The xylem is a continuous tissue throughout the plant. It has three primary functions: transport of water and mineral nutrients, storage of nutrients, and structural support (Esau, 1965). Fastidious, xylem-inhabiting bacteria are associated with tracheary elements of two types, tracheids and vessel members, that function primarily in transport. In some hosts, the bacteria are found more frequently in the smaller, thick-walled tracheids than in larger vessels (Hopkins et al., 1973; Kitajima et al., 1975). Occasionally, however, the bacteria are found in the intercellular spaces of the xylem (Goheen et al., 1973). In the process of xylem differentiation, tracheary elements form cell walls with apertures, termed pits. Later, the cells become devoid of cytoplasm, leaving a hollow vessel. All tracheary elements are connected by paired pits which have membranes that separate the adjoining elements. In addition, vessel members are joined end-to-end, forming vessels, and the adjoining ends have open perforation plates. Vessels are not continuous throughout the plant, but are of finite length. The length of vessels is difficult to determine; it varies with plant species and with the time of year the vessels develop. In some species (e.g., *Eucalyptus obliqua*) most vessels are less than 50 cm in length; however, vessels in tree species with ring-porous wood may extend several meters (Esau, 1965; Zimmerman and McDonough, 1978). Sap flows from one vessel to another through pit membranes (Esau, 1965; Zimmerman and McDonough, 1978). Bacteria apparently move from one tracheary element to another by breaching pit membranes, but whether the membranes are enzymatically, or otherwise, dissolved or are forcefully ruptured is unknown. Often, some tracheary elements are packed with bacteria while adjacent elements are not. Pit membranes often appear to prevent lateral spread of the bacteria, but open perforation plates allow relatively unimpeded longitudinal spread within vessels.

Xylem-inhabiting bacteria are confronted with a unique physical and nutritional environment. The ascending flow of xylem sap from the roots fluctuates in response to transpiration of water by the plant; the direction of flow may even reverse under conditions of high atmospheric humidity combined with low soil moisture (Bollard, 1960). Since no evidence of motility has been observed in xylem-inhabiting bacteria, it has been assumed that the flow of xylem sap plays an important role in bacterial dissemination within the plant. However, there is some question as to whether or not vessels might be rendered dysfunctional upon the initial entry of bacteria. Zimmerman and McDonough (1978) suggested that an instantaneous embolism usually results from the invasion or introduction of bacterial pathogens into tracheary elements, thus causing dysfunction. However, Purcell (1989) suggests that such damage to vessels might be minimized by the

highly evolved feeding mechanism of the Homopteran vectors of *X. fastidiosa.* Regardless of the initial consequences of bacterial introduction, colonization of tracheary elements is likely to impede normal xylem function. If infested tracheary elements are dysfunctional, sap from adjacent functional tracheary elements might serve as one source of diffusable nutrients for xylem-inhabiting bacteria. The bacteria might also obtain nutrients from the cytoplasmic remains within the lumen of tracheary elements. Conceivably, sap flow might also be important in removal of bacterial waste products.

The composition and concentration of solutes in xylem sap varies with plant species, location within the plant, time of day, plant age, seasonal cycle, plant nutritional state, and health of the plant (Pate, 1976). The xylem sap provides a qualitatively rich but dilute nutritional environment. Xylem sap usually contains 1–20 mg/ml solids in contrast to phloem sap, which usually contains 50–300 mg/ml solids. These solids contain numerous soluble compounds that might serve as a source of diffusable nutrients for fastidious bacteria. Possible carbon sources for the bacteria include mono- and disaccharides such as glucose, sucrose, and fructose, organic acids such as citrate and succinate, and a number of other organic compounds including amino acids and plant-growth regulators (Andersen et al., 1989; Bollard, 1960; Pate, 1976; Wormall, 1924). Possible nitrogen sources include both organic and inorganic compounds. One organic nitrogenous compound often predominates (Pate, 1976). Amino acids, alkaloids, ureides, and amides are included among the nitrogenous compounds that occur in xylem sap. Organic phosphorous, sulfur-containing compounds, and essential inorganic salts are also present in xylem sap, and vitamins are sometimes present in low concentrations. In view of the low solute concentration of their environment, fastidious xylem-inhabiting bacteria may need special mechanisms for the acquisition of nutrients from sap.

In electron micrographs of ultrathin sections of infected plant material, fastidious, xylem-inhabiting bacteria are sometimes found embedded in an electron-dense matrix that is presumably of plant origin (Huang et al., 1986; Mollenhauer and Hopkins, 1974). Fibrous strands called "osmophilic lines or microfibrils" (Lowe et al., 1976) have frequently been seen connecting these bacteria (French et al., 1977; Lowe et al., 1976; Mollenhauer and Hopkins, 1974; Nyland et al., 1973). Such fibrous stands, discussed in greater detail in this chapter under Identification, resemble the fibrous polysaccharide coats that surround adherent bacteria in diverse habitats (Brooker and Fuller, 1975; Costerton et al., 1978; Latham et al., 1978; McCowan et al., 1978). Costerton et al. (1978) suggest that these are polysaccharide fibers (termed a "glycocalyx") which function in survival and pathogenesis. They suggest that the glycocalyx may confer such advantages to bacteria as: 1) maintaining position in a beneficial environment; 2) adhesion to one another for conservation and concentration of digestive enzymes; 3) provision of a food reservoir that may serve as an ionic net similar to an ion exchange resin; and 4) protection against host defense mechanisms or other stress. If the fibrous stands associated with fastidious, xylem-inhabiting bacteria confer such advantages, this would help to explain how these bacteria survive in the dilute but dynamic environment of the xylem.

With the exception of the fastidious, xylem-inhabiting bacteria associated with some tree diseases (Hearon et al., 1980; Kostka et al., 1984, 1986a, 1986b; Sherald et al., 1983, 1987), the bacteria generally occur in geographical areas with mild winter climates. Purcell (1977, 1979) has proposed that the geographical distribution of some of the diseases may be limited more by cold winters than by the lack of insect vectors or host plants. Exposure of grapevines with Pierce's disease to $-8°C$ to $-12°C$ for various periods of time resulted in remission of symptoms or complete recovery from the disease in some test plants (Purcell, 1977). However, when infected grapevines were exposed to various winter climates, the highest rate of recovery from Pierce's disease was not always associated with colder climates (Purcell, 1980), suggesting that factors other than cold temperatures alone may play an important role in their survival. Perhaps, desiccation of xylem tissues in dormant plants is important in this respect. Another factor might be location of the bacteria within their plant host; longer growing seasons in warmer climates might allow the bacteria the time needed after transmission by insect vectors to systemically spread from leaves and small branches to larger branches, trunks, and roots where there is possibly greater protection from adverse environmental conditions.

Symptoms of diseases in which xylem-inhabiting bacteria are involved include marginal necrosis of leaves, stunting, decline in vigor, and decrease in yield. Such "wilt" symptoms are also produced by many other vascular pathogens of plants, including bacterial pathogens in the genera *Xanthomonas, Pseudomonas, Erwinia, Clavibacter,* and *Curtobacterium* (Nelson and Dickey, 1970; Van Alfen, 1982). Host response varies greatly among plants colonized by fastidious, xylem-inhabiting bacteria. Such

variation may be a function of both the relative disease resistance of different hosts and the distribution of the bacteria within host plants. Peach trees infected with the bacterium that causes phony disease of peach and plum leaf scald disease do not develop marginal necrosis of leaves as symptoms, whereas plums grafted onto peach trees with phony disease develop this symptom (French et al., 1978); leaf marginal necrosis is a characteristic symptom of plum leaf scald disease. Populations of the pathogen are generally much larger in roots than in shoots of both peach and plum; however, greater proportions of the populations are present in plum shoots than in peach shoots (Wells et al., 1980). Interestingly, although wild plum is a symptomless host of the pathogen, it is important in the epidemiology of phony disease of peach. The pathogen apparently is more prevalent in shoots of wild plum than in shoots of peach, as evidenced by graft transmission studies (Hutchins et al., 1953). In grapevines with Pierce's disease, leaf marginal necrosis develops first in older, more mature leaves, and the extent of vascular colonization by the pathogen is directly correlated with development of this symptom (Hopkins and Thompson, 1983). Furthermore, colonization is greater in cultivars which are more susceptible to the disease.

A wide range of plant species can be colonized by fastidious, xylem-inhabiting bacteria. Strains of *X. fastidiosa* causing Pierce's disease of grapevines can colonize members of at least 28 families of monocotyledonous and dicotyledonous plants; however, recognizable disease symptoms are produced in only a few of these (Freitag, 1951; Hopkins and Adlerz, 1988; Raju et al., 1980; Raju et al., 1983). Similarly, strains of *X. fastidiosa* causing phony disease of peach have been found to colonize a wide range of host plants, many of which are symptomless hosts (Wells et al., 1980). Hopkins (1989) speculates that the list of natural hosts of all strains of *X. fastidiosa* is probably limited more by the effort spent looking for other hosts than by the host specificity of the bacterium.

Plant Phloem Habitat

Like the xylem, the phloem is also a continuous tissue throughout vascular plants and comprises another important habitat for fastidious bacteria. It functions primarily in the transport of nutrients synthesized by the plant. The ecological circumstances permitting colonization of the phloem by microorganisms involves a specialized insect fauna of plants that specifically utilizes this tissue. The habitat breadth of the phloem pathogens, therefore, is significantly influenced by the plant-host range of the insect vectors (Whitcomb and Williamson, 1979).

The phloem of plants consists, in part, of sieve tubes that are comprised of sieve cells (or sieve-tube elements) that form a long, pressurized conduit. Continuity of the fluids in the tissue is provided by pores between sieve elements. Although the pores may be less than 1 μm in diameter, they may be as wide as 14 μm, and average more than 2 μm. Thus, prokaryotic organisms can generally pass unrestricted from sieve cell to sieve cell. Electron micrographs of microorganisms jammed into sieve pores are, therefore, probably artifacts resulting from the release of pressure upon sampling of the tissue (McCoy, 1979).

In the phloem of susceptible plants, the microorganisms take advantage of a fluid that is rich in many potential nutrients. These include inorganic cations and anions, organic acids, amino acids, proteins, and carbohydrates. The composition of phloem sap can be favorably compared with the composition of insect hemolymph (Saglio and Whitcomb, 1979). Together, the two fluids comprise an ecological niche that has been filled by several prokaryotic taxa. These include the noncultivable, wall-less prokaryotes that induce proliferation and virescence in plants (see Chapter 229) and the spirophasmas (class Mollicutes; family Spiroplasmataceae; see Chapter 89). The phloem habitat contrasts sharply with that of the xylem. The xylem exudates of sugar beet (*Beta vulgaris,*) contain less than one-tenth the concentration of total solids, sucrose, reducing sugars, and total nitrogen that was found in phloem sap (Fife et al., 1962). Also, nitrogenous compounds were especially low in xylem exudates; physical parameters, such as viscosity, specific gravity, electrical conductivity, pH, and osmotic pressure, also differed in the sap of the two tissues (Bollard, 1960; Fife et al., 1962; Pate, 1976).

Fastidious bacteria of the phloem-insect habitat are small, elongate organisms (1–3 μm × 0.2–0.5 μm). At least 12 disease agents may be included in the group. In certain cases (Küppers et al., 1975; Petzold et al., 1973), the organisms reportedly occur not only in sieve elements, but in other phloem cell types as well. Such observations are not unique to phloem bacteria but have been made for phloem mycoplasma-like organisms as well. Considering that passage through plasmadesmata of the plant cell walls would be necessary for organisms to gain access to cells adjoining the sieve tube elements without disruption of the walls and that cells of developing phloem tissue are difficult to identify, McCoy (1979) concluded that part or all of the

reports of mycoplasma-like organisms in cells other than sieve tube elements can be attributed to misidentification, either of sieve tube elements as parenchyma cells or of membrane-bound vesicles of host origin as mycoplasma-like organisms. Certainly, the difficulties facing mycoplasma-like organisms in such plasmadesmatal passages would be even more insurmountable for the walled (and therefore less plastic) prokaryotes that are discussed in this chapter, unless some possess the ability to actively ramify through plant tissues. Such movement might help to explain reports of fastidious bacteria simultaneously inhabiting the phloem and xylem tissue, and occasionally the parenchyma and meristematic cells (Nienhaus and Sikora, 1979).

In their plant hosts, the phloem-inhabiting bacteria cause diseases characterized by leaf stunting and clubbing. Symptoms are often mild, and spontaneous recovery may be a significant feature (Klein et al., 1976). Other symptoms, such as proliferation of shoots with a resulting witches' broom appearance (Hirumi et al., 1974; Holmes et al., 1972; Maramoroush et al., 1975; Nienhaus et al., 1976; Neinhaus and Schumutterer, 1976) or floral virescences (Black, 1944; Lui and Black, 1974), may be observed in some cases. Symptoms of proliferation and virescence are more characteristic of diseases caused by another group of phloem inhabitants, the mycoplasma-like organisms (see Chapter 229), than those caused by phloem-inhabiting bacteria. At present the physiological basis for the proliferation and virescence syndrome is poorly understood.

Invertebrate Habitat

Despite occasional suggestions that some of the fastidious prokaryotic pathogens of plant vascular tissues are soil borne (Neinhaus et al., 1976; Rumbos et al., 1977), all well-defined vector relationships involve insects. The evolution of insect vector relationships with prokaryotic plant pathogens and the mechanisms involved in insect transmission of these pathogens has been reviewed by Purcell (1982a, 1982b). A large but well-defined group of insect species transmits the xylem-inhabiting bacteria classified as *X. fastidiosa.* Sharpshooter leafhoppers (Homoptera; Cicadellidae; Cicadellinae) and spittlebugs or froghoppers (Homoptera; Cercopidae) are the only known vectors of these pathogens, and both apparently are xylem-feeding insects (Purcell, 1979). The transmission of xylem-inhabiting bacteria by Homopteran insects has recently been reviewed (Purcell, 1989). Little is known about the means of transmission of the fastidious, xylem-inhabiting bacteria that have not been taxonomically classified as *X. fastidiosa.* Machaerotid spittlebugs appear to be principally involved in the transmission of the Sumatra disease bacterium (Eden-Green et al., 1986). Strains of *X. fastidiosa* that cause Pierce's disease are transmitted by at least 26 species of leafhoppers (Frazier, 1966; Hopkins, 1977) and five species of spittlebug (Severin, 1950). Those vectors that have been examined also transmit the pathogen to alfalfa, resulting in the development of alfalfa dwarf disease (Hewitt et al., 1946) and to almond, resulting in the development of almond leaf scorch disease (Auger et al., 1974; Mircetich et al., 1976). Furthermore, the capacity of this pathogen to infect a wide range of plant species, including symptomless as well as symptomatic hosts, was originally determined by means of insect transmissions (Freitag, 1951). This was accomplished even before the nature of the pathogen was known by using susceptible grapevine cultivars as indicator hosts. Transmission of different pathogenic variants among *X. fastidiosa* by the same leafhopper species has been demonstrated on several occasions. For example, *Homalodisca coagulata, Oncometopia undulata,* and *Cuerna costalis* transmit both the Pierce's disease pathogen (Kaloostian et al., 1962) and the phony disease pathogen (Turner and Pollard, 1959), and *Oncometopia nigricans* transmits the pathogens causing Pierce's disease (Hopkins, 1977) and the periwinkle wilt disease (McCoy et al., 1978). Thus, it appears that insect-vector transmission of *X. fastidiosa* is not governed by strict vector-pathogen specificities. In this respect, the vector relationship may mirror the pattern of wide host preference of the vectors themselves. Host preference of vectors, in turn, may be governed largely by the amino acid composition, especially amides, of xylem sap (R. F. Mizell, personal communication).

Although other sap-feeding, suctorial insects have been observed to probe the xylem, only those adapted for prolonged ingestion of xylem sap are efficient vectors of *X. fastidiosa* (Purcell, 1989). A large cibarial pump and pump musculature permits these insects to ingest copious amounts of xylem sap, and a highly developed filter chamber in their digestive tract facilitiates the efficient absorption of nutrients from the sap (Andersen et al., 1989). The mechanism of transmission of *X. fastidiosa* has been extensively studied in only a few vector species. Transmission appears to be noncirculative but persistant over the adult lifetime. There is no evidence that *X. fastidiosa* is pathogenic to its insect vectors. Evidence supporting the noncirculative transmission of *X. fastidiosa* includes:

1) the ability of some vectors to very quickly acquire and transmit the bacterium (Purcell and Finlay, 1979); 2) the lack of transovarial passage of the bacterium from one generation of insect to the next (Severin, 1949); 3) the failure of vector insects to transmit following experimental injection of the bacterium into their body cavity (McCoy et al., 1978; Purcell et al., 1979); and 4) the lack of transtadial transmission, in other words, the failure of previously transmitting insects to transmit after molting (Purcell and Finlay, 1979). This last feature directly points to the involvement of the foregut in transmission, because the lining of the foregut is lost during molting.

Microscopic examinations have revealed extensive colonization of the foregut of leafhopper vectors by *X. fastidiosa* (Fig. 1) (Purcell et al., 1979; Brlansky et al., 1983). Mats of the bacterium have been observed lining the entrance to the cibarial pump chamber and the chamber itself. Colonization of the precibarium has also been noted. Purcell (1989) suggests that from a functional standpoint, the precibarium is most likely the site from which bacteria are egested into plants by these vectors. One interesting feature of insect colonization by *X. fastidiosa* is the polar attachment of the bacteria to the lining of the foregut. This manner of attachment leds one to suspect that the fibrous strands seen extending from the polar ends of *X. fastidiosa* in electron micrographs might be directly responsible for attachment. Because of the high velocity of xylem sap passing through narrow portions of the foregut, such attachment may be essential for insect colonization (Purcell et al., 1979) and, ultimately, survival of *X. fastidiosa.*

In many respects, knowledge of insects as habitats for phloem-specialized bacteria is scanty. Most of these agents are known only as suspected plant pathogens; although they are assumed to be insect borne, in most cases no vector is known. Vertical transmission (transmission from one generation to the next) has been demonstrated in the leafhoppers (Homoptera: Cicadellidae) that carry two of these agents (Black, 1944; Grylls, 1954); the rates were as high as 99%. The demonstration that the clover club leaf pathogen was transmitted vertically through multiple generations (Black, 1948, 1950) was the first demonstration that a microorganism could multiply in both animal and plant reservoirs in the course of a complex biological cycle. In contrast, little is known of the vector-pathogen relationships in the case of the leafhopper vectors of other clover diseases or the psyllid (Homoptera; Psyllidae) vectors of citrus disease (Capoor et al., 1974; Catling and Atkinson, 1974; McClean and Oberholzen, 1965). In the latter case, there is some evidence that the organisms multiply in the vector hemolymph (Moll and Martin, 1973). This claim offered hope for eventual cultivation of the agents, since other agents that multiply extracellularly in arthropods, such as *Rochalimaea quintana* (Vinson, 1966) and spiroplasmas (Whitcomb and Williamson, 1979) have proven to be cultivable. Recent reports on isolation of the citrus greening disease agent (Garnett, 1985) would seem to support this contention if they can be substantiated; however, it should also be noted that with few possible exceptions, the phloem borne bacteria and mycoplasmalike organisms remain noncultivable despite their ability to exist extracellularly in insects.

Isolation

Selection of Host Material

Plant hosts are frequently used as a source for isolation of fastidious, xylem-limited bacteria. Isolation from insects is also possible but is more difficult because they normally harbor contaminating microorganisms which can not be eliminated by surface sterilization. However, the efficiency of isolation can be improved by using only the heads of surface-sterilized insects (Purcell et al., 1979), thus avoiding microflora associated with other body parts. Factors that govern the choice of plant material used for isolation include: 91) distribution of the organism within the plant; 92) avoidance of potential contaminants; and 93) ease of bacterial extraction from tissue. It is advisable to avoid necrotic tissues and, when possible, older tissues that harbor more contaminants. Generally, the bacteria are isolated more easily from more mature tissues of the current year's growth. Plant parts with mild symptoms, or that are adjoining symptomatic parts, are preferable. In this respect, petioles of leaves exhibiting marginal necrosis symptoms have frequently been used.

Surface Sterilization

Selective media are not available for isolation of fastidious, xylem-inhabiting bacteria; consequently, surface sterilization of host material is necessary to avoid contamination by other microorganisms. Surface sterilization of plant material is effective largely because the bacteria are systemically distributed within and limited to the xylem where few, if any, other microorganisms exist. Aqueous solutions of sodium hypochlorite may be used for surface sterilization of plant parts (Davis et al., 1978). The plant material is immersed in a 0.5% or 1.0% hypo-

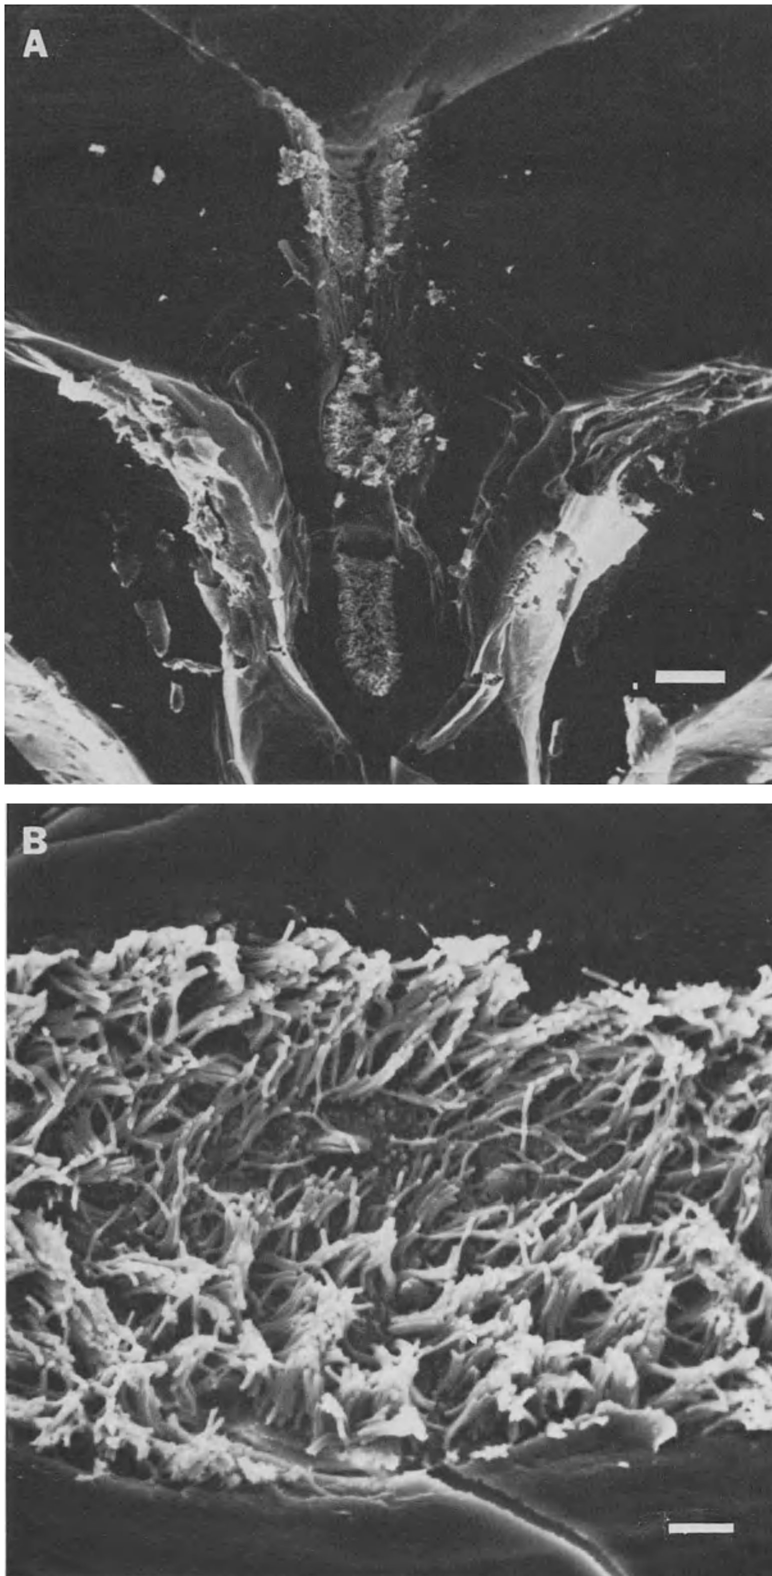

Fig. 1. Scanning electron micrograph of the precibarium of the leafhopper vector *Homalodisca coagulata* colonized by *Xylella fastidiosa.* (A) Epipharynx of the precibarium; floor of the cibarial pump visible at top and precibarial valve visible toward bottom. Bar = 25 μm. (B) Enlargement of anterior (distal) precibarium colonized by a dense mat of *X. fastidiosa.* Bar = 5 μm. (Courtesy of R. H. Brlansky.)

chlorite solution for 2–5 minutes and rinsed 2–3 times with sterile water to remove residual hypochlorite. It is helpful to first dip the plant material into 95% ethanol before treatment with sodium hypochlorite solution. In addition to being a disinfectant, ethanol also acts as a wet-

ting agent to facilitate surface sterilization. Unwanted portions of the plant material, such as cut ends that may have absorbed the hypochlorite solution, are then aseptically excised and discarded.

Inoculum Preparation for Isolation

Several different procedures have been used to extract fastidious, xylem-inhabiting bacteria from surface-sterilized plant parts. Extracts are often prepared by expressing sap from stems, rhizomes, petioles, or other plant parts with the aid of sterile forceps, pliers, or a hand vice. The sap is then collected with a pipette or blotted directly onto agar-solidified media. To obtain extracts, some plant parts may be ground in several volumes of buffer, such as 0.01 M phosphate buffer, pH 6.9, using a sterile mortar and pestle or a mechanical homogenizer. The liquid is then decanted from the plant debris and used as inoculum (Davis et al., 1981). A similar procedure has also been used to isolate the bacteria from their insect vectors (Davis, unpublished observations). Centrifugation or vacuum infiltration may be used to obtain extracts directly from sections of roots and stems. Such procedures are advantageous because extracts often contain relatively high numbers of xylem-inhabiting bacteria and are free of most plant debris. Although it has not been a widely recognized problem, plant tissue extracts may inhibit bacterial growth. Such inhibition has been found for the Sumatra disease bacterium when grown in the presence of tissue from clove trees (Bennett et al., 1987). When centrifugation is used, the plant material is aseptically placed in a conical centrifuge tube such that it does not contact the sap after extraction. Otherwise, the sap will often be drawn back into the plant material by capillary action. Centrifugation at 1000–4000 × times *g* for 1–5 minutes is routinely used to obtain sap containing *Clavibacter. xyli* subsp. *xyli* from sugarcane stalk sections (Davis et al., 1980a; Davis and Dean, 1984), and grapevine sap containing the Pierce's disease bacterium has been obtained in a similar manner from leaf petioles using a microcentrifuge (Davis et al., 1978). In the vacuum infiltration procedure, sections of stems or roots are attached to a vacuum flask via rubber couplings (Davis et al., 1980a; French et al., 1977; Teakle et al., 1973); cells of the pathogen are then flushed out by pulling water or buffer through the xylem with vacuum pressure.

Inoculation of Culture Media

Several methods of media inoculation have been successfully used to isolate fastidious, xylem-inhabiting bacteria. Direct inoculation of a medium with plant extracts is often the most expedient method and may be done simply by streaking extracts onto medium or by repetitive blotting of expressed sap from the cut surface of the plant material onto the medium. Serial dilutions of extracts may be used as inoculum resulting in the elimination of less numerous microbial contaminants by dilution. Furthermore, plating a series of dilutions enables enumeration of single colonies for quantitative studies. Spot inoculations with small volumes of inoculum, usually 10 μl, may prove useful. Spot inoculations allow different inocula or several dilutions of the same inoculum to be placed on the same plate of agar medium, thereby, conserving medium and labor. Also, because only a small portion of the surface of the medium is inoculated, locating and counting the small colonies commonly developed by fastidious, xylem-inhabiting bacteria may be easier.

Culture Media

The requirements for culture media vary among the different species and strains of xylem-inhabiting bacteria. For *X. fastidiosa,* this variation is usually much less among strains of specific pathogens grouped together within the species. The bacteria causing Sumatra disease of cloves (Bennett et al., 1987), bacterial wilt of Toronto creeping bentgrass (Roberts et al., 1981), and some strains of *X. fastidiosa* (Kostka et al., 1986b; Fry et al., 1988) will grow on full-strength or diluted nutrient agar. In general, however, isolation and continuous cultivation of the xylem-inhabiting bacteria is better on media specifically formulated for these organisms. Following the initial isolation of the Pierce's disease bacterium (Davis et al., 1978), the PD2 medium was developed for culturing this bacterium (Davis et al., 1980c). Two completely autoclavable derivations of the PD2 medium were also developed by replacing bovine serum albumin with either potato starch (2 g/l; PD3 medium) or activated charcoal (0.5 g/l; PD4 medium). Growth of the Pierce's disease bacterium may be slightly better on the PD2 medium than on the autoclavable formulations.

PD2 Medium for Xylem-Inhabiting Bacteria

Pancreatic digest of casein (Tryptone [Difco] or Trypticase peptone [BBL]	4 g
Papaic digest of soy meal (Soytone [Difco] or Phytone peptone [BBL]	2 g
Trisodium citrate	1 g
Disodium succinate	1 g
Hemin chloride stock (0.1% bovine hemin chloride dissolved in 0.05 N NaOH)	10 ml
$MgSO_4 \cdot 7H_2O$	1 g

K_2HPO_4	1.5 g
KH_2PO_4	1 g
Agar	15 g
Distilled water	1 liter
BSA stock (20% bovine serum albumin fraction five [sigma Chemical Co.] in water)	10 ml

All ingredients except the BSA stock are autoclaved in one liter of distilled or deionized water. After autoclaving, the medium is cooled to 50°C, and the filter-sterilized BSA stock is aseptically added. The final pH of the medium should be approximately 6.9 without adjustment.

