Knobloch, 1988). These cell wall antigens have been used to detect specific antibodies in the sera of bartonellosis patients and may, therefore, have diagnostic value (Knobloch et al., 1985). L-forms of *Bartonella* have been isolated from cultures grown on penicillin-containing medium (Sharp, 1968).

Culture forms of *Bartonella* have flagella at one pole (Fig. 3) (Perez-Alva and Giustini, 1957; Peters and Wigand, 1951). This characteristic serves to differentiate *Bartonella* from *Grahamella* cells, which are non flagellated. Both motile and nonmotile forms may be flagellated. A correlation generally exists between

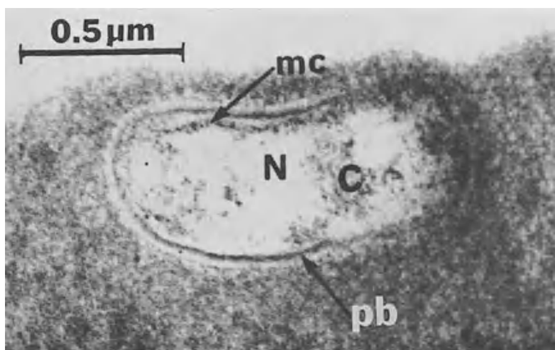

Fig. 2. *Bartonella bacilliformis* in blood cells prepared for electron microscope examination showing cell wall (pb), cell membrane (mc), cytoplasm (C), and nucleoid region (N). (From Takano-Moron, 1970, with permission.)

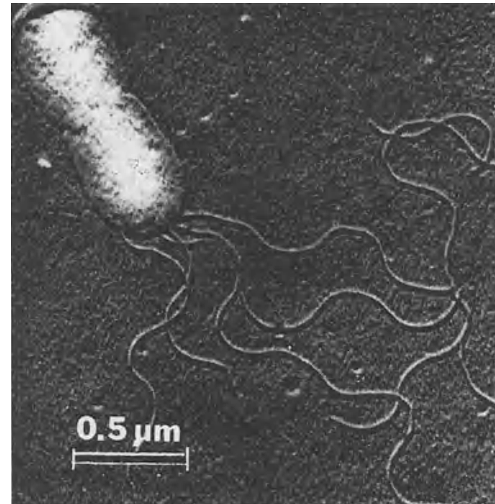

Fig. 3. *Bartonella bacilliformis* from a culture showing flagella and commencement of binary fission. (From Peters and Wigand, 1952, with permission.)

the degree of motility and colony size, with large-colony-size variants exhibiting greater motility (Benson et al., 1986; Walker and Winkler, 1981). *Bartonella* in red blood cell ghosts (G. Mernaugh, personal communication) have been observed to move at a speed of 45 μm per second. This is comparable to or even faster than that reported for most other motile bacteria (Macnab and Koshland, 1972).

The ability to grow in vitro further differentiates *Bartonella* and *Grahamella* from *Haemobartonella* and *Eperythrozoon. Bartonella* grows optimally at a temperature of 28°C and a pH of 7.8 (Noguchi and Battistini, 1926). Colonies are generally visible between the 5th and 8th day of incubation. They are translucent, mucoid, slightly adherent to the agar, and vary in size from minute to 1–2 mm in diameter. Bartonellae are non hemolytic and fail to ferment a variety of common carbohydrates (Noguchi and Battistini, 1926). They are susceptible to the action of penicillin, streptomycin, chloramphenicol, tetracycline, and erythromycin (Aldana et al., 1948; Larrea, 1958; Merino, 1945; Payne and Urteaga, 1951).

Electron microscopic studies have shown that *Bartonella* can adhere to and enter red blood cells (Cuadra and Takano, 1969; Takano-Moron, 1970) where they may be seen within vesicle-like structures. In vitro, the organism can attach to erythrocytes, causing them to spin or "dance" (Cuadra, 1978). Continued interaction between *Bartonella* and the red blood cells leads to extensive deformation of the red cell surface, as pits, trenches, and invaginations develop (Figs. 4 and 5) (Benson et al., 1986; G. Mer-

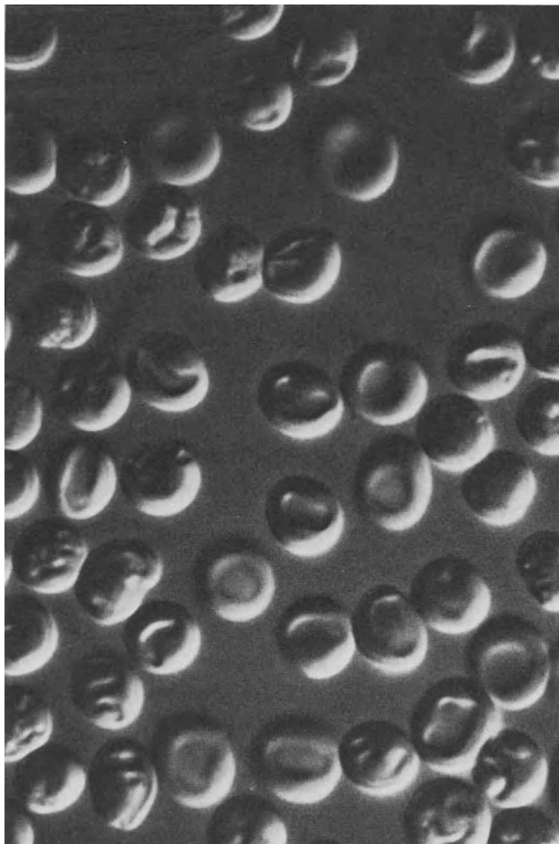

Fig. 4. Deformation of erythrocytes induced by *Bartonella bacilliformis* as seen by scanning electron microscopy. (From Benson et al., 1986, with permission.)

naugh, unpublished observations). The mechanisms by which *Bartonella* adhere to and invade erythrocytes are not known. It has been suggested that specific receptors on the red cell, possibly glycolipid in nature, are involved in the initial recognition step (Walker and Winkler, 1981). The *Bartonella* receptor for binding appears to be located at the polar end opposite the flagellum (Ihler and Tosi, 1987). Furthermore, since individual bacteria do not agglutinate red cells, whereas clusters of bacteria can, it has been proposed that there may be only one binding site per bacterium (Cuadra, 1978). Entry into the red cell most likely involves a process of forced endocytosis since *Bartonella* can be found within vacuoles where their movement is restricted by the confines of the vacuole. Rupture of the vacuoles by hypotonic shock releases the organism into the red cell interior (Benson, et al., 1986; Ihler and Tosi, 1987).

Only the verruga stage of bartonellosis can be experimentally reproduced with regularity in animals; the experimental animal of choice is the rhesus monkey. The symptoms of Oroya fever appear to be unique to humans (Noguchi, 1926; Weinman and Pinkerton, 1937a).

Based on its morphological and biological characteristics, *Bartonella bacilliformis* is considered a true bacterium (Nauck, 1957). It has a cell wall and flagella, divides by binary fission, and can be grown in vitro in culture media. Taxonomically, it is grouped with the rickettsias along with other hemotrophic bacteria (Ristic and Kreier, 1984a).

Bartonella is a somewhat neglected pathogen due to its restricted geographic habitat and the fact that insecticides and antibiotics effectively control its vector and the disease it causes. Nevertheless, it is an interesting organism because it is unique among human pathogens in its parasitic capabilities and in the disease states which it induces.

Grahamella and Its Habitats

GEOGRAPHICAL DISTRIBUTION. The Grahamellae have a world-wide distribution, one consequence of their pattern of cyclic flea-borne transmission. No climatic barriers to their occurrence exist, and a variety ecological niches are used by *Grahamella* when suitable hosts are present. The incidence of *Grahamella* infections in small mammals reflects generation dynamics and the undulating population densities of the respective vertebrate and arthropod host communities. At least outside the tropics, a characteristic rise in incidence of infection usually occurs in the late summer and early fall when the most favorable conditions for transmission occur (Krampitz and Kleinschmidt, 1960). The parasites can be recognized in stained blood films (Fig. 6). The percentage of hosts which appear to be infected in the field usually fluctuates between 0 and 30%, with an average of 10%. This was already known to Graham-Smith (1905), who first observed the parasites in British moles (*Talpa europea*). A "*Drosophila*-like" scale (Chaline, 1977) of both host fertility and parasite generation time favors the development of limited host specificity and of parasite speciation.

AS SYMBIONTS OF ARTHROPODS. Parasitized cells can readily be isolated from arthropods (Fig. 7). The appearance of these cells reminds us of those shown in the photographs by Pinkerton and Weinman (1937) of tissue explants infected with *Bartonella bacilliformis.* There are more or less stable differences between strains of grahamellae from different host species. While only rarely has the experimental transmission from one vertebrate host species to another proved successful (Krampitz and Kleinschmidt, 1960), a species specificity does not exist for arthropods. It has been confirmed

Fig. 5. Deformation of erythrocytes induced by *Bartonella bacilliformis,* as seen by Nomarski microscopy. (Courtesy of G. Mernaugh.)

experimentally that any xenotype of *Grahamella* can use any vector species of the same order (Krampitz and Kleinschmidt, 1960).

For rodent grahamellae, fleas act as arthropod hosts and vectors. This was first proved by Vassiliadis (1935) in Egypt and then confirmed experimentally by Krampitz and Kleinschmidt (1960) and Krampitz (1962) in Germany and Fay and Rausch (1969) in Alaska. It is not known whether other ectoparasites are involved. Adult fleas newly infected with blood discharge large masses of infective parasites a few days after infection (Fig. 8); this discharge persists for several weeks at least. *Grahamella* are ingested by larval fleas from the sheddings of their parents. Infected adults never develop from such infected larvae. No evidence exists for transovarial passage in fleas. It remains to be determined, however, whether grahamellae can penetrate or be transported through the gut wall and invade the fleas' hemocoel. This possibility was taken into consideration by Hertig and Wolback (1924) in their studies on rickettsia-like organisms in insects and by Ito et al., (1975) for *Rickettsia mooseri* but no definite conclusions were reached by those workers. Normally, the fleas' salivary glands and saliva are not involved in transmission (Krampitz, 1962). Since survival outside the host body seems to be limited, direct contamination of the vertebrates' mucous membranes or of small skin wounds by feces appears to be the common mode of infection.

AS PARASITES OF VERTEBRATES. The vertebrate host range (Weinman and Kreier, 1977) is limited mainly to rodents, insectivores, chiroptera, and marsupials. Reported infections in domestic animals, except the dog (Herrer, 1944), have so far not been culturally confirmed. Only a few reports of *Grahamella* in subhuman primates, carnivores, ruminants, reptiles, and fishes exist. Human beings do not seem to be infected. Most of the approximately 40 named species are described only on the basis of their appearance in stained blood films of various host species. For a list of names and citations, see Weinman and Kreier (1977). The last descriptions of that kind were of *G. cuniculi* in Egyptian rabbits (Haiba, 1963) and *G. legeri* in norway rats in Rio de Janeiro (Furlong, 1978).

The stroma of red cells is the exclusive habitat of *Grahamella* in the vertebrate host. Reproduction in this site is by binary fission (Fig. 9). *Grahamella* seen in blood monocytes (Fig. 10) are forms phagocytized after release from lysed erythrocytes. In the arthropod vector, there is obviously an intimate relationship with the cells of the gut wall (see Fig. 7). The common statement that grahamellae are not known to multiply in fixed tissue cells should be restricted to descriptions of its development in the vertebrate host.

Parasites of the genus *Grahamella* seem to be forgotten organisms in the research on blood parasites of animals. We are still missing much basic information about their metabolic and antigenic properties, information available for most of the other parasitic prokaryotes. Only the gross features of their parasitic life can be outlined. Despite their intracellular growth in the erythrocytes of appropriate vertebrates and the intestinal tract of suitable arthropod vectors, the organisms do not cause serious damage to the host cells or produce disease. There may be a mild transitory reticulocytemia in the initial phase of the infection when a large infectious dose is given (see Fig. 6), but a hemolytic crisis, as occurs following infection with some other hemotrophic bacteria that results in a complete breakdown of the erythrocyte population, never takes place.