The more fastidious strains of *X. fastidiosa* will not grow on PD2 medium. Several media formulations have been developed which will support growth of at least some if not all of these strains in culture (Davis et al., 1980a; Davis et al., 1981; Chang and Walker, 1988; Wells et al., 1981). The PW medium (Davis et al., 1981) is perhaps the most widely used of these formulations and will support the isolation and continued cultivation of even the most fastidious strains of *X. fastidiosa,* such as those that cause both phony disease of peach and plum leaf scald disease. The SC medium (Davis et al., 1980a) was developed for cultivation of *C. xyli.* subsp. *xyli* and *C. xyli.* subsp. *cynodontis,* which will not grow on PD2 or PW media, and will also support growth of less fastidious strains of *X. fastidiosa.* Consequently, it may be advantageous to employ several media when attempting to isolate a xylem-inhabiting bacterium whose identity is unknown. Generally, cycloheximide can be added to the PD2, PW, or SC media to inhibit fungal contamination without affecting bacterial growth; it is filter-sterilized and added to the medium at a final concentration of 50 mg/l.

PW Medium for Isolating More Fastidious Strains of *X. fastidiosa*

Pancreatic digest of casein (Tryptone [Difco] or Trypticase peptone [BBL]	1 g
Papaic digest of soy meal (Soytone [Difco] or Phytone peptone [BBL]	4 g
Hemin chloride stock (0.1% bovine hemin chloride dissolved in 0.05 N NaOH)	10 ml
$MgSO_4 \cdot 7H_2O$	0.4 g
K_2HPO_4	1 g
KH_2PO_4	1.2 g
Agar	12 g
Phenol red stock (0.2% phenol red in water)	10 ml
Distilled Water	1 liter
BSA stock (20% bovine serum albumin fraction five in water)	30 ml
Glutamine (8% glutamine in water)	50 ml

All ingredients except the BSA and glutamine stocks are autoclaved in one liter of distilled or deionized water. After autoclaving, the medium is cooled to 50°C, and the filter-sterilized BSA and glutamine stocks are aseptically added. The final pH of the medium should be approximately 6.6 without adjustment.

SC Medium for Isolating Xylem-Inhabiting Bacteria

Papaic digest of soy meal (Soytone [Difco] or Phytone peptone [BBL]	8 g
Hemin chloride stock (0.1% bovine hemin chloride dissolved in 0.05 N NaOH)	15 ml
$MgSO_4 \cdot 7H_2O$	0.2 g
K_2HPO_4	0.5 g
KH_2PO_4	1.5 g
Corn meal agar (BBL)	17 g
Distilled Water	1 liter
Glucose (50% glucose in water)	1 ml
Cysteine (free base; 10% cysteine in water)	10 ml
BSA stock (20% bovine serum albumin fraction five in water)	10 ml

All ingredients except the glucose, cysteine, and BSA stocks are autoclaved in one liter of distilled or deionized water. After autoclaving, the medium is cooled to 50°C, and the filter-sterilized glucose, cysteine, and BSA stocks are aseptically added. The pH should be 6.6–6.7 without adjustment.

Several broth formulations have been used for cultivation of fastidious, xylem-inhabiting bacteria. The PD2 and PW media can be prepared as broth media by omitting the agar. The elm leaf scorch bacterium (*X. fastidiosa),* which has been difficult to isolate on agar solidified media, can be isolated in S8 broth (SC medium without cornmeal agar) inoculated with infected wood chips (Kostka et al., 1981). However, once isolated in broth culture, this bacterium will grow when transferred onto semi-solid PD2, SC, or PW media.

Cultivation

All of the fastidious, xylem-inhabiting bacteria are obligate aerobes and grow best in culture at 27–29°C. One to three weeks of incubation are usually required to produce visible growth in primary cultures. Since most contaminating bacteria grow much faster than this, plates can be screened early for such contaminants. Because of this relatively long incubation period, precautions against excessive desiccation of the medium are often necessary.

Preservation of Cultures

Cultures of *X. fastidiosa* lose viabity rapidly when incubated past log-phase growth, and viability has not been successfully prolonged by refrigeration. Viability can be maintained at room temperature (25°C) for 1 to 2 months when cells are suspended in 0.01 M phosphate

buffer, pH 7.2, or 10% skim milk in water and for at least 4 months at −40°C in 10% skim milk in water or 15% glycerol in PW broth medium (Jimenez and Davis, unpublished observations). Long-term preservation of *X. fastidiosa* is possible with preparations that have been freeze-dried in 10% skim milk and stored at −20°C (Davis, unpublished observations). Long-term preservation of the bacteria on silica gel in a freezer has also been recommended (Hopkins, 1988).

Identification

Xylem-Inhabiting Bacteria

CELL MORPHOLOGY AND ANATOMY The Gram-negative, fastidious, xylem-inhabiting bacteria are all nonmotile, aflagellate rods usually measuring 0.25 μ to 0.5 μm in width and 1 μm to 4 μm in length (Chen et al., 1982; Hopkins, 1977, 1989). Constriction furrows in the cell wall have been interpreted as evidence that the bacteria reproduce by binary fission (Hopkins, 1977; Lowe et al., 1976; Mollenhauer and Hopkins, 1974). In culture, elongated forms of these bacteria, which measure several times the normal cell length in the host plant, are sometimes found (Davis et al., 1978; Davis et al., 1981; Wells et al., 1981). Fewer elongated cells were seen on media that support more rapid growth of the bacteria, suggesting that cell elongation without division occurs in response to a sub-optimal nutritional environment (Davis et al., 1978). The association of filamentous forms with smooth colonies and shorter rods with rough colonies was also reported (Wells et al., 1987). The cell walls of the bacteria have a typical Gram-negative type ultrastructure with outer and inner trilaminar unit membranes enclosing a periplasmic space (Fig. 2) (Bennett et al., 1987; Brlansky et al., 1983; Lowe et al., 1976; Mollenhauer and Hopkins, 1974). A peptidoglycan or "R-layer" has often been observed in the periplasmic space. Although many Gram-negative bacteria have outer cell wall membranes which have periodic enfoldings, the enfoldings of *X. fastidiosa* are often more exaggerated. The outer membranes have been described as rippled, ridged, corrugated, and furrowed, and the enfoldings tend to be perpendicular to the long axis of the cells. Within the plant, host, the cell topography may vary within individual tracheary elements, ranging from greatly enfolded to smooth (Mollenhauer and Hopkins, 1974). This variation may be a result of cell deterioration due to aging (Mollenhauer and Hopkins, 1974) or defense mechanisms of the host (Huang et al., 1986).

The cytoplasm of fastidious, xylem-inhabiting bacteria resembles that of other prokaryotes in its content of ribosomes, nuclear regions with DNA-like strands, and osmophilic granules (Bennett et al., 1987; Lowe et al., 1976; Mollenhauer and Hopkins, 1974; Nyland et al., 1973). Membranous inclusion bodies, which appear to be associated with the cytoplasmic membrane, were seen in situ in the Pierce's disease bacterium (Davis, 1978; Lowe et al., 1976). Occasionally, an electron-lucent zone, which may be an artifact of fixation or a capsule, has been observed surrounding individual bacteria in plants (Davis, 1978; Hopkins, 1977; Lowe et al., 1976; Mollenhauer and Hopkins, 1974).

In the tracheary elements of plants, fastidious, xylem-inhabiting bacteria often form aggregates that appear to be held together by extracellular material produced by the bacteria (Mollenhauer and Hopkins, 1974). This material has been termed fibrous forms (Mollenhauer and Hopkins, 1974), "osmophilic lines" or microfibrils (Lowe et al., 1976), and electron-dense strands (French et al., 1977; Nyland et al., 1973). Often these strands are more abundant at the ends of the bacteria (Fig. 2) (French et al., 1977; French and Kitajima, 1978; Lowe et al., 1976). Negatively stained preparations of the phony disease bacterium revealed filaments (French et al., 1977), which might be analogous to either the acid polysaccharide coat (Costerton et al., 1978) or to fimbriae (Ottow, 1975) observed in other bacteria. Other filaments, possibly composed of subunits, were observed either attached to the cell wall or in the vicinity of cells (Lowe et al., 1976; Nyland et al., 1973). Hopkins (1977) considered these to be analogous to either fimbriae or possibly to sex pili in other bacteria. These filaments were 28–30 nm in diameter and of undetermined length; their width was approximately three times the usual width of fimbriae. Similar appendages have been observed attached to the cell wall of a bacterial symbiont in the pharyngeal diverticulum of the olive fly (Poinar et al., 1975). The extracellular materials of *X. fastidiosa* may also be associated with virulence within the plant host in addition to their possible role in the attachment of cells to the lining of the foregut of its insect vectors as discussed previously in the section on invertebrate habitat. Cells of these bacteria tend to agglutinate when suspensions are made from recently isolated cultures, and Hopkins (1989) has observed that a correlation exists between the loss in culture of the ability to agglutinate and of virulence.

CULTURE CHARACTERISTICS. Fastidious, xylem-inhabiting bacteria usually produce colonies on semi-solid media which are circular with entire

margins and convex, but sometimes colonies are produced that are also circular with undulate margins and have an umbonate to flat appearance. With the phony disease of peach and plum leaf scald bacteria, the convex colonies have a smooth surface, whereas the umbonate to flat colonies have a rough surface, and both colony types can appear in cultures of the same strain (Davis et al., 1981). Colonies of freshly isolated strains of the Pierce's disease bacterium are often very viscid, becoming almost granular with age, and do not disperse easily in water or broth medium. Colonies are usually clear to opalescent white and without pigmentation. Generally, the slower growing pathogens, such as the phony disease bacterium, produce colonies in 2 to 3 weeks that reach diameters from 0.1 to 0.7 mm. The faster growing pathogens, such as the Pierce's disease bacterium and Sumatra disease bacterium, produce colonies in 1 to 2 weeks that reach a diameter from 0.5 to 5 mm. In broth cultures, doubling times ranging from 9 hours to 2.3 days have been reported for different strains of *X. fastidiosa* (Davis, 1978; Wells et al., 1987).

SEROLOGY. Serological techniques, such as gel double diffusion, immunofluoresence, and enzyme-linked immunosorbent assay (ELISA), presently provide the most practical means of differentiating *X. fastidiosa* from other bacteria. Both monoclonal (Wells et al., 1987) and polyclonal (Davis et al., 1979; French et al., 1978; Davis et al., 1981; Davis et al., 1983b; Lee et al., 1978; Nome et al., 1980; Raju et al., 1978) antibodies have been used. All strains of *X. fastidiosa* appear to be antigenically related, but quantitative differences exist among strains as measured by ELISA (Davis et al., 1983b; Nome et al., 1980; Raju et al., 1982; Wells et al., 1983). However, serological means to distinguish among different pathogens within *X. fastidiosa* have not been found, and preliminary reports suggest that alternative means, such as analysis of protein profiles from cell envelopes (Chang and Schaad, 1982) or cloned DNA probes (Jimenez and Davis, 1987), may prove more useful in this respect.

PHYSIOLOGICAL AND BIOCHEMICAL CHARACTERISTICS. All fastidious, xylem-inhabiting bacteria are oxidase negative, catalase positive, and obligately aerobic. Strains of *X. fastidiosa* hydrolyze gelatin, and utilize hippurate but do not produce indole, H_2S, β-galactosidase, lipase, amylase, coagulase, or phosphatase (Wells et al., 1987). Generally, the optimum temperature for growth in culture is 26–28°C, and the optimum pH is 6.5–6.9. Growth of strains of *X. fastidiosa* and the Sumatra disease bacterium in culture is usually accompanied by increased alkalinity of the medium (Bennett et al., 1987; Davis et al., 1980c; Wells et al., 1987). In minimal medium, strains causing Pierce's disease utilize organic acids, such as succinate and citrate, but not carbohydrates, such as glucose and sucrose (Davis, 1983), and similar results were obtained in more complex media (Davis et al., 1980c). However, in modified PW medium, growth of a number of strains of *X. fastidiosa,* representing different pathogenic types, was stimulated by glucose and several other carbohydrates and organic acids but inhibited by citrate and succinate (Wells et al., 1987). This discrepancy may be due to strain differences or inadequacy of the methods used to test utilization of organic acids and carbohydrates. Interestingly, the predominant organic compounds in xylem fluid of four of the plant host species of *X. fastidiosa* include citrate and succinate but not carbohydrates (Andersen et al., 1989). Completely defined media would be useful to examine the nutritional requirements of fastidious, xylem-inhabiting bacteria but have not been developed. Alternatively, Chang (1988) has examined the enzyme activities of two strains of the Pierce's disease bacterium and found no indication that these bacteria have a glycolytic pathway. The strains derived energy through the Krebs cycle and pentose phosphate shunt. The Krebs cycle enzymes found to be active were citrate synthetase, aconitase, fumarase, succinyl-CoA synthetase, isocitrate dehydrogenase, α-ketoglutarate dehydrogenase, succinate dehydrogenase, and malate dehydrogenase. Phosphohexose isomerase and glucose-6-phosphate dehydrogenase, but not lactate dehydrogenase, were also detected. These results support the earlier contention that organic acids are the primary source of energy for *X. fastidiosa.*

A high degree of DNA homology (75–100%) exists between pathologically different strains of *X. fastidiosa,* suggesting that the strains are indistinguishable at the species level (Kamper et al., 1985; Wells et al., 1987). Less than 5% homology was found between these strains and other strains representing different genera containing phytopathogenic bacteria and other Gram-negative bacteria. The content of guanine plus cytosine (GC) in various strains of *X. fastidiosa* ranged from 49.5 to 53.1 mol%, and the genome size ranged from 1.27 to 1.6×10^9 daltons. Similarity and signature analysis of 16S rRNA sequences indicated that strains of *X. fastidiosa* were most closely related to xanthomonads; the highest similarity being with a strain of *Xanthomonas maltophilia* (Wells et al., 1987).

Analyses of the composition of total cellular fatty acids of strains of *X. fastidiosa* indicate uniformity within the species (Wells and Raju, 1984; Wells et al., 1987). The major components were $C_{16:0}$ (30%), $C_{16:1}$ (26.7%), $C_{17:0}$ (11.6%), and $C_{15:0}$ (8%) fatty acids. The profile was unique when compared to those of other taxa. The percentage of saturated, odd-numbered carbon straight chains was higher than in other Gram-negative, phytopathogenic bacteria, and cyclopropane acids were entirely absent.

PATHOGENICITY. Host colonization and pathogenicity in plant diseases caused by fastidious, xylem-inhabiting bacteria has recently been reviewed (Davis, 1989; Hopkins, 1989; Purcell, 1989). In many situations, pathogenicity tests are impractical for routine identification of these bacteria, because of the long incubation period required for symptom development in plants, usually 2–6 months. Furthermore, loss of virulence in culture may complicate matters (Hopkins, 1984). Also, the pathogenicity of some fastidious, xylem-inhabiting bacteria has not been conclusively established.

Often, plants can be successfully inoculated with fastidious, xylem-inhabiting bacteria from culture; however, at least in one case, attempts to use insect vectors to transmit the bacteria from culture to plants has met with very limited success (Davis et al., 1978). Various modifications of two techniques, the vacuum infiltration technique (Davis et al., 1978; Davis et al., 1980b; Sherald et al., 1983) and the needle puncture technique (Davis et al., 1980b, Hopkins, 1980), have frequently been used for inoculation of plants. Inoculation of roots wounded to expose the xylem has also been reported to result in a low frequency of infection (Davis et al., 1980b). The prerequisite for successful inoculation regardless of the technique used appears to be the direct introduction of inoculum into the xylem which is necessary because the bacteria apparently do not have an active mechanism for ingress (or egress) through other tissues.

Phloem-Inhabiting Bacteria

Lafleche and Bove (1970) were the first to recognize a group of fastidious, phloem-inhabiting prokaryotes, whose limiting structure was more complex than that of the wall-less prokaryotes. Their studies, discussed also by Saglio et al. (1972), clearly showed that the limiting structure of the suspected causal agent of citrus greening disease consists of a double membrane and, therefore, differs fundamentally in its structure from that of the phloem-inhabiting, wall-less agent which has since been named *Spiroplasma citri* (Saglio et al., 1973) and shown to incite citrus stubborn disease (Markham et al., 1974).

Although there have been reports of the in vitro cultivation of the fastidious, phloem-inhabiting bacteria associated with plant disease, these reports have not been independently confirmed. They include the cultivation in chick embryos of a bacterium from yellows-diseased grapevine (Nienhaus et al., 1978) and the cultivation in axenic culture of the bacterium associated with citrus greening disease (Garnett, 1985). With these possible exceptions, failures in cultivation have prohibited the development of a clear taxonomic concept. However, the organisms appear to have several common structural features, which may indicate a common phylogeny and eventual recognition as a taxon. The organisms are elongate, 1.3 × 0.2–0.5 μm, with the usual ribosomal and diffuse nuclear regions characteristic of prokaryotic cells (Fig. 3). They are bounded by a "wavy" structure that consists, in part, of two single membranes (about 8 nm wide). Presence of cell wall constituents is suggested by the total width of the limiting structure (20–30 nm) and by the susceptibility of the organisms to penicillin derivitives. It is generally agreed that these phloem organisms are similar to Gram-negative bacteria, although their dimensions are certainly at the lower limit of the size range. Of special significance is the apparent absence of an R-layer in the periplasmic space of the cell wall (Moll and Martin, 1974), which is characteristically present in the Gram-negative cell wall (Costerton et al., 1974). Although the organisms have been referred to as "rickettsia-like" by many authors, there is no direct analogy to members of the Rickettsiaceae; for this and other reasons, Moll and Martin (1974) preferred to refer to the organisms as "bacteria-like," a term that has gained some acceptance (Klein et al., 1976). Some of the organisms are so small that they are visible by phase-contract microscopy, but not by conventional brightfield microscopy (Liu and Black, 1974). Under phase-contrast microscopy, the organisms exhibit an undulatory motility in 30% glycerol that ceases upon the addition of mercuric chloride or potassium penicillin G (Lui and Black, 1974). Thus sensitivity to the inhibition by penicillin of cell wall biosynthesis has been shown both in vivo and in vitro (Windsor and Black, 1973a; Ulrychova et al., 1975). The in vivo sensitivity of the organisms to tetracycline derivatives has also been established (Schwarz and Van Vuuren, 1971; Schwarz et al., 1974; Su and Chang, 1976).

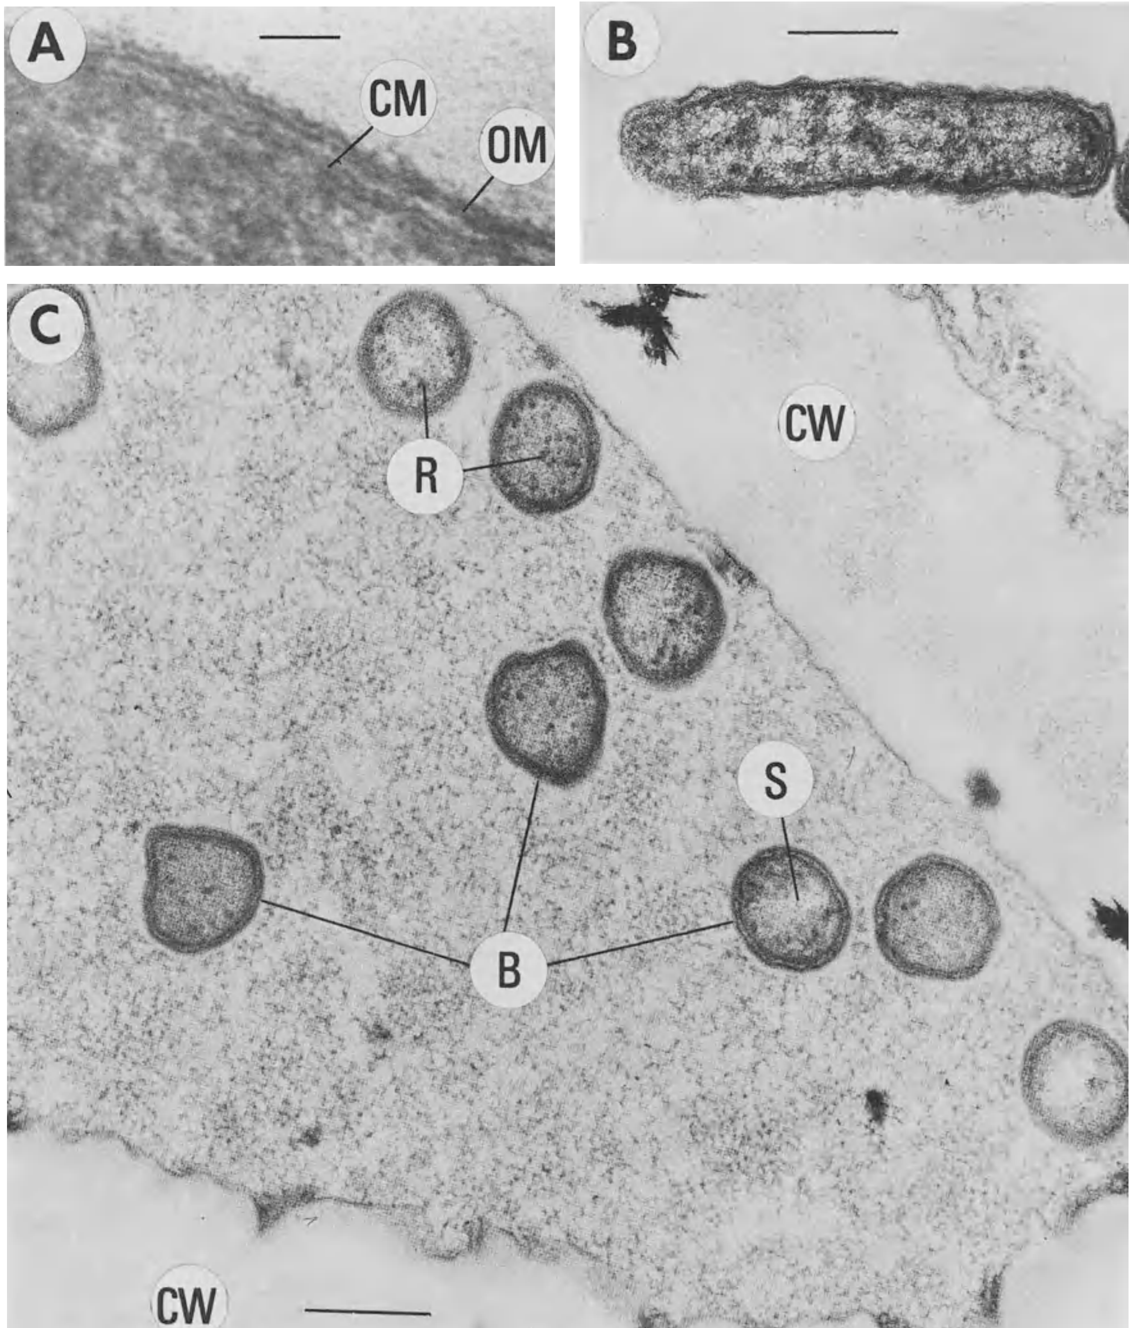

Fig. 3. Fastidious phloem bacteria. (A) Detail from thin section of cell of citrus greening bacterium. Cytoplasmic membrane (CM) and outer membrane (OM) are present. Bar = 40 nm. (Courtesy of J. M. Bove.) (B) Thin section of bacterium from phloem of white clover (*Trifolium repens*). Cells are elongate with wavy contour. Bar = 0.2 μm. (Courtesy of P. G. Markham.) (C) Cells of clover club leaf bacterium (B) in transverse section of phloem cell of periwinkle (*Catharanthus roseus*) shoot. The cells contain ribosome-like particles (R) and fine strands (S) representing DNA. CW, cell wall. Bar = 0.2 μm. (From Windsor and Black, 1973b.)

Lui and Black (1974) were able to partially purify the clover club leaf organism, prepare antiserum that agglutinated organisms to a titer of 1/1024, and stain the organisms specifically in leafhopper tissue using the fluorescent antibody test. More recently, monoclonal antibodies have been produced for detection of the citrus greening bacterium (Garnier et al., 1987). Serological techniques may eventually be used to demonstrate relationships even in the ab-

sence of successful cultivation of the fastidious, phloem-inhabiting bacteria.

Applications

Although the economic importance of fastidious bacteria of plant vascular tissues is presently related directly to their role as plant pathogens, ironically, some may eventually prove useful in the control of plant disease and pestilence. This point is exemplified by the recent effort to control lepidopterous plant pests through genetic enhancement of *C. xyli* subsp. *cynodontis* (Kostka et al., 1988). By inserting the gene for production of the δ-endotoxin from *Bacillus thuringensis* var. *kurstaki* into the genome of *C. xyli* subsp. *cynodontis,* it is hoped that the bacterium will effect a degree of pest control by systemically colonizing plants and at the same time producing sufficient amounts of the toxin. This concept for an endophytic delivery system relies on the relatively wide host range of this fastidious, xylem-inhabiting bacteria and the negligible amount of damage due to its presence in target hosts. A further advantage of using *C. xyli* subsp. *cynodontis* is the lack of insect vectors which lessens the risk of environmental release of the recombinant organism. Other fastidious, xylem-inhabiting bacteria with insect vectors might make more suitable delivery systems in some situations, if factors governing virulence and vector transmission can be understood and manipulated when necessary.

Mycoplasma-Like Organisms—Plant and Invertebrate Pathogens

BRUCE C. KIRKPATRICK

Mycoplasma-like organisms (MLOs) are wall-less prokaryotes that cause disease in many higher plants and in some cases in the insects that transmit them. Although MLOs morphologically resemble culturable members of the class Mollicutes and are susceptible to the same antibiotics, the inability to continuously culture these organisms in vitro has prevented their definitive classification as Mollicutes (Razin and Freundt, 1984). However, recent sequence analysis of MLO 16S ribosomal RNA (rRNA) has clearly established that these pathogens form a unique cluster of organisms that are phylogenetically related to Gram-positive bacteria and to culturable mollicutes. These results, and rapid advancements in MLO taxonomy made possible by serological and nucleic acid hybridization analyses, suggest molecular analyses will generate the most important criteria for classifying currently nonculturable wall-less prokaryotes.

The primary subject of this chapter is plant pathogenic MLOs; other plant-associated mycoplasmas are only briefly discussed. Emphasis is placed on the advancements that have been made in MLO detection, taxonomy, and phylogeny.

Biological and Biophysical Characteristics of MLOs

Since their discovery by Doi et al. (1967), MLOs have been shown to be associated with more than 200 diseases of higher plants (McCoy et al., 1989). MLOs were originally thought to be large, unstable viruses (Black, 1954; reviewed by Whitcomb and Black, 1982). Electron microscopic observations of plants infected with "yellows agents" revealed the presence of pleomorphic, wall-less prokaryotes in the phloem sieve tube elements of infected plants. These pathogens ranged in size from 50 nm, theoretically nonviable "elementary bodies" (Maniloff and Morowitz, 1972; McCoy, 1979), to filaments that were several microns long (McBeath et al., 1972). Because these long, thin filaments appear to be small spherical cells when sectioned transversely, the true morphology of an MLO cell is best revealed by constructing three dimensional models from serial sections (Waters and Hunt, 1980; Florance and Cameron, 1978). Such analyses show that at least some MLOs are highly pleomorphic, multi-branched, filamentous organisms, whose filaments are often aligned parallel to the length of the sieve tube element. Numerous ribosomes and occasional fibers, which are thought to be DNA, are usually observed within sections of viable MLOs (Fig. 1 and 2). These structures are useful morphological markers for differentiating MLOs from host vesicles that are often present in plant phloem. Although similar morphological characters are observed in MLO-infected insect vectors (Fig. 2), the true morphology of MLOs in their insect vectors has not

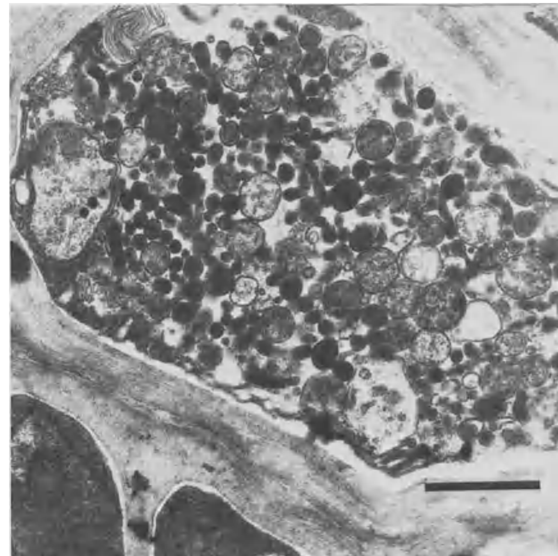

Fig. 1. Electron micrograph of X-disease mycoplasma-like organisms (X-MLOs) in a sieve-tube element of sweet cherry (*Prunus avium*). Bar = 1 μm.

been rigorously established by serial thin sections.

MLOs are susceptible to antibiotics, such as tetracyclines, that inhibit prokaryotic metabolic functions. Because MLOs are wall-less, they are resistant to antibiotics such as penicillin that block cell wall synthesis (Ishiie et al., 1967; Davis et al., 1968). When MLO-infected plants are injected with tetracyline antibiotics, or given foliar application or root drenches of this antibiotic there is a temporary remission of plant disease symptoms and a concurrent reduction in the number of MLOs within the plant. Tetracycline antibiotics have thus served as a basis of therapy and prophylactic treatment for some tree crops, such as coconuts (McCoy et al., 1976), pears (Nyland and Moller, 1973), peaches, and cherries (Nyland, 1971; Rosenberger and Jones, 1977). Unfortunately, the therapeutic benefits of tetracycline are only temporary and symptoms recur unless plants are regularly treated.

MLOs systemically infect plants by passing through phloem sieve plate pores. Their small size and lack of a rigid cell wall allow MLOs, like culturable mycoplasmas, to pass through filters (0.45 μm) that normally exclude most bacteria. The ability of MLOs to pass through filters has also been exploited for separating MLOs from host contaminants (Kirkpatrick et al., 1987; Davis et al., 1988). In addition, extracts containing infectious MLOs are usually filtered prior to injection into healthy insect vectors in order to exclude potentially deleterious bacteria (Gold and Sylvester, 1982; Markham, 1982b).

Habitats

Plant Pathogenic MLOs

Plant pathogenic MLOs are obligate, intracellular parasites that are primarily restricted to phloem sieve tubes. Although there were several early reports of MLOs residing within phloem parenchyma and cell types other than phloem, McCoy (1979) dismissed these as either misidentifications of immature phloem as parenchyma or misidentifications of plant vesicles as MLOs. However, the hypothesis that MLOs reside only within phloem sieve elements remains controversial. For example, two recent reports provide substantial evidence that MLOs can be found, at least in some plants, in cells other than phloem sieve elements. Siller et al. (1987) provided very thorough and convincing histological evidence that MLOs can be found in the parenchyma cells of a dodder species, *Cuscuta odorata.* Their numerous micrographs clearly documented the presence of MLOs in thin-walled, nucleated cells that contained mitochondria, dictyosomes and other plant organelles not normally found in mature sieve tubes. Sears and Klomparens (1989) examined MLO-infected *Oenothera* growing as differentiated plantlets in tissue culture and described MLOs in nucleated cells that contained plastids and mitochondria. Based on the presence of these organelles and other morphological criteria, they classified these MLO-infected cells as phloem parenchyma. Although it should be noted that neither the MLO-infected *Cuscuta* nor the tissue-cultured *Oenothera* represent "typical" MLO plant hosts, evidence presented

in these and other reports (Esau et al., 1976) suggests that MLOs are not restricted only to phloem tissues in all infected plants. One major question raised by these reports is how the MLOs were able to enter the parenchyma cells because parenchyma plasmodesmata are thought to be too small (less than 50 nm) to permit the passage of viable MLOs. The dilemma posed by MLO movement through parenchyma plasmodesmata is further supported by observations that culturable mycoplasmas cannot pass through 0.1 μm filters.

MLOs can be classified into three main groups on the basis of plant disease symptoms (Markham, 1982a; Kirkpatrick, 1989): 1) The "decline agents" produce a general stunting, foliar chlorosis, limb or shoot dieback, root necrosis, and a reduction in leaf and flower size; however, flower color and morphology is normal. 2) "Proliferation agents" may produce some of the same symptoms as the decline agents, but this group also causes proliferative growth of leaves and shoots whose internodes are shortened in at least some of their plant hosts. These infected plants have a bunchy growth habit, producing symptoms that have been described as "witches' brooms." 3) Most "virescence agents" also cause leaf chlorosis and leaf, shoot, and flower proliferation. In addition, flower morphology and pigmentation are dramatically altered. Plant tissues that would normally become petals and sepals instead develop into leaf-like structures (phyllody) and normally pigmented flowers become green (virescence).

Symptoms produced by virescence MLOs strongly suggest that these pathogens alter the normal balance of plant growth regulators in infected plants. Several studies have shown altered levels of phytohormone activity in virescence-infected plants (Davey et al., 1981; Gaborjanyi and Sziraki, 1978). However, it is not known whether the MLOs synthesize plant growth regulators, like some other phytopathogenic prokaryotes (Panopolous and Peet, 1985; Morris, 1986) or if the MLOs interfere with the normal balance of endogenous plant hormones. Perhaps the best example of an MLO that appears to produce a plant growth regulator is the beet leafhopper transmitted virescence agent (BLTVA-MLO) (Golino et al., 1987). Several plants that normally require short photoperiods or cold temperatures to induce flowering will flower under noninductive conditions when infected with the BLTVA-MLO. Exogenous applications of gibberellic acid (GA) also induce similar flowering responses in these plants. Inhibitors that block the action of GA prevent the premature flowering of BLTVA-MLO-infected plants, suggesting either that the BLTVA-MLO may produce a compound(s) with GA-like activity or that this pathogen alters normal endogenous GA levels in the plant (Golino et al., 1988).

MLOs appear to systemically colonize plant hosts in one of two ways, depending on the pathogen and possibly the plant species. One colonization pattern is typified by the X-disease MLO (X-MLO), which first multiplies to high cell densities in the roots of experimental plant hosts such as celery *(Apium graveolens)* and periwinkle *(Catharanthus roseus)*. As the roots become necrotic, the numbers of X-MLO cells in the leaves increase and typical foliar symptoms develop. Celery or periwinkle infected with virulent X-MLO isolates usually collapse one or two months after inoculation, at which time virtually nothing remains of the root system (Kirkpatrick, 1986, 1989). Extensive root necrosis is also observed in several other MLO "decline diseases" such as pear decline (Schaper and Seemüller, 1982), apple proliferation (Seemüller et al., 1984a, 1984b), and elm yellows (Braun and Sinclair, 1976). Most of the decline agents of perennial woody plants recolonize the above-ground portions of their hosts from the roots each spring (Seemüller et al., 1984a 1984b). Decline-type MLOs also differentially colonize the above ground portions of a plant host. For example, in the spring the X-MLO initially multiplies to higher densities in the fruit peduncles than in the leaves of sweet cherry *(Prunus avium)* trees (Kirkpatrick, 1986). X-MLO densities are highest in the peduncles when the fruit is fully mature, are low in the leaves until after the fruit ripens and senesces, and they continue to increase in the leaves until late in the fall. The ability of healthy insect vectors to acquire X-MLO from infected cherry trees also correlates with this seasonal change of MLO densities in the leaves (Suslow and Purcell, 1982; Kirkpatrick et al., 1987).

In contrast to the decline agents, the "virescence" MLOs, such as the aster yellows (AY) pathogens, usually cause little root necrosis, and infected plants may live as long as healthy ones. Furthermore, the colonization pattern of periwinkle by the severe strain of western aster yellows MLO (SAY-MLO) was quite different from the X-MLO (Kuske, 1989; Kuske and Kirkpatrick, 1990b). After a SAY-MLO-infected scion was grafted onto a healthy plant, the pathogen colonized and multiplied to high numbers in the immediately adjacent shoot, rather than in the roots. The SAY-MLO continued to preferentially multiply in the shoots, and pathogen numbers remained uniform and comparatively low in the roots.

MLOs Associated with Insect Vectors

Despite numerous attempts, it has not been possible to mechanically infect healthy plants with infectious MLO extracts. Although the reasons for this failure are uncertain, the rapid accumulation of callose and P-protein that occurs when a phloem sieve tube is injured may play a significant role (McCoy, 1979). Because of the cost and logistical difficulties involved with maintaining colonies of healthy and MLO-infectious insect vectors, the development of methods to mechanically inoculate MLOs into plants would greatly facilitate research on this group of recalcitrant plant pathogens.

Although MLOs can be transmitted from infected to healthy plants by scion and root grafts, most natural transmission occurs via phloem-feeding insects, especially leafhoppers (Cicadellidae). A few species of planthoppers (Fulgoridae) and psylla (Psyllidae) also transmit MLOs (Tsai, 1979). The specificity of MLO/vector relationships has been historically important in identifying and differentiating MLOs. However, there are some insect vectors, such as the leafhopper *Fieberiella florii,* that can efficiently transmit several distinctly different types of MLOs (Severin, 1946; Wolfe et al., 1951). The utility of vector transmission characteristics in classifying MLOs is therefore limited.

All MLOs circulate through and multiply in their insect vectors before being transmitted to a healthy plant. The transmission latent period within a vector is typically 2 to 8 weeks (Tsai, 1979; Purcell, 1982). After the MLO is acquired from the phloem of infected plants, it penetrates and multiplies in the vector's gut epthelial cells. The MLO then passes through the gut epithelial cells, enters the insect's hemocoel, and presumably multiplies in the hemolymph. Depending on the particular MLO, it may also invade adipose tissues, nerve ganglia, the brain, and other organs of the insect vector (Fig. 2) (Whitcomb et al., 1967, 1968a, 1968c; Nasu et al., 1970; Sinha and Chiykowski, 1967). However, the MLO can be transmitted to a healthy plant only if it can penetrate, multiply in, and exit from the insect's salivary gland. The existence of gut and salivary gland "barriers" has been experimentally substantiated. One can bypass the "gut barrier" and greatly shorten the normal latent period within the vector by injecting MLO-infectious insect extracts into healthy vectors using fine needles (Whitcomb et al., 1966; Markham, 1982b). If infectious MLO extracts are injected into a nonvector, the MLOs can multiply in the nonvector's hemolymph and possibly other organs, but the pathogen will not enter the salivary gland nor will it be transmitted to healthy plants (Purcell et al., 1981). Similarly, some MLOs can multiply in a nonvector's gut cells, but in such cases MLOs are not found in the hemolymph or salivary glands and the insects do not transmit the pathogen to healthy plants (Sinha and Chiykowski, 1967). Thus, there are a number of tissue-specific "barriers" within a potential insect vector that an MLO must cross before it can be transmitted to a plant host. Furthermore, once inoculated into a potential plant host, the MLO may or may not multiply; the factors determining plant host susceptibility are currently unknown.

It has been clearly established that some MLOs are pathogenic to their insect vectors. Jensen (1959) reported that *Colladonus montanus* leafhoppers infected with the peach yellow leafroll strain of X-MLO lived approximately half as long as uninfected leafhoppers. Light microscopy revealed numerous pathological lesions in the brain, thoracic ganglia, salivary gland, and adipose tissues of X-MLO-infectious *C. montanus* leafhoppers (Whitcomb et al., 1967, 1968a, 1968c). Electron microscopic examination of infectious *C. montanus* leafhoppers showed that these same tissues contained large numbers of X-MLOs (Nasu et al., 1970), thus suggesting that MLO-induced pathologies were responsible for increased vector mortality. Jensen (1971) also established that X-MLO-infected *C. montanus* produced fewer offspring than did healthy leafhoppers. Similar increases in mortality were reported for six leafhopper species which transmit the maize bushy stunt MLO (MBS-MLO) (Madden and Nault, 1983; Nault et al., 1984), although no deleterious effects were observed on two other MBS-MLO vector species. In summary, it appears that some decline agents (X-MLO) and proliferation agents (MBS-MLO) negatively affect their insect vectors. Interestingly, there does not appear to be any significant deleterious effect of the AY-MLO, a virescence agent, on the longevity or fecundity of its insect vectors (Severin, 1946); however, some cytological abnormalities were observed in AY-MLO-infected *Macrosteles severini* (Hemmati and McLean, 1980; Hemmati, 1977).

At least two plant pathogenic mycoplasmas can change the host plant preference of a nonvector leafhopper. *Dalbulus maidis,* a leafhopper that can transmit both the MBS-MLO and *Spiroplasma kunkelii,* will normally feed and reproduce only on maize *(Zea mays)* and closely related species such as teosinte *(Zea mays mexicana)* (Nault, 1985). When experimentally confined to other plant hosts the leafhoppers quickly die. However, *D. maidis* placed on any of several plant species infected with the AY-

MLO (Maramorosch, 1958; Purcell, 1988) or *Spiroplasma citri* (Purcell, 1988) subsequently live for prolonged periods on nonhost plants. *D. maidis* never transmitted either AY-MLO or *S. citri* to plants.

Nonphytopathogenic MLOs in Insects

Nonculturable, walled and wall-less prokaryotes have been observed in many insect orders that feed on plant vascular fluids, especially the Homopterans, several families of which transmit plant pathogenic mycoplasmas (Buchner, 1965; Houk and Griffiths, 1980). Extensive electron microscopic examination of *Colladonus montanus,* a vector of X- and AY-MLOs, and *Macrosteles severini,* a vector of the AY-MLO, documented the presence of wall-less prokaryotes in these healthy leafhoppers (Fig. 3) Nasu et al. (1970) reported that the extracellular MLOs were normally associated with the midgut epithelial cells of healthy *C. montanus.* However, if an extract containing these wall-less symbionts from healthy *C. montanus* was injected into healthy *C. montanus* leafhoppers, the gut-associated symbionts rapidly multiplied to high cell densities in the fat bodies, malpighian tubules, and even the salivary glands of injected leafhoppers. But, the gut-associated organisms were apparently never transmitted to plants. Similar nonculturable mycoplasmas were observed in the midgut epithelial cells of *M. severini* (Hemmati, 1977). Unlike some of the plant pathogenic MLOs, the wall-less organisms associated with *M. severini* did not appear to produce pathology in the cells that they colonized.

Given the prevalence of obligate insect symbionts and the intimate relationship the plant pathogenic MLOs have with their insect vectors, it may be possible that plant pathogenic MLOs evolved from an insect symbiont(s) or a common progenitor mollicute. The ability to isolate and characterize evolutionarily conserved markers, such as the 16S rRNA, may provide direct genetic evidence concerning the possible relationship between insect symbionts and plant pathogenic mollicutes.

Mollicutes Isolated from Plant Surfaces

A number of culturable, nonhelical and helical mollicutes have been isolated from plant surfaces, especially flowers (reviewed by Tully, 1989; Hackett and Clark, 1989; see also Chapter 89). Because no organisms were isolated from flowers caged to exclude insects, it is assumed that these mollicutes were deposited in the floral nectaries by visiting insects. Whether these wall-less prokaryotes are truly epiphytes is uncertain because it has not been established that they multiply on plant surfaces.

A spiroplasma, later designated *Spiroplasma floricola* (Davis et al., 1981), and some nonhelical mycoplasmas were isolated from non-surface-sterilized flowers of the tulip tree, *Liriodendron tulipifera* (Davis, 1978). Although the nonhelical isolates obtained in this study were not further characterized, other workers have isolated both mycoplasmas and acholeplasmas from insect-visited plants. A serologically unique acholeplasma, *Acholeplasma florum,* was isolated from the surface of several tropical flowers growing in South Florida (McCoy et al., 1984). Several sterol-requiring mycoplasmas, which were serologically unrelated to the 80 recognized *Mycoplasma* species, were isolated from *Melaleuca quinquenervia* flowers. One of the isolates was characterized, and it has been proposed that this organism be named *Mycoplasma melaleucae* (Tully et al., 1990). Even though their A·T rich genome should be sus-

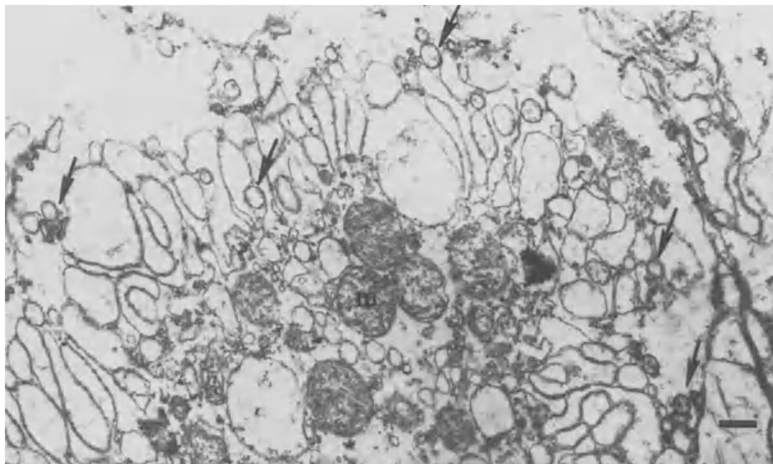

Fig. 3. Wall-less prokaryotes (arrows) associated with a midgut cell in a healthy *Macrosteles severini* leafhopper. m, mitochondrion. Bar = 0.5 μm. (Courtesy of K. Hemmati).

ceptible to damage by ultraviolet-induced thymine dimerization, it appears that some *Mycoplasma* species can survive on leaf surfaces. For example, a serologically distinct organism, whose proposed name is *M. lactucae,* was isolated from nonsterilized lettuce leaves (Somerson et al., 1982; Rose et al., 1990). These studies suggest that a number of other mycoplasmas will likely be isolated from plant surfaces that are visited by insects or other animals. Future studies directed towards understanding the effects of these organisms on the microbial ecology of the phyllosphere and the relationship they have with their insect hosts should be most interesting.

Cultivation of MLOs

As previously stated, there have been no confirmed reports of continuous in vitro cultivation of nonhelical, plant pathogenic mollicutes. Some success has been achieved in maintaining the infectivity of insect-derived MLO extracts for several days (Nasu et al., 1974b; Smith et al., 1981). The infectivity of X-MLOs residing within dissected salivary glands was maintained for 120 days in insect tissue culture medium; however, there was no evidence that the MLOs within the cultured salivary glands multiplied (Sugiura et al. 1984).

Several very fastidious spiroplasmas were recently cultured in vitro by growing the spiroplasmas in media conditioned by monolayers of cultured insect cells (Hackett and Lynn, 1985; Hackett et al., 1986). Although similar attempts to infect monolayers of cultured leafhopper epithelial cells with the X-MLO were unsuccessful (Richardson and Jensen, 1971), the particular system used to culture the fastidious spiroplasmas has not yet been applied to MLO culture.

Some of the virescence MLOs have been successfully maintained for long periods of time in plantlets but not undifferentiated callus grown in tissue culture. Jacoli (1974, 1978) maintained an isolate of eastern aster yellows MLO (EAY-MLO) in carrot explants growing in plant tissue medium containing kinetin and auxin. In contrast to the numerous roots produced by healthy carrot tissues, the EAY-MLO-infected explants produced numerous shoots, but no roots. Similarly, Sears et al. (1989) were able to maintain AY-MLO-infected *Oenothera* explants in plant tissue culture. Like the MLO-infected carrots, these explants also produced numerous shoots but no roots. In both cases the MLOs grew to very high cell densities, offering a uniform and continuous supply of MLO-infected tissues which can be easily manipulated in the laboratory.

Microscopic Identification of MLOs

Electron microscopy (EM) provided the first evidence that plant yellows diseases were caused by wall-less prokaryotes rather than by viruses (Doi et al., 1967). Transmission EM is still a valuable tool for confirming the presence of MLOs in a particular plant or insect host. The reader is referred to several excellent reviews concerning the specifics of sample preparation and potential interpretation problems inherent in EM studies (Waters, 1982; Markham, 1988; Chen et al., 1989; Norris and McCoy, 1983). Because MLOs are pleomorphic organisms, neither electron nor light microscopy can be directly used to morphologically distinguish one MLO from another (McCoy, 1979). However, EM may be useful for differentiating MLOs from spiroplasmas, if the latter organisms exhibit their typical helical morphology in the tissues being examined.

Several staining procedures have been used to visualize MLOs by light microscopy (reviewed by Waters, 1982). Perhaps the most widely used light microscopic technique involves staining MLO DNA with DAPI (4′-6-diamidino-2-phenylindole), a DNA-binding fluorochrome, and examining stained tissues with an epifluorescence microscope. Although this method is considerably faster than examining tissues by EM, it requires some experience to differentiate the fluorescence of DNA-containing organelles such as mitochondria from MLOs. DAPI visualization of MLOs is most efficacious for examining high titer herbaceous plant hosts; however, if the appropriate controls are used, this technique can also be used to detect MLOs in woody plants (Seemüller, 1976; Douglas, 1986; Schaper and Converse, 1985), in which they are usually present in low numbers.

Purification of MLOs from Infected Hosts

Considerable progress has been made recently in the development of protocols to purify MLOs from infected plant and insect hosts (reviewed by Kirkpatrick, 1989). Although MLO-enriched fractions can now be routinely obtained from both infected plants and insects, much of the early work on purifying MLOs was done with infected insects. Infected insects, rather than plants, were used in these early studies because the MLO numbers were much higher in insects than in plants. The efficacy of a particular purification protocol was bioassayed by injecting

the preparation into healthy vectors and observing whether the injected insects transmitted the pathogen to test plants. Extracts derived from plants were never as infections as extracts derived from insects, possibly because of lower pathogen numbers and inhibitors present in plant extracts (Liao and Chen, 1980). Early infectivity assays helped establish the optimum buffers, pH, and osmolarity that best maintained MLO infectivity (Lee and Chiykowski, 1963; Whitcomb et al., 1968b; Smith et al., 1981). Viability of the pathogen was achieved using buffers between pH 6.5 to 8.0 containing divalent cations and glycine, and whose osmolarity was 300 to 900 mOsmol.

Most MLO purification protocols are very similar to those that are used to isolate mitochondria from plant or insect hosts (reviewed by Kirkpatrick, 1989). In such procedures, the tissue is disrupted and the MLOs are separated from host debris and large organelles by differential centrifugation. MLOs are then pelleted by centrifugation at approximately 20,000 × *g* for 20 minutes. In some cases these simple extracts have been used as immunogens for the production of MLO-specific polyclonal or monoclonal antibodies (Caudwell et al., 1982; Clark et al., 1983, 1989). However, polyclonal antisera produced against partially purified MLOs usually requires extensive cross-absorption with healthy plant extracts to reduce cross reactions with plant antigens. In other protocols, MLO-enriched extracts were further purified by repeated differential centrifugation or fractionation on sucrose (Whitcomb et al., 1968b; Nasu et al., 1974a) or Percoll[R] density gradients (Jiang and Chen, 1987; Davis et al., 1988). Other modifications of this basic isolation technique include the use of plant-cell-wall degrading enzymes to enhance the recovery of intact MLOs (Lee and Davis, 1983, 1988) and the removal of host contaminants from MLO-enriched extracts using antibodies directed against healthy host antigens (Kirkpatrick, 1986 and unpublished observations). High quality MLO preparations were also obtained by affinity chromatography using MLO-specific monoclonal antibodies (Jiang et al., 1988). However, even MLOs purified by affinity chromatography still contain some residual host contaminants which may or may not interfere with MLO-specific analyses.

Serological Detection and Antigenic Properties of MLOs

Historically, the taxonomy of mycoplasmas has relied heavily on the serological differentiation of these cultivable but morphologically indistinguishable organisms. It is now clear that like the classical mycoplasmas, MLOs can also be differentiated on the basis of their antigenic properties. The results of the following MLO serological studies are summarized in Table 1.

Several polyclonal (Pab) and monoclonal (Mab) antisera have been prepared against plant pathogenic MLOs isolated from plants. Sinha and coworkers used an elaborate purification procedure to obtain immunogens from plants infected with Canadian asters yellows (CAY), Canadian clover phyllody (CCP) and Canadian isolates of eastern X-disease (EX) MLOs (Sinha, 1974, 1979; Sinha and Chyikowski, 1984). Pabs produced against these immunogens were used in enzyme-linked immunosorbent assays (ELISA) and immunospecific electron microscopy to detect these MLOs in plants. In their studies, the CAY-MLO and the CCP-MLO were serologically indistinguishable and neither was serologically related to the EX-MLO (Sinha and Benhamou, 1983). In contrast, Clark et al. (1983) produced Pab against European clover phyllody (ECP) MLO and reported no cross reactivity between this antiserum and an isolate of European AY (EuAY-MLO). Because very high ELISA readings were obtained when strawberry plants infected with green petal disease were tested using the ECP-MLO antiserum, these two diseases are probably caused by similar, if not identical, MLOs. The apparent antigenic similarity between these two MLOs also agrees with previous insect vector transmission studies (Frazier and Posnette, 1957). Hobbs et al. (1987) produced Pab against the peanut witches' broom (PWB) MLO using an extraction protocol very similar to Clark's. No serological cross reactions were observed with the other MLOs that were examined. Similar procedures were used to prepare immunogens and Pab against four virescence MLOs (eastern and western AY, potato witches' broom and clover phyllody) (da Rocha et al., 1986). When used in an indirect immunofluorescence labelling procedure, all four antisera detected MLOs in infected periwinkle tissues and all of the antisera cross-reacted with all four MLOs.

Caudwell et al. (1982) were the first to produce MLO-specific Pab using leafhopper-derived immunogens. MLO-specific antibodies were obtained when extracts of *Euscelidius variegatus* leafhoppers infected with the MLO that causes grapevine flavescence doree (FD-MLO) were injected into rabbits. FD-MLO-specific antibodies were also produced against FD-MLO immunogens prepared from infected *Vicia faba* plants. Antisera produced against the leafhopper immunogen were most effective in detecting the pathogen in plants, and antibodies

against the plant-derived immunogen were most useful for detecting FD-MLO in leafhoppers. Antigenic relationships between the FD-MLO and other MLOs were not reported. Specific Pab were also obtained from rabbits injected with immunogens prepared from western X (WX) MLO-infected *C. montanus* leafhoppers (Kirkpatrick and Garrott, 1984). No antigenic relationship was observed between the WX- and the AY- or BLTVA-MLOs, *S. citri,* or *S. kunkelii.* However, strong antigenic similarity was found between the western and eastern strains of X-disease and the walnut bunch (WB) MLO. Weaker, but positive, ELISA readings were obtained with periwinkle plants infected with the elm yellows (EY) pathogen. Western blot analyses of infected plants showed that the major WX-MLO antigen was a 29 kDa protein which was also present in the WB- and EY-MLOs (Kirkpatrick et al., 1988b). Immunogens derived from BLTVA-MLO-infected *Circulifer tenellus* leafhoppers were used to elicit Pab against this MLO. No antigenic cross reactions were obtained between the BLTVA- and the WX- or AY-MLOs or *S. citri* (Golino et al., 1989).

Although MLO-specific Pab are comparatively easy to prepare and can potentially recognize several MLO antigens, most have relatively high background reactions with healthy host antigens. Healthy host background reactions are virtually eliminated in ELISA and immunofluorescence analyses using MLO-specific monoclonal antibodies (Mabs). Lin and Chen (1985) were the first to produce Mabs against MLOs. Mabs produced against a New Jersey strain of eastern aster yellows (EAYI-MLO) provided sensitive and specific detection of this pathogen in plants. These Mabs did not react with antigens in seven other MLO-infected plants or the two plant pathogenic spiroplasmas that were tested. Unexpectedly, EAYI-MLO Mabs did not react with other geographic isolates of AY-MLOs. These results were the first to suggest that although Mabs provide very sensitive and specific detection of a particular MLO isolate, they may be of limited utility for defining larger taxonomic groups of MLOs.

Mabs produced against the maize bushy stunt MLO (MBS-MLO) also provided sensitive detection of that MLO in infected maize by ELISA and immunofluorescence. No reactions were obtained between MBS-MLO Mabs and seven other MLOs, *S. citri,* or *S. kunkelii* (Chen and Jiang, 1988). Mabs have also been prepared against the eastern (Jiang et al., 1989) and the western (M. F. Clark, personal communication) X-disease MLOs. EX-MLO Mabs reacted with both EX- and WX-MLO antigens but no reactions occurred with plants infected with several virescence MLOs or plant pathogenic spiroplasma species. In extensive comparisons between WX-MLO Pabs and Clark's WX-MLO Mabs, both serological reagents tested positively with the same field and laboratory samples. Healthy host background reactions of the Mabs were lower than those obtained with Pabs (B. C. Kirkpatrick and M. F. Clark, unpublished observations). Pabs were produced against European aster yellows (EuAY-MLO) and Mabs were produced against the virescence MLO causing primula yellows (PY-MLO) (Clark et al., 1989). Strong heterologous ELISA reactions were obtained between PY- and EuAY-MLO antisera, suggesting that these two MLOs are antigenically similar. No reaction was obtained when either EuAY- or PY-MLO antisera were tested against European clover phyllody (ECP) MLO-infected plants, results that confirmed earlier observations (Clark et al, 1983). Similar results were obtained by Garnier et al. (1990) who produced Mabs against another ECP-MLO isolate and the stolbur MLO (S-MLO). No antigenic cross reactions were obtained when ECP-MLO Mabs were tested against another isolate of EuAY-MLO, providing additional evidence that the ECP- and EuAY-MLO are antigenically distinct. S-MLO Mabs detected this pathogen in naturally infected tomato plants, whether or not the plants showed virescence symptoms. S-MLO Mabs were highly specific for this pathogen; no cross reactions were observed with plants infected with five other MLOs or with *S. citri* or *S. kunkelii.*

In addition to characterizing the antigenic properties of MLOs these serological diagnostic reagents have been valuable tools in identifying alternate plant hosts and insect vectors of these MLOs (B. C. Kirkpatrick, unpublished observations).

Genetic Characterization of MLOs

Isolation and Composition of MLO DNA

Although antigenic properties have been the primary basis for differentiating species of mollicutes, DNA-DNA and DNA-rRNA hybridization analyses are also used to establish taxonomic relationships among other prokaryotes. Until recently it was not possible to obtain MLO DNA that was free of host nucleic acids so that direct comparisons between MLO genomes using DNA-DNA hybridization analyses were not possible. Recently, two groups have reported the purification of MLO DNA by

equilibrium centrifugation in cesium chloride/bisbenzimide gradients (Sears et al., 1989; Kollar and Seemüller, 1989; Kollar et al., 1990). Bisbenzimide preferentially binds to A·T rich DNA and, depending upon the base composition of a particular plant host, it can be used to separate MLO DNA from plant DNA. A unique band of A·T rich DNA was isolated from tissue-cultured *Oenothera* explants infected with a virescence MLO (O-MLO) (Sears et al., 1989). No hybridization occurred between this DNA and chloroplast- or mitochondria-specific hybridization probes, suggesting that this DNA band was primarily MLO DNA. The GC content of the O-MLO DNA was 29.5 mol%, a value similar to that of most culturable mycoplasmas (Stanbridge, 1979; Bové, 1984; Razin, 1985). In another study, repeated equilibrium centrifugations in cesium chloride/bisbenzimide gradients were used to purify five MLO DNAs from infected plants (Kollar and Seemüller, 1989). The GC contents of the MLO DNAs ranged from 23.0 mol% for an isolate of EuAY-MLO to 26.2 mol% for an MLO causing virescence in *Diplotaxis.* Although the presence of contaminating host DNA in these preparations was not determined, several MLO-specific fragments were cloned from one of these preparations (Kollar et al., 1990). As yet there have been no reports on the homology between various MLOs using these gradient-purified DNAs.