The method by which the organisms invade the red cells without causing sufficient injury to the membrane to induce pathologic effects is not known. The existence of a host receptor

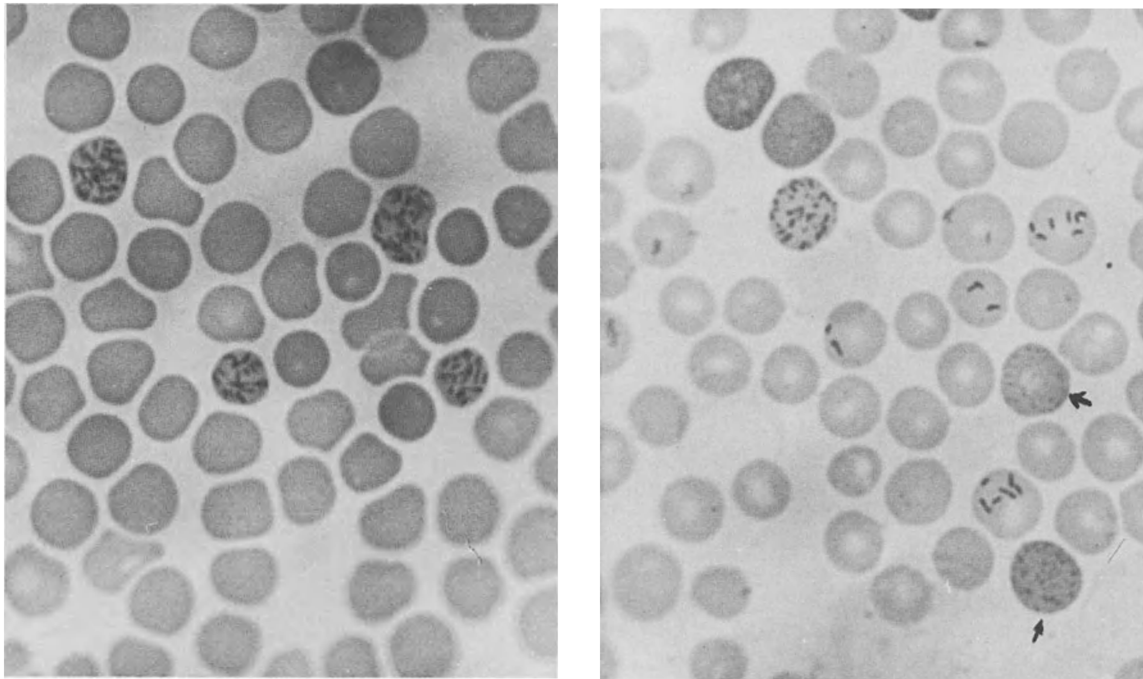

Fig. 6. Development of *Grahamella* sp. in erythrocytes of a European bank vole (*Clethrionomys glareolus*). Left: 3 days after experimental infection; a slight reticulocytosis is evidence of a light anemia. Right: The same infection 6 days after infection; strongly basophilic granulations in young red cells occur frequently in rodent blood and are sometimes misinterpreted as parasites (arrows).

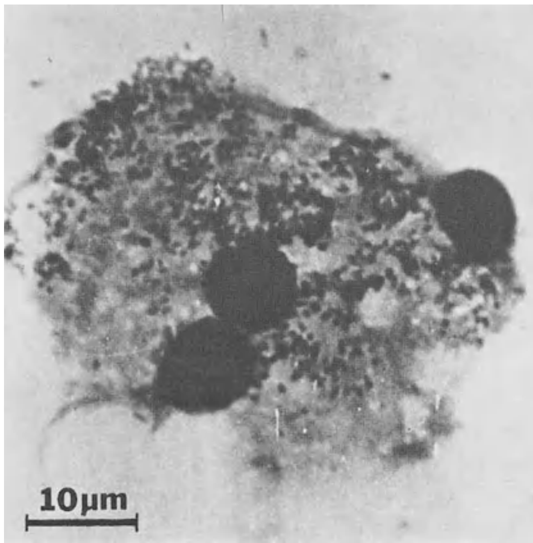

Fig. 7. Isolated midgut cells of the tropical rat flea (*Xenopsylla cheopis*) containing numerous cells of *Grahamella*. Giemsa stain.

mechanism could explain host specificity. The hosts' and parasites' mutual identification methods are unknown. The process of entry into the erythrocyte itself, however, seems different from that of *Bartonella bacilliformis* (Benson et al., 1986; E. Göbel, personal communication). The term "grahamellosis" is more of a construction analogous to the term "bartonellosis" than a term appropriate for characterization of the pathological disorder produced by *Grahamella* in their hosts. The lack of interest in *Grahamella* of the medical and veterinary professions is probably due to their lack of pathogenicity and their failure to infect either humans or domestic animals.

Isolation of *Grahamella*

The difficulty in producing a parasitemia in a susceptible host animal after inoculation of infected donor blood is one of the most puzzling features of the in vivo isolation and maintenance of *Grahamella* strains. The failure is not dose-dependent, nor is it controlled by previous sensitization of the receptor animal in any way. This aspect of *Grahamella* behavior is very different from that of all related intraerythrocytic microorganisms. The reason for this behavior is unknown. However, every *Grahamella* strain can be isolated in a highly virulent condition from the feces of infected fleas (see Fig. 8). The parasites grow easily in vivo when splenectomized, susceptible hosts are inoculated intraperitoneally with the forms from the vector's feces.

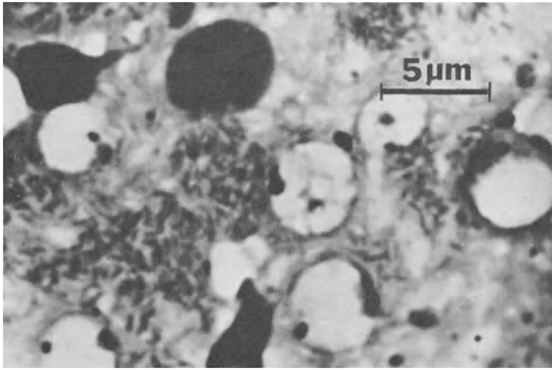

Fig. 8. Infective *Grahamella* in feces of the tropical rat flea (bank vole strain). Giemsa stain.

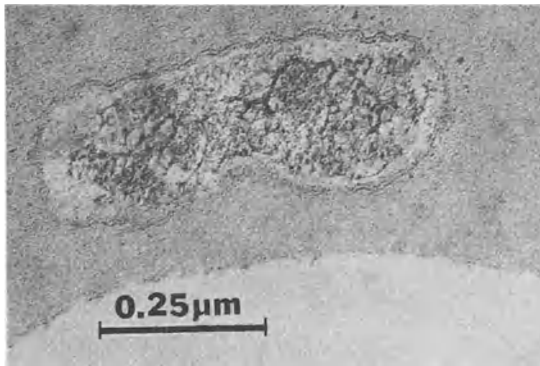

Fig. 9. Binary fission of *Grahamella.* The parasites are within the stroma of the red cell. Ultra-thin section, fixed in glutaraldehyde, embedded in Durcupan ACM (Fluka). (Courtesy of E. Göbel.)

The parasitemia starts 3–6 days after infection with an extensive spread of the organisms all through the bloodstream and with intensive intraglobular reproduction. As many as half the erythrocytes (Fig. 6) may be infected in such animals (Krampitz, 1962). In its density, the early massive blood infection due to *Grahamella* is very "*Bartonella*-like," but only a moderate reactive polychromasia takes place. The parasite does not use reticulocytes or nucleated cells as its microhabitat in the vertebrate at any time. However, in nearly all blood preparations with many *Grahamella*-infected red cells, monocytes can be seen which contain phagocytized and partially disintegrated parasites (Fig. 10). Destruction, not reproduction, occurs in nucleated mammalian blood cells.

The normal aspect of a *Grahamella* infection in its late stages is a concentration of many parasites in only a few host cells which are sometimes difficult to detect. A dense parasitemia guarantees better results if one intends in vitro cultivation or isolation for morphological studies or infection of experimental vectors.

A further remarkable difference between the grahamellae and most other hemotrophic organisms is the failure of splenectomy to accelerate the blood infection unless surgery is carried out immediately after infection, or prior to the infection. Basically, no qualitative differences seem to exist among the numerous xenotypes or species in their host-related properties and behavioral patterns.

In vitro growth of *Grahamella* occurs 2–3 mm below the surface in stab cultures and suggests an oxygen requirement slightly less than that of air (Fig. 11). Only a few semi-defined media have been found to be suitable for growth of *Grahamella,* but little systematic work has been done so far. In view of the organism's proven microaerophilic character, some reservations are appropriate about reports of easy growth on the surface of blood agar and other solid media.

Semisolid media developed for *Leptospira* and *Bartonella* are suitable for *Grahamella.* An important first step in cultivation was the development of the thin serum agar medium by Noguchi and Battistini (1926). Tyzzer (1941) was the first to cultivate *Grahamella* strains from American small mammals in this medium. Krampitz and Kleinschmidt (1960) grew parasites of European origin in rabbit serum with an agar base at pH 7.2. Additional enrichment of the medium with hemoglobin promotes growth.

Medium for Growing *Grahamella*

Saline (0.9%)	800 ml
2% Agar (pH 7.2)	100 ml

Sterilize the agar and distribute 2 ml volumes into small glass tubes. Hold the tubes at 60°C. Add 0.2–0.25 ml sterile (filtered) rabbit serum and 0.1 ml of a concentrated rabbit-hemoglobin solution released from erythrocytes by aqueous lysis. Mix by shaking and autoclave for 30 min at 56°C.

The transfer of cultivated material from tube to tube should be carried out with the platinum loop introduced into the upper part of the medium as for deep stab cultivation. The tubes must be sealed to prevent desiccation. Sand-grain-size colonies appear along the stab 7–10 days after inoculation, most abundantly within a zone situated 3–5 mm below the surface of the medium (Fig. 11); colonies are occasionally also in ring form. The morphology of the colony is greatly influenced by the inoculation technique and the quantity of organisms inoculated. Since no surface growth occurs, it is evident that a reduced amount of oxygen favors growth. An incubation temperature of 27–30°C seems adequate. The white spherical colonies developed

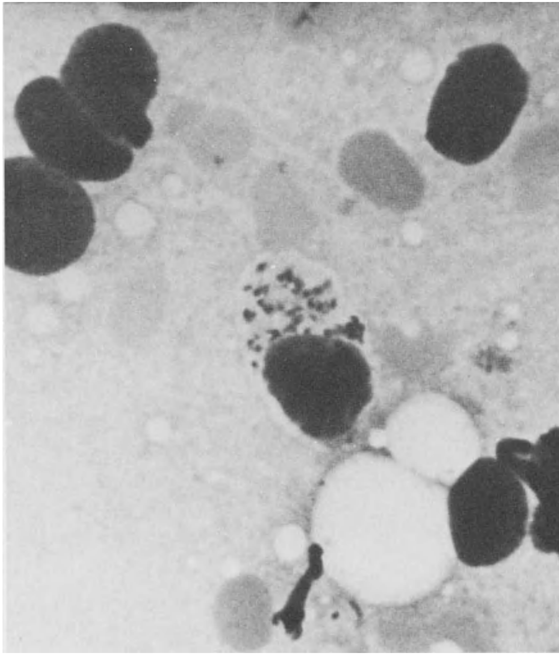

Fig. 10. *Grahamella* sp. in *Clethrionomys glareolus.* Phagocytized and partially destroyed parasites in mononucleated blood cells. Giemsa stain.

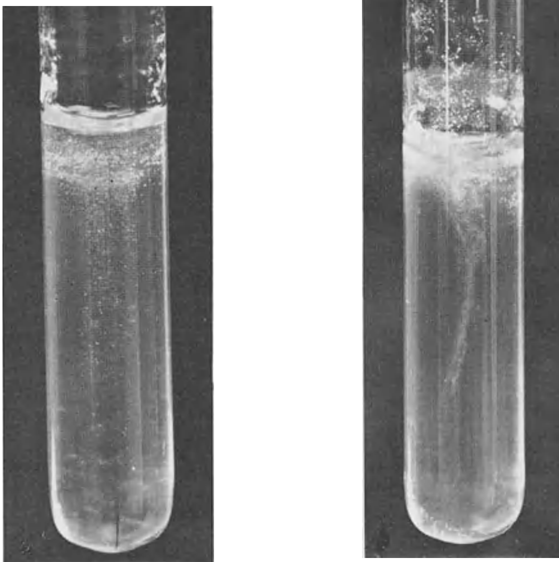

Fig. 11. Deep stab cultures of *Grahamella* in Noguchi's medium. Original isolation from vole blood. (From Krampitz and Kleinschmidt, 1960, with permission.)

on primary inoculation are solid, and they are easy to remove from the medium; colonies produced on subculture are more diffuse and look like snow flakes. Subculture to experimental animals from these cultures may be carried out. Host specificity is never lost in vitro (Krampitz and Kleinschmidt, 1960; Tyzzer, 1941), indicating its genetic basis. Noguchi originally proposed use of rabbit serum in the medium. The addition of hemoglobulin from various sources, even human, promotes in vitro growth of grahamellae of voles and shrews. It is evident, therefore, that host specificity cannot depend on simple nutritional factors.

It is possible to maintain the organisms in the frozen state. All developmental stages except those in the blood may be maintained frozen. The best material for long-term preservation of living strains is the gut content of experimentally infected fleas containing metacyclic grahamellae. The infected gut content must be suspended in the blood of the appropriate host species. Culture material can be preserved in a similar manner, but its infectivity decreases with increasing time of storage. The best methods for preserving grahamellae in the frozen state are those used routinely for preserving blood protozoa (Swoager, 1972). No information is available about cultivation of the organisms in tissue cultures or in hens' eggs, nor have attempts been made to lyophilize the grahamellae, nor has their drug sensitivity been tested.

Identification of *Grahamella*

The easiest characteristic to use for identification of the grahamellae by light and electron microscopy is their appearance inside the erythrocytes. Proper preparation and staining techniques are required and hemolysis of the sample to be analyzed must be prevented. Attempts to concentrate scarce parasitized red cells in thick films have not been successful. In thin blood films stained by the Giemsa method and examined with the aid of a light microscope, grahamellae appear predominately within the erythrocytes as rod-, dumbbell-, or string-shaped purple-red bacteria 1–2 μm long (Fig. 6). Sometimes V- or Y-like figures are found, rarely single cocci, never ring or star forms or chains of several segmenting organisms. Grahamellae are Gram-negative, non acid fast, non flagellated, immobile, and non gas forming. In highly parasitized blood films, groups of extracellular rods can usually be found ("Schwärmende Haufen"; Jettmar, 1932). These are released when injured erythrocytes are broken during film preparation. It is unlikely that free forms can survive and circulate for any significant time. Phagocytes full of *Grahamella* may be observed in stained blood and tissue impression films (Fig. 10). No attempts have been made to determine the organisms' nutritional requirements, metabolic properties, DNA homology, or antigenic structure.

The gross features of the parasites can be established by ultrastructural methods (Krampitz and Kleinschmidt, 1960). Thin sections of the parasitized erythrocytes show *Grahamella* lying within the red cells, always clearly separated from the surface membrane (Fig. 9). They show a cytoplasmic membrane, internal structures, and a trilaminar cell wall characteristic of true bacteria. Reproduction takes place by binary fission. That there is a close ultrastructural relationship between rodent grahamellae and *Bartonella bacilliformis* in human blood is obvious when one compares micrographs of the two organisms (Cuadra and Takano, 1969). The morphological and biological characteristics of the Bartonellaceae are more similar to true bacteria than to the rickettsiae, mycoplasmas, or viruses. The similarities of the characteristics of *Grahamella* and *Bartonella* and their differences from those of the organisms *Anaplasma, Haemobartonella, Aegyptianella,* and *Eperythrozoon* support the legitimacy of the creation of the two families, Bartonellaceae and Anaplasmataceae.

The Family Anaplasmataceae

Eperythrozoon and *Haemobartonella* and Their Habitats

GEOGRAPHICAL DISTRIBUTION. These organisms are obligate parasites, transmitted among vertebrate hosts by a variety of direct and vector-borne means. The distribution of the eperythrozoa and haemobartonellae is therefore, primarily limited only by the distribution of their hosts. In general, the organisms can be assumed to be present within appropriate hosts on all six continents (Gothe and Kreier, 1977; Kreier and Ristic, 1968).

Table 2. Approved *Eperythrozoon* species and principal vertebrate hosts.[a]

Species	Principal vertebrate host
E. coccoides	Albino and wild mice; albino rats; rabbits; hamsters
E. ovis	Domestic sheep, goats, deer, antelope
E. parvum	Domestic pigs
E. suis	Domestic pigs
E. weyoni	Domestic cattle

[a]Based on the *Approved List of Bacterial Names* (1980) or subsequently validly published in the *International Journal of Systematic Bacteriology.* Organisms described as *Eperythrozoon* have been reported from a large number of vertebrate hosts but have not been formally recognized. For a complete list, see Goethe and Kreier (1977).

Table 3. Approved *Haemobartonella* species and principal vertebrate hosts.[a]

Species	Principal vertebrate host
H. muris	Albino and wild mice; albino rats; hamsters
H. canis	Domestic dogs
H. felis	Domestic cats

[a]Based on the *Approved List of Bacterial Names* (1980) or subsequently validly published in the *International Journal of Systematic Bacteriology.* Organisms described as *Haemobartonella* have been reported from a large number of vertebrate hosts but have not been formally recognized. For a complete list, see Goethe and Kreier (1977).

AS SYMBIONTS OF ARTHROPODS. Arthropod-borne transmission between vertebrate hosts is suspected as the primary mode of infection with most species of eperythrozoa and haemobartonellae, and has been proven with several species. Ixodid ticks (for *Haemobartonella canis*), fleas (for *Haemobartonella muris* and *Eperythrozoon coccoides*), and lice (for *Eperythrozoon suis*) are known vectors, while fleas and lice are suspected to be possible vectors for other organisms (Berkenkamp and Wescott, 1988; Crystal, 1958; Nash and Bobade, 1986; Seneviratra et al., 1973). Little information is available on the growth and development of organisms within their arthropod hosts.

AS PARASITES OF VERTEBRATES. The vertebrate host range of both *Eperythrozoon* and *Haemobartonella* is wide and diverse. Although only five species of *Eperythrozoon* (Table 2) are included in the *Approved List of Bacterial Names*, incompletely characterized organisms described as *Eperythrozoon* have been reported from a large number of vertebrate hosts (Kreier and Ristic, 1984). Similarly, while only three species of *Haemobartonella* have been formally recognized (Table 3), there are numerous reports of *Haemobartonella*-like organisms in variety of mammalian and nonmammalian vertebrate hosts (Kreier and Ristic, 1984). Within both genera, a large number of species has been described based primarily on vertebrate host origin. Most are in wild and domestic animals, but there are rare reports of eperythrozoa and *Haemobartonella* in humans (Lwoff and Vaucell, 1930; Kallick et al., 1972; Punaric, 1986). Data supporting speciation is often limited.

In the vertebrate host, *Haemobartonella* infection is limited to the erythrocyte. Eperythrozoa are found either free in the plasma or on the surface of erythrocytes (Kreier and Ristic, 1981). Cells other than erythrocytes (and possibly platelets) do not appear to be infected. Organisms in both genera replicate by binary fission, as seen in Fig. 12 (Tanaka et al., 1965).

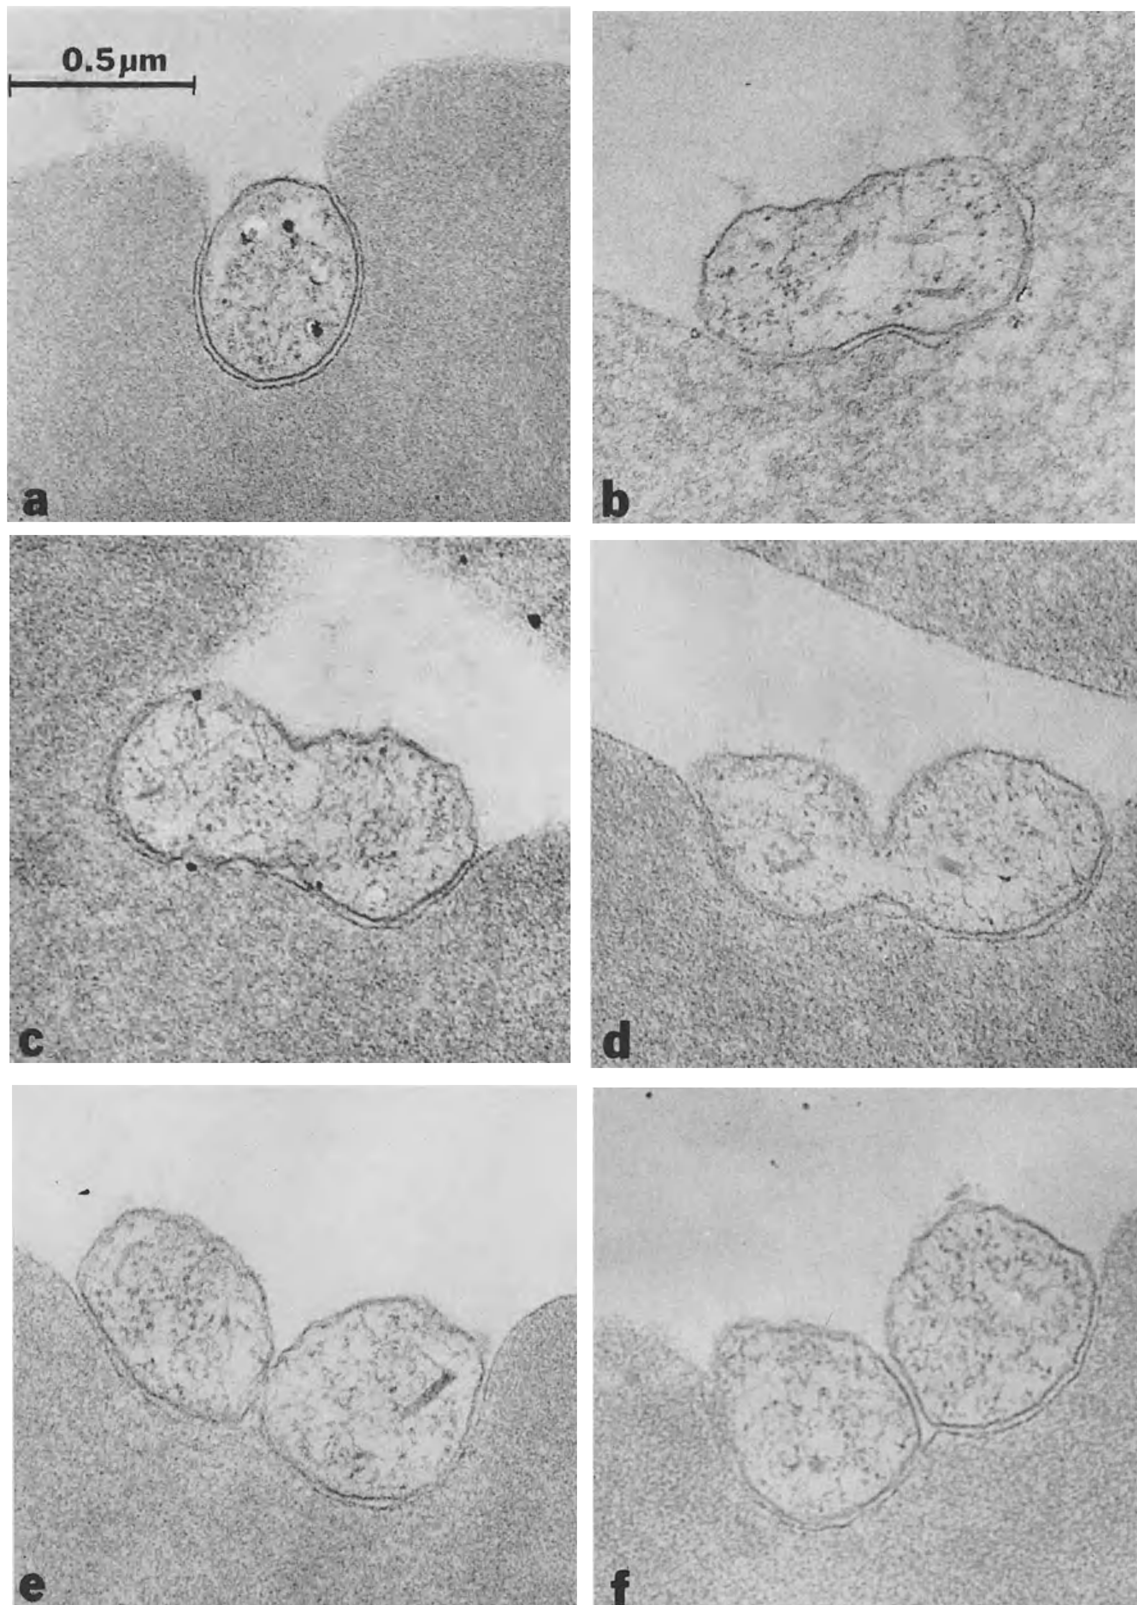

Fig. 12. Transmission electron micrographs of a dividing cell of *Haemobartonella muris.* The coccus first elongates and then constricts in the middle; finally, the two daughter organisms separate. The organisms remain attached to the erythrocytes during reproduction. The erythrocyte membrane appears to remain intact at the site of attachment. (From Tanaka et al., 1965, with permission.)

Organisms do not survive for significant periods outside of their hosts.

Typically, these organisms persist in the blood of immunocompetent hosts without causing significant clinical disease. Serologic assays are available to diagnose persistent infections in animals (Daddow, 1977; Hyde et al., 1973; Smith and Rahn, 1975; Wigand, 1956) Both *Eperythrozoon suis* and *Haemobartonella felis* are pathogenic in healthy, immunocompetent hosts. Acute infection of neonatal pigs with *Eperythrozoon suis* causes severe anemia and frequently high mortality rates (Splitter, 1950). Chronic infection is usually subclinical, but can cause reproductive problems (Blood et al., 1983). *Haemobartonella felis,* the etiological agent of feline infectious anemia, frequently causes anemia in cats immunosuppressed by infection with the feline leukemia virus (Bobade et al., 1988; Cotter et al., 1975). Several reports describe *Haemobartonella* as a cause of anemia in colony-reared nonhuman primates (Adams et al., 1984; Aikawa and Nussenzweig, 1972). *Eperythrozoon ovis* and *E. wenyoni* have been reported to cause anemia in sheep and cattle but are usually not considered pathogenic by themselves (Blood et al., 1983). Immunosuppression of the host by chemotherapy or splenectomy increases the severity of infection with eperythrozoa or haemobartonella (Bellamy et al., 1978; Maede, 1978).