Taxonomic Relationships Determined by Cloned MLO DNA

Cloned fragments of the MLO genome have also provided considerable insight into grouping and differentiating MLOs. The results of comparative hybridization studies using cloned, MLO-specific DNA probes is discussed below and summarized in Table 2.

Twenty-four unique, cloned fragments of the WX-MLO chromosome were identified on the basis of hybridization with ^{32}P-labelled DNA from X-diseased but not healthy plants and insects (Kirkpatrick et al., 1987). These WX-MLO-specific fragments were used as hybridization probes to investigate the genetic relatedness of the WX-MLO with other MLOs and culturable mollicutes. No hybridization occurred between any of the WX-MLO cloned probes and DNAs extracted from seven *Mycoplasma* species or 16 strains of plant pathogenic and other spiroplasmas. In contrast, most of the WX-MLO cloned probes hybridized with DNAs extracted from plants infected with several decline agents, such as eastern X-disease, walnut and pecan bunch, and peach yellows MLOs. Only two of the WX-MLO genomic probes hybridized with DNA from several strains of western aster yellows MLO (Kirkpatrick et al., 1988b, 1990). In similar studies, several chromosomal fragments of the apple proliferation MLO (AP-MLO), a European tree decline agent, were recently cloned and characterized (Bonnet et al., 1990). Two of the AP-MLO clones that were characterized hybridized with the decline MLOs that cause apricot chlorotic leafroll and "dormancy breaking disease" of plum. Neither AP-MLO DNA probe hybridized with DNA from plants infected with EuAY- or S-MLO. These results indicate that the X-MLO and several other decline type MLOs form a cluster of genetically related organisms which are distinct from the virescence agents. The decline MLOs are even less closely related to culturable *Mycoplasma* and *Spiroplasma* spp. than they are to the virescence MLOs.

Similar hybridization analyses, using cloned fragments of an eastern strain of aster yellows (EAY-MLO), established the existence of a cluster of genetically related virescence agents (Lee and Davis, 1988). Although hybridization occurred between cloned fragments of the EAY-MLO and DNA from some decline MLOs under low stringency conditions, ^{32}P-labelled EAY-MLO RNA probes hybridized only with three other virescence MLOs under more stringent hybridization and wash conditions. Similar results were obtained using two cloned chromosomal fragments from the severe strain of western aster yellows (SAY-MLO) (Kuske et al., 1991a). Positive hybridization was obtained with DNA from 14 virescence isolates from North and South America and Europe; no hybridization occurred with eight decline agents from North America, Europe, and Thailand. In addition, it was possible to subdivide those virescence isolates that hybridized with the SAY-MLO chromosomal probes on the basis of similarities in restriction fragment length polymorphisms (RFLPs). Hybridization analyses also established that some virescence agents are genetically distinct from the "typical" AY-MLO strains that are transmitted by *Macrosteles severini.* For example, no hybridization occurred between cloned SAY-MLO probes and DNA from Canadian isolates of aster yellows, clover proliferation or potato witches' broom, nor DNA from sesame phyllody MLO-infected plants from Thailand (Kuske et al., 1991a). Neither the EAY- (Lee and Davis, 1988) nor the SAY-MLO (Kuske et al., 1991a) DNA probes hybridized with DNA from plants infected with the beet leafhopper transmitted virescence agent (BLTVA), a virescence MLO that is transmitted by *Circulifer tenellus,* a leafhopper that does not transmit the AY-MLO.

Extrachromosomal MLO DNA

Extrachromosomal DNA has been found in many of the MLOs that cause virescence in herbaceous hosts. Davis et al. (1988) were the first to clone MLO extrachromosomal DNA from a Florida isolate of the maize bushy stunt MLO (MBS-MLO). Four MBS-MLO-specific recombinant clones hybridized with several low-molecular-weight, extrachromosomal DNAs in MBS-MLO-infected corn and *D. maidis* leafhoppers. Unexpectedly, no hybridization occurred between any of the four extrachromosomal DNA probes and DNA from a Texas isolate of MBS-MLO, indicating the Texas isolate had no extrachromosomal DNA. Nevertheless, hybridization occurred between Florida MBS-MLO chromosomal DNA probes and chromosomal DNA of the Texas isolate. Symptoms produced by the Texas MBS-MLO were very similar to symptoms produced by the Florida isolates, so the function of plasmid-encoded genes in the MBS-MLO, as well as all of the other MLO plasmids identified thus far, are unknown.

Supercoiled, extrachromosomal DNAs present in three strains of western aster yellows were isolated on cesium chloride/ethidium bromide gradients (Kuske and Kirkpatrick, 1990a; Kuske, 1989). Although virus-like particles (VLPs) have been occasionally associated with some MLOs (Allen, 1972; Giannotti et al., 1973; Gourret et al., 1973), no VLPs were observed in these strains of western aster yellows infected plants (Hemmati and McLean, 1980; B. C. Kirkpatrick, unpublished observations). For this reason, these extrachromosomal DNAs are most likely MLO plasmids and not DNAs from encapsidated viruses. Four plasmids, ranging in size from 7.4 to 1.7 kbp, were isolated from the severe strain of western aster yellows (SAY-MLO). Similar, but not identical, plasmids were found in the dwarf and Tulelake strains (Freitag, 1964) of western aster yellows. The native SAY-MLO plasmids were labelled and used as probes in Southern blots of decline and virescence MLO DNA. Most of the virescence agents that were examined contained plasmid DNAs which shared some homology with SAY-MLO plasmids (Kuske et al., 1991b).

Unexpectedly, SAY-MLO plasmid DNA hybridized with MBS-MLO extra-chromosomal DNA. In reciprocal experiments, a recombinant plasmid containing a fragment of MBS-MLO extrachromosomal DNA hybridized with all of the native western AY-MLO plasmids (Kuske et al., 1988, 1991b). These results are significant because both the plant host range and the insect vectors of the AY- and MBS-MLO are presently mutually exclusive (Nault, 1980, 1985), which suggests these ecologically distinct MLOs either evolved from similar ancestors or that they occupied common habitats, or niches, at some time in the past. Both native and recombinant SAY-MLO plasmids hybridized with numerous virescence isolates from North America and Europe; however, the number and size of the plasmids in these virescence agents varied considerably (Kuske et al., 1991).

Although no hybridization occurred between SAY-MLO plasmids and DNA isolated from BLTVA-MLO-infected plants, we have identified and cloned portions of several plasmids that are present in the BLTVA-MLO (Shaw and Kirkpatrick, 1990). Thus it appears there are at least two major subgroups of the virescence agents whose chromosomal and extrachromosmal DNAs, as well as their antigenic properties, are distinct.

No extrachromosomal DNAs have been found in any of the tree decline agents examined thus far either by Southern blot analysis using AY-MLO plasmids as probe or MLO DNA electrophoresced in ethidium-stained gels (Kuske, 1989). These data provide additional evidence that the virescence and decline MLOs represent distinctly different groups of pathogens.

The identification of plasmid DNA in the virescence MLOs may provide a means for introducing foreign DNA into MLOs. It is theoretically possible to identify specific MLO genes by transposon mutagenesis using engineered MLO plasmids. For example, a Gram-positive transposon, Tn*916*, has been introduced into *Mycoplasma* and *Acholeplasma* species (Dybvig and Cassell, 1987; Dybvig and Alderete, 1988; Mahairas and Minion, 1989). In addition, it may be possible to characterize plasmid-encoded genes if MLO plasmids could be introduced into a genetically compatible, culturable prokaryote. Phylogenetic analyses suggest that *Acholeplasma* species, and perhaps even *Bacillus subtilis,* might be amenable to transformation with MLO plasmid DNA.

Phylogenetic Relationships Between MLOs and Other Prokaryotes

Nucleotide sequences of evolutionarily conserved genes, such as the 5S and 16S rRNA, have been extensively used to determine the phylogenetic relationships of the class Mollicutes (Woese et al., 1980, 1985; Rogers et al., 1985; Weisberg et al., 1989) and other prokaryotes (Woese, 1987). Because it is not necessary

to culture an organism in order to clone and sequence its rRNA genes, it is possible to determine the phylogenetic relationships of MLOs using this evolutionarily conserved marker. Early comparisons, using 16S rRNA oligonucleotide catalog sequences, indicated the culturable mollicutes were derived from a Gram-positive clostridial ancestor from which *Bacillus* and *Lactobacillus* species also evolved (Woese et al., 1980). Full-length 16S rRNA sequences provide the most comprehensive data for phylogenetic comparisons and more than 50 full-length 16S rRNA sequences of wall-less prokaryotes have now been determined, nearly all of these obtained by Weisburg and colleagues (1989).

Full-length 16S rRNA sequences have been determined for three MLOs to date. Lim et al. (1989) cloned and sequenced the 16S rRNA gene of an MLO (O-MLO) that was obtained from field-infected *Oenothera* plants in Michigan. The O-MLO is thought be a strain of the eastern aster yellows MLO because it can be transmitted by *Macrosteles severini* leafhoppers. However, the exact identity of this MLO is uncertain because symptoms produced by the O-MLO in vector-inoculated test plants are not typical of eastern AY-MLO (Sears and Klomparens, 1989). Full-length sequence comparisons of the O-MLO and other culturable prokaryotes established that the O-MLO was most closely related to *Mycoplasma capricolum* (80% homology), followed by *Bacillus subtilis,* thus establishing that MLOs are evolutionarily related to Gram-positive rather than Gram-negative organisms. Comparisons of the O-MLO 16S sequence with 16S rRNA oligonucleotide catalog sequences of selected mycoplasmas and clostridial bacteria suggested that the O-MLO was more closely related to *Acholeplasma laidlawii* than to other *Mycoplasma* or *Spiroplasma* species.

The full-length 16S rRNA sequence of another virescence agent, the SAY-MLO, has been determined (Kuske and Kirkpatrick, 1989; Kuske, 1989). The sequence of the SAY-MLO 16S structural gene was 99.2% homologous to the O-MLO, indicating that these two virescence agents are very closely related phylogenetically. Analysis of oligonucleotide rRNA catalog sequences also supported the conclusion that the SAY-MLO was closely related to *A. laidlawii.*

The 16S rRNA sequence of a decline type MLO, the WX-MLO, was also recently determined (Kirkpatrick and Fraser, 1989). The sequence of the WX-MLO 16S gene was 78% homologous to both *M. capricolum* and *B. subtilis* and only 72% homologous with *E. coli,* providing evidence that decline MLOs are also evolutionarily related to Gram-positive organisms. The WX-MLO was 89% homologous to both the SAY- and the O-MLOs. Although the 89% homology between the WX-MLO and the two virescence MLOs is higher than WX-MLO homologies with other prokaryotes, this relatively low value indicates that decline and virescence MLOs are distinctly different groups of MLOs, a conclusion supported by the results of serological and DNA hybridization analyses.

The 16S rRNA sequence of the O-, SAY-, and X-MLOs were recently compared with those or other mollicutes and Gram-positive prokaryotes (C. R. Woese, personal communication). The three MLOs were more closely related to each other than to any other prokaryotes. The MLOs formed a phylogenetically distinct cluster within the "anaeroplasma group" which contains all the *Anaeroplasma* species that were examined, as well as *Acholeplasma laidlawii* and *A. modicum* (Weisburg et al., 1989). In addition to finally establishing that MLOs are truly members of the class Mollicutes, this information may also provide valuable clues for those who are attempting to culture these obligate plant pathogens.

Several interesting structural features were also identified in the MLO rRNA operons. A $tRNA^{ile}$ gene was found in the spacer region between 16S and 23S rRNA genes of the X-, SAY- and O-MLOs. However, at least one significant difference was found between the two virescence agents. A $tRNA^{tyr}$ gene was found just upstream from the 16S rRNA structural gene in the SAY-MLO (Kuske, 1989) but not in the O-MLO (P. -O. Lim, personal communication). No tRNAs were found within a 1.2 kb region upstream from the WX-MLO 16S rRNA gene. Two putative rRNA operon promoters were identified upstream from the SAY-MLO 16S rRNA gene. These were similar to rRNA promoters identified in culturable mollicutes and *Bacillus subtilis* (Kuske, 1989). Similarly, two putative promoters, that were very similar to the rRNA operon promoter of *B. subtilis,* were identified upstream from the WX-MLO 16S gene (Kirkpatrick and Fraser, 1988a).

Further evidence that MLOs are related to Gram-positive organisms was provided by the sequence of the RNase III cleavage site in the stem region formed from sequences flanking the SAY-MLO 16S rRNA structural gene. The SAY-MLO cleavage site sequence was highly homologous to culturable *Mycoplasma* species and *B. subtilis* but not to *E. coli.* A Gram-positive RNase III cleavage site whose sequence was nearly identical to the SAY-MLO site, was identified in the WX-MLO.

The MLO rRNA sequences also provided a sensitive method for detecting very low numbers of MLOs using techniques originally developed for culturable mycoplasmas (Göbel et al., 1987). Computer-assisted sequence comparisons of the WX-MLO 16S rRNAs with the 16S rRNA sequences of other prokaryotes and plant organelles identified several oligonucleotide sequences that were MLO-specific. ^{32}P-labelled oligonucleotide probes provided 10 to 20 times more sensitive detection of the X-MLO than similarly labelled fragments of the X-MLO chromosome (Kirkpatrick and Fraser, 1989).

Conclusion

In the short period of time since the first edition of this Handbook was published, there have been several significant advances in our ability to detect and differentiate plant pathogenic MLOs. The development of sensitive, MLO-specific serological and nucleic acid hybridization assays has greatly facilitated both basic and applied studies on plant pathogenic MLOs and the diseases they cause. Genetic analyses using cloned fragments of MLO DNA, together with comparisons of MLO 16S rRNA sequences, have clearly established that the MLOs represent a diverse but distinct taxon of presently nonculturable mollicutes. The ability to isolate and characterize MLO DNA, RNA, and antigenic proteins has obviated, at least to some extent, the requirement to culture these pathogens in order to characterize some of their basic biological properties. Future classification and differentiation of wall-less prokaryotes will be based on serological, genetic, phylogenetic, and other biological data. If the criteria established for naming and classifying wall-less prokaryotes can be revised, more formal taxonomic designations may eventually be proposed for plant pathogenic MLOs.

Acknowledgments

The L-Forms of Bacteria

SARABELLE MADOFF and JOHN W. LAWSON

Introduction

It is clearly established that many or possibly all bacteria can produce L-forms as a result of the complete or partial inhibition of cell wall synthesis. The resultant wall-deficient organisms (L-forms) lack the classical bacterial structure; in culture they manifest a distinctly variant type of independent growth. Under certain conditions, L-forms have the potential to revert to the parent bacterial form.

The modern microbiologist can profit from a knowledge of the bacterial L-forms. Bacteria are exposed to traumatic influences exerted by environmental changes, host-dependent mechanisms, and biologic interdependency with other microorganisms. In this context, evolutionary trends and pathologic conditions may be the result of genetic modifications of bacteria mediated by changes in their cell wall.

In recent years, the L-forms have come to be recognized as invaluable tools in new and innovative areas of microbial research. With the recent advances in molecular biology, the L-forms are being used to study the biosynthesis of bacterial membranes, ribosomal functions, the replication of DNA, plasmid-related effects, mechanisms of antibiotic activities on bacteria and their membranes, and many other aspects of bacterial physiology at the genetic level. The study of these complex and divergent disciplines can be expected to yield valuable information as to the role of L-forms in the biology of bacteria and as to their participation and significance in infectious disease processes. For a recent review, see Madoff (1986).

The discovery of the L-forms over 50 years ago ushered in a new era in the understanding of the bacterial cell. The name L-forms (L for Lister Institute) was first proposed by Klieneberger (1935); she discovered colonies resembling mycoplasma in cultures of *Streptobacillus moniliformis* isolated from the rat, and named them L_1. Dienes (1939) studied the spontaneous development of the L_1 from *Streptobacillus* and its reversion to the bacillary form. Dienes thereby established the bacterial derivation of the L-forms. Within a few years, the spontaneous development of L-form colonies was observed in cultures of *Bacteroides, Haemophilus, Escherichia,* and *Neisseria.* For an early review, see Dienes and Weinberger (1951).

The discovery that L-forms could be induced by exposure of bacteria to penicillin (Pierce, 1942) was an important advance. Other antibiotics were found to produce a similar result by interfering with biosynthesis of cell wall. Exposure of bacteria to bacteriostatic chemicals, to phage, and to antibodies also resulted in L-transformation. In 1954, Sharp recognized that organisms lacking a rigid cell wall needed osmotic protection and he induced L-forms from group A streptococci on media containing high salt concentrations. The current belief is that conversion to L-forms may be a universal property of bacteria provided that suitable conditions for induction and growth can be determined. L-forms have been derived from bacteria of many genera (Hijmans and Clasener, 1971) as shown in Table 1.

Terminology and Biological Characteristics

An L-form is a cell-wall-deficient organism derived or induced from a bacterium following suppression of the synthesis of its rigid cell wall.

Table 1. Some bacterial genera from which L-forms have been derived.

Agrobacterium	*Erysipelothrix*	*Salmonella*
Bacillus	*Escherichia*	*Sarcina*
Bacteroides	*Flavobacterium*	*Serratia*
Bartonella	*Haemophilus*	*Shigella*
Bordetella	*Listeria*	*Staphylococcus*
Brucella	*Neisseria*	*Streptobacillus*
Clostridium	*Proteus*	*Streptococcus*
Corynebacterium	*Pseudomonas*	*Vibrio*

In culture the classical bacterial forms are replaced by soft spherical granular forms and large bodies that penetrate the agar gel and produce colonies that resemble those of the mycoplasma. Other characteristics similar to those of the mycoplasma, such as fragility, pleomorphism, and filterability, may be related to the absence of rigid wall (Dienes, 1968). These are the fundamental characteristics of the L-forms and represent the criteria by which they are recognized. Definite identification can be made microscopically by means of agar blocks stained in situ by the Dienes technique (Madoff, 1960). The terms "L-phase" and "L-phase variants" are synonymous and have been used interchangeably with the term L-forms.

Protoplasts and spheroplasts are not the same as L-forms. Rather, they are spherical structures that originate from bacteria following partial (spheroplasts) or complete (protoplasts) removal of the cell wall by enzymatic digestion in a hyperosmolar environment (Brenner et al., 1958). A major difference from the L-forms is that protoplasts and spheroplasts are unable to replicate as such. However, they may be capable of producing L-forms when transferred to solid media of the proper osmolarity. Thus, "spheroplast L-forms" and "protoplast L-forms" are descriptive for L-forms that differ in properties relating to the presence or absence of cell wall components. (Ghuysen et al., 1986).

Atypical, aberrant, transitional, or variant bacterial forms are bacteria with altered cell walls that are occasionally recovered from clinical specimens (McGee et al., 1971). These forms have unstable morphology and may require osmotic protection for isolation and growth. However, they tend to regain normal growth characteristics upon subculture without producing L-type growth. Most clinical isolates of wall-defective bacterial forms probably fall within this group (Wittler, 1968).

The ability of "unstable" L-forms to revert to their parent bacteria is an important property. When this ability is lost, the cultures are considered to be "stable." Reversion is unpredictable, however, and has been shown to occur in apparently stable L-forms. The term "stabilized" would, therefore, be more appropriate. Bacteria recovered from the L-forms most often retain the essential characteristics of the parent strains. However, certain revertant bacteria may show profound alterations that indicate that changes can occur at some time during conversion, propagation, or reversion of the L-forms (Dienes, 1970; Pachas and Madoff, 1978; Owens and Nickerson, 1989).

Given the currently available methodology, a description of the L-forms only in terms of morphology and ultrastructure is insufficient. Future investigators should include other pertinent data in the description of the organisms, such as origin of the parent bacterium, method of L-transformation, requirements for osmotic protection, tendency for reversion, extent of the wall defectiveness, and, if possible, some comparative information on the physiological and biochemical properties of the parent, the derived L-forms, and the revertant bacteria. In this manner, the nomenclature will be clarified and the essential information regarding the L-cultures will be made available. For detailed studies of the physiology and biochemistry of the bacterial L-forms in comparison with mycoplasma, see Smith (1971, 1978).

The production of L-forms may reflect genetic differences among the bacteria in a population. In one well-known experiment with *Streptococcus*, only 1 colony out of 20 was shown to produce progeny capable of L-transformation (Hijmans and Dienes, 1955). Biochemical studies support the hypothesis of genetic determinants in the transformation to the stable L-form state. Stable L-forms of streptococci were shown to be defective in important stages of cell wall biosynthesis. Altered constituents of cytoplasmic membrane (Cohen and Panos, 1966) and the lack of certain cell wall components (King et al., 1970) have also been demonstrated. Gregory and Gooder (1977) noted the loss of enzyme function is *S. faecium* L-forms at the membrane stage of peptidoglycan synthesis. Pachas and Shor (1977) suggested that penicillin had a mutagenic effect, based on structural and functional changes in *Proteus* L-forms. Differences in antibiotic sensitivity patterns seen in L-forms of various species are also suggestive of genetic modifications (Schmitt-Slomska and Roux, 1977). Stable L-forms of a phytopathogenic bacterium, *Erwinia*, have been produced by ultraviolet irradiation with apparent mutagenic effect (Cabezas de Herrera and Garcia Jurado, 1977).

There is a paucity of studies at the molecular level. An important contribution in this area was made by Hoyer and King (1969), who demonstrated the loss of a portion of the chromosomal DNA in a stable L-form of *Streptococcus faecalis*. Wyrick et al. (1973) used DNA transformation to transfer the stable L-form state to intact cells of *Bacillus subtilis*. Further studies by molecular biologists should do much to elucidate the nature of the L-forms and to explore their role as a factor of genetic change in bacteria. (For review and discussion, see Gilpin and Young, 1986.)

Induction of L-forms: General Principles

The techniques used for the induction of L-forms have been described in several diverse publications (Dienes and Weinberger, 1951; Gooder and Maxted, 1961; Guze, 1968; Hijmans et al., 1969; Lawson, 1982; Madoff, 1986; Madoff et al., 1967; Sharp, 1954). The general principles of induction and maintenance will be reviewed here and detailed directions for particular strains will be given.

The conversion of a bacterium to the L-form depends on the species, the strain of the species, and the experimental conditions. In general, induction is accomplished by exposing bacteria to penicillin or other β-lactam antibiotics on a suitable medium. Important aspects of the medium are its physical and chemical properties, which include the consistency of the agar gel, the presence of animal serum, and, especially, the osmolarity (Dienes and Sharp, 1956).

In general, the L-forms prefer a fairly soft medium with the addition of 10–20% of serum. Many bacteria, notably the Gram-negative *Proteus, Salmonella,* and *Shigella* species, can be converted to L-forms on media containing the normal concentration of sodium chloride (0.5%). Others require a hypersomolar environment for stabilization. These include the Gram-positive bacteria (e.g., *Streptococcus, Staphylococcus, Corynebacterium, and Listeria*) and some Gram-negative species (e.g., *Neisseria, Serratia, and Pseudomonas*). Sodium chloride (1–5%) is the commonly used osmotic stabilizer. Other neutral salts (e.g., potassium chloride, magnesium chloride, and phosphates) have also been used. Sucrose, in concentrations ranging from 5–20%, plus Mg^{2+} can be more effective for osmotic stabilization in some strains. The combination of sodium chloride and sucrose in varying concentrations has been successful in some experiments. Polyvinylpyrrolidone (PVP) has also been found to support L-form growth in several bacterial species (Lawson and Douglas, 1973; Wyrick and Gooder, 1977).

Often, even a slight modification in the concentration of inducing agent or osmotic stabilizer may make a decisive change in the success of an experiment. Anaerobiosis may be necessary for L-transformation for some species; for others it is helpful for primary induction. The L-cultures can later be adapted to aerobic growth. Certain strains of bacteria appear to be impervious to all known methods of induction.

The penicillins, with their action on the peptidoglycan cross-linkages of bacterial cell wall, are the most effective inducing agents. Other antibiotics that act on the cell wall (cycloserine, ristocetin, bacitracin, vancomycin, and the cephalosporins) have also been shown to produce L-forms. High concentrations of certain amino acids, notably glycine, methionine, and phenylalanine, have been shown to produce L-forms from some bacteria. Inorganic salts such as mercury, lithium, and cadmium have also been used to produce L-type growth.

L-forms can be induced by certain enzymes, particularly lysozyme, that digest the peptidoglycan of the cell wall of bacteria. The bacteria are grown in osmotically protective media and are treated with the enzyme. Protoplasts are released which then produce L-forms when transferred to appropriate hyperosmolar solid media (King and Gooder, 1970; Madoff et al., 1967) (see Fig. 1). In 1961, Gooder and Maxted produced protoplasts of group A streptococci using a phage-associated muralytic enzyme found in a group C phage lysate. After inoculation on appropriate agar media, a high yield of L-forms developed. This method has been successfully applied to many other strains of *Streptococcus* (Hryniewicz, 1977).

For the induction of L-forms with penicillin, a culture is grown in broth medium for several hours. A small aliquot of broth culture is then spread over the surface of an appropriate agar medium and allowed to dry. A penicillin gradient is established in the plate by means of antibiotic discs saturated with varying concentrations, or the penicillin is introduced into small troughs cut in the agar. Other inducing agents (antibiotics, lysozyme, and amino acids) may also be tested in this manner. The concentration of the inducing agent may be a critical factor; later, the appropriate concentration can be incorporated into the medium for maintenance of the L-cultures. The use of pour plates may be effective; the inoculated agar medium is poured into a plate containing a thin layer of solid medium with similar nutrient and penicillin concentrations.

The experimental bacterial culture should be tested on a variety of media, both with and without osmotic stabilizers. L-forms have been obtained on routine culture media (e.g., horse blood agar), even from strains that would seem to require high salt concentration. L-forms induced on media of high osmolarity can sometimes be adapted to media of normal osmolarity. Adaption may represent either selection or mutation of viable organisms (Hijmans and Clasener, 1971; Leon and Panos, 1976; Panos, 1986).

L-forms of some organisms (e.g., *Proteus* and *Bacillus* species) may be formed several hours after exposure of the bacteria to penicillin

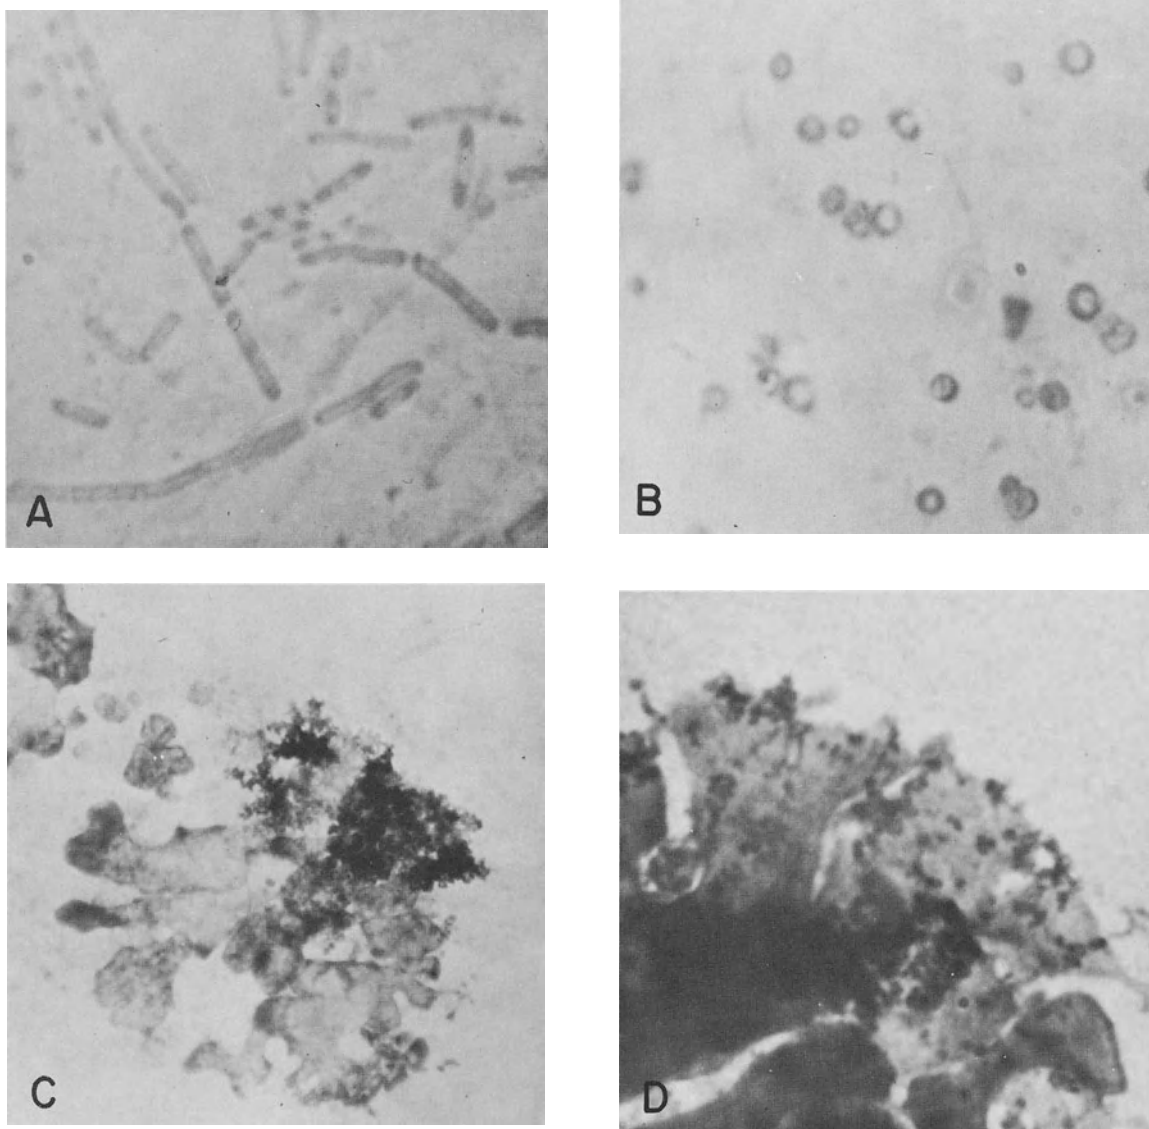

Fig. 1. Induction of L-forms of *Bacillus* species by means of lysozyme treatment. Photomicrographs made from Dienes-stained preparations. ×2,250. (A) Organisms grown 2 h in broth medium. (B) Following incubation for 2 h, in the presence of lysozyme, protoplasts are formed which are then transferred to hypertonic L-form agar medium. (C) Protoplasts enlarge to large body forms with granular elements developing into L-forms colony. (D) Detail of periphery of mature L-colony.

whereas others (e.g., *Streptococcus, Staphylococcus,* and *Listeria*) may take several days or weeks to develop. Successful transfer of the L-culture depends on the viability of the organisms; some require frequent transfers and others remain viable for extended periods.