Isolation of *Eperythrozoon* and *Haemobartonella*

No successful cultivation of these organisms has been reported (Gothe and Kreier, 1977). Organisms are isolated by collecting blood from an infected host and maintaining it and the contained organisms in liquid nitrogen (equal volumes of blood and Alsever's solution containing either 10% dimethylsulfoxide or 5% glycerol). Alternatively, because these organisms persist indefinitely in their hosts, a carrier animal can be maintained as a source of the agent. Both methods risk contamination of the organism with infectious agents other than the one desired. Prior to propagation of the organism in a splenectomized host, the recipient animal should be screened for the presence of viruses, other hemotrophic bacteria, and protozoa. Inoculation of organisms from either a frozen blood specimen or carrier animals into the appropriate splenectomized host will result in an infection detectable by microscopic examination of Giemsa-stained blood smears.

In vitro short-term cultivation of hemotrophic rickettsiae is feasible for radiolabeling proteins, carbohydrates, and nucleic acids (Davis et al., 1978; Barbet et al., 1983). The procedure is similar to that used for short-term cultivation of *Anaplasma marginale* and is described later in this Chapter in the section on short-term cultivation of *A. marginale.*

Identification of *Eperythrozoon* and *Haemobartonella*

Microscopic examination of Giemsa- or Wright-stained blood films is used to identify *Eperythrozoon* or *Haemobartonella* organisms during acute stages of infection in the host. Both *Eperythrozoon* and *Haemobartonella* are Gram-negative microbes. They stain poorly with the counter stains used in the Gram-stain procedure. They are non acid fast. Acridine orange may be used as a fluorescent label for organisms in both genera. Morphology and host range are used to classify the organisms into species (Kreier and Ristic, 1984). The morphology of the organisms should be evaluated in animals during the early stages of the infection, prior to development of anemia and reticulocytosis. Host range is helpful in speciation because most *Eperythrozoon* or *Haemobartonella* species usually will grow only in one or, at most, several closely related hosts (Gothe and Kreier, 1977).

Eperythrozoa parasitize the plasma surface of the erythrocyte membrane and appear as rings or cocci 0.5 to 1.0 μm in diameter (Fig. 13). Chains of rod-shaped eperythrozoa may partially or completely circumscribe the erythrocyte. The organisms are clearly separated from the erythrocyte membrane but interact with it in a yet poorly defined manner (Zachary and Basgall, 1985). Eperythrozoa are easily dislodged from the erythrocyte membrane and are frequently found free in the plasma.

Haemobartonellae also parasitize the surfaces of erythrocytes, appearing as 0.3- to 0.5 μm cocci (Fig. 14). Rods are frequently seen, which in reality are composed of pairs and chains of cocci. Organisms appear to bind to the erythrocyte plasma membrane at intermittent "points"; however, the mechanism of binding is unknown (Demaree and Nessmith, 1972; Simpson et al., 1978; Venable and Ewing, 1968). Haemobartonellae are rarely found free in the plasma.

Aegyptianella

Habitats of *Aegyptianella*

GEOGRAPHICAL DISTRIBUTION. Aegyptianellosis of poultry, which is caused by *Aegyptianella pullorum,* occurs enzootically in all the coun-

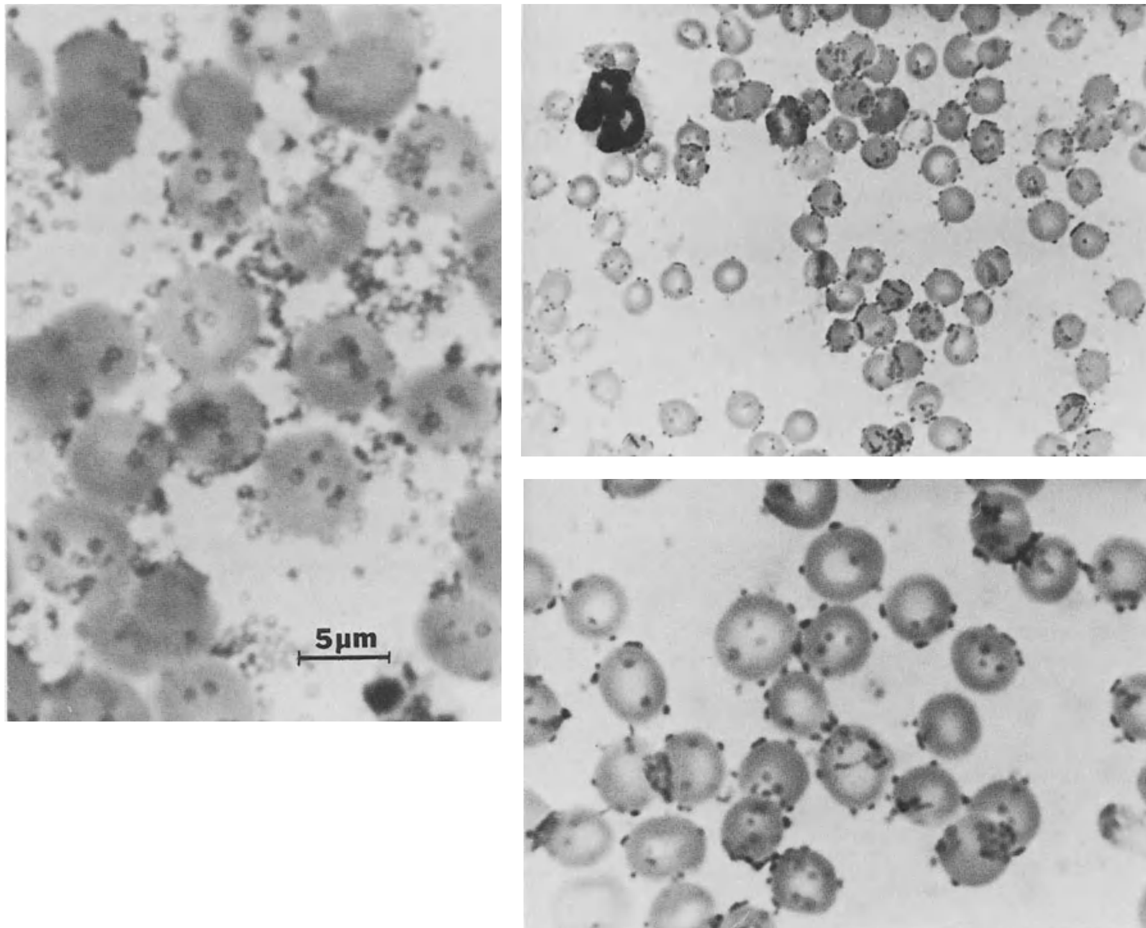

Fig. 13. Photomicrographs of Giemsa-stained thin blood films; blood infected with *Eperythrozoon.* (a) *Eperythrozoon coccoides* may be seen on the erythrocytes and free in the plasma. Organisms appear either as delicate rings on the surface of the erythrocytes and in the plasma or as more deeply staining chains of cocci or rods on the margins of the erythrocytes. (Courtesy of H. J. Baker.) (b) *Eperythrozoon dispar* Bruynoghe & Vassiliadis 1929 in the peripheral blood of a splenectomized, wild-caught European common vole (*Microtus arvalis*) from northern Germany shown at low magnification. Ring forms are not readily visible; (c) ring forms become more apparent at higher magnification.

tries of Africa, the region around the Mediterranean Sea, southern Europe, and southern Asia to Formosa (Gothe, 1971). In these areas, it is of considerable economic significance for the breeding of endemic stock and the maintenance of imported animals. The data concerning the distribution of these parasites are, however, still incomplete and reflect only a fragmentary picture of the actual geographical extension. This is partly because detection of *Aegyptianella* is complicated by the fact that *Borrelia anserina* infections, which are transmitted by the same species of ticks, can mask aegyptianellosis; and *A. pullorum* infections are predominantly latent in older animals.

AS PARASITES OF ARTHROPODS. The complete developmental cycle of *A. pullorum* in *Argas (Persicargas) walkerae* takes approximately 30 days and progresses in three clearly separate phases (Gothe, 1967a, 1971; Gothe and Becht, 1969; Gothe and Koop, 1974). In larval, nymphal, and adult female ticks of this species, it develops and multiplies in epithelial cells of the intestine, then in hemocytes, and finally in the cells of salivary glands. In this latter organ, the infectious forms develop. They are 0.3 to 0.5 µm in diameter, and are roundish anaplasmoidal bodies which are inoculated into the vertebrate with the saliva of the ticks at the next blood meal. Transovarial passage also occurs. *Argas (P.) persicus, Argas (A). reflexus* (Gothe, 1971; Gothe et al., 1981), as well as *Argas (P.) radiatus, Argas (P.) sanchezi* (Gothe and Englert, 1978), and *Argas (A.) africolumbae* (Gothe et al., 1981) can all function as biological vectors. The frequency of infection in ticks can be very high in areas where the parasites occur.

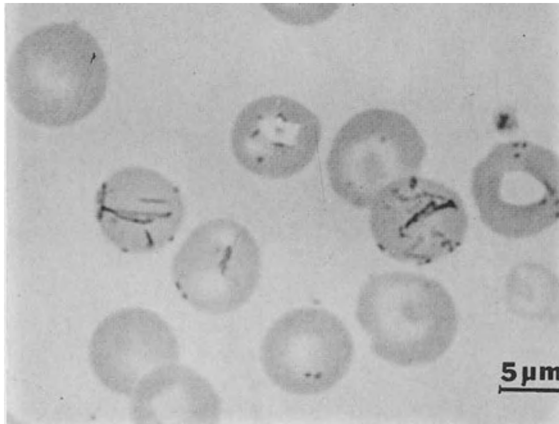

Fig. 14. Photomicrograph of a Giemsa-stained thin blood film from a dog. *Haemobartonella canis* may be seen on the erythrocytes. The organisms appear as solid dots or rods on the surface and margins of the erythrocytes. (From Venable and Ewing, 1968, with permission.)

Gothe and Schrecke (1972a, 1972b) were able to isolate these parasites in 10 out of 11 *Argas walkerae* populations from various parts of the Transvaal. Similarly, all of the 19 wild-derived populations of *Argas (P.) persicus* and the 3 populations of *Argas (A.) africolumbae* collected in chicken coops, dens, and sleeping places from various regions of Burkina Faso transmitted *A. pullorum* to susceptible chickens (Gothe et al., 1981).

AS PARASITES OF VERTEBRATES. In vertebrate hosts, five different species of the genus *Aegyptianella* Carpano, 1928, have been identified and named: *A. pullorum* (Carpano, 1928) from various species of birds; *A. emydis* (Brumpt and Lavier, 1935) from a turtle; *A. moshkovskii* (Schurenkova, 1938) from various species of wild birds; *A. carpani* (Battelli, 1947) from a snake, and *A. ranarum* from various *Rana* spp. (Desser, 1987). Other intraerythrocytic parasites of poikilothermic animals, and also their possible relationship to *Aegyptianella,* were extensively discussed by Pierce and Castleman (1974) as well as Johnston (1975). Gothe (1978) summarized the information on *Aegyptianella-, Anaplasma-,* and *Piroplasma*-like parasites of vertebrates. He described parasites resembling *Aegyptianella* from over 33 species of wild birds and domesticated poultry. The specific identity of these organisms is not clear. Of this genus only *A. pullorum* has been studied sufficiently to provide valid information, thus the characteristics and features of this genus are based exclusively on studies of this species.

A. pullorum, extensively discussed by Gothe (1971), Gothe and Kreier (1977), and Kreier and Gothe (1976), is the agent of an infections but noncontagious infection of birds, which parasitizes only the erythrocytes of the vertebrate host and is transmitted cyclically by argasid ticks.

Vertebrate hosts of *A. pullorum* are chickens, ducks, geese, and quail, as well as ostriches. Concerning guinea fowl, there are contradictory data; doves and turkeys can not be infected (Gothe, 1971). Subinoculations of blood from wild turkeys (*Meleagris gallopavo intermedia*) in Texas, USA, into susceptible domestic broad-breasted white turkeys, however, revealed intraerythrocytic pleomorphic organisms, which were considered on the basis of light and transmission electron microscopic investigations to be *A. pullorum* (Castle and Christensen, 1985). Some wild birds may also be infected at least briefly (Curasson, 1938; Curasson and Andrjesky, 1929; Huchzermeyer, 1969).

In vertebrate hosts, only erythrocytes are host cells. On the basis of electron microscopic studies it is possible to deduce the intraerythrocytic development cycle. The round parasite, 0.3–0.5 μm in diameter, is first seen eperythrocytically situated, surrounded by a double membrane. In the erythrocyte an additional membrane is formed which separates the parasite from the cytoplasm and encloses it in a vacuole in the host cell. In the vacuoles, the parasites grow to 1 μm in size. The process of division starts with invagination of the parasite's double membrane on one or both sides. These invaginations penetrate deeper and deeper, until the organism is cut completely through, and two daughter cells are formed. This process is repeated several times and leads finally to the formation of fully mature marginal bodies containing as many as 26 roundish forms, which each are as little as 0.3–0.5 μm in diameter. The intraerythrocytic development of *A. pullorum* can be completed in 36 h (Gothe, 1967c, 1971). Scanning and transmission electron microscopic studies using ruthenium red as a marker of the red cell plasma-lemma produced evidence of an endocytosis followed by an erythrocytic vesiculation as the possible mode of entrance of *A. pullorum* into erythrocytes. The presence of ruthenium red coating the membrane around the parasitophorous vacuole during the whole invasive process and the complete absence of the stain inside the host cell indicate that the entry of the aegyptianellae is accomplished by invagination of the host cell plasma-lemma and is not preceded nor followed by its breakage. One possible mode of exit of aegyptianellas from parasitized erythrocytes appears to be the invasive mechanism in reverse order, an exocytosis. Generally, however, the affected erythrocytes

are injured by parasitization, resulting in release of the parasites into the plasma following host cell lysis (Gothe and Burkhardt, 1979).

Besides those in the erythrocytes, parasites and fully matured marginal bodies can be observed outside the red blood cells. They occur free in the plasma, and intracellularly in large and small lymphocytes, in neutrophile and eosinophile leukocytes, in monocytes, and in the Kupffer cells of the liver. The proportion of forms outside erythrocytes grows in direct proportion to the extent of the parasitemia. It is probable that most of the parasites in leukocytes have been phagocytized after release from erythocytes. There is probably no exoerythrocytic development parallel to the intraerythrocytic cycle. The plasma forms are transitory phases initiating the infection of new erythrocytes (Gothe, 1969).

The salivary gland forms from the ticks penetrate erythrocytes immediately after injection or at least remain infectious in the blood. Histological investigations of naturally infected chickens have not revealed an exoerythrocytic phase in the development of *A. pullorum* (Gothe, 1967c, 1971).

AS INAPPARENT PARASITES OF BIRDS AND ARTHROPODS. *Aegyptianella pullorum* has a two-host or heteroxenous cycle. The vertebrate hosts function as carriers and thereby as donors of this agent. The argasid species are both biological vectors and an infection reservoir. Parasites existing in both arthropods and vertebrates constitute an important habitat for maintenance of the population in nature.

Isolation of *Aegyptianella*

Attempts to culture *Aegyptianella pullorum* in cell-free media, tissue cultures, or extraerythrocytically in embryonated chicken eggs have all failed. Parasites can only be grown in vivo in their vertebrate and invertebrate hosts. Susceptible birds can be infected very easily by intravenous, subcutaneous, intraperitoneal, or intramuscular injections of parasite-infected blood, as well as through scarification of the skin. The agent can be maintained by serial transfer of infected blood. Chicks infected at 3 weeks have remained carriers for over 1 1/2 years. The duration of the infection in ticks is lifelong and any development stage is infective. The infection has been shown to be present for over 810 days in ticks (Gothe, 1967a, 1971).

Cryopreservation is possible. Any standard procedure for preserving blood protozoa is satisfactory (Swoager, 1972). In liquid nitrogen the maximal storage time determined to date is 6.97 years (Raether and Seidenath, 1977). Freeze-drying of *A. pullorum* is also possible (Bartkowiak et al., 1988). Cryopreservation does not affect the viability of *A. pullorum* or its ability to propagate in the vector tick *Argus Persicargas) walkerae*. The cryopreserved aegyptianellae are capable of transovarial passage (Gothe and Hartmann, 1979).

Identification of *Aegyptianella*

When examined with the aid of a light microscope, *Aegyptianella pullorum* inclusions appear in Giemsa-stained blood films (Fig. 15) in a variety of roundish forms, some ranging up to 0.6 μm in diameter; some as ring forms of 0.8–3.2 μm diameter; and some as half-moon or oblong structures. The roundish structures contain up to 26 small organisms and are approximately 0.3–0.5 μm in diameter. In thin sections examined by electron microscopy (Fig. 16), the parasites appear to be surrounded by a sheath, which consists of two 6- to 8-nm membranes separated by a space of 28 nm. The internal structure or the parasites is made up of electron-dense aggregates of a finely granular material embedded in a less-dense substance. There is no membrane-bound nucleus. The parasites are separated from the host cell plasma by a 6- to 8-nm membrane (Gothe, 1967b, 1971). *Aegyptianella* possess RNA and DNA; the amount of DNA is significantly less than the amount of RNA. The DNA is completely masked by the RNA in conventionally stained preparations (Gothe, 1971). The parasites are susceptible to the action of tetracyclines and certain dithiosemicarbazones (Barrett et al., 1965; Gothe, 1971; Gothe and Kreier, 1977; Gothe and Lämmler, 1970a; Lämmler and Gothe, 1967, 1969). Pleuromutilins also have aegyptianellicidal efficacy (Gothe and Mieth, 1979).

APPLICATIONS. Because of the high cost of experimentation with bovine *Anaplasma*, the biologically and morphologically related *A. pullorum* may be used as an alternative model for quantitative evaluation of the therapeutic and prophylactic effectiveness of drugs (Gothe and Lämmler, 1970b) or in *Anaplasma* vaccine research (Bartkowiak et al., 1988). Investigations on the genetics, immunology, and biochemistry of *Aegyptianella*, however, are still lacking.

Anaplasma and Its Habitats

GEOGRAPHICAL DISTRIBUTION. *Anaplasma marginale*, *Anaplasma centrale*, and *Anaplasma ovis* are obligate intraerythrocytic bacteria of ruminants and are naturally transmitted

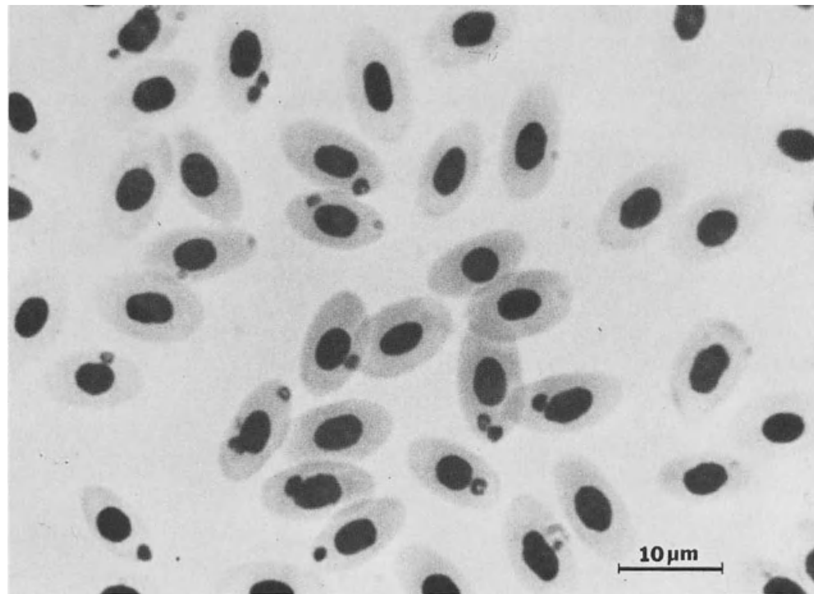

Fig. 15. Photomicrograph of a thin blood film from a chicken with aegyptionellosis stained with Giemsa. A variety of roundish forms, which are the parasitic inclusions, are present in the cytoplasm of the erythrocytes.

biologically and mechanically by a large and diverse group of arthropod vectors. Accordingly, *Anaplasma* infections are widespread in sheep-and cattle-raising areas throughout the tropical, subtropical, and warmer temperate climates, wherever conditions support sufficient populations of the arthropod vectors. Infection prevalence in tropical livestock production regions commonly exceeds 50%, and 90% prevalence of *A. marginale* infection in cattle has been confirmed in tropical South American and Australia (Nicholls et al., 1980; Patarroyo et al., 1978; Rogers and Shiels, 1979). In contrast, prevalence in more temperate areas is fre-

quently less than 50% (Mass et al., 1986). There is little information on prevalence in wild ruminants independent of contract with domestic livestock; certainly, *Anaplasma* infects numerous species of wild ruminants (Kuttler, 1984). The role of wild ruminants as reservoirs of infection for transmission to cattle, or conversely the role of domestic livestock in maintaining a source of infection for spread to wildlife, has not been definitively determined.

Anaplasma marginale is the primary cause of anaplasmosis in cattle and is common on all six continents (Losos, 1986; Theiler, 1910). *A. centrale* is a closely related species, if not the same, which was originally isolated in southern Africa. It is a cause of mild anaplasmosis in cattle (Theiler, 1911). *A. centrale* has been deliberately introduced into Australia, Asia, and South America for use as an agent for immunizing against anaplasmosis by *A. marginale*. *A. ovis* is the etiologic agent of ovine and caprine anaplasmosis. It has a widespread distribution similar to that of *A. marginale* in tropical-to-temperate climates (Bevan, 1912; Lestoquard, 1924).

AS SYMBIONTS OF ARTHROPODS. A diverse group of arthropods may serve as vectors for the transmission of *Anaplasma.* Although 29 species of ticks and numerous hematophagous flies and mosquitos have been shown experimentally to transmit *A. marginale,* the significant natural vectors of *A. marginale* (and probably *A. centrale*) appear to be ticks in the family Ixodidae and flies in the family Tabanidae (Ewing 1981; Yeruham and Braverman, 1981). Ixodid ticks are efficient biological vectors and are believed to be the principal vectors in most regions of the world. The three-host *Dermacentor* ticks have been shown to be important vectors in temperature western North America, while ticks of the one-host *Boophilus* species are highly significant vectors in tropical and subtropical regions worldwide (Callow 1974; Peterson et al., 1977; Potgieter, 1979). Both genera of ticks support transstadial transmission but transovarial transmission has not been reproducibly documented (Connell, 1974; Ewing, 1981; Stich et al., 1989). Within the tick, *A. marginale* undergoes a complex life cycle with development and replication in the midgut epithelial and gut muscle cells (Kocan, 1986). Although *A. marginale* developing within the midgut does become infective to cattle in its latter stages of development, natural transmission likely involves the recently demonstrated infective forms which are found within the salivary glands (Figs. 17 and 18) (Kocan et al., 1988). Ixodid ticks appear to be the predominant natural vectors of *A. ovis.*

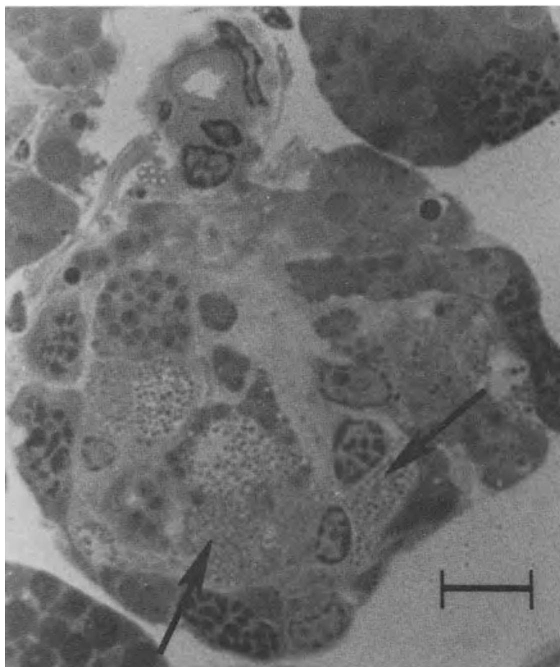

Fig. 17. Photomicrograph of *Anaplasma marginale* colonies (arrow) within salivary glands of infected *Dermacentor variabilis.* Mallory's stain. Bar = 5.0 μm.

Tabanids are efficient mechanical vectors, remaining capable of transmission for up to two hours post-feeding, and have been implicated as the principal vector for *A. marginale* in certain regions within both North America and Africa (Hawkins et al., 1982; Weisenhutter 1975). Certain *A. marginale* isolates, including the Illinois and Florida isolates, have been shown not to infect the predominant North American tick vectors, *Dermacentor andersoni* and *D. variablis,* and may be uniquely dependent on transmission by flies, fomites, or in utero spread (Wickwire et al., 1987).