Subcultures are made from agar to agar by the "push-block" technique, in the manner used for mycoplasma. A block of agar bearing L-form growth is cut from the plate and pushed gently along the surface of the fresh medium. The agar block should be left on the plate because growth in the transplant may occur only under the block. Growth in broth is also initiated with agar blocks, but in contrast to mycoplasmas, is often difficult to obtain. A long period of adaptation to growth in broth may be necessary to obtain an adequate concentration of viable organisms. This difficulty has hampered the study of many important biological properties of the bacterial L-forms. An alternative method of inducing broth cultures is by the use of a diphasic medium. The appropriate broth is added after the production of L-form growth on agar slants in tubes of flasks. After further incubation, the L-colonies may be dislodged by shaking or by the use of a Vortex mixer, and serial subcultures in broth are continued.

Growth in chemically defined media is not easily obtained; only a few species of L-forms have been adapted to grow in such media (van Boven et al., 1967; Gilpin et al., 1973; Bacigalupi and Lawson, 1973). Periodic transfer of broth cultures to agar are always necessary to determine viability as well as stability of the L-cultures.

Reversion and Identification of Revertants

Transfer of freshly isolated L-colonies in the absence of inducing agent will often result in reversion to the parent bacterium. For some species, when the cultures have become stabilized reversion can no longer be effected under any known circumstances. Special techniques have been devised to induce reversion of L-forms. Thus, reversion of *Bacillus subtilis* has been achieved by changes in the physical environment, e.g., by increasing the agar concentration, by the use of 15–35% gelatin in the medium, or by the application of membrane filters (Landman et al., 1968). Similar techniques using gelatin media were employed successfully with *Streptococcus* L-forms (King and Gooder, 1970; Wyrick and Gooder, 1977). In rare instances, reversion of L-forms has been influenced by the presence of factors produced by other bacteria or fungi. Landman and Halle (1963) induced reversion of *B. subtilis* L-forms by using *B. subtilis* cell wall material as a primer for wall regeneration. In L-forms of *H. influenzae* growth and reversion were found to be enhanced by a low-molecular-weight peptide produced by a strain of *Neisseria perflava* (Madoff, 1977, 1979).

The identification of an L-form culture from an unknown source depends, to a large extent, on its ability to achieve reversion. In cases where the L-form is no longer revertible, DNA-base composition and DNA hybridization may provide information as to its origin. Serological testing by agglutination, complement fixation, and fluorescent antibody methods may be useful for identifying unknown L-forms (Feinman et al., 1973; Lynn and Haller, 1968). Modified biochemical tests, useful for bacteria and their derived L-forms, can aid in characterizing and identifying stable, nonreverting L-forms (Cohen et al., 1968). Comparison of membrane proteins by polyacrylamide gel electrophoresis appears to offer a reliable method for comparing L-forms and bacteria (King et al., 1969; Gilpin and Young, 1986). Further studies are needed to detect key antigenic and metabolic markers for the L-forms.

Induction of L-Forms: Selective Procedures

Variations in requirements for nutrients, osmotic protection, inducing agents, and gel consistency make it necessary to tailor the techniques to the experimental organism. The following media and methods have proved successful with certain strains of selected species:

Gram-Negative Species (Dienes and Weinberger, 1951; Madoff and Pachas, 1970)

For induction and maintenance of L-forms of Gram-negative species (*Proteus, Salmonella, and Shigella),* a simple medium consisting of trypticase soy agar (BBL) or brain heart infusion (Difco), containing 10% horse serum will support L-form growth. Yeast extract (5%) may be added. Penicillin concentrations vary according to the strain. Anaerobic incubation may be useful. Other Gram-negative species may require a hyperosmolar environment. As examples, *Escherichia coli, Serratia marcescens,* and *Klebsiella* and *Pseudomonas* species have been converted to L-forms and maintained only in the presence of high salt or sucrose concentrations (Guze et al., 1976; Lederberg and St. Clair, 1958).

High-Salt-Requiring L-Forms (Marston, 1968; Sharp, 1954; Madoff, 1970)

For the induction and propagation of L-forms requiring high-salt concentration (*Streptococcus, Staphylococcus, Corynebacterium,* and *Listeria,* an all-purpose L-form medium is prepared in the author's laboratory as follows:

To 300 ml of distilled water is added 12 g of trypticase soy agar (BBL). The solution is thoroughly mixed and autoclaved without previous heating. The agar is cooled to 56°C (in a water bath) and the following sterile components are added in the order listed (it is advisable to warm the solutions slightly and to mix well after each addition): 30 ml of a 30% solution of NaCl, 30 ml of inactivated horse serum (56°C for 30 min), and 15 ml of yeast extract. The inducing agent may be incorporated into the medium or added, as noted above. The medium is poured into sterile petri dishes; plates are used after standing overnight at room temperature.

This medium is also useful for maintaining stock L-form cultures which normally do not require increased salt concentration e.g., (*Proteus* and *Salmonella.,*).) For maintenance, penicillin is added to the medium in concentration of 500–1,000 units per milliliter.

Liquid media that can be used are Todd-Hewitt or Mycoplasma Broth Base (BBL) containing similar concentrations of horse serum, yeast extract, NaCl, and the appropriate antibiotic. Growth may be enhanced initially by the addition of 0.1% agar.

Sucrose in varying concentrations has been used most successfully as an osmotic stabilizer with L-forms of numerous bacterial species (*Listeria,* Brem and Eveland, 1968; *Neisseria,* Roberts, 1966; *Streptococcus,* Madoff, 1970). Madoff and Dienes (1958) induced growth of

L-forms of pneumococci in media containing 10–20% sucrose, 0.01% $MgSO_4 \cdot 7H_2O$ and 10% horse serum. With the pneumococcus, the critical factor was the appearance of L-forms only in a narrow range of low penicillin concentrations (0.1–0.3 units per milliliter).

Streptococcus by Lysozyme (Gooder, 1968; Wyrick and Gooder, 1977)

Protoplasts were prepared in the following manner: Cultures of *Streptococcus faecium* strain F 24 were grown overnight (stationary phase) in trypticase soy broth, harvested, and washed three times in distilled water. Sucrose (0.6 M) or polyethylene glycol (Carbowax 4000, Union Carbide Co.) 8% (w/v) was used as osmotic stabilizer in 0.01 tris-chloride buffer, pH 7.1. A mixture of $2 \times 10_9$ streptococcal colony-forming units (CFU) and 200 μg lysozyme (Nutritional Biochemicals Corp.) per milliliter was incubated at 37°C for 2 h. Tenfold serial dilutions of the protoplast suspension were then plated onto the surface of tryptone soy agar (Oxoid) containing 0.43 M NH_4Cl, 0.5% (w/v) additional glucose, and 2% inactivated horse serum. Incubation of the plates was at 37°C. L-colonies could be counted in 2–5 days.

Broth medium for *S. faecium* L-forms consisted of Albimi brucella broth (Gibco Diagnostics) prepared in 0.43 M NH_4Cl with 0.5% glucose added. Reversion medium consisted of tryptone soy broth prepared in 0.6 M sucrose and 35% gelatin (Difco) as the solidifying agent. Plates were incubated at 25°C.

Neisseria (Lawson, 1986; Roberts, 1966; Roberts and Wittler, 1966)

L-forms of *Neisseria meningitidis* were produced with penicillin using the gradient plate technique. The medium consisted of brain heart infusion (BHI; Difco) of pH 7.2–7.4 containing 1.2% agar, 10% sucrose, 0.5% yeast extract, and 10% inactivated horse serum. L-forms obtained were serially propagated on media containing benzylpenicillin (1,000 units per milliliter). Incubation of plates was at 37°C in CO_2 (candle jar). L-forms of *N. meningitidis* have also been produced by methicillin, ampicillin, cycloserine, cephalothin, ristocetin, bacitracin, and vancomycin.

L-forms of *N. gonorrhoeae* were induced and propagated under similar conditions with the exception that 100 units penicillin per milliliter was required. Growth of L-forms in broth was obtained by the use of diphasic media. Agar slanted in flasks was inoculated and then overlayered with BHI broth of similar composition but containing 0.01% agar. Frequent serial transfers were required before heavy L-form growth was obtained in broth lacking traces of agar.

Lawson and Bacigalupi (1977) produced L-forms of *N. gonorrhoeae* using penicillin and L-form media supplemented with 7.0% PVP as osmotic stabilizer. The PVP was subjected to extensive dialysis before use. Induction frequencies were higher than those obtained in the presence of sucrose. Two other antibiotics which inhibit cell wall synthesis, cephalothin and D-cycloserine, also permitted L-transformation; transformation did not occur with vancomycin, bacitracin, or novobiocin. The L-forms of *Neisseria* species were reviewed by Lawson (1986).

Identification of L-Forms

Transformation of bacteria to L-forms may occur in periods ranging from several hours to several days. Cultures must be examined frequently. In a penicillin gradient plate, L-colonies may be detected by the naked eye or with a hand lens in the zone of penicillin inhibition. Microscopic examination under oil immersion is necessary for the identification of L-form colonies. The Dienes technique of stained agar preparation is recommended (Madoff, 1960). The method is simple and equally applicable to mycoplasma; it is indispensable for distinguishing L-colonies and viable organisms from tiny bacterial colonies and from artifacts.

The Dienes-staining solution is made by dissolving 2.5 g of methylene blue, 1.25 g of Azur II, 10 g of maltose, 0.25 g of NA_2CO_3, and 0.2 g of benzoic acid in 100 ml of distilled water. A thin film of stain is painted on a coverslip by means of a cotton applicator and allowed to dry. Many coverslips can be prepared at a time and stored for future use. The coverslip is cut into convenient squares with a diamond pencil. A block of agar bearing suspected colonies is cut from the plate and placed face up on a glass microscope slide, and the stained coverslip is placed face down on the agar. The preparation is then ready for microscopic observation.

Microscopically, L-colonies and mycoplasma colonies stain a deep blue at the center and pale blue at the periphery. Nonviable organisms and artifacts either do not stain or they assume a pinkish to violet hue. Viable bacterial colonies also take the Dienes stain. Decolorization of the stain may occur in bacterial colonies, as in large L-colonies, if the preparation is not examined at once. Contrary to other reports, decolorization of the Dienes stain is not a criterion for distinguishing between mycoplasma and L-form colonies. Identification is based rather on the distinctive morphologic characteristics of the organisms.

Morphology and Ultrastructure

The use of stained agar preparations and oil immersion magnification permits the observation of the transformation from bacteria to L-forms to be followed in serially examined

blocks of agar. The initial change is the enlargement of the bacterial cell to produce a "large body." In some instances, large bodies are formed during division when swelling occurs within segmenting cells. The large bodies appear to form a connecting link between the growth of bacteria and the transformation of L-forms (Dienes, 1968). The large body stage may be followed by fragmentation of these forms with release of typical bacterial forms. Alternatively, granular elements of varying size develop within or at the periphery of the large bodies; these soon penetrate the agar and multiply, forming an L-colony. The L-colony may grow to resemble the mycoplasma, with dense central growth into the agar surrounded by a periphery of surface growth ("fried egg" appearance), as shown in Fig. 2A; or the colony may become grossly irregular in shape and contour (Fig. 2B). L-colonies are usually larger and of coarser appearance than those of the mycoplasma. The distinctive morphology of the L-form colonies results from the growth into the agar of coarse granular elements, the presence of large bodies, and the complete absence of any residual bacterial forms (Dienes, 1939, 1968, 1970).

Young L-colonies of some bacterial species, notably, *Haemophilus influenzae, Corynebacterium* species, various streptococci, and *Streptobacillus moniliformis,* can be very small, irregular, and consist of very small granular forms. Therefore they can be difficult to distinguish from mycoplasma colonies purely by morphology. A problem can arise if such tiny colonies are produced on penicillin-containing media inoculated primarily for the isolation of mycoplasma from clinical material. In such cases, the final identification of the L-forms is by proof of derivation from the bacterium by their reversion to the parent, or by serological or biochemical means. This may present considerable difficulty in some instances.

Two morphologic types of L-colonies have been described, the A-and B-type L-forms (Fig. 3). Partial loss of cell wall by the bacteria usually produces the highly revertible B-type L-forms (Fig. 3, middle), whereas the complete loss of cell wall yields the stable or difficult-to-revert A-type L-forms (Fig. 3, bottom). Gram-positive organisms such as streptococci, staphylococci, and corynebacteria tend to produce A-type colonies almost exclusively.

Enterobacteriaceae and other Gram-negative species may produce B-type L-forms predominantly, but can also produce the stable A-type. In *Proteus,* for example, L-colonies growing on agar medium are distinguished by their small size, fine granularity, and scarcity of large bodies. With electron microscopic examination, they are seen to be devoid of cell wall (Dienes and Bullivant, 1968). The pleomorphic elements are bound by a single unit membrane and they are filled with ribosomes and DNA material. Their resemblance to mycoplasma is notable. Mesosomal bodies are absent. By light microscopy, the B-type colonies appear to be composed almost entirely of large bodies. When examined with the electron microscope, L-organisms of the B-type show the presence of cell wall components apparently similar to the wall of the parent bacteria, but lacking its rigidity.

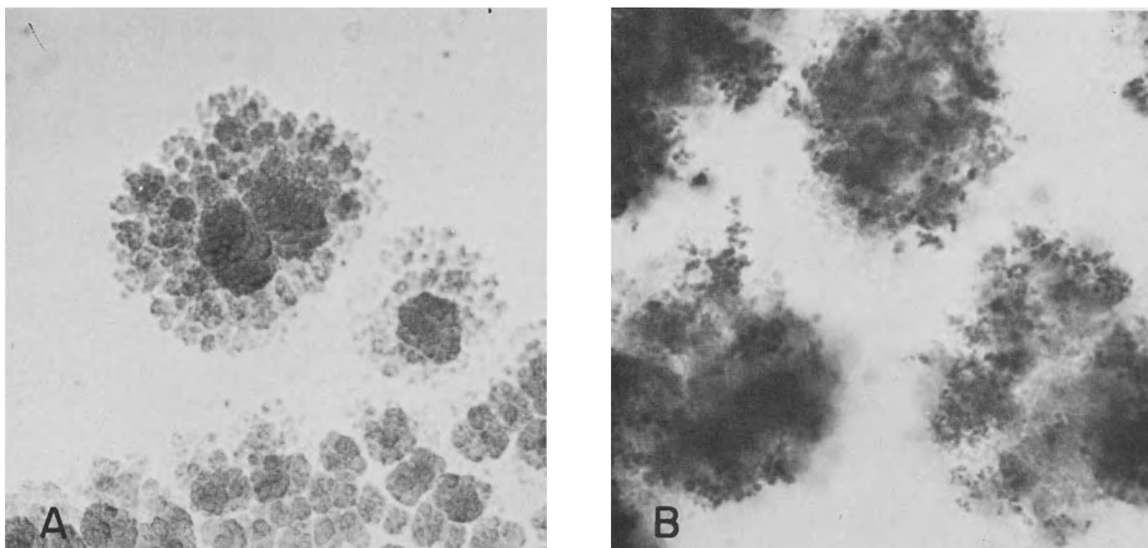

Fig. 2. (A) L-forms of *Neisseria gonorrhoeae.* ×65. (B) L-forms of *Streptococcus pyogenes.* ×110.

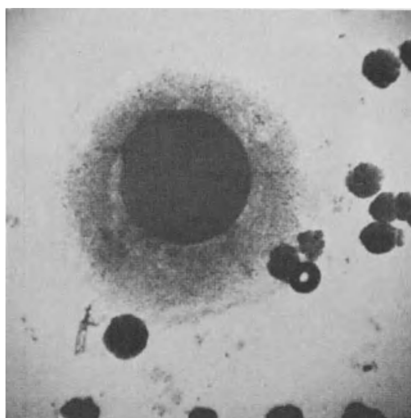

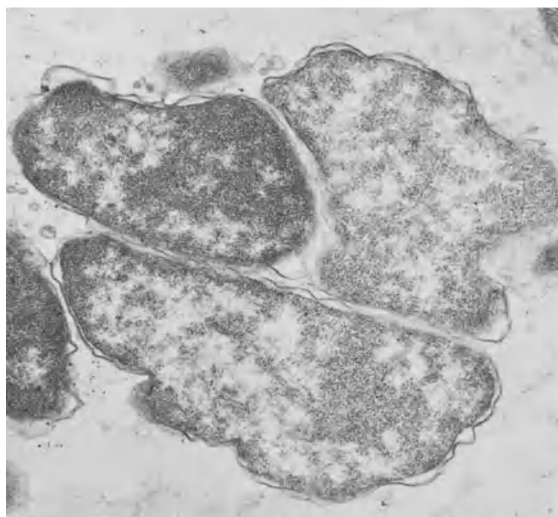

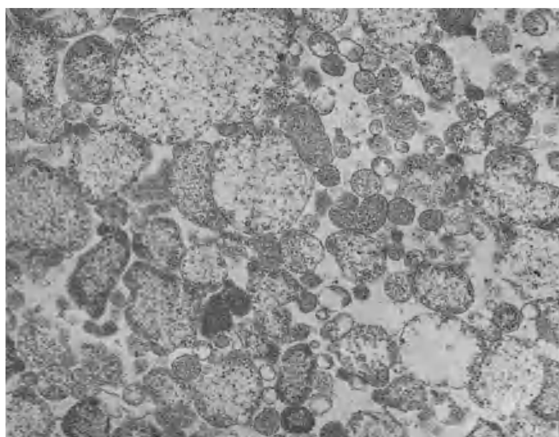

Fig. 3. L-forms of *Proteus*. In the electron micrographs, the presence of cell wall constituents is clearly visible in the B-type (middle photograph). In the A-type (bottom photograph) there is only the cytoplasmic membrane. Note the size difference between the colonies of A- and B-type L-forms (top photograph). ×65. [Reproduced by permission of the American Society for Microbiology (Pachas and Madoff, 1978).]

The presence of altered mucopeptide layers in revertible B-type L-forms of *Proteus* has also been noted (Cole, 1971).

Similarly, in *Proteus mirabilis,* exposure of the bacteria to β-lactam antibiotics has led to the production of the stable "protoplast L-forms" and the unstable "spheroplast L-forms," the latter retaining portions of defective cell wall and the former having the plasma membrane as the sole integument. With a long period of subcultivation of the spheroplast L-forms in the presence of benzylpenicillin, spheroplast L-forms can be detected that are stable and have lost the ability to revert (Martin et al. 1977). Concomitantly, these forms show resistance to the action of benzylpenicillin and mecillinam combined. Thus, as emphasized by Dienes (1970), the presence or absence of cell wall constituents does not appear to be the decisive factor in the ability of an L-form to revert to the parent form. At the present time, the mechanism by which these "mutants" are formed remains unexplained. (For a comprehensive review of B-lactam induced *Proteus* L-forms, see Ghuysen et al., 1986.)

Conflicting morphological descriptions are also given for other L-forms, particularly of the Gram-negative species. In *Escherichia coli, Neisseria meningitidis,* and *Brucella abortus,* L-forms have been shown to possess a layer of damaged cell wall external to the cytoplasmic membrane. In PVP-stabilized L-forms of *Neisseria gonorrhoeae* (Lawson and Bacigalupi, 1977) and in L-forms of *Haemophilus influenzae* (Madoff, 1977), only the unit cytoplasmic membrane was visible. In studies of thin section of *Bacillus licheniformis, Bacillus subtilis,* and *Salmonella paratyphi,* no trace of cell wall could be seen and the organisms were bounded only by cytoplasmic membrane (Wyrick and Rogers, 1973).

D. Albrewczynski and J. W. Lawson (unpublished observations) have isolated from gelatin a low-molecular-weight (<1,000 MW) peptide which, on addition to a culture of stable L-forms of *S. faecalis* strain F24L, induces near-complete conversion of the culture to large bodies. This peptide was obtained after 4 days of dialysis of 60% gelatin. The dialysate was then filtered through a 1,000 MW cutoff filter using an Amicon ultrafiltration apparatus. Upon freezing the filtrate, biologically active crystals precipitated. The crystals were recovered by filtration and solubilized in L-broth. The induced large bodies attained diameters of more than 20 μm and upon rupture-released viable units. Imidazole (30 μm), a cyclic AMP (cAMP) phosphodiesterase stimulator, induced similar changes in the L-form cultures. On the other

hand, the anti-pyretic analgesic drug indomethacin, a cAMP phosphodiesterase inhibitor, inhibited large body formation in the presence of the gelatin factor but not imidazole. The level of cAMP in L-form broth cultures and cultures supplemented with indomethacin rose steadily during exponential growth and then fell rapidly. The cAMP levels in the gelatin factor and imidazole supplemented cultures remained low until the stationary phase and then rose slowly. Electron microscopy revealed that large bodies in imidazole supplemented cultures appeared devoid of internal membranes. In contrast, large bodies from cultures containing the gelatin factor were highly vacuolated and contained viable granules.

By electron microscopy, stable L-forms of a strain of *Escherichia coli* show the presence of laminate structures and microtubules (Eda et al., 1976) resembling similar configurations previously observed in *Streptococcus faecalis* (Cohen et al., 1968) and in *Pseudomonas* species. Microtubule-like cores have also been observed in thin sections of L-forms of *Nocardia* (Beaman, 1986). The nature and function of these structures have not been established.

Replication and Reversion

As seen with transmission and scanning electron microscopy, L-forms of diverse bacteria species are surprisingly similar in their morphology and reproductive processes. Although organisms as small as 200 to 300 nm have been seen, the size of the smallest units which are viable and capable of reproduction remains unclear. Like those of the mycoplasma, the mechanisms of replication appear to vary from simple binary or asymmetric fission to budding or segmentation of small, dense bodies from large, spherical, or filamentous forms in sequential growth. In *Proteus* L-forms, sequential enlargement of protoplasmic bodies appears to be followed by release of new viable granules (Dienes and Bullivant, 1968; Cole, 1971). Thin sections of L-form colonies of *Haemophilus influenzae* grown within agar reveal small, dense bodies seen as condensations at the periphery of large cells apparently capable of detachment as budding forms (Madoff, 1977).

Among the Gram-positive bacteria, growth and reversion of L-forms have been studied in *Bacillus subtilis* (Landman and Forman, 1969; Landman et al., 1968), *Bacillus licheniformis*, (Elliott et al., 1975), *Streptococcus pyogenes* (Cole, 1970), *S. faecalis* (Green et al., 1974b), and *S. faecium* (King and Gooder, 1970; Wyrick and Gooder, 1977). Of particular interest in these reports are the studies that describe the sequential stages of reproduction and the reversion of L-forms to bacteria.

Green et al. (1974b) have proposed a reproductive cycle for L-forms of *S. faecalis*. Small, dense, nonvesiculated L-form bodies are thought to divide by simple binary fission and budding and develop within vesicles of mature "mother" forms; under certain conditions, these dense forms may undergo transition and revert to the bacteria. Reversion may be accompanied by the formation of mesosome-like structures in a manner similar to that seen in *B. subtilis* (Landman et al., 1968). In a study of *S. faecium* with ferritin labeling, reversion appears to arise through excretion of cell wall material around the unstable L-forms. Pieces of wall associated with cell membrane form a scaffolding to create the intact (complete) bacterial cell wall (Wyrick and Gooder, 1977).

Antibiotic Sensitivities of L-forms and Parent Bacteria

The susceptibilities of L-forms to antimicrobial agents have been reviewed in several publications (Hijmans, et al., 1969; Schmitt-Slomska and Roux, 1977. For a recent review, see Schmitt-Slomska, 1986). Although the subject is too extensive to treat here, a few general statements can be made.

L-forms are not susceptible to the β-lactams or to other drugs that inhibit the synthesis of the bacterial cell wall. In recent years, the interaction of β-lactams with bacteria has been the focal point of extensive investigations. Such studies show the existence of multiple, functionally different penicillin targets: pencillin-binding proteins (PBPs), penicillin-sensitive enzymes, and murein-hydrolases have been described. The modes of action of other inhibitors of peptidoglycan synthesis (e.g., bacitracin, ristocetin, and D-cycloserine) are poorly understood. Neither has shown any effect on the growth of L-forms.

Polymixin B increases the permeability of the cell membrane through affinity for the phospholipid of the membrane. It has been shown to exert a greater effect on L-forms than on the parent bacteria. L-forms derived from polymyxin-resistant Gram-negative bacteria, *N. gonorrhoeae, Brucella melitensis*, and *Proteus* species are as resistant to polymyxin as the parent bacteria.

The broad-spectrum antibiotics exert their primary influence by inhibition of nucleic acid functions and protein synthesis. They have, in

general, a greater effect on the L-forms than on the parent bacteria. Greater susceptibility has been shown by the L-forms of *S. faecalis* to the tetracyclines and to the aminoglycoside antibiotics, kanamycin, streptomycin, and vancomycin (Montgomerie et al., 1966). *Staphylococcus* L-forms have also shown greater susceptibility to the tetracyclines. In *N. meningitidis* and *N. gonorrhoeae,* both parent bacteria and derived L-forms showed similar susceptibilities to tetracylcine, novobiocin, erythromycin, and sulfadiazine (Roberts, 1966; Roberts and Wittler, 1966). More recent studies with *Neisseria* L-forms (Lawson and Bacagalupi, 1977) showed considerably greater susceptibility of the L-forms than the parent to the same antibiotics. The authors explain the divergent results as being due to the complete absence of cell wall constituents in the PVP-stabilized forms of *Neisseria* as opposed to those induced on sucrose-containing media.

Studies with the L-forms of *Proteus* species (Ghuysen et al., 1986) and with *Streptococcus pyogenes* (Leon and Panos, 1988) have shown changes in numbers and relative concentrations of penicillin-binding proteins with the loss of normal cell synthesis.

In summary, the L-forms share with their parent bacteria, to a greater or lesser degree, susceptibility to antibiotics other than those that act on bacterial cell wall. Agents that exert their influence on cytoplasmic membrane tend to have a greater inhibitory effect on the wall-defective forms. Recent studies confirm the unpredictability of the degree of susceptibility of the L-forms in comparison with the parent bacteria, and, in particular, with bacterial revertants from L-forms. Alterations in biochemical or genetic properties of the cytoplasmic membranes following prolonged cultivation in the L-form may be important factors. Should the L-form be found to play a significant role in infectious disease, these considerations could be important (Schmitt-Slomska, 1986).

Occurrence and Pathogenicity

The controversial aspects of L-forms as pathogens have been discussed in several publications (Clasener, 1972; Hijmans et al., 1969; Kagan et al., 1977; Pachas and Madoff, 1978; Roux, 1977; Wittler, 1968). For a thorough review, see Pachas (1986).

L-forms of the following species have been found to be adaptable to growth in tissue cultures of diverse origin: *Brucella abortus* in hamster kidney cells (Hatten and Sulkin, 1968); *Streptococcus faecalis* in human embryonic kidney cells (Green et al., 1974a); and *S. pyogenes* in human heart cells (Leon and Panos, 1976). In the last example, a marked cytotoxic effect was found with a L-strain adapted to physiologically isotonic environment (Panos, 1986).

Early experiments with L-forms in animals failed to show any pathogenicity unless it was caused by the revertant bacteria, as in *Streptobacillus* and *Listeria,* or unless toxins were produced, as in *Clostridium* and in *Vibrio* species. *Staphylococcus* L-forms failed also to colonize experimental endocarditis in rabbits (Linneman et al., 1973). The persistence of L-forms of *Streptococcus* has been shown in mouse experiments, but pathogenic effects have not been noted (Schmitt-Slomska et al., 1967). L-forms of *Streptococcus pyogenes,* which had been adapted to grow in isotonic conditions, survived in immunosuppressed mice (Panos, 1986) suggesting that the minimal response of the mouse (host) may play a role in suppressing the L-forms in vivo.

Some recent studies in vivo suggest a pathogenic role for the L-forms. Khostikian et al. (1987) have shown that the intraperitoneal inoculation of stable L-forms of group B streptococci into animals led to a progressive inflammatory, necrotic and sclerotic degeneration of the hypothalmus, hypophesis, and adrenal glands. Persistence of the organisms appeared to result in hormonal disturbances. Owens (1987) demonstrated that L-forms of *Staphylococcus aureus* could be isolated from bovine mastitis lesions following penicillin treatment. After cessation of therapy, the cows that harbored L-forms yielded the parent organisms. This observation may perhaps account for the poor response of staphylococcal bovine mastitis to treatment with antibiotics.

The L-forms of *Nocardia* have clearly shown their pathogenic potential. L-forms of actinomycetes, *Nocardia, Actinomyces,* and *Actinomadura* have been isolated from infected tissues of humans and animals (Beaman, 1982, 1985, 1986; Buchanan et al., 1982). The possible relationship between these L-forms and clinical manifestations have been studied. It was shown that the immunologically intact host induced the formation of L-forms (probably by activated macrophages) (Bourgeois and Beaman, 1974), which persisted within the tissues for long periods. In contrast, L-forms were not isolated from T-cell deficient hosts (Beaman, 1980; Beaman and Scates, 1981). In experimental murine infections with *Nocardia caviae* (Beaman, 1980; Beaman and Scates, 1981), it was shown that L-forms could grow in tissues to form granules characteristic of those found in mycetomas. Frequently, the L-forms reverted to the parental

cell so that both cell types could be recovered from these granules; however, some remained composed entirely of bacterial L-forms. It was shown that in vitro induced L-forms of *N. caviae* injected into mice induced mycetomatous disease. Furthermore, the L-forms from these lesions could be isolated in vitro, and transmitted to new animals, with the resultant formation of new lesions, thus, fulfilling "Koch's postulates" for the pathogenicity of *Nocardia* L-forms (Beaman, 1980, 1982, 1985; Beaman and Scates, 1981).