AS PARASITES OF VERTEBRATES. Only ruminants may be infected with *Anaplasma.* Speciation of *Anaplasma* has been based upon morphologic appearance within erythrocytes (Fig. 19) and pathogenicity in ruminant hosts (Ristic and Kreier, 1984b). *Anaplasma marginale,* the principal cause of bovine anaplasmosis, and *Anaplasma ovis,* the pathogen causing ovine and caprine anaplasmosis, are the only two species included in the *Approved List of Bacterial Names* or in names validly published in the *International Journal of Systematic Bacteriology* (Ristic and Kreier, 1984b). The validity of the speciation of *Anaplasma* into the two species *A. marginale* and *A. ovis* is supported by the lack of cross immunity and differences in sur-

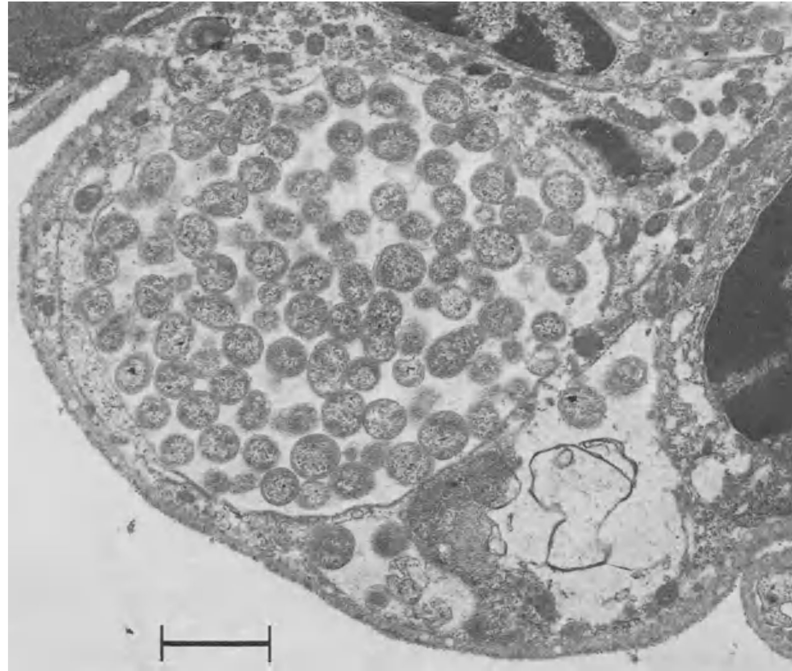

Fig. 18. Transmission electron micrograph of *Anaplasma marginale* within a salivary gland of infected *Dermacentor variabilis*. Bar = 2.0 μm. (Courtesy of K. M. Kocan and D. Stiller.)

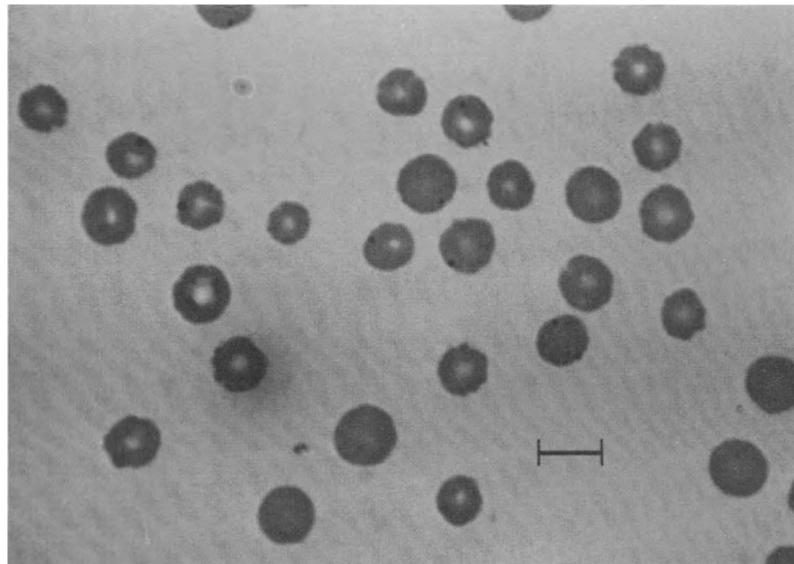

Fig. 19. Photomicrograph of Giemsa-stained *Anaplasma marginale*-infected erythrocytes. The intensely staining inclusion bodies resemble Howell-Jolly bodies in some respects such as size and position in the erythrocyte. They differ from Howell-Jolly bodies, however, in staining characteristics. *Anaplasma* more closely resemble a spot of flat finish paint than one of enamel, i.e., they are not shiny or refractile to light. Bar = 5.0 μm. (Courtesy of K. M. Kocan.)

face antigens of these two organisms (Palmer et al., 1988a; Splitter et al., 1956). Two additional species, *A. caudatum* and *A. centrale,* have been proposed as causes of bovine anaplasmosis (Ristic and Kreier, 1984b; Theiler, 1911) but these names have not been approved. Some authors have not considered the data from antigenic, genetic, and protein structural characterization to be sufficient to warrant differentiation of the proposed *A. caudatum* from *A. marginale* (Barbet et al., 1983; McGuire et al., 1984; Oberle et al., 1988; Palmer et al., 1988a). *A. centrale* was originally proposed as a variant of *A. marginale* by Theiler (1911) based on its more central intraerythrocytic location and on its being less virulent in cattle. Traditionally, *A. centrale* has been considered to be a separate species. While there are demonstrated antigenic and genetic differences between *A. marginale* and *A. centrale,* whether these are great enough to justify speciation is doubtful (Ambrosio and Potgieter, 1987; Kuttler, 1967; Palmer et al., 1988a).

A. marginale and *A. centrale* are defined principally as pathogens of domestic cattle but have been shown experimentally to infect numerous wild ruminant species (Kuttler, 1984). Clearly, certain wild ruminants, such as the black-tailed

deer in western North America, are naturally infected with *A. marginale* and may have a significant epidemiologic role (Osebold et al., 1962). In contrast, natural infection by *Anaplasma marginale* in other animals, such as the giraffe, has not been confirmed (Kuttler, 1984). Domestic sheep can be experimentally infected with *A. marginale* but do not develop clinical disease (Donatien and Lestoquard, 1930). *A. ovis* is principally a parasite of domestic goats and sheep but has been shown experimentally to infect wild ruminants in Africa and North America (Kuttler, 1984). *Anaplasma ovis* can be shown experimentally to infect domestic cattle but in this species it does not cause clinical disease (Kuttler, 1981).

In the vertebrate host, *Anaplasma* infect mature erythrocytes with formation of an erythrocyte-derived vacuole around the organism (Francis et al., 1979). Each organism is 0.55–0.85 μm in diameter and contains dense granular aggregates in an electron-lucid protoplasm, all enclosed in a double membrane 40–50 nm thick (Fig. 20) (Kocan et al., 1978). Within the erythrocyte, the bacteria replicate by binary fission to form up to eight individual organisms within a single vacuole (Fig. 21) (Ristic and Watrach, 1963). *Anaplasma* organisms exit the erythrocyte, using a poorly defined but apparently nonlytic mechanism, and infect additional erythrocytes (Erp and Fahrney, 1975). Following infection of a ruminant host, the number of infected erythrocytes increases with an apparent doubling time of between 24 and 48 hours. The infection becomes patent microscopically two to six weeks post-transmission depending on the number of organisms transmitted and the virulence of the isolate. At peak infection greater than 75% of the erythrocytes may be infected, and a severe anemia develops which persists for one to two weeks. Susceptible animals lose significant weight and may abort if pregnant. A case fatality rate of up to 36% has been documented in acutely ill cattle (Alderink and Dietrich, 1981). *Anaplasma*-infected erythrocytes are rapidly cleared from the blood as immunity develops. Following recovery from acute infection, animals remain infected with a low, microscopically undetectable number of organisms in the blood. The number of infected erythrocytes in this persistent infection, termed the carrier state, has been shown to vary dramatically (from >0.000025% to <0.0025%) both among individual carrier animals and temporally within an individual (Eriks et al., 1989). This variation may significantly influence the efficiency of arthropod transmission from individual animals.

Isolation of *Anaplasma*

Cultivation procedures for *Anaplasma* have not been sufficiently enough established to allow recovery and propagation in vitro. Preservation is currently best achieved by collecting infected erythrocytes and maintaining the organism in the frozen state in dimethylsulfoxide. To each volume of washed, packed erythrocytes to be prepared, an equal volume of 4 M dimethylsulfoxide is added; the mixture is dispensed in convenient volumes and preserved in liquid nitrogen (Love et al., 1976). Infective organisms

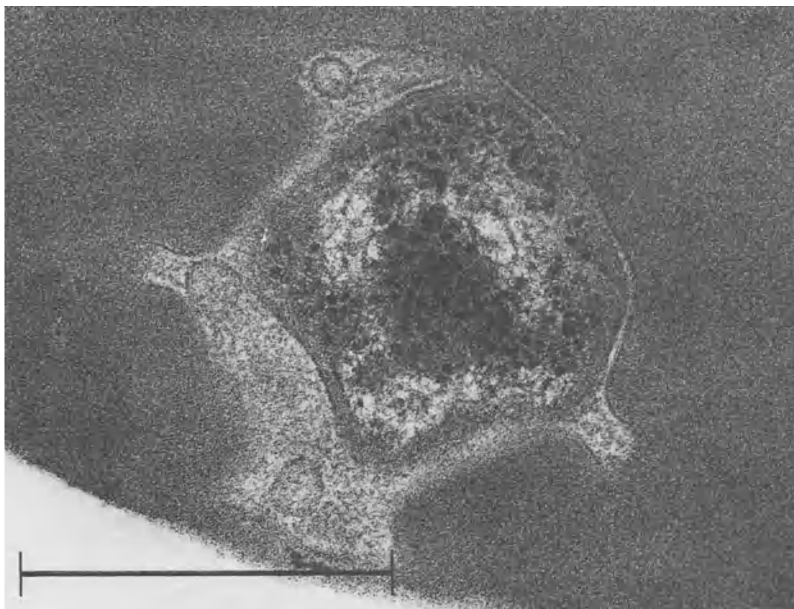

Fig. 20. Transmission electron micrograph of a single *Anaplasma marginale* organism within a vacuole in an intact infected erythrocyte. Bar = 0.5 μm. (From Kocan et al., 1978, with permission.)

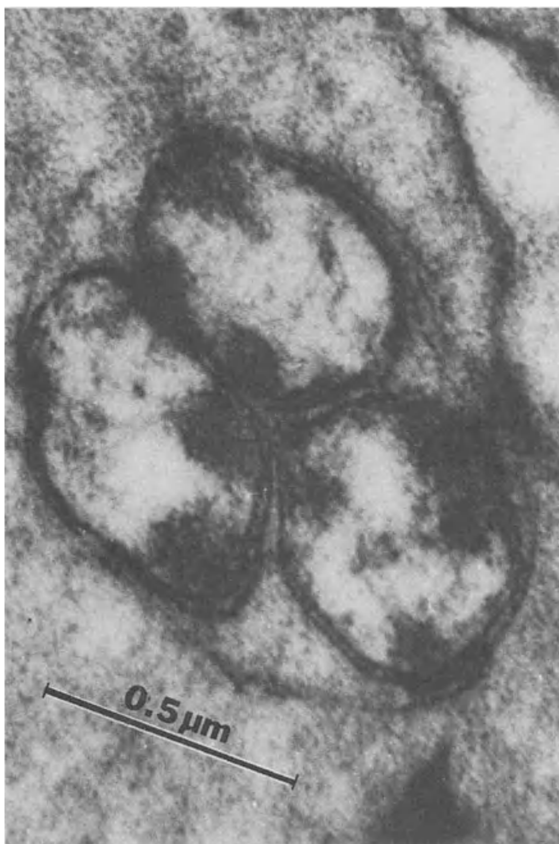

Fig. 21. Three organisms in an inclusion body. (Courtesy of M. Ristic.)

can be separated from the infected erythrocytes using ultrasonic disruption and differential centrifugation. Frozen erythrocytes can be used in this procedure (Palmer and McGuire, 1984). Propagation of the organisms in the cryopreserved isolate is by inoculation of a ruminant host (cattle for *A. centrale* and *A. marginale;* sheep or goats for *A. ovis);* the host subsequently develops an acute infection. Splenectomized animals develop more serious infections with significantly higher numbers of infected erythrocytes than do nonsplenectomized ones. There are no known animal hosts of *Anaplasma* other than domestic and wild ruminants.

In vitro cultivation is currently limited to short-term maintenance within mature erythrocytes. Short-term cultivation has been used to radiolabel *Anaplasma* polypeptides in vitro for structural and antigenic research (Barbet et al., 1983; Palmer et al., 1985—, 1986a, 1986b). Cultivation in nucleated cells has not been reproducibly effective as a source of organisms.

Procedure for the Short-Term Cultivation of *Anaplasma marginale*

The following procedure (Barbet, 1983; Palmer et al., 1985) is used for ^{35}S-methionine labeling of the organism: Blood is collected from splenectomized calves during the ascending parasitemia of animals with acute infection, washed three times in calcium- and magnesium-free Hanks balanced salt solution, and once in Eagle minimal essential medium without methionine; the buffy coat is removed after each centrifugation. The washed, parasitized erythrocytes are added to Eagle minimal essential medium without methionine (10% fetal bovine serum, 2 mM L-glutamine, 100 μg of streptomycin per ml, and 100 units of penicillin per ml) at a ratio of 1 ml packed erythrocytes to 7 ml of medium. The cultures are incubated for 48 hours with ^{35}S-methionine (125 μCi per 5 × 10^8 parasitized erythrocytes) at 37°C in 5% CO_2 in air. Cells are washed four times with Hanks balanced salts solution without calcium or magnesium, and the pelleted erythrocytes are lysed by a 50 mM Tris (pH 8.0) buffer containing 5 mM EDTA, 5 mM iodoacetamide, 1 mM phenylmethylsulfonyl fluoride, 0.1 mM N-alpha-*p*-tosyl-L-lysyl-chloromethyl ketone (TLCK), 1% Nonidet P-40, and 0.1% sodium dodecyl sulfate (SDS). After centrifugation to pellet the insoluble material, the clean supernatant is collected.

Identification of *Anaplasma*

Microscopic examination of Romanowsky-stained peripheral blood films is used to identify intraerythrocytic *Anaplasma* during acute infection in the ruminant host. *Anaplasma* are Gram-negative microbes that do not stain well with the counter stains used in the Gram stain procedure. Staining with Giemsa or Wright solutions is the most common method of preparation of blood films to be examined for the presence of *Anaplasma.* Infected erythrocytes at a frequency of as low as 0.1% can be detected by this method. What is seen is the round, 0.5- to 1.0-μm inclusion, which stains bluish-purple (see Fig. 19). A frequency of less than 0.1% of infected erythrocytes can be detected by nucleic acid hybridization with defined RNA or DNA probes. It has also been reported that *A. marginale* was detected by nucleic acid hybridization in blood films with as few as 0.000025% infected erythrocytes. *A. ovis* has also been detected by nucleic acid hybridization but sensitivity appears to be lower. *A. ovis* infection was detected in blood films with 0.00035% infected erythrocytes (Goff et al., 1988; Shompole, S. P., 1989; Visser and Ambrosio, 1987). Nucleic acid probes have been used to detect persistently infected carrier animals in field studies (see later).

Differentiation of species is most frequently based on host specificity, which appears to be reliable for the known hosts of *A. marginale* and

A. ovis. Intraerythrocytic location of the organism is the traditional basis for differentiation of *A. centrale* from *A. marginale*. Positive identification of *Anaplasma* can result from nucleic acid hybridization studies using defined nucleic acid probes and from fluorescent antibody staining using monoclonal antibodies (Palmer et al., 1988a; Shompole, S. P., 1989).

Numerous isolates of *A. marginale* which differ one from the other have been described. The isolates differ in antigenic nature, polypeptide composition, and composition of DNA in genes encoding surface proteins (Barbet et al., 1983; Kreier and Ristic, 1963a, 1963b; McGuire et al., 1984; Oberle et al., 1988; Palmer et al., 1988, 1988a). Reactivity in fluorescent-antibody-staining tests with panels of isolate-specific monoclonal antibodies is most commonly used to identify an isolate. Our inability to clone *Anaplasma* and thus to ensure that all organisms in an isolate are derived from a single parent has led to the use of the term "isolate" rather than "strain." Undoubtedly, genetically distinct clonas of *Anaplasma* could be produced, but to date this has not been accomplished.

Anaplasma can be identified within tick tissues by light microscopic examination of tissue sections stained by Mallory's technique and by examination of thin sections with an electron microscope. The morphology of the various developmental stages of *A. marginale* in *Dermacentor* ticks has been well described (Kocan, 1986). The infective stage in the salivary glands is composed of membrane-bound colonies of organisms (see Figs. 17 and 18) (Stiller et al., 1989). Identity of *Anaplasma* in tick tissues can be confirmed using immunofluorescence or nucleic acid hybridization (Friedhoff and Ristic, 1966; Goff et al., 1988).

In one sense *Anaplasma* resembles members of the order Rickettsiales, since it utilizes regulatory elements similar to consensus *Escherichia coli* signals to regulate their genes as do rickettsiae (Anderson et al., 1988; Barbet et al., 1987). There may, however, be differences between *Anaplasma* and the rickettsiae in ribosome-binding sites. The similarity between *Anaplasma* and the rickettsiae in their regulatory signals has allowed expression of *Anaplasma* genes in *E. coli,* using rickettsial promoters. The GC composition of *A. marginale* and *A. centrale* DNA have been reported as respectively, 48.5 and 45.1 mol% GC (Ambrosio and Potgieter, 1987).

Application of Molecular Biology Techniques

Research on the molecular genetics and immunology of *Anaplasma* has been applied in three principal areas: 1) identification of protective immunogens for vaccine development; 2) development of improved serologic diagnostic assays; and 3) development of nucleic acid probes for detection of low numbers of *Anaplasma* and for speciation of *Anaplasma.*

Our inability to cultivate *Anaplasma* has impeded development of effective, widely used vaccines. Immunization at present is only by infection and treatment or by infection with attenuated *Anaplasma* strains (Ristic and Carson, 1977). Identification of protection-inducing surface antigens on *A. marginale* and the cloning and expression of these antigens in recombinant *E. coli* provides a basis for the development of nonliving vaccines (Palmer, 1989). Two surface proteins, major surface protein-1 (MSP-1) and major surface protein-2 (MSP-2), have been shown individually to induce protection in immunized cattle (Palmer et al., 1986a, 1987, 1988). Both surface proteins share common epitopes with *A. centrale* and with various isolates of *A. marginale* from Africa, Asia, North America, and South America (Palmer et al., 1988a). Genes encoding the surface proteins have been expressed in recombinant *E. coli* (Barbet et al., 1987; Palmer, 1989). Although development of *A. ovis* vaccines is also needed, research on development of vaccines for *A. ovis* has not been reported.

Serologic assays with improved sensitivity and specificity for diagnosis of *A. marginale* infected cattle have been developed which utilize individual immunodominant antigens in an enzyme-linked immunosorbent detection system. An 86 KD at *A. marginale* protein is specifically reactive with sera from cattle infected with many different isolates of *A. marginale* regardless of the stage of infection (Palmer et al., 1986b). This assay is more sensitive than are tests using whole organisms as antigens, such as the capillary agglutination test (Ristic, 1962).

The development of nucleic acid probes specific for *A. marginale, A. centrale,* and *A. ovis* has allowed more reliable speciation, and easier identification of persistently infected carrier animals and of *Anaplasma* in tick tissues (Eriks et al., 1989; Goff et al., 1988; Shompole, S. P., 1989; Visser and Ambrosio, 1987).

CHAPTER 226

Streptobacillus moniliformis

JAMES R. GREENWOOD and SYDNEY M. HARVEY

Introduction

The genus *Streptobacillus* is presently represented by one species, *Streptobacillus moniliformis,* the etiologic agent of rat-bite fever and Haverill fever. *S. moniliformis* has also been known as *Haverhillia multiformis, Actinomyces muris, Actinobacillus muris,* and *Haverhillia moniliformis.* Although the genus *Streptobacillus* was described in the 1920s, taxonomically it continues to be a genus of uncertain affiliation. Previously this genus was placed in the families Parvobacteriaceae (Tribe Haemophileae) and Bacteroidaceae. Since the 8th edition of *Bergy's Manual, Streptobacillus* has been described as a genus of "uncertain affiliation." It was recently suggested (Savage, 1989) that *S. moniliformis* is more similar to some of the Mycoplasmatales. This suggestion is based on the low GC content of the DNA (24–26 mol%), serum or blood requirements for growth, cholesterol incorporation into the cell membrane, animal parasitism, and production of L-phase organisms. Further clarification of the taxonomic position of this genus awaits genetic studies, such as DNA-RNA hybridizations.

Habitats

S. moniliformis is found in the nasopharynx of laboratory and wild rats, with some studies reporting as many as 50–100% of wild rats carrying it as a commensal organism and excreting it in their urine (McHugh et al., 1985). It is reported to have caused tendon sheath infections in turkeys, cervical abscesses in guinea pigs, epizootics in laboratory mice, and lesions in laboratory rats with bronchopneumonia. Humans become involved in the transmission cycle through rat bites or from the bites of squirrels, weasels, and such rat-eating carnivores as dogs, cats, and pigs. Rat bite fever has also been reported following the handling of dead rats. Haverhill fever may result from the ingestion of milk to which rats have had access.

Selective Enrichment

S. moniliformis is both fastidious and slow growing; consequently it is frequently overgrown by normal flora. Because it is an uncommon human pathogen, little work has been done to develop a selective culture medium. Recently, however, colistin nalidixic acid agar (CNA) was used in conjunction with other media to isolate Gram-negative *S. moniliformis* from a 2-month old with a fatal infection following a bite by a wild rat (Sens et al., 1989). CNA is inhibitory for many other Gram-negative bacteria and the use of this medium or a modification combining colistin, nalidixic acid and serum might provide a new approach to isolation of *S. moniliformis* from nonsterile body sites.

Isolation

S. moniliformis growth media should be supplemented with either blood, serum, or ascitic fluid. Because L-phase variants might be present in clinical samples, media formulations must also take the specialized growth requirements of these forms into account. The bacterial phase has been isolated on media with either a meat infusion or tryptose base enriched with 20% horse serum or 15% sterile defibrinated rabbit blood. L-phase variants are more easily observed in culture when grown on the clear, serum-containing agar. Agar plates should be incubated in a humid environment with increased CO_2, such as that obtained in a candle jar, or in a humidified CO_2 incubator. Plates should be incubated at temperatures between 35–37°C. *S. moniliformis* colonies are greyish, round, and have a butyrous consistency. They generally have a discrete edge and reach approximately 1–2 mm after incubation for 3 days. The L-phase colonies exhibit a typical mycoplasma-type "fried egg" appearance and are considerably smaller than bacterial colonies.

When blood cultures are required to diagnose *S. moniliformis* endocarditis, thioglycolate broth appears adequate to support growth. However, it appears important not to use broth that contains sodium polyanethol sulformate, as this has been reported to be inhibiting at levels as low as 0.0125% (Lambe et al., 1973).

Identification

Table 1 lists the salient features of *S. moniliformis*. Because of the fastidious nature of these organisms, the literature frequently reports numerous discrepant biochemical features probably resulting from the use of different basal media. The most comprehensive studies on biochemical reactions of this genus are presently based on the studies of Aluotto et al., (1970) and Cohen et al., (1968).

Perhaps the most reliable and accessible method of testing carbohydrate fermentation is to inoculate a 24-h broth culture of *S. moniliformis* into a cystine trypticase agar (CTA) base that contains one drop of rabbit serum and 1% carbohydrate in final concentration. These tubes are incubated at 35°C and reactions read at 1, 2, 7, and 14 days. Inoculated tubes should be compared to control tubes consisting of CTA with added carbohydrate and serum. For detection of other biochemical features, the work of Cohen et al. (1968) should be consulted. Fatty acid profiles have also been used to rapidly identify *S. moniliformis* during an outbreak of Haverhill fever (Rowbotham, 1983). In this work, strains were grown in serum broth for 24 h, and the cultures were used to prepare fatty acid methyl esters. *S. moniliformis* strains had consistent peaks of palmitic, linoleic, oleic, and stearic acid.

Table 1. Salient features of *Streptobacillus moniliformis*.

Sucrose	−

[a]d = Different biotypes.

The microscopic morphology of *S. moniliformis* may vary depending on the media used, cultural conditions, and age of culture. Generally, cells appear as elongated Gram-negative rods, frequently in chains and filaments with occasional thickenings along the filaments giving rise to a necklace appearance ("moniliformis" means necklace-shaped). *S. moniliformis* is nonencapsulated, nonmotile, and facultatively anaerobic.

Preservation of Cultures

Cultures of *S. moniliformis* can be lyophilized for effective storage. They can also be subcultured in broth, but transfer to fresh broth medium is required as frequently as every 24 h to maintain viability. Refrigerated agar plate cultures can survive up to 15 days.

Applications

Animal research personnel are at risk from developing rat bite fever when working with laboratory rats. From 1958 to 1983, of 13 cases of rat bite fever reported in the United States, six of the cases were associated with bites of laboratory rats (Anderson et al., 1983). This is in keeping with the high rate of colonization by *S. moniliformis* in these animals. Studies on the mechanism of pathogenicity, virulence, and host range have not been reported.

CHAPTER 227

The Genus *Toxothrix*

PETER HIRSCH

The first description of a bacterium that produced twisted bundles of thin filaments which contained oxidized iron was given by Cholodny (1924). He called this organism *Leptothrix trichogenes,* the filament-producing *Leptothrix.* The flexible bacterium was observed in a water basin next to the river Dnjepr near Kiev, Russia. Its cells (diameter approximately 0.5 μm) were connected to form a trichome of up to 400 μm in length. A peculiar movement was observed: the U-shaped trichome glided with its rounded part forward; both ends of the trichome left bundles of twisted filaments of polymer as parallel "railroad tracks." Occasionally, parts of the bundles appeared to be drawn out in a fan-shaped fashion (Figs. 1a, 2).

Although this first description was very accurate, as we know now, later scientists failed to notice the presence and importance of the flexible, gliding bacterium (trichome); they only observed the often rigid, brittle, iron-encrusted bundles of filaments. Consequently, these filaments were interpreted to be alive, to comprise the organism. It appears strange that the producer of these structures did not attract greater interest.