Summary

The pathogenicity of the bacterial L-forms remains unclear. Certain factors in persisting and recurrent infections may predispose to the production of wall-defective organisms. Factors such as the dissolution of bacterial cell wall by immune mechanisms, by cellular enzymes, or by antibiotics may create favorable conditions for the establishment of chronic infections by wall-defective organisms.

To establish a definitive role for the L-forms in disease, a conscientious search will have to begin with careful observations in the laboratory. In searching for L-forms in human infection, however, it is important to keep in mind the potential for misinterpreting bacteria that show atypical or aberrant morphology. In the last decade, progress on the clinical significance of the L-forms has produced little new information. On the other hand, strong new data such as the production of chronic or latent infection in animals by bacterial L-forms offer interesting possibilities for future studies, particularly as they may relate to similar conditions in humans.

Clinical studies have reported the recovery of L-forms and other wall-defective organisms from blood, body fluids, and tissues of animals and humans. However, their relation to pathogenic states are at present unclear. Studies by Domingue et al. (1977) describe the recovery of variant wall-defective bacterial forms from the blood of normal as well as diseased humans. Likewise, the role of L-forms of *Mycobacteria* in tuberculous infection or in resistant states merits further attention (Mattman, 1968; Khomeno et al., 1980). A comprehensive survey of the L-forms and bacterial variants in clinical disease has been presented by Pachas (1986).

The bacterial L-forms deserve investigations with new experimental models, isolation methods, and culture techniques. For example, provocative observations have been made on the stimulation of growth of L-forms by certain bacteria (satellite effect) (Bouvet and Acar, 1977; Madoff, 1977, 1979; Falcon et al., 1989). Studies showing the enhanced survival of L-forms of *Streptococcus* in immunosuppressed mice (Panos, 1986) and the production of mycetomatous disease in animals with L-forms of *Nocardia* (Beaman, 1986) represent new and promising avenues of approach.

The L-forms of bacteria deserve to be studied for their intrinsic scientific value. That the bacteria can, under certain conditions, enter into a wall-less state, that they can survive and reproduce themselves in this wall-deficient state, that they can ultimately revert to their bacterial form—or lose the ability to revert—are remarkable phenomena. These phenomena cannot be insignificant. Further studies with regard to their structure, biochemical function, and genetic composition should elucidate the role of the L-forms in the biology of bacteria and their potential role in clinical disease.

CHAPTER 231

The Genus *Gallionella*

HANS H. HANERT

The bacteria of the genus *Gallionella* belong to the so-called "iron bacteria," which achieved their theoretical importance after Winogradsky (1888, 1922) postulated his conception of chemolithotrophy for these organisms. These bacteria also have practical significance since they clog drains, water pipes, and wells with deposits of iron oxide compounds. In connection with freshwater supply problems and the rapid growth of agriculture, hydrotechnicians and land-reclamation (underground drainage) specialists have become increasingly interested in bacterial iron oxidation as a common source of interference with wells and drainage systems (Ford, 1978; Hanert, 1974b; Khrutskaya, 1970; Martin et al., 1978). Iron bacteria are also interesting for ecological and biogeochemical reasons. Like algae, iron bacteria may develop in their natural habitats in such masses that the idea of their participation in the sedimentary formation of iron ore is plausible, as was recognized in the first description of the iron bacterium *Gallionella ferruginea* (Ehrenberg, 1836).

Iron bacteria are reputed to be difficult to work with. The general opinion of microbiologists is that it is difficult to cultivate these organisms in the laboratory and that there are difficulties in isolating and identifying them. Therefore, it is one of the main purposes of this contribution to show that this poor reputation is unjustified. It will be demonstrated that cultivation and handling of the treated bacteria are in no way more difficult than for other microorganisms, if attention is paid to only a few fundamental peculiarities, such as "sessility" and "gradient growth." Disregard of these factors may be one of the most common practical reasons for failure to locate these organisms in natural habitats, for failure to cultivate them successfully, for misinterpretation of presumed developmental stages, and for discouragement which can often be observed when students are starting in this field. Therefore, the following text is narrowly restricted to methods and practical advice—without any theoretical discussion on the controversial life cycle, taxonomic position, and physiology, which are described in the literature cited.

This paper is taken directly from the 1st edition of *The Prokaryotes*.

Habitats

Chemistry of the Habitats

Gallionella ferruginea characteristically occurs most abundantly in very pure, iron-bearing waters that contain only traces of organic material. Habitats with the best prospects for a successful search are ferruginous mineral springs, water works, wells, and drainages, especially underground drainages in regions near the groundwater table. Swamp ditches and lakes are unusual habitats that contain *Gallionella* in large quantities only at places where pure, ferrous waters infiltrate. Occurrence is not restricted to fresh waters or to low-temperature habitats, as commonly assumed; *Gallionella* has been convincingly found in salt water, marine bays, and thermal springs with temperatures up to 47°C (Hanert, 1973b, 1981a; Sharpley, 1961; Volkova, 1939; Vouk, 1960).

Common to all of the various *Gallionella* localities investigated are sharply limited physicochemical conditions characterized by a low redox potential in an Eh range of +200 to +320 mV (rH_2 values generally vary from 19 to 21) and a slightly acidic environment caused by the solution of considerable amounts of CO_2. Adding the data determined by Volkova (1939) in slightly alkaline mineral waters, the pH environmental limits range from 6.0 to 7.6, which excludes growth in acid habitats. Occurrence of *Gallionella* in acid mine waters as described by Walsh and Mitchell (1969, 1970) may be a result of confusing *Gallionella* with *Metallogenium* and/or nonbiological structures.

These Eh and pH limits characterize *Gallionella* as a very good example of a gradient

organism that develops under neither strongly reducing conditions nor in a highly oxidizing zone, but in a level between the two extremes with redox conditions about 200–300 mV lower than typical surface waters. This region in which *Gallionella* grows characterizes the lowest zone of Eh-pH environmental limits of iron bacteria established by Baas-Becking et al. (1956), in which there are usually only low concentrations of oxygen.

Comparison with geochemical-stability field data for ferrous iron, published by Garrels and Christ (1965) and Hem (1972), shows that the *Gallionella* Eh-pH milieu, in all the cases that have been measured, lies significantly within the zone in which ferrous ions are stable. This stability appears to be the essential factor in the environmental conditions for the existence of *Gallionella,* much more important than the factors of temperature and oxygen content to which *Gallionella* manifests greater adaptability than generally thought. The marked psychrophily and the microaerophily generally ascribed to *Gallionella* seem to be only secondary effects that depend on the fact that bivalent iron is most stable under these conditions (Hanert, 1975). Thus, it is easy to understand why *Gallionella* also occurs in O_2-saturated waters, for example, in aerated, iron-removal treatment plants in water works or in thermal springs, when the only essential condition, stability of bivalent iron in the presence of oxygen, is fulfilled. These observations do not invalidate the most common values of physicochemical factors measured in *Gallionella* habitats, which are 0.1–1 mg/liter O_2, 8–16°C, 5–25 mg/liter Fe(II), around 20 or more mg/liter CO_2, and a very slight content of organic material, not above 12 mg/liter $KMnO_4$ (Hanert, 1975).

Growth Measurement and Analysis of Iron-Oxidation Structures by In Situ Exposure

The red-brown deposits at *Gallionella* sites consist primarily of the typical spiral bands of dead matter excreted from the terminal *Gallionella* cells. These deposits may be extremely pure. However, their *Gallionella*-nature may be very difficult to recognize when the deposits have been altered by additional chemical iron-oxidation processes. False conclusions may then be drawn about the nature of the iron-oxide precipitation. A direct measurement of *Gallionella* growth is indispensable for analyzing such structures, as well as for determining whether or not *Gallionella* is actually growing on the site.

There are three proven methods of in situ exposure for light microscopy and for transmission and scanning electron microscopy: (1) The exposure of cover slips or slides for several hours or days, singly or in multiple vertical alignment, in plastic clamp fittings. This method, a modification of the on-growth method of Naumann (1919) and Cholodny (1924) allows the localization of the zones in which *Gallionella* develops in still waters, the densitometric and photometric registration of the total iron oxidation (Hanert, 1981a) and, by determining stalk production, the quantification of the momentary *Gallionella* development (Hanert, 1973a). (2) The exposure of Formvar-coated, platinum or gold, electron-microscope grids (copper grids are inappropriate due to the frequent presence of H_2S). With these procedures, the fine structure of the bands, as well as of the terminal *Gallionella* cells on the sessilely excreted intact stalks, may be observed. The latter is not included when suspension preparations of the stalk fragments are used (Hanert, 1970; Hirsch and Pankratz, 1970). (3) Exposure of round glass slides for scanning electron microscopy and electron probe microanalysis (FeKα). This procedure is especially important because it allows tiny globular particles (0.04–0.3 μm in diameter) to be chemically and physically analyzed (Hanert, 1981a). Until now, they were thought to be mycoplasma-like developmental stages and buds of *Gallionella,* but they have been shown to be pure Fe(III)-oxide particles.

The advantages of these three procedures, which all make use of the sessile way of life, are obvious when one considers that the failure to find the characteristic apical cells in natural habitats (van Iterson, 1958) was the starting point for the studies that aimed at proving the mycoplasma-like and *Metallogenium*-like viable nature of *Gallionella* stalks (Balashova, 1967b, 1969, 1974; van Iterson, 1958; Zavarzin, 1961). The three procedures described above may also be applied to pure cultures of *Gallionella.*

Isolation

Physiological Basis for Isolation

Although chemolithotrophy has not as yet been generally recognized for *Gallionella,* it must be emphasized that all of the successful cultures were able to develop only in mineral media with iron(II) as energy source. This is true for Lieske's first cultures (1911) containing metallic iron as well as for the excellent culturing procedures of Kucera and Wolfe (1957) that use ferrous sulfide as a source of reduced iron. Culture procedures that used organic media con-

taining serum, as suggested by Balashova (1969), have remained unsuccessful. Classic *Gallionella* organisms with stalks and apical cells as well as developmental stages producing such forms have not been obtained. It thus seems evident that *Gallionella* is truly a chemolithotrophic bacterium and that ferrous-containing mineral media are best for cultivation and isolation.

Isolation Principles and Procedures

Two isolation procedures have proven useful. Both use mineral Wolfe's FeS medium (see below) as a selective isolation medium for *Gallionella,* in which neither sheathed nor capsulated iron bacteria will grow.

One procedure is a test-tube dilution method in which a final concentration of one colony per culture is reached. The ability to stick to the vessel walls is used to separate *Gallionella* from the contaminants (Engel and Hanert, 1967; Hanert, 1968; Hanert 1981b).

Isolation of *Gallionella* by Dilution and Serial Transfer (Engel and Hanert, 1967; Hanert, 1968)

One *Gallionella* colony is withdrawn with a capillary pipette from the wall of a test tube containing an enrichment culture, suspended homogeneously in 10 ml of Wolfe's medium without FeS, diluted to 10^{-5} (maximally 10^{-6}, one colony of 1 mm in diameter consists of about 100,000 apical cells), and then inoculated into test tubes with Wolfe's FeS medium (30–50 parallel cultures starting with a 10^{-4} dilution).

After 1 week of culture, a one-colony culture is treated, in essentially the same way as above, to obtain a pure culture. The colony, which is attached to the wall of the test tube, is carefully rinsed using a pipette with approximately 200 ml of fresh, sterile medium without FeS, after first disposing of the FeS sediment (1 ml) and the mineral medium (9 ml). Then the colony is transferred five times into test tubes containing 10 ml of sterile medium (without FeS) and washed with gentle shaking to rid the colony of clinging contaminations. The washed colony is then suspended into sterile medium (10 ml) and again inoculated into test tubes containing Wolfe's FeS medium at dilutions of maximally 10^{-6} (again 30–50 parallel cultures). Five to ten serial transfers are necessary to achieve pure culture in this manner. Although this procedure requires up to 10 weeks, it is a very certain method of continually reducing the number of contaminants and obtaining a pure culture (Hanert, 1975).

The second isolation technique requires much less time and leads, according to the authors, to a pure culture in 7 out of 10 cases. It is based on the observation that some strains of *Gallionella,* in contrast to most contaminants, is resistant to 0.5% formalin.

Isolation of *Gallionella* by Formalin Resistance (Nunley and Krieg, 1968)

Five-tenths milliliter of formalin (40% formaldehyde solution) was added to a dilution bottle of Wolfe's medium containing 10 ml of ferrous sulfide agar and 100 ml of fluid medium. Samples of *Gallionella* from its natural source were centrifuged at 3000 × *g* for 3 minutes. One to five milliliters of sediment was transferred to the Wolfe's medium with formalin. The medium was incubated at 25°C for 1–2 days. One-milliliter aliquots of the culture were transferred to fresh Wolfe's medium without formalin. Cultures were incubated at 25°C for 2–3 weeks. Tests for culture purity were performed using the third serial transfer after the formalin treatment.

Purity is checked by use of a variety of heterotrophic and autotrophic test media; for example, yeast extract bouillon, nutrient agar, *Nitrosomonas* medium, *Ferrobacillus* medium, and *Thiobacillus* agar. The length of observation is up to 4 weeks.

Micro- and Macrocultures and Axenic Maintenance

There are no principal difficulties in cultivating *Gallionella* in containers ranging from small chambers to 12-liter fermentors. The difficulties of culture that have been reported in almost all publications on *Gallionella* generally are due to overlooking interactions in the medium among the following factors: phosphate, ferrous and ferric iron, oxygen, pH, and redox potential. The most important growth-inhibiting chemical processes in the medium are: (1) iron phosphate precipitation caused by too high a concentration of phosphate; (2) chemical autoxidation of ferrous iron caused by too high a concentration of oxygen or by the redox potential being too high; and (3) the pH becoming more acidic when elevated O_2 concentration causes hydrolysis of ferric iron. All three processes eventually reduce the Fe(II) content of the mineral medium of the FeS cultures below the lower limit of 5 ppm. In order to retain the required Fe(II) concentration, it is absolutely necessary to have the following initial conditions in the medium: oxygen content 1 ± 0.2% (0.42 ppm), pH 6.0 (values from Co_2 bubbling, border values between 5.5 and 6.3), Eh +330 mV to +350 mV (Eh border values from −55 to +395 mV), phosphate (as K_2HPO_4) 0.05 g/liter. These conditions were established in optimum growth zones of 3-liter Erlenmeyer flasks and confirmed in test tube cultures (Hanert, 1975). They lead, following interactions between mineral medium and FeS-sediment, to an iron(II) concentration of 10–20 ppm which guarantees good growth of *Gallionella.* The conditions of gassing must be varied according to the volume in each vessel, so that

common standardized instructions may not be given for all sizes of flasks. Identical for all cultures, though, is the production and storage of ferrous sulfide as well as the production of modified mineral Wolfe's medium. During the first process, essential mistakes may be made that inhibit the growth of *Gallionella.*

Preparation and Storage of Ferrous Sulfide

For preparation of ferrous sulfide, two precipitation reactions with equal molar quantities are possible. FeS can be produced either by reacting 78 g ferrous ammonium sulfate [$(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$] with 44 g sodium sulfide ($Na_2S \cdot 9H_2O$) or 140 g ferrous sulfate ($FeSO_4 \cdot 7H_2O$) with 120 g sodium sulfide in deionized water (50°C; ferrous salts are added in solid form while stirring). The resulting FeS precipitate must be washed extensively using deionized water (decanting of the supernatant and its replacement with deionized water at 50°C), removing Na^+, NH_4^+, and, above all, S^{2-} ions until the precipitate reacts neutrally (pH measurement in FeS, not in the supernatant).

Washing of FeS while continually checking pH is indispensable, since hydrolysis of any residual sulfide ions ($S^{2-} + H_2O \rightarrow HS^- + OH^-$) raises the pH to 7.7 directly over the FeS sediment. The elevated pH prevents bivalent iron from dissolving and *Gallionella* development does not begin (Gebauer, 1978). Because of this indirect effect of sulfide on the development of *Gallionella,* sodium sulfide, used to manufacture FeS, is added in slightly less than the equimolar amount. The separation of the adsorbed sulfide ions from the FeS precipitate during the washing procedure is a slow process and takes approximately 5 days (5–9 washings at intervals of at least 4 h). Delayed FeS sedimentation caused by formation of FeS-hydrosol can easily be eliminated by including a few drops of a saturated $FeCl_3$ solution or by once washing with tap water. After this cautious washing, FeS precipitate can be stored without oxidation in glass-stoppered bottles that are completely filled.

Modified Mineral Wolfe's Medium

The modified mineral medium contains per liter distilled water: 1 g NH_4Cl, 0.2 g $MgSO_4 \cdot H_2O$, 0.1 g $CaCl_2 \cdot 2H_2O$, and only 0.05 g $K_2HPO_4 \cdot 3H_2O$ (one-tenth of the original concentration).

With the strongly reduced concentration of phosphate, it is no longer necessary to separately autoclave the individual components (no earth alkali phosphates are formed during autoclaving). Low phosphate concentration also prevents iron phosphate precipitate in the culture medium. Such precipitation would result in a total growth inhibition of *Gallionella* due to lack of dissolved iron(II).

Microculture Slide Chambers for In Vivo Studies on Cell Division, Cell Rotation, and Stalk Twisting

In constructing a chamber, one cover glass (20 × 50 mm) is mounted on each slide (26 × 76 mm). The cover glass is maintained at 0.05 or 0.1 mm above the slide by initially inserting a 0.05- or 0.1-mm flat bar and then sealing the two sides with sealing wax. The bar is removed, the third side (bottom of the chamber) is then sealed, and the slide is held erect for filling. First, a tiny drop of FeS is inserted (by capillary pipette) and then mineral medium is added so that the chamber is two-thirds full, whereby the final ratio of FeS:medium is 1:10. The chamber is then inoculated and the fourth side is sealed. Microaerobic conditions are produced by replacing the air with CO_2 or with a mixture of 94% N_2–5% CO_2–1% O_2. *Gallionella* growth (stalk production) starts immediately after the chamber is closed (Hanert, 1974a).

Procedure for Maintenance of Axenic Cultures of *Gallionella.*

The following procedure has proven useful in maintaining pure cultures of *Gallionella.*

Thirty-four test tube cultures are set up with the dilutions 10^{-1} (4 cultures; inoculum 150,000–300,000 cells), 10^{-2} (5 cultures), 10^{-3} (15 cultures), and 10^{-4} (10 cultures; inoculum 150–300 cells). For this purpose, the cotton-plugged test tubes are aseptically filled with 9 ml autoclaved mineral medium. Then, 22.8 cm^3 of cotton-filtered CO_2 is bubbled through each tube using a 1-ml pipette (length of bubbling approximately 5 s; the pH of the medium is now 4.5–4.8). One milliliter of sterile FeS precipitate is then slowly added with a pipette.

Six hours after the addition of FeS, the inoculation follows subsequent to dissolving 5–10 ppm bicarbonatic Fe(II) in the medium; meanwhile, the tubes are stored in jars at 17°C under an atmosphere of 94% N_2–5% CO_2–1% O_2. In preparing the initial suspension for inoculation (10^0 dilution), two colonies with a diameter of 2 mm (or one colony with a diameter of 4 mm) are suspended in 10 ml of sterile medium using a vortex mixer. Dilution series and inoculation are repeated as described above. The cultures are then incubated in preserving jars at 17°C in an atmosphere of 94% N_2–5% CO_2–1% O_2. This gas mixture can also be used for bubbling through the cultures (135 cm^3 for each test tube). The best *Gallionella* growth is usually at a dilution of 10^{-3} and is macroscopically visible after 3–5 days. Enrichment cultures may be obtained in the same manner, using a drop of natural *Gallionella* sediment for inoculation. Cultures are transferred every 4 weeks.

Preservation of *Gallionella* culture material in viable form for at least 13 weeks has been reported by Nunley and Krieg (1968) using the following procedure.

Culture Preservation by Freezing (Nunley and Krieg, 1968)

The organisms were centrifuged at 3000 × *g* for 3 minutes, resuspended in the fluid portion of fresh Wolfe's medium containing 15% glycerol, and stored in 1-ml quantities in a low-temperature cabinet at −80°C. Sur-

vival was tested by transfer to Wolfe's medium at weekly intervals; in every case, the organisms were viable, forming a distinct mat of growth on the submerged ferrous sulfide agar after 7–10 days.

Batch Cultures in Erlenmeyer Flasks for Physicochemical Studies in the Optimal *Gallionella* Growth Zone

In order to obtain the described physicochemical growth conditions, FeS (100 ml of FeS precipitate or 100 ml of 1.5% FeS agar) is added to the sterile culture medium (2 liters) in 2-liter Erlenmeyer flasks (silicon stoppers with glass tubes for bubbling), and then bubbled with 94% N_2–5% CO_2–1% O_2 up to pH 6 (gassing takes approximately 90 min). Then, pH, O_2, and Eh values are checked electrometrically and the medium is additionally gassed with N_2 and CO_2 to adjust to the required conditions (see above). The inoculation is with a suspension containing 10–15 *Gallionella* colonies (2 mm in diameter) into 10 ml of mineral medium. *Gallionella* growth becomes macroscopically visible after a lag phase of 4–6 days, during which the redox potential of the culture medium is lowered 300–400 mV by the bacteria (Hanert, 1975).

Fermentor Cultures in Mineral Ferrous Bicarbonate Medium

A clear $Fe(HCO_3)_2$ medium is made by adding 200 ml of FeS precipitate to 10 liters of modified Wolfe's medium, and CO_2 is bubbled through for approximately 24 h until a Fe(II) concentration of 50 ppm (pH 4.6) is reached. After FeS sedimentation, 4.5 liters of the supernatant, combined with 4.5 liters of modified Wolfe's medium [without Fe(II)], is filtered into the autoclaved fermentor through a membrane-filter apparatus containing coarse prefilter (10-μm pore size) followed by a Sartorius membrane filter (0.2-μm pore size) using a gas mixture of 94% N_2–5% CO_2–1% O_2 under 2 atm pressure. This filtration results in 9 liters of culture volume with 25 ppm ferrous iron. For measurement, control, and eventual readjustment of the physicochemical conditions with N_2 or CO_2 gas, the solution is left in the fermentor vessel for 24 h. The conditions are so reductive that no autoxidation of the ferrous iron occurs (culture temperature, 17°C). Inoculation is with 10–15 colonies (4 mm in diameter), suspended in 10 ml of medium. In contrast to normal fermentation cultures, the medium should be only moderately stirred (25 rpm) and gassed (1 bubble/2 s).

Gallionella growth becomes macroscopically visible after 2 days (white flakes on the walls of the vessel; after 5 days, the entire Fe(II) in the culture medium has been oxidized. *Gallionella* grows on all the inner surfaces of the culture vessel without gradient formation. This procedure seems suitable for the development of *Gallionella* fermentor cultures with a continuous flow of culture solution, during which it is particularly important to prevent contamination of the culture (changing of redox potential during *Gallionella* growth; Hanert, 1975).

Identification

The characteristic, spirally twisted, stalk structure formed by rotation of the apical cell makes *Gallionella* very easy to identify. It is uncertain, though, whether the genus consists of one or more species. This question has repeatedly been discussed at length (Beger and Bringmann, 1953; Pringsheim, 1949; van Iterson, 1958; among others). These authors have pointed out—and rightly so—that in almost all cases the differentiation into species has been based only on differences visible under light microscopy in the bands of *Gallionella* collected in nature.

Studies on quantification of the iron content of the bands of pure cultures of *Gallionella ferruginea* (Hanert, 1975) have shown that, due to additional chemical-physical iron oxidation on the surface of the bands, these surfaces may vary greatly in morphology. Six stalk types have been differentiated. Thus, the differentiation into species on the basis of light-microscopic band differences is definitely unreliable.

The genus is presently differentiated into two species, *Gallionella ferruginea* (stalk consists of 40 filaments or more) and *Gallionella filamenta* (stalk consists of only 3–8 filaments), based on the electron-microscopic band differentiation of Balashova (1967a, 1968). But this differentiation is only a morphological definition in another dimension; it does not exclude the possibility that "filamenta" is only an underfed "ferruginea." It seems conceivable that the presumption of Pringsheim (1949), which we favor, is accurate—the genus may consist of only a single species *(Gallionella ferruginea)* and all the other described species are only ecological growth forms of this one. The proof of this presumption by the results of additional physiological investigations would show that this bacterium—unique in its physiology and stalk excretion—is not nearly as complex as *Gallionella* literature may give the impression.

CHAPTER 232

The Genus *Nevskia*

PETER HIRSCH

The Russian microbiologist A. Famintzin (1892) discovered a rod-shaped bacterium that was characterized by the formation of a laterally excreted slime stalk. The organism was often slightly bent; during division, both daughter cells continued to laterally produce the slime, which therefore became dichotomously branched. Groups of cells were thus kept together by a disk-shaped or spherical structure consisting of the polymer (Fig. 1). Famintzin (1892) named this morphologically unique organism *Nevskia ramosa.*

Famintzin observed this bacterium on the water surface of aquaria in his laboratory, but he was unable to obtain a culture of it. The bacterium, together with its polymer stalk, vaguely resembled aggregates of *Pasteuria ramosa* Metchnikoff, a bacterial parasite on (in) *Daphnia,* which had just been described. *P. ramosa* had rosettes of drop-shaped cells and was thought to divide longitudinally. But Famintzin correctly recognized and described the nature of the center of *Nevskia* aggregates, a polymer soluble in 1% KOH.

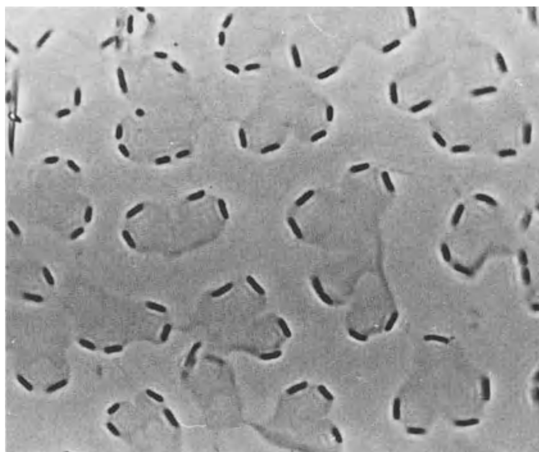

Fig. 1. *Nevskia* sp. cell families surrounding the central polymer. From a pond water enrichment culture with 0.1% Na lactate. × 1,280.

This paper is taken directly from the 1st edition of *The Prokaryotes.*

Additional observations made by Famintzin (1892) must be considered significant for the recognition of *Nevskia* spp. He described *N. ramosa* to contain highly refractile spherical bodies of variable diameter. In 35% ethanol, these globules swelled; in 70% ethanol, they completely dissolved. Famintzin thought that the globules consisted of "ethereal oils." Occasionally, he also observed that individual cells of a group actively left the central polymer to disappear in the water. Although motility was not observed as such, he inferred that such cells had become motile.

It is surprising that, with its rather peculiar properties, *Nevskia* was not seen very often later on. Henrici and Johnson (1935), in their now-famous paper on the stalked bacteria, mention finding *Nevskia* on the surface of a water sample taken from a greenhouse lily pond "to which a little sodium sulphide had been added to encourage a growth of *Beggiatoa.*" They were able to transfer *Nevskia* to new water samples containing Na_2S, but pure culturing was not attempted.

Babenzien (1965) reported seeing *Nevskia* spp. on the water surface of a swamp ditch; surface-contact preparations that had been transferred to sterilized pond water (pH 5.9, with 0.1% Na lactate) yielded pure cultures of slime-producing bacteria, but the lateral slime stalk was only seen occasionally, in older cultures. Additional information on *Nevskia* was published later (Babenzien, 1966, 1967; Babenzien and Schwartz, 1970).

H. Hippe (personal communication, 1964) found *Nevskia* on a greenhouse pool. From his samples, the present author successfully isolated neuston bacteria of the *Nevskia* shape and size, capable of slime production. But lateral polymer stalks could not be found. Zimmermann (1975) showed a scanning electron micrograph of a Nuclepore-filter preparation with *Nevskia* sp. His sample came from the brackish water of the Bight of Kiel (Baltic Sea). The di-

chotomously branched, lateral slime stalks are clearly recognizable.

Habitats

Most findings of *Nevskia*-like bacteria have been reported from the water surface, usually from fresh water. In fact, *Nevskia* appears to be a typical neuston microorganism, according to Babenzien, (1965, 1966, 1967) and to Babenzien and Schwartz (1970). Table 1 summarizes observations of various authors on the occurrence of *Nevskia* spp. The lengths of lateral polymer stalks evidently varied considerably, as did the cell sizes. It is quite probable that identification solely on the basis of lateral slime production and intracellular granules may not have been sufficient and, thus, various different bacteria could have been observed.

Nevskia-like bacteria are widely distributed in shallow, aquatic habitats; they have never been reported from soils. Their occurrence in brooks, ponds, and even lakes is shown in Table 2. From these data, we can see that bacteria with lateral polymer stalks can be found during most of the year. There does not seem to be a distinct temperature dependency and, in all but one case, the organisms were found in or near the (aerobic) water surface. *Nevskia*-like bacteria do not show preference for a specific type of aquatic environment as long as they can live at the surface and are not overgrown by other organisms.

Isolation

Henrici and Johnson (1935) obtained their *Nevskia* enrichments by adding "a little sodium sulphide" to a jar of water taken from a greenhouse lily pond. Continued growth was observed when the *Nevskia*-containing scum was serially transferred to sterilized, Na_2S-containing water from the same lily pond. Babenzien (1965) could not confirm beneficial effects of a sulfide addition.