The explanation for the failure to recognize the true nature of *Toxothrix* came from Krul, Hirsch, and Staley (1970), who employed a partially immersed, phase-contrast microscope to study the formation of such filament bundles in an iron spring in Michigan. The bacterial trichome was observed to consist of up to 40 rods each of 0.5–0.75 × 3–6 μm, with a total length of up to 240 μm. The forward movement of the often U-shaped trichome consisted of symmetrical rotation of both trichome ends, which thereby left a track on their attachment surface that consisted of twisted polymer fibers. Occasionally, the torque on the rounded center part of the U was released by an upward twist followed by a downward "printing" of polymer onto the surface of the glass slide. Later these polymer fibers became encrusted with iron oxide. Attempts to study the flexible filaments in the laboratory resulted in an explosive lysis that occurred within a few minutes after the living

This paper is taken directly from the 1st edition of *The Prokaryotes.*

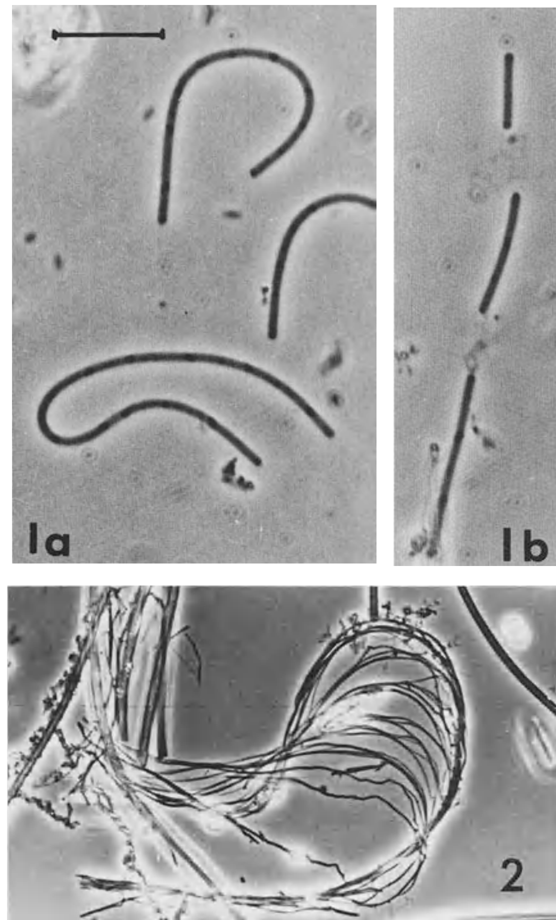

Fig. 1. *Toxothrix trichogenes* growing on a slide submerged in an iron-spring basin. The flexible trichomes with dense granules. (a) Typical U-shape of gliding cells. (b) A trichome has fragmented. Bar = 10 μm.

Fig. 2. *Toxothrix* polymer filaments (twisted bundle, fan-shape) with iron encrustations. There are also sheaths of *Leptothrix* sp. and *Gallionella* bands. Preparation from the same site as in Fig. 1.

preparation had been made (Fig. 1b). Thus the absence of trichomes in samples of many earlier observers could be explained (Krul, Hirsch, and Staley, 1970).

The fact that the bundle of twisted fibers was different from the "true" sheaths produced by other *Leptothrix* spp. caused Molisch (1925) to name this organism *Toxothrix ferruginea* (*toxon,* Greek noun, a bow). Later, Beger and Bringmann (1953) changed the name partially back into *Toxothrix trichogenes,* a more proper name (Hirsch and Zavarzin, 1974).

Habitats

The organism is not at all common in nature, although in specific habitats it has been found with a worldwide distribution. Most observers have seen *Toxothrix trichogenes* in fairly cold iron springs under conditions of reduced oxygen tension and slightly acidic pH (Table 1). The highest water temperature at which *Toxothrix* has ever been reported to grow is 15.5°C; thus this bacterium is obviously a psychrotroph. Concentrations of ferric iron were, when measured, low: 1–2.7 mg/liter Fe^{2+}. Many authors do not mention, in their reports, the occurence of the gliding *Toxothrix* trichomes, and thus the organism itself could have been absent when the more persistent, iron-encrusted filament bundles were seen and the parameters measured.

If one studies the variety of other bacteria present with *Toxothrix trichogenes,* one discovers that *Gallionella ferruginea* usually accompanies it. *Leptothrix* spp., *Siderocapsa* spp. or *Sphaerotilus, Naumanniella* spp., and *Ochrobium tectum* also occur, but if present they appear in smaller numbers. The natural habitat of *Gallionella* seems to be very similar to that of *Toxothrix.* But while the former grows best in nutrient-poor environments, the *Toxothrix* trichomes seem to prefer a higher concentration of organic matter. Also, *Toxothrix* grows best under microaerophilic conditions (Table 1).

Occurrence of *Toxothrix* in lakes or ponds has rarely been reported. Gorlenko, Dubinina, and Kusnezov (1977) found this organism in a 7- to 8-m depth in a Karelian mesotrophic lake and state that, if meromictic lakes were studied, *Toxothrix* could be found in one out of three such lakes.

Enrichment Suggestions

Toxothrix trichogenes has not been obtained in pure culture to date. However, natural *Toxothrix* samples—especially from cold iron springs with low pH—can be kept in the laboratory for several months, provided they contain some sediment with organic matter and are kept cold (5°C) and dark.

Microscopic examination of such stored samples often results in rapid lysis of the trichomes, a behavior also observed in some other gliding bacteria. The reason for the rapid lysis is not entirely clear. It could not be caused by a temperature that is too high, since lysis will occur below temperatures of some natural habitats. Light intensity and lack of oxygen could also be ruled out for the same reasons. *Toxothrix* trichomes may be extremely sensitive to pressure. Therefore, the cover slip of a preparation for microscopy should be carefully supported by small fragments of cover slip glass. It may also be quite harmful to these organisms to be streaked out, for the same reasons.

Future enrichments should be made with natural samples that contain many actively gliding trichomes; the number of twisted rope structures is quite irrelevant. The liquid medium should probably have a pH of 5.5–6.5, a constant iron supply of not more than 1–2 mg/liter Fe^{2+}, and an oxygen concentration of about 1 mg/liter. The incubation should be performed in the dark and at 5–10°C.

Identification

In the absence of iron-encrusted, excreted filament bundles, *Toxothrix trichogenes* could be mistaken for other gliding bacteria such as *Herpetosiphon* spp. The genus *Haliscomenobacter* (= *Streptothrix*), described from polluted environments (see Chapter 201), also shows some morphological similarities to *Toxothrix.* It is quite possible that gliding bacteria without such filamentous sheaths that have been observed in various freshwater, marine, or polluted habitats could have been *Toxothrix* spp. The absence, in *Toxothrix* trichomes, of constrictions at the cross-wall sites is quite characteristic. Their mode of gliding (in the form of a U) separated them from the equally colorless, filamentous, and gliding *Achroonema* spp., which normally remain fairly straight.

Fragmentation of *Toxothrix* trichomes into short rods is more common in some habitats than in others, and indicates the possibility of there being more than one *Toxothrix* species. Even before fragmentation, one recognizes many dense (electron-dense) granules in the *Toxothrix* trichomes. These may be polyphosphate granules (volutin). After fragmentation, each rod-shaped cell usually has two such granules, one at either end.

Fastidious Bacteria of Plant Vascular Tissues and Their Invertebrate Vectors

MICHAEL J. DAVIS

Prokaryotes have been recognized as plant pathogens since the pioneering research of Burrill (1881). However, the concept that these pathogens include noncultivable or extremely fastidious prokaryotes developed recently, following the discovery by Doi et al. (1967) and Ishie et al. (1967) that mycoplasma-like organisms are consistently present in the phloem of plants afflicted with various diseases of the yellows type (See Chapter 229). This discovery inspired renewed investigations into the etiology of numerous infectious plant diseases, many of which had been assumed to be of viral etiology. Subsequently, not only were additional mycoplasma-like organisms found associated with plant disease, but several new groups of fastidious prokaryotes were discovered. These organisms include both spiroplasmas (See Chapter 89) and bacteria that are confined to the vascular system of their plant hosts.

The fastidious plant pathogenic bacteria are the subject of this chapter. They are usually limited to either the xylem or phloem of the vascular system, but some inhabit both tissues. They are usually transmitted from plant to plant by insect vectors which also serve as hosts. At first, the bacteria were frequently referred to as "rickettsia-like" because of their fastidious nature, and because their morphology, ultrastructure, and insect transmission resembled those of animal pathogens in the Rickettsiaceae. However, subsequent studies have shown that this resemblance is superficial. Altogether, the fastidious bacteria of plant vascular tissues are phylogenetically diverse and are grouped together largely because of their association with plant disease, their endophytic habitat within plants, and their fastidious nature.

Because these bacteria could not be readily cultured on conventional bacteriological media, their existence in plants was first revealed by light and electron microscopy. Subsequently, the fastidious, xylem-inhabiting bacterium that causes Pierce's disease of grapevines, almond leaf scorch disease, and alfalfa dwarf disease was isolated on media specifically devised for its axenic culture (Davis et al., 1978). Following the development of additional media formulations, most known fastidious, xylem-inhabiting bacteria have been axenically cultured. Furthermore, their role as plant pathogens has been confirmed in most cases.

The fastidious, xylem-inhabiting bacteria include both Gram-positive and Gram-negative organisms. The Gram-positive bacteria include the causal agents of ratoon stunting disease of sugarcane (Davis et al., 1980a) and Bermudagrass stunting diseases (Davis and Augustin, 1984; Davis et al., 1983a). These two plant pathogens were found to be related to some other phytopathogenic coryneform bacteria and were placed together with these pathogens in the newly described genus *Clavibacter* (see Chapter 62) (Davis et al., 1984). Most of the Gram-negative, fastidious, xylem-inhabiting bacteria have been found to be related to one another and have been classified as *Xylella fastidiosa* (Wells et al., 1987). Members of *Xylella* are phylogenetically related to the xanthomonads based on 16s rRNA analysis and belong within the gamma subgroup of the eubacteria. The remaining fastidious, xylem- or phloem-inhabiting bacteria have not been taxonomically classified.

The plant diseases known to be caused, or at least are suspected of being caused, by bacteria classified as *X. fastidiosa* include: Pierce's disease of grapevines (Davis et al., 1978; Goheen et al., 1973; Hopkins and Mollenhauer, 1973), alfalfa dwarf disease (Goheen et al., 1973; Thomson et al., 1978), almond leaf scorch disease (Davis et al., 1980b; Mircetich et al., 1976), phony disease of peach (Davis et al., 1981; Hopkins et al., 1973; Nyland et al., 1973; Wells et al., 1981; Wells et al., 1983), plum leaf scald disease (Davis et al., 1981; French and Kitajima, 1978; Kitajima et al., 1975; Raju et al., 1982; Wells et al., 1981), elm leaf scorch disease (Hearon et al., 1980; Kostka et al., 1984, 1986a); mulberry leaf scorch disease (Kostka et al., 1986b); oak leaf scorch disease (Chang and Walker, 1988; Hearon et al., 1980; Kostka et al.,

1984); periwinkle wilt disease (Davis et al., 1983b; McCoy et al., 1978); Ragweed stunt disease (Timmer et al., 1981); leaf scorch of red maple (Sherald et al., 1987); sycamore leaf scorch disease (Hearon et al., 1980; Sherald et al., 1983); and citrus blight (Feldman et al., 1977; Hopkins, 1982; Hopkins et al., 1978). Diseases associated with other Gram-negative, fastidious, xylem-inhabiting bacteria include: bacterial wilt of Toronto creeping bentgrass (Roberts et al., 1981); Sumatra disease of cloves (Bennett et al., 1987; Hunt et al., 1987); leaf scorch of *Macadamia integrifolia* (Jimenez, 1982); and a dieback of Chinaberry (Yehsiung et al., 1986).

Except for unconfirmed reports, none of the fastidious, phloem-inhabiting bacteria have been isolated in axenic culture, including those which are also capable of inhabiting the xylem. Consequently, little is known about their relationship to one another and to other bacteria. Phloem-inhabiting bacteria have been associated with diseases in citrus (Garnier and Bove, 1977; Garnier et al., 1984a, 1984b; Moll and Martin, 1974), clover (Behncken and Gowanlock, 1976; Benhamou, 1978; Benhamou et al., 1978, 1979; Black, 1944; Grylls, 1954; Liu and Black, 1974; Markham et al., 1975; Windsor and Black, 1973a, 1973b), carrot (Giannoti et al., 1974a), coconut palm (Steiner et al., 1977), grapevine (Rumbos et al., 1977; Ulrychova et al., 1975), hop (Vanek et al., 1976), larch (Nienhaus et al., 1976), onion (Konvicka et al., 1978), *Melaleuca armilaris* (Klein et al., 1979), potato (Klein et al., 1976), *Sida cordifolia* (Hirumi et al., 1974), spinach (Nienhaus and Schmutterer, 1976), sugar beet (Green, 1978; Nienhaus and Schmutterer, 1976; Urbina-Vidal, 1974), wheat (Ploaie, 1973), and willow (Holmes et al., 1972). The bacteria associated with rosette disease of sugar beet were also observed in the parasitic plant, dodder, which was shown to transmit the bacterium to sugar beet (Green, 1978). Double infection of the phloem of dodder with both mycoplasma-like organisms and fastidious bacteria has also been observed (Giannotti et al., 1974b).