Babenzien (1965) collected his *Nevskia* sp. by touching the swamp brook-water surface with a glass slide, by washing the film off the slide with sterile water from the same site (pH 4.8), and by repeatedly transferring to new, sterile water. Growth of families occurred within 4 weeks. Addition of C or N sources other than 0.1% Na lactate to this water resulted in overgrowth of the *Nevskia* by the other microorganisms. Finally, a pure culture was obtained using water from a dystrophic pond (pH 5.9), 0.1% lactate, and agar. The organisms grew only on the water's surface, and lateral polymer stalks developed only in cultures after 2 weeks of incubation at 20–28°C.

The enrichment technique employed by H. Hippe (personal communication, 1964) resembled that of Henrici and Johnson (1935) somewhat. A water sample from a greenhouse pool was enriched with water lily leaves, then filled to the top, closed, and incubated in darkness and warmth for several months. When this sample was exposed to light and air, a surface pel-

Table 1. Occurrence and habitats of *Nevskia* and similar bacteria as reported in the literature.

Location	Depth	Remarks: Habitat	Remarks: *Nevskia* cells	Reference
Aquarium in laboratory, St. Petersburg	Surface		Size: 2–6 × 12 μm; globules of ethereal oils; lateral stalks	Famintzin (1892)
Greenhouse lily pond	Surface	Surface scum	Size: 1 × 3–4 μm; each cell with 3–4 "vacuoles," considered to be sulfur	Henrici and Johnson (1935)
Greenhouse pool	Surface	Sample with water lily leaves, kept warm	Cells small; lateral stalks; cells motile	H. Hippe (personal communication, 1964)
Swamp ditch	Surface	Water, pH 4.8; in surface pellicle	Size: 0.7 × 1.8–2.7 μm; stalks 3 μm; cells with 1–3 flagella and 1–6 storage bodies (not S°)	Babenzien (1965)
Little Lake, Wisconsin	8 m	Anaerobic, 4°C	Cells short rods with gas vesicles; stalks long and slender	D. E. Caldwell (personal communication, 1975)
Kiel Bight (Baltic Sea)	?	Brackish water	Cells small, with lateral polymer stalks	Zimmermann (1975)

licle that contained 90% *Nevskia* developed within a month. Transfers into sterile water with or without 0.1% Na acetate resulted in some growth, but *Nevskia* developed better without acetate. These enrichments were inoculated by the present author into pond water, whose pH had been adjusted to 5.9 with H_3PO_4 and to which 0.1% of Na lactate had been added after sterilization. Excellent development of *Nevskia* occurred within 7 days of dark incubation at 22°C. *Nevskia* likewise grew well under these conditions when the inoculum came from Occom Pond, a eutrophic pond in Hanover, New Hampshire. Isolation of these organisms was accomplished by streaking onto the same medium solidified with 2% Noble agar (Difco). The pure cultures obtained, however, produced polymer all around the cells rather than just laterally.

Enrichment of *Nevskia* from Lake Water

Enrichment from lake surface water was done repeatedly by using the following procedure: 100 ml of surface-water samples (0–20 cm) are poured into 500-ml Erlenmeyer flasks and covered with a loose cotton plug. To some flasks, 0.005% (wt/vol) of either peptone (Difco) or yeast extract (Difco), or 1 ml of vitamin solution no. 6 (Van Ert and Staley, 1971) are added. Incubation is in the dark and at room temperature (20–22°C). *Nevskia* families will occur on the surface within 30–40 days. The enrichments will have to be monitored often, since a *Nevskia* cell bloom develops rapidly and lasts only for a few days; lysis will then cause a rapid drop of cell numbers. Although the polymer structures remain for a long time, the only remnants of *Nevskia* cells after lysis are dense, dark granules located at the former site of the cell. Addition of 0.005% (wt/vol) peptone (Difco) usually results in the greatest numbers of *Nevskia* families.

Identification

Nevskia ramosa Famintzin 1892 has not been obtained in pure culture. Key characteristics, such as slime formation and the presence of fragile, reserve-material globules, are also found in other rod-shaped bacteria that are slightly bent *(Brachyarcus thiophilus, Microcyclus aquaticus)*. However, *lateral* slime formation has not been found too often. *"Bacterium pediculatum,"* described by Koch and Hosaeus (1894) as a contaminant of sugar factories, showed with its long, branched stalks a certain morphological similarity to *Nevskia* spp. Henrici and Johnson (1935) regarded this organism as a species of *Nevskia*. *Siderophacus corneolus*

(Dorff) Beger 1949, 12 (=*Gallionella corneola* Dorff 1934, 26) may also be related to *Nevskia* spp. But its longer and less-branched stalks, as well as the deposition of ferric oxide hydrate on the stalks, distinguish it from *Nevskia* spp.

The type species, *Nevskia ramosa,* was described by Famintzin (1892) as being 2–6 × 12 μm in size ("the average length of the cell measures 0.012 mm, in the mature state it is 2–6 times longer than wide"). One wonders if these measurements could have been correct. Although within the bacterial range, Henrici and Johnson (1935) pointed out that all other *Nevskia*-like bacteria seen to date were smaller. The average sizes were: 0.4–0.8 × 1.0–3.3 μm (from lakes); 0.7 × 1.8–2.7 μm (only from swamp ditch); and 0.6–1.0 × 1.7–5.8 μm (from ponds, brooks, aquaria, etc.). Therefore, more than one species of the *Nevskia* genus might exist. Famintzin (1892) mentioned that he had seen a form identical to *N. ramosa,* but of much smaller dimensions. Babenzien and Hirsch (1974) list but one species.

Apart from size, there were remarkable differences with respect to stalk formation. Stalk formation depends on the original source as well as on growth conditions and cell age (Babenzien, 1965). Slow growth under oligotrophic conditions and greater cell age favor lateral stalk formation; faster growth and younger cell age result in less polymer formation, equally produced over the whole cell surface.

The physiology of *Nevskia* spp. is still nearly unknown. From the data in Tables 1 and 2, as well as from the work of Babenzien (1965, 1966, 1967), we can deduce the following properties: *Nevskia* spp. should be chemoorganotrophic and oligocarbophilic, with an ability to utilize low concentrations of lactate and perhaps acetate. They are aerobic, nonphotosynthetic, occasionally motile (1–3 flagella), and capable of cell lysis and storage of alcohol-soluble reserves. They should be mesophilic and may be rather UV resistant (since they are found in the neuston). Nevskiae evidently prefer slightly acid environments (pH < 6.0). Growth is probably not vitamin dependent. There may be forms that are slightly halotolerant.

The organisms found by D. E. Caldwell and this author in Little Lake and Knaack Lake (Wisconsin) contained gas vesicles. Their cells (short rods to almost cocci) sat on long, slender stalks with only few branches. They came from anaerobic, cold strata of these two meromictic lakes. All of these properties render them distinctly different from the other *Nevskia* spp.

Acknowledgments

The author gratefully acknowledges the information and interest kindly provided by H.-D. Babenzien (Griefswald), H. Hippë (Göttingen), and D. E. Caldwell (Albuquerque, New Mexico). H. Hippe donated enrichment cultures of *Nevskia* spp. Part of the work mentioned here was supported by the Deutsche Forschungsgemeinschaft.

CHAPTER 233

The Genera *Caulococcus* and *Kusnezovia*

JEAN M. SCHMIDT and GEORGI A. ZAVARZIN

Perfil'ev and Gabe (1965) observed bacteria of the genera *Caulococcus* and *Kusnezovia,* along with *Metallogenium* and *Siderococcus,* as manganese- and, to a lesser extent, iron-depositing or -oxidizing organisms of mud and sandy deposits. The use of capillary devices that permit microscopic observation (peloscopes) has permitted some observations of structure and colonial morphologies. Their morphologies suggest that these organisms might be related to *Acholeplasma, Metallogenium,* or *Siderococcus,* but lack of axenic cultures has prevented thorough study of their physiology and composition; understanding of the nature of these rather rare bacteria is quite meager.

Habitats

Caulococcus has been found in samples of mud and sandy deposits as observed with microcapillary techniques (Kutuzova et al., 1972; Perfil'ev and Gabe, 1961; Perfil'ev et al., 1965). It was originally found in Lake Khepo-Yarvi (Karelian Isthmus), "especially in ore deposits," and was "frequently observed in the upper layers of bottom mud deposits, above the reducing horizon," or in the bottom water (periphyton) over the mud (fine mineral or sandy) surface (Perfil'ev et al., 1965).

Kusnezovia was observed, using the peloscope technique, only "in mud samples from Lake Ukshezero, Karelian ASSR" (Perfil'ev et al., 1965), and in secondary profiles in zones of manganese oxidation of mud samples stored in the laboratory.

As described by Perfil'ev and Gabe (1965), in capillary peloscope samples from many ore-bearing lakes, for all those "with a black-orange microzone, the blackish-brown horizon of the microzone in the peloscope canals showed a mass-development of *Metallogenium,* rarely *Caulococcus,* and sometimes *Kusnezovia,* the biogenic deposits of which consist mostly of manganese oxides."

Isolation

Neither *Caulococcus* nor *Kusnezovia* has been isolated in pure culture. Distinctive morphologies, particularly those of microcolonies using microcapillary techniques, have been used to define these two groups (Perfil'ev et al., 1965).

Organisms could be maintained in the isolated samples of mud (Perfil'ev et al., 1965): a sample of water (approximately ⅓) and mud (⅔) from the natural habitat was mixed thoroughly and incubated in a 200-ml beaker at room temperature for months. Peloscopes were placed across the upper 3 cm of the mud. Development of manganese- and iron-depositing organisms was observed to occur in sharp, horizontal microzones (a few millimeters in width) in the upper layers of mud following the reduction of metal oxides in the bottom layers.

Identification

In the absence of axenic cultures and information on cultural traits, colonial morphology is used, along with the characteristic manganese deposition, for tentative recognition of these kinds of bacteria. To observe cell morphology, Perfil'ev and Gabe (1965) dissolved manganese deposits with 0.2–1.0% oxalic acid, washed them with distilled water, and stained them with a carbol solution of gentian violet. All steps were monitored with the light microscope. The bacteria appeared as minute bodies without sharp contours, and appeared to reproduce by budding. They were embedded in a matrix or connected with thin filaments. For identification, the original illustrations of Perfil'ev et al. (1965) should be consulted. Some other characteristics are given in Table 1.

Colonial morphology is variable. Three sorts of microcolony morphologies have been de-

This paper is taken directly from the 1st edition of *The Prokaryotes.*

Table 1. Characteristics of *Caulococcus* and *Kusnezovia* spp.

Trait	*Caulococcus manganifer*	*Kusnezovia polymorpha*
Coccoid cell diameter (μm)	0.5	0.5–1.5
Connecting filament diameter (μm)	0.1	0.1–0.2
Mode of reproduction	Budding (?)	Budding (?)
Motility	Present	Not observed
Gram reaction	Not reported	Not reported
Zoogleal accumulations	Present	Not observed
Oxygen relationship	Microaerophilic	Microaerophilic (presumed)
Occurrence	Rare, in iron-manganese ore from several lakes (Karelian Isthmus, ASSR)	Extremely rare, found in only one lake (Ukshezero, Karelia)

scribed for *Caulococcus manganifer.* The most commonly observed microcolonies occur as dense, irregular clusters, the surfaces of which appear ribbed. The central portion of the microcolony is more heavily mineralized than the periphery, due to manganese deposition. The mineralized colonies are blackish brown in color. Occasionally, colonies have radial arms (termed "radial lobate" colonies); the rarest colonial form in *Caulococcus* microaccretions is the trichospherical colony with very fine, radiating processes.

Kusnezovia polymorpha microcolonies (polymorphous cenobia) also occur in a variety of forms: filamentous sprouts, open lily-of-the-valley leaves, or goblets with a toothed margin, with the wider portion of the microcolony pointing downward in the peloscope canals. Candelabra-like and clavate, filamentous cenobia structures attached to the peloscope wall, with an appearance analogous to *Cladonia* (a bryophyte), have also been attributed to *Kusnezovia.* Removal of manganese from these deposits revealed the cocci, connected by thread (Perfil'ev et al., 1965).

These organisms will require further attention in order to distinguish them from other quite similar manganese depositers, such as *Metallogenium.* In fact, we strongly suspect that these genera, particularly *Caulococcus,* are merely growth forms of *Metallogenium* in a certain habitat. The description of *Siderococcus* (this handbook, Chapter 236) should be consulted, since these iron-depositing organisms are very probably members of the same group, although they are not presently classified as such.

The Genus *Brachyarcus*

PETER HIRSCH

Light-microscopic investigation of the microorganisms in the hypolimnion of many lakes, shows the presence of a highly diverse population of bacteria. Here, most of the recognizable forms have never been cultured and many of them have not even been described morphologically. Among these bacteria are rod-shaped organisms that are bent in an arc by asymmetric, polar cell growth and that frequently assume the shape of a pretzel. Cell division in the center and separation result in two arcs that face each other. Additional cell divisions and the presence of masses of polymer lead to even numbers of arcs facing each other in a symmetric, mirror-image way (Fig. 1).

Phase-contrast light microscopy, using slides coated with water agar to improve resolution, reveals the presence of gas vesicles in most of these organisms. The wide distribution and often the high cell numbers of such arc-shaped bacteria warrants attempts to cultivate and study them, but such attempts have been unsuccessful. Skuja (1964) found similar bacteria in a Lappish lake, and he described them as *Brachyarcus thiophilus*. The species name was used to suggest a possible sulfur metabolism, since the cells occasionally possessed intracellular structures resembling sulfur globules.

Since *Brachyarcus* spp. have never been cultivated, not even in enrichments, their possible identification presents some problems. In fact, a rodlike, arc-shaped cell shape is quite common among other bacteria. But the cell arrangement after division, the presence of gas vesicles, the absence of photosynthetic pigments, and the frequent observation of these bacteria among other "thiophilic" organisms may indeed allow a recognition sufficient for a descriptive treatment here, as has been done in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Hirsch, 1974).

Habitats

The original observations were made by Skuja (1964) on a hypolimnion water sample collected April, 1953, at a depth of 12–13.5 m in Lake

This paper is taken directly from the 1st edition of *The Prokaryotes*.

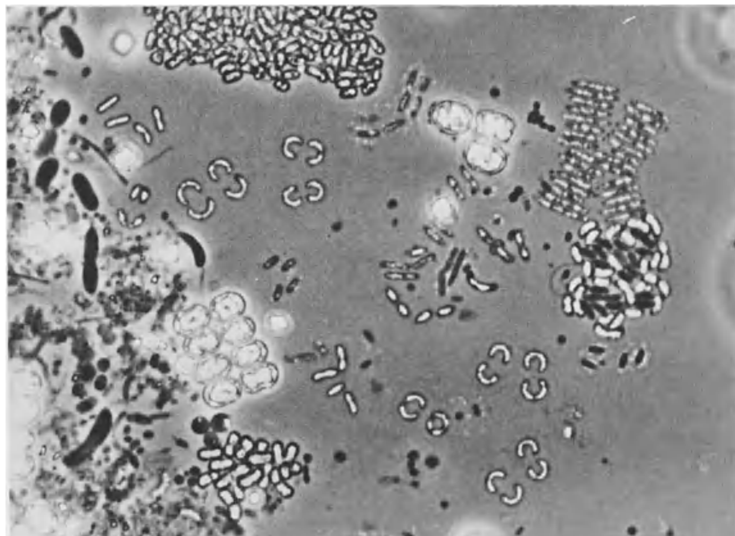

Fig. 1. Arc-shaped cell families of a *Brachyarcus* sp. from Wintergreen Lake (Michigan), collected from 4 m. Magnification × 1,280.

Vuolep Njakajaure, Swedish Lappland (408 m above sea level). The water sample had a temperature of 2°C; the lake was ice-covered. Together with *Brachyarcus thiophilus,* large numbers of other "thiobiontic" bacteria were found, many of which contained sulfur storage globules but none of which has ever been cultured (for nomenclature, see Skuja, 1964), e.g., *Macromonas bipunctata, M. mobilis, Gigantomonas cucullata, G. capitata, Thiovulumspora, Hyalobotrys hypolimnicus.* Also present in this sample were some photosynthetic bacteria (*Thiocystis violacea, Pelochromatium roseum* consortium) and sulfate reducers *(Microspira desulfuricans).*

Similar crescent-shaped organisms have been found by other authors (Table 1) in various lakes or ponds. Bacteria of such cell arrangement and/or shape were also found in soil (Nikitin, 1971, 1973; *"Renobacter vacuolatum"*) or even in reindeer rumen (Tarakanov, 1972). The latter bacteria were 0.4–0.5 × 1.1–1.2 μm and occurred in the above-described cell-plate arrangements. Their shape, however, was more that of a vibrio than that of an arc.

Isolation

Although isolation has not yet been successful, the data on occurrence in Table 1 allow us to speculate on possible enrichment techniques. In Wintergreen Lake, temperatures in the *Brachyarcus* layers during the time of observation varied between 11° and 20°C, with the maximum cell density of *Brachyarcus* spp. at 13°C (depth, 5 m). In the other sites—as far as data are available—temperatures ranged from 5° to 12.5°C. These observations indicate that *Brachyarcus* is psychrophilic.

In all cases observed, the organism occurred under anaerobic conditions. A pH of 7.5 and a phosphate concentration below 2.56 mg/liter would be additional parameters. No information is available on the carbon nutrition, although one could guess that *Brachyarcus* (being nonphotosynthetic) would have a chemoorganotrophic metabolism. Their presence in strata that contain methane (Wintergreen Lake) or reducible sulfate (Lake Vuolep Njakajaure) points to preference for a low redox potential in the environment. Storage of intracellular sulfur

globules indicates participation in the sulfate reduction or sulfide oxidation processes.

Identification

Brachyarcus Skuja 1964, 19, is a genus of colorless rod-shaped bacteria of approximately 1.0 × 1.5–2.5 μm that usually contain few to many gas vesicles (Fig. 1). Occasionally, globules resembling sulfur were observed by Skuja (1964), but these have not been reported by other authors nor have they been seen by this author. The cells are bent like a bow or arc, almost to a circle or even a pretzel shape. Upon division, a 3-shape is initially assumed until two semicircles lie opposite each other, embedded in a thick polymer capsule with diffuse edges (Fig. 1) Families of two to 16 synchronously dividing cells are common; they often form cell plates, which may be free floating or grow attached to a surface. Three-dimensional, free-floating families of polymer-embedded cells of up to 100-μm family size or larger have been observed. The type species is *Brachyarcus thiophilus* Skuja 1964, 20, so named for the "thiophilic" environment in which it has been found.

Identification is still largely on the basis of morphology. Cells or cell aggregates of similar shape are formed by the purple bacterium, *Rhodocyclus* (Rhodospirillaceae), or by the green bacteria, *Chlorobium vibrioforme* and *Pelodictyon luteolum* (Gorlenko, Dubinina, and Kuznetsov, 1977; Pfennig, 1978). The former two bacteria lack gas vesicles while *P. luteolum* does contain them. Since *Brachyarcus* has been described (Skuja, 1964) and has subsequently been found to be colorless (see Table 1), differentiation from these photosynthetic bacteria should be possible.

Morphological similarity with a colorless, gas-vacuolated soil bacterium called *Renobacter vacuolatum* (Nikitin, 1971, 448; 1973) also holds true for the size (0.7–1.0 × 1.6–1.8 μ). However, this bacterium appears to grow out, before cell division, to an S-shape rather than a 3-shape or pretzel. Similarity also exists with *Microcyclus* spp. Electron micrographs of the nonvacuolated *Microcyclus marinus* (Raj, 1977) or the gas-vacuolated strains of *M. aquaticus* (Van Ert and Staley, 1971) show cells that appear to be more vibrioid; in pure culture, the characteristic orderly arrangement in symmetric cell plates, as seen in *Brachyarcus* (in nature), is not seen in the genus *Microcyclus*. Furthermore, both of the *M. aquaticus* strains that were studied in greater detail had temperature optima of 37° and 30°C, respectively, and neither strain grew anaerobically. *Brachyarcus thiophilus* can be expected to be an anaerobic psychrophile.

Acknowledgments

Information on *Brachyarcus* kindly supplied by H. Skuja in 1968 is gratefully acknowledged. M. Klug and R. Wetzel (Kellogg Biological Station, Michigan State University) supplied data on Wintergreen Lake for 22 July 1975.

CHAPTER 235

The Genus *Pelosigma*

PETER HIRSCH

The Danish scientist E. Warming observed, during a walk along Kallebo Beach in 1874, a reddish discoloration of mud and decaying algae. His microscopic investigation of a sample started the now-famous study of "bacteria living on Denmark's coasts" (Warming, 1875). One of the organisms he found in "stinking mud at the height of decay" at several locations was a highly unusual, flat and striated, motile "bacterium" (which he called *Spiromonas cohnii*) that resembled a flagellate *Spiromonas* previously described from Switzerland. Although Warming himself was not quite sure of what he saw, his drawings are remarkably accurate illustrations of bacteria that can still be found in hypolimnia and on anaerobic sediment surfaces.

About 40 years later, these organisms were observed again and described as the bacterial genus *Pelosigma* (Lauterborn, 1913, 1915). Lauterborn clearly stated that a bacterium could not belong to a flagellate genus, but otherwise his observations confirmed the findings of Warming. Another 40 years later, a study on Swedish lakes revealed *Pelosigma* organisms in many different locations (Skuja, 1956). But now the old theory that this organism was a flagellate—at least in part—was revived. Skuja was convinced that he had found another example of a flagellate/bacterium symbiosis, and he produced detailed drawings of various stages of such consortia. Nevertheless, the genus name *Pelosigma* was retained for the consortium for both the flagellate and the bacterium organisms.

Detailed microscopic investigations of aquatic microorganisms and the study of several lakes and ponds in the United States and northern Germany revealed the presence of *Pelosigma* spp. in many locations, often in large numbers (P. Hirsch, unpublished observation). These studies allowed a preliminary description and interpretation for the eight edition of *Bergey's Manual of Determinative Bacteriology* (Hirsch, 1974). Since then, many additional samples have been found to contain *Pelosigma* spp., and evidence is mounting that these are, indeed, bacteria living in sigmoid, bundle-shaped aggregates just as originally drawn by Warming (1875) and described by Lauterborn (1913, 1915). Unfortunately, all attempts to cultivate these organisms so far have failed. Suggestions for enrichment cultures can be made, however, on the basis of the observed occurrence.

This paper is taken directly from the 1st edition of *The Prokaryotes*.

Habitats

The original description (Warming, 1875) does not contain many details on the natural habitat. It is not even clear whether *Spiromonas (= Pelosigma) cohnii* was found in mud of salt water, brackish water, or fresh water. However, the location "Limfjord" suggests brackish water, and the purpose of the article by Warming was to describe bacteria living at the coasts. Warming listed four locations for *S. cohnii* and stressed its occurrence in mud that was most active in the decaying process. He stated also that *S. cohnii,* like other bacteria discussed later in his paper, did not contain granules such as those of the organism now known as *Chromatium okenii.* His description of these granules makes it quite likely that he meant sulfur globules. Although obviously an anaerobe, *S. cohnii* thus did live in a sulfide-rich environment but did not store elementary sulfur.

The habitat of *Pelosigma (=Spiromonas) palustre* (Lauterborn, 1913) was likewise poorly described: fresh water; in the decaying sediment especially in ponds with characean algae.

The observations of Skuja (1956) could be added to the habitat description, if one accepts the interpretation that his *Pelosigma* organisms indeed were identical with those seen by Warming and Lauterborn. Skuja found *Pelosigma* spp. in Swedish lakes (Hönsan, Lushavet, Munkbosjön, Tjärnatjärn), usually at depths ranging from 10 to 14 m. Although he did not describe these environments chemically or

physically, some information can be obtained from the list of accompanying bacteria. Skuja mentioned *Peloploca* spp. *(P. pulchra, P. fibrata, P. taeniata), Macromonas mobilis, Achroonema* sp., *Pelonema tenue, Achromatium oxaliferum, Gigantomonas cucullata, Ochrobium tectum, Beggiatoa arachnoidea, Leukobium maior, Pelochromatium roseum,* and *Thiocystis violace* (nomenclature sensu Skuja, 1956). These bacteria are generally known to be anaerobic or microaerophilic, hypolimnetic organisms, many of which are found in sulfide-rich environments. Thus, we can expect the presence of low sulfide concentrations in an otherwise mostly anaerobic and dark environment.

More information comes from recent observations on *Pelosigma* habitats (Table 1; P. Hirsch, unpublished). The presence of *Pelosigma* spp. appears to be correlated with anaerobic conditions and, generally, temperatures below 11°C. Like *Brachyarcus* spp., often found in the same location, *Pelosigma* spp. can be expected to be psychrophilic. It should be pointed out, however, that *Pelosigma* spp. have been found occasionally at higher temperatures.

The presence, in Wintergreen Lake (Michigan), of sulfide together with measurable concentrations of dissolved methane during *Pelosigma* occurrence points to a need of these organisms for a low redox potential.

Isolation

From the data given by Warming (1875), Lauterborn (1915), Skuja (1956), and in Table 1, an enrichment procedure could be conceived. It would consist of inoculating an anaerobic medium of pH 7.5 that contains organic matter (such as organic acids, amino acids, etc.), a mixed vitamin solution and, perhaps, a low concentration of sulfide (10^{-4} M or less). The sample for inoculation should be drawn anaerobically, and it should be kept at temperatures below 10°C. Incubation would be in the dark at 5–10°C.

Identification

All *Pelosigma* spp. observed were more or less flat, band-shaped aggregates of slender, long, and S-shaped bacterial rods. The aggregates appear to be formed preferentially by four cells or by multiples of four. At least one end of the aggregates appears to be more pointed. If a flagellar structure is present, it is located at the more pointed end. The overall length of the aggregates (9–25[30] μm) is not the length of the individual, component rod, since uneven elongation and cross-division occur. The maximum width of aggregates is 5–11 μm and depends on the number of rods in the aggregate (Fig. 1).

At present, there are two species recognized (Hirsch, 1974): *Pelosigma cohnii* (Warming) Lauterborn 1913, 100 (synonym: *Spiromonas cohnii* Warming 1875, 370) and *P. palustre* Lauterborn 1915, 418. Both species show great morphological similarity but differ in size. Aggregates of *P. cohnii* are 1.2–4 μm wide and 9–20 μm long, while those of *P. palustre* are 8–10 μm wide and 20–25 μm long. The aggregates of *P. cohnii* are usually pointed at both ends (and

Data from P. Hirsch, unpublished observations.

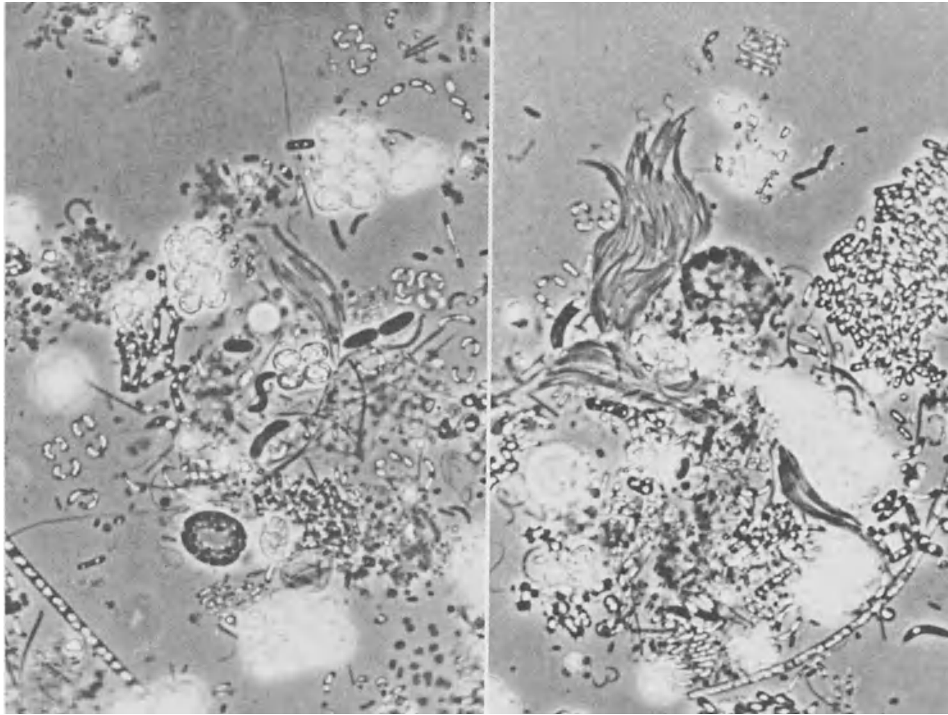

Fig. 1. A mixed bacterial flora with *Pelosigma palustre* cell aggregates from Wintergreen Lake (Michigan), collected from 4.5 m on 5 August 1970. × 1,280.

often flagellated on both ends), they are actively motile, and the individual cells measure approximately 0.4 μm in diameter (from the drawings of Warming, 1875). The aggregates of *P. palustre* normally show only one pointed end; they are much less actively motile, and flagella have not been seen. They occur in freshwater habitats.

The *Pelosigma* aggregates found by Skuja (1956) were thought to surround a colorless flagellate which multiplied by longitudinal fission. One to eight (usually four) colorless, S-shaped rods were kept by the flagellate "subpellicularly" with the ends sometimes sticking out. The aggregate (consortium) of bacteria and flagellate were described as *"Pelosigma cohnii"*; the overall sizes were 1–7 × 11–27 μm. The bacterial component was 0.3–0.4 × 7–15 (20) μm in size, colorless, without any granules, and sometimes yellowish pigmented. Cross-division was not synchronous with the longitudinal fission of the monad. The consortium did not have two flagella; the aggregates seen by Warming were likewise not supposed to have front and rear flagella—despite the fact that Warming (1875) mentions these and has actually drawn three double-flagellated aggregates (Table VII, Fig. 4a, 4c by Warming). The consortium was thought to be "oligothiophilic" and possibly involved in the decomposition of cellulose and/or hemicelluloses.

The aggregates described in Table 1 (Fig. 1) were, in general, 19.5 μm long and either 5–6 or 10–11 μm wide; thus, they resembled *P. palustre.* One sample (Wintergreen Lake, 4.5 m, August 1970) had much larger aggregates with thinner cells. None of the numerous aggregates seen contained anything that could have resembled a flagellate. Only two cases of flagellation and motility were seen; in both cases, the flagellum had the appearance of bacterial flagella, with a permanent, constant wavelength. Therefore, the author believes that such visible flagella constitute tufts of several prokaryotic flagella, attached polarly to each individual bacterium and combined to form the visible structure. Another argument against a eukaryotic flagellum would be the absence of two flagella from the "dividing" cell pole (as would be formed during longitudinal fission of a eukaryotic flagellate). Instead, the *one* "flagellum" (tuft) is located on the nondividing cell pole. Occasional bipolar flagellation (as has been observed by Warming) would be expected to occur in polarly flagellated bacteria. The transparent area in between the aggregate's bacteria is probably filled with an extracellular, common polymer. It is also possible that there exist, in nature, *Pelosigma*-like consortia of S-shaped bacteria

with colorless flagellates. Only observation of laboratory cultures and directly embedded and sectioned natural material could solve this problem. For the time being, it may be advisable to restrict the name *Pelosigma* to the bacteria that are agreed upon by all observers.

Acknowledgments

This work was supported and encouraged by G. Lauff, Director, Kellogg Biological Station of Michigan State University. Data on Wintergreen Lake and kind hospitality were provided by M. Klug and R. Wetzel during part of this work. The author is also grateful to D. E. Caldwell for information on Little Lake (Wisconsin) and to J. Overbeck (Plön) for information and help with Lake Plußsee. Kellogg Biological Station Publication No. 402.

CHAPTER 236

The Genus *Siderocapsa* (and Other Iron- or Manganese-Oxidizing Eubacteria)

HANS H. HANERT

This chapter discusses those species of *Siderocapsa* and members of the family Siderocapsaceae (Pribram, 1929) whose morphology, ecology, and to some extent, culture physiology, have been so exactly described that, in spite of disagreement concerning their taxonomic position, there can be no doubt of their existence and great ecological significance. The discussion concentrates on such existing and ecologically significant representatives of this family in order to preserve the practical orientation of this Handbook. Information on many genera and species whose position is uncertain has been drawn together in *Bergey's Manual of Determinative Bacteriology,* eighth edition (Buchanan and Gibbons, 1974; contributor G. A. Zavarzin) and seventh edition (Breed et al., 1957; contributor R. S. Breed in cooperation with H. Beger) and by Dorff (1934). A comparison of the genera and species treated in these references provides a bird's-eye view of this entire group of organisms.

The family Siderocapsaceae is defined as unicellular, nonfilamentous or nonstalkforming, iron and/or manganese bacteria that are able to deposit these metal oxides under natural conditions, on or in capsules or on extracellular mucoid material excreted by these bacteria. This definition is taxonomically rather imperfect, but for practical purposes it is quite adequate. That the validity of this family, in particular of the species of the genus *Siderocapsa,* has often been questioned is to be ascribed exclusively to the present taxonomic inadequacy of the definition. Such questions have been raised most recently by Dubinina and Zhdanov (1975); but a final clarification of the taxonomic question will not be possible until the complete developmental cycle of these bacteria in their natural habitat has been clearly described. Culture experiments are doubtless very helpful here, but they cannot provide a final clarification of the taxonomic question as long as the natural development of the organisms remains unknown.

Merely because there have been controversial questions of taxonomy it does not follow that these bacteria do not exist. Their existence and great ecological significance have become firmly established in the last decades through the discovery of their mass development in the hypolimnion of many lakes.

This paper is taken directly from the 1st edition of *The Prokaryotes.*

Habitats

Occurrence and Natural Mass Development

Siderocapsaceae are widely distributed in nature (see Table 1). They are found in all habitats which contain iron and manganese. They were first found in meadow and swamp ditches and mesosaprobic flowing streams, as well as in stagnant waters (Dorff, 1934; Drake, 1965; Galinsky and Hanert, 1979a; Hardman and Henrici, 1939; Molisch, 1910; Naumann, 1921). The organisms occur in these habitats as epiphytes on submerged water plants or on growths of exposed slides, or they are free-living and neustonic in metallic, glossy, iron oxide films on the water. A second important source of these organisms is deep wells, pipes, and waterworks, as described by Beger (1949) and by Hässelbarth and Lüdemann (1967). Greatest development of Siderocapsaceae has been found in the hypolimnion of lakes, often near growths of *Metallogenium.* At present, five species of the genus *Siderocapsa* (see Table 1) have been shown to be planktonic, not sessile, and so are not susceptible to slide growth (Kalbe, 1965; Redinger, 1931; Skuja, 1948, 1956; Wawrik, 1956).

The occurrence of Siderocapsaceae is not limited to typical freshwater habitats. As the investigations by Ten (1967, 1968, 1969) have shown, the family Siderocapsaceae *(Naumanniella polymorpha)* occurs in brown forest soils and iron-manganese crusts on soil-forming rocks as well. A marine *Siderocapsa* has been found in the iron bay of Palaea Kameni in Santorini, Greece (Hanert, 1981).

Table 1. Spectrum of Siderocapsaceae habitats and environmental parameters.

Habitats	Organisms	Environment	Physicochemical basic conditions inferred from natural occurrence or culture experiments
Iron-rich meadow and swamp ditches, flat pools (often stagnant) and mesosaprobic flowing streams	*Siderocapsa*		
	S. treubii	Typically epiphytic (attached to submerged roots and leaves of water plants; also ongrowth on slides; mesosaprobic waters)	Aerobic, organotrophic, pH 6.2–8.7
	S. major	Neustonic and epiphytic	As above
	S. monoica	Epiphytic	Aerobic tending to microaerobic, organotrophic
	Siderocystis		
	S. vulgaris	Ongrowth in the upper water layer	Aerobic, organotrophic, pH 6–7
	S. confervarum	Forming large iron aggregates on algae	Aerobic, organotrophic, pH 6–7
Wells, pipes, and waterworks	*Siderocapsa*		
	S. botryoides		
	Naumanniella		
	N. pygmaea	All found in cool waters of pipes and deep wells by Beger (1949)	Microaerobic, psychrophilic, organotrophic
	N. elliptica		
	N. minor		
	N. catenata		
	Siderobacter		
	S. gracilis		
	S. brevis		
	S. latus		
Lakes (planktonic forms)	*Siderocapsa*		
	S. anulata	Epilimnetic (water surface up to 6 m)	Aerobic, pH around 8.0, organotrophic
	S. coronata	Generally neustic, mass development at time of vernal thaw, also found at depths of 17–20 m	Aerobic to microaerobic, organotrophic
	S. arlbergensis	Epilimnetic in alpine pools with mass development at time of thaw	Aerobic, organotrophic, ferrous iron up to 4 ppm, pH 4.5–8.5
	S. eusphaera	Generally hypolimnetic in larger meso- and eutrophic lakes, at depths of 6–30 m, mass development	Microaerobic to aerobic, organotrophic
	S. geminata	Generally hypolimnetic, epilimnetic occurrence during vernal and autumnal circulation, at depths of 0–26 m, mass development in lakes	Microaerobic to aerobic, organotrophic
	Metallogenium		
	M. personatum	Hypolimnetic with mass development in the chemocline zone, where O_2 disappears, at an iron and manganese content of 1–5 ppm	Microaerobic, organotrophic
Soils, bottom deposits of water bodies, mud, iron manganese crusts on soil-forming rocks	*Siderocapsa* sp. (Ten, 1967)	Different soil types	Aerobic to microaerobic, organotrophic

(*continued*)

Table 1. *Continued*

Organisms	Environment	Physicochemical basic conditions inferred from natural occurrence or culture experiments
Naumanniella		
N. polymorpha	Iron-manganese crusts and brown forest soils	Aerobic to microaerobic, possibly mixotrophic by manganese oxidation
Siderococcus		
S. limoniticus	Mud horizons and bottom deposits of fresh waters	Microaerobic, neutral pH

In all habitats, the most characteristic feature of *Siderocapsa* is its capacity to form large masses of iron and/or manganese oxide. This mass development of Siderocapsaceae, like that of the classical stalk- and threadforming iron bacteria, is often visible to the naked eye. Such readily visible deposits usually develop during vernal and autumnal circulation or during vernal thaw in alpine lakes and pools; deposits have been reported from all planktonic lake Siderocapsaceae, as well as from some epiphytic *Siderocapsa* species (Sokolova, 1959). A yearly cycle of Siderocapsaceae development with vernal and autumnal maxima in swamp ditches has

Table 2. Procedures for Siderocapsaceae enrichment in natural waters and synthetic media.

Procedure	Procedure suitability and incubation time
A. Procedures using natural waters:	Procedure suitability and incubation time:
1. Maintenance of sample flasks (totally or 2/3 filled) at 4°C and room temperature without any stirring. Flask size: up to 1 liter. Modifications: addition of 1 mg $MnCO_3$/liter or 1 mg $FeCO_3$/liter.	These procedures with natural waters seem suitable for the majority of all known Siderocapsaceae
2. Test tubes filled with sample water underlayed by 1 ml natural sediment. Modification as above.	
3. 30- to 40-liter aquarium cultures adding 0.07 g yeast extract/liter and 1 mg $FeCO_3$/liter or 1 mg $MnCO_3$/liter (divided in 5 portions added in intervals of 2 days).	Incubation time: up to 3 weeks
B. Procedures with synthetic liquid media (frequently used with 0.1% agar):	
1. Yeast extract-$MnSO_4$ medium; Pringsheim (1949)—medium in modification of Tyler and Marshall (1967) and application according to Dubinina and Zhdanov (1975). Composition (%): yeast extract, 0.005; $MnSO_4$, 0.002; distilled water, 1 liter—in place of manganese, to the bottom of the test tubes iron oxalate or ferrous sulfide were added.	
2. Peptone-$MnCO_3$ medium; manganese-peptone media have been frequently used, see Schweisfurth, 1972. Composition according to Schmidt (1976) with addition of glucose (%): peptone, 0.00002; $MnCO_3$, 0.0002; glucose, 0.00002; distilled water, 1 liter.	Growth usually within 2–3 days
3. Yeast and beef extract–manganese–iron medium (according to Mulder and van Veen, 1963). Composition (%): $MnCO_3$, 0.2; $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$, 0.015; Difco yeast extract, 0.0075; beef extract, 0.1; cyanocobalamin, 0.005 mg/liter, Na-citrate-2-hydrate, 0.015; distilled water, 1 liter.	
4. Starch-$MnCO_3$ medium (Zavarzin, 1964—medium modified according to Dubinina, 1970). Composition (%): starch, 0.1; $MnCO_3$, 0.5 (freshly prepared); distilled water, 1 liter.	
C. Procedures with solid media for isolation: Media as B 1–4 with 1–1.5% agar in petri dishes.	Growth within 2 days; iron and/or manganese oxidation within 7 days

been demonstrated and quantified for *Siderocystis vulgaris* (Galinsky and Hanert, 1979b). Detailed measurements which give some impression of Siderocapsaceae mass development in nature were taken by Dubinina, Gorlenko, and Suleimanov (1973) in the meromictic lake Gek-Gel', using the membrane-filter method (filters stained with erythrosine and treated with potassium ferricyanide and hydrochloric acid). These determinations counted up to 60,000 cells/ml at a depth of 27–29.5 m in the zone of massive development of *Siderocapsa eusphaera* (distinct narrow zone below *Metallogenium* growth zone), and also demonstrated the gradient growth of this organism (see also Sorokin, 1968).

Aspects of Siderocapsaceae Physiology Deduced from Environmental Variables

The old idea that Siderocapsaceae are aerobic iron bacteria arose from their initial discovery in epiphytic, neustonic, and surface film habitats. More recent discoveries of Siderocapsaceae in deep wells, and especially in the hypolimnion of lakes, have forced the revision of this idea. *Siderocapsa treubii, Siderocapsa major,* and *Siderocapsa monoica* (which are probably only growth forms of one species—Drake, 1965; Hardman and Henrici, 1939) as well as *Siderocystis vulgaris, Siderocystis confervarum, Naumanniella neustonica,* and possibly *Siderocapsa anulata* (see Table 1) appear to be the only markedly aerobic species. All the other Siderocapsaceae (*Siderococcus limoniticus, Naumanniella polymorpha,* and the lake *Siderocapsa* species) tend to be microaerophilic. The oxygen content of the mass growth zone in lakes is at the level where oxygen disappears (narrow water layer at the chemocline: $O_2 < 1$ ppm, $rH_2 < 19$, Fe^{2+} 1–2 ppm, Mn^{2+} 1–5 ppm; Dubinina, Gorlenko, and Suleimanov, 1973). These natural mass growth conditions established for *Siderocapsa eusphaera* are very similar to those for *Siderocapsa geminata* (Schmidt, 1976), which also grows under extremely microaerobic conditions (see later, Fig. 2a-f). Generalizing, and including the macroscopic observations concerning the onset of a mass development of lake *Siderocapsa* described by the first observers (see Table 1), it seems that optimal Siderocapsaceae growth takes place at the beginning of a change from extremely reduced to oxidized conditions in a neutral-to-light alkaline environment.

Table 3. Enriched or presumably isolated Siderocapsaceae.

Organism	Enrichment or isolation procedure[a]
Siderocapsa	
S. treubii	Enriched: method A3 (Moldau-water resp. tap water + 0.1% $MnCl_2$ as epiphytic growth; Molisch, 1910).
	Enriched: method A3 (swamp-ditch water + 0.007% yeast extract + 0.0001% $FeCO_3$; growing as neustic form in the water surface layer).
S. eusphaera	Enriched: method B1; presumably isolated: on medium B1 with 1% agar by Dubinina and Zhdanov (1975).
S. geminata	Enriched: method A1; presumably isolated: on media B1-4 by Schmidt (1976).
Naumanniella	
N. neustonica	Enriched: method A3 (swamp-ditch water + 0.007% yeast extract + 0.0001% $FeCO_2$; growing as neustic form in the water surface layer).
N. polymorpha	Presumably isolated: on Beijerinck's medium.
	(K_2HPO_4, 0.05%; NH_4Cl, 0.05%; $MnCO_3$ or $Mn(HCO_3)_2$, 1%; agar, 2%); further on Aristovskaya's (1965) medium (ulminofulvate complex) and on iron ammonium salt of citric acid by Ten (1968, 1969).
Ferribacterium	
F. duplex	Enriched: modified method A2 underlayed with peat and iron bars, Brussoff (1916); presumably isolated: in iron ammonium citrate medium, Brussoff (1916).
Siderocystis	
S. vulgaris	Enriched: method A1 in 3-liter Erlenmeyer flasks 3/4 filled with swamp-ditch water; growing as rust-spot ongrowth on the flask walls at room temperature, H. H. Hanert (unpublished observations).
S. confervarum	Enriched: method A1 in 100-ml flasks filled to the top with swamp-ditch water and some algae threads, cultivated at room temperature and near a window (daylight).
Siderococcus	
S. limoniticus	Enriched: method A2, coupled with slide and capillary ongrowth, Dorff, 1934; Zavarzin, 1972; Kutuzova, 1974.
S. communis	Enriched: in ferrous ammonium citrate, Dorff, 1934.

[a]See Table 2 for methods.

Table 4. Procedures necessary for identification of Siderocapsaceae.

Procedure	Methods for realization
1. Exact light-microscopic visualization of the bacterial cell and surrounding iron capsule	a. Phase-contrast observation: Yellowish iron capsule with light-refrangible central bacterial cell. b. Direct microscopic control of capsular ferric iron dissolution by adding 5% HCl to the edge of the cover glass (suspension preparations), immediately followed by carbolfuchsin staining of the central cell under microscope. c. Carbolfuchsin–Prussian blue double-staining (air-dried preparations): Prussian blue solution (70 ml 0.1% HCl + 30 drops 2% $K_4[Fe(CN)_6]\cdot 3H_2O$): 10 min (cuvette); washing with water (cuvette); 10 min into nonheated Ziehl-Neelsen carbolfuchsin (cuvette). d. Benzidine staining for manganese reaction: Material on slides or filters is first wetted with benzene, and 2 or 3 drops of 0.5% benzidine hydrochloride in 50% acetic acid are applied to the wet surface. After 1–2 s, the benzidine is removed with filter paper (Dubinina, Gorlenko, and Suleimanov, 1973). e. Fluorescence staining of the bacterial cell: air-dried preparations covered with a filtered FITC solution for 5 min (0.1 N Na_2CO_3 + 0.1 N $NaHCO_3$ in 3:2 proportion + 3.5 mg FITC per 10 ml)—washing with the same buffer. Very suitable for visualization of bacterial cells in rust-spot-forming bacteria.
2. Scanning electron microscopy and electron probe microanalysis	a. Stereoscan: Necessary for detection of the slimy nature of the capsule as well as the globular ferrihydrite particles in rust spots. Preparation in the usual way, placing a drop of material directly onto the specimen stub or using ongrowth method (specimens metal-coated). Figs. 1 (without 1h), 2a–d, and 2h–k. b. Electron-probe microanalysis for proof concerning iron or manganese incorporation of the capsules using X-ray analysis (area- or point-scanning). Figs. 1h, 2e, f, and 1.
3. Transmission electron microscopy	Realization in the usual way using formvar-coated grids (ongrowth method for sessile Siderocapsaceae; see also Kutuzova, 1974, 1975; Kutuzova, Gabe, and Kravkina, 1972); cell observation is better when capsular iron or manganese is removed by dissolving.
4. Direct microscopic observation of developmental cell cycle in micro-chambers or reverse light microscope	The possibility of pleomorphic development of Siderocapsaceae members makes it necessary to compare cell development in chambers filled with habitat water or culture media for identifying growing cells with the natural originals. This should be possible by directly proving stalk excretion from the apical cell in the way done for *Gallionella* (Hanert, 1974) or by using the reverse microscope (Schmidt, 1976, cell cycle of *Siderocapsa geminata;* see also Dubinina and Zhdanov, 1975, cell cycle of *Arthrobacter siderocapsulatus*).

A more essential difference between classical stalk- or threadforming bacteria and capsular iron bacteria appears to be the latter's obvious growth dependence on organic material. It appears to be no accident that Siderocapsaceae have not yet been found in iron springs or mineral water, very poor in organic substances (with the exception of certain results concerning very unsure forms obtained by Beger, 1949). From this standpoint, classifying Siderocapsaceae as a chemolithotrophic bacterial group (Buchanan and Gibbons, 1974) appears less justified and a physiologically indeterminate classification would correspond better to the facts

Fig. 1. Identification and differentiation of Siderocapsaceae cells, capsules, and ferrihydrite particles. (a–c) *Siderocapsa treubii,* in situ growth on slide in aquarium-natural water culture: (a) single cells at the initial phase of capsule formation; (b) two cells coated with slime and iron particles; (c) slime capsule completely coating the cell. (d–f) *Siderocapsa* sp. from the Siderocapsaceae zone in the marine iron bay of Palaea Kameni, in situ growth on slide, Hanert, 1981: (d) thread-slime capsule; (e) capsule with two holes; (f) cell half-coated with thread-slime capsular material. (g–i) Globular, chain-forming ferrihydrite particles on the slime surface of the rust-spot bacteria (formed in the marine bay): (g and i) ferrihydrite particles; (h) FeKα picture to (g). (j) Single cell of *Siderocystis vulgaris* surrounded by ferrihydrite particles. (k) Single cell of the marine rust-spot-former surrounded by ferrihydrite particles. (l) Slime capsule of the marine *Siderocapsa* sp. coated with ferrihydrite particles.

and would avoid invalid inferences. Until now, only *Naumanniella polymorpha* cultivated by Ten (1968, 1969) in Beijerinck's $MnCO_3$ medium appeared to have a certain probable capacity for mixotrophic growth by manganese oxidation.

For the other capsular iron or manganese bacteria, the natural conditions of the habitat suggest that the highest probability is organotrophic nutrition, possibly of the sort first postulated by Aschan (1907) (utilizing the organic portion of iron humates or other iron organic substances and precipitating ferric iron in or on the capsules).

Isolation

Enrichment

Table 2 lists suitable enrichment procedures for Siderocapsaceae. In particular, the procedures with natural water are extraordinarily simple, straightforward, and characteristic for the speedy enrichment of iron bacteria in general. In habitat-water samples maintained in cold storage or at room temperature without any stirring, a rapid growth of iron bacteria begins within a few days (often overnight). The growth can be recognized mostly by the formation of yellow to black-brown (iron and/or manganese oxides) flocs which sediment slowly. The Siderocapsaceae in general are no exception; nor, for example, is *Siderocapsa geminata,* observed in the hypolimnion of the "Plußsee" (Plön, Germany) and investigated by Schmidt (1976), among others. Our own samples from the same site behaved in the same way, and led within a week to an intensive development of *Siderocapsa geminata* in the sample flasks.

A second suitable enrichment method involves the use of 30- to 40-liter aquaria cultures with habitat water after the addition of 0.007% yeast extract and 0.0001% $FeCO_3$ or $MnCO_3$. At first, within 2 days after the culture start and before the addition of yeast extract and $FeCO_3$, thread-forming bacteria develop. Then, 7 days after the addition of $FeCO_3$ and yeast extract and the start of desulfurication, an intensive development of Siderocapsaceae takes place at the end of the desulfurication phase. The Siderocapsaceae form an ochreous layer, 2–3 mm thick, on the water surface. This method makes enrichment possible by more closely simulating natural conditions, particularly with *Siderocapsa treubii* and *Naumanniella neustonica,* which both form dense nests of bacterial cells. The first enrichment of a *Siderocapsa* strain, as carried out by the discoverer of this organism group, is fundamentally similar; *Siderocapsa treubii* was cultivated as an epiphytic growth on water plants in aquaria with the addition of 0.1% $MnCl_2$ (Molisch, 1910). Test tubes with sample water underlayed with natural sample mud were successfully used for the enrichment of *Siderococcus limoniticus,* and showed growth 3–4 days after the beginning of the culture (Dorff, 1934). The enrichment of *Siderocystis confervarum,* an organism which grows in direct contact with filamentous algae, also uses natural sample water.

In Table 2, section B, four synthetic media are presented which have proven to be particularly suitable for cultivating Siderocapsaceae. Yeast extract is particularly suitable as an organic carbon and nitrogen substrate, as is peptone and beef extract in weak concentration; iron and manganese are best given as carbonate or sulfate salts. On the basis of the presently available facts, in particular the culture experiments by Dubinina and Zhdanov (1975) and Schmidt (1976), as well as indications from the older literature (summarized by Schweisfurth, 1972), Siderocapsaceae can be regarded as organisms that grow well in weak concentrations of organic media, when cultivated in a neutral environment under aerobic to microaerobic conditions. Growth without oxygen appears to be impossible. Table 3 provides a bird's-eye view of all Siderocapsaceae that have been enriched so far.

Isolation

The isolation of Siderocapsaceae is much more a problem of identification than the application of particular isolation techniques. As Dubinina and her co-workers indicated for *Siderocapsa eusphaera* (1973, 1975), Schmidt for *Siderocapsa geminata* (1976), and Ten for *Nauman-*

niella polymorpha (1968, 1969), pure cultures of these organisms could be conventionally produced without difficulty in liquid and solid media, using serial solution or plating techniques, respectively, (Table 3).

The main problem in isolating Siderocapsaceae is the question of relating the isolated organism with the Siderocapsaceae organism of the inoculated material from the natural environment. The isolated strains of *Naumanniella polymorpha, Siderocapsa eusphaera,* and *Siderocapsa geminata* show—as described by the authors—an extreme polymorphism and a quite complex cycle of development, whereas it has not yet been possible to demonstrate corresponding changes directly in the natural environment immediately from an individual object. This is one of the reasons why the task of identifying Siderocapsaceae has such crucial importance at the moment, and why isolation work cannot lead to really secure results so long as the individual developmental cycle remains unexplained.

Identification

Initial Identification

Siderocapsaceae are defined purely morphologically, without physiological features and the morphological definition provided by the people who first described them refers to their morphology in their natural environment or in habitat water cultures. This fact is the starting point from which all identification work has to proceed. The second important point to make is that the first morphological descriptions of the organisms corresponded to the then present state of microscopic technology; the descriptions used only light-microscopic photographs or drawings and the natural ultramorphology and ultrastructure remained unknown. *Siderocapsa anulata* is the only Siderocapsaceae which, at the time of its discovery, was described by means of an electron microscope (Kalbe et al., 1965) so that a clear picture of its morphology was produced which was completely adequate for purposes of identification.

The description which defines the morphology of the Siderocapsaceae contains three components: the bacterial cell, the capsule or excreted gelatinous material, and iron and/or manganese compounds deposited in or on the excreted material. The capacity to form capsule-like material has been recently shown for *Siderococcus limoniticus* (Kutuzova, 1974), which had previously been regarded as a non-capsule-forming Siderocapsaceae, so that this component appears to be common to all Siderocapsaceae. For the identification of Siderocapsaceae, the analysis of natural ultramorphology of these three components is of crucial importance, and thus, in virtue of new ideas concerning the pleomorphic development of these organisms, the analysis of the individual natural development must be added as a further new component.

Identification by Analysis of the Natural Ultramorphology and Development

The methods that are indispensable for a clear identification, which must be carried out with all Siderocapsaceae whose existence has been made certain by repeated finds, and ecological descriptions are summarized in Table 4. They relate to the visualization of the bacterial cell, the differentiation of cell and capsule or slime material, the ultramorphology of the capsular material, the specific evidence for the presence of iron and manganese, the ultramorphology of the iron deposits, and the analysis of the individual development under natural conditions.

LIGHT MICROSCOPY, STAINING, AND DIFFERENTIATION OF THE BACTERIAL CELL. In phase contrast microscopy, the central cells can only be distinguished from the surrounding capsule which contains metal oxide by their differing light reflection. This appearance can also be created by the shape of the capsule, and cell and capsule staining are indispensable. Carbolfuchsin and fluorescence staining have been found suitable for cell staining. Erythrosine staining has been applied just as successfully by other authors. In combination with the Prussian blue reaction for iron and the benzidine hydrochloride reaction for manganese, a differentiating double staining of the cell and metal-containing capsule is possible. Fluorescein isothiocyanate (FITC) fluorescence staining is especially suitable for the visualization and differentiation of the bacterial cells from iron/manganese oxides in rust-spot-forming bacteria, since the inorganic deposits are not stained (Hanert, 1981). A specific staining of the capsular polysaccharides has not yet been carried out, so that the capsule until now has only been made recognizable by staining the iron or manganese which it contains.

ULTRAMORPHOLOGY OF THE CAPSULE AND EXCRETED GELATINOUS MATERIAL. In all the Siderocapsaceae material which has been sampled in the natural environment or in habitat water cultures, the capsules showed a very characteristic slime-thread ultramorphology and struc-

ture, which can be recognized best with scanning electron microscopy. The capsules are slimy but, nevertheless, form casings which the bacteria vacate, leaving a noticeable hole when they depart. The bacteria produce this gelatinous thread slime, cover themselves with it—at this stage the bacteria cannot be recognized with a scanning electron microscope—and break through the capsule after a certain time. Even though this process cannot be observed in vivo, the electron microscope pictures allow scarcely any other inference. (See Fig. 1a-c, *Siderocapsa treubii;* Fig. 1d-f, *Siderocapsa* sp.; Fig. 2a-d, *Siderocapsa geminata* from flocs.) On the basis of this characteristic ultramorphology, it seems reasonable to think that the slime capsule might be a very characteristic feature of genuine Siderocapsaceae. It should be noted that the gelatinous slime of the Siderocapsaceae also resembles ultramorphologically those thread slimes which we have observed without the formation of capsules in *Metallogenium* habitat water cultures (Fig. 2g-k, *Metallogenium* flocs).

ULTRAMORPHOLOGY OF DEPOSITED IRON PARTICLES AND ELEMENT-SPECIFIC, X-RAY DETERMINATION OF THE PRESENCE OF IRON/MANGANESE IN THE CAPSULES IN COMBINATION WITH POSTULATED DEVELOPMENTAL STAGES. There has been intensive discussion concerning the existence of tiny mycoplasma-like developmental and budding stages in certain iron and manganese bacteria, for example, in *Gallionella* (Balashova, 1969), *Metallogenium* (Dubinina, 1970), and also in Siderocapsaceae (*Siderococcus limoniticus,* Kutuzova, 1974; Kutuzova, et al., 1974; *Naumanniella polymorpha,* Ten, 1968, 1969; *Siderocapsa geminata,* Schmidt, 1976). Evidence which has previously been presented in favor of this hypothesis has largely been pictures obtained by transmission electron microscopy which, however, show only tiny dense particles.

Relevant here are observations on rust-spot-forming bacteria (rust spots in the Palaea Kameni Bay, Hanert, 1981; *Siderocystis vulgaris* rust spots, Galinsky and Hanert, 1979a). The

Table 5. Siderocapsaceae which have clearly been shown to exist by repeated finds.

Organisms	Morphological features and characteristic ecology
Siderocystis	
S. confervarum	Large ovoid iron precipitations on *Conferva*-algae; iron-containing swamp ditches.
S. vulgaris	Forming rust spots up to 1 mm in diameter on exposed glass slides (Fig. 1j); iron-containing swamp ditches.
Naumanniella	Slim rods with a thin, sharply limited iron capsule in the form of a torus (marginal thickening); single and in short chains.
N. neustonica	Rod-shaped cells, including the torus, 1.8–3.3 by 4.9–10 μm; surface of iron-bearing well and swamp water.
N. polymorpha	Ellipsoid rods of 0.7–1.0 × 1.0–2.0 μm that form coccoid cells by budding and fission; thin capsules; manganese- not ferrous iron-oxidizing; colony-forming in manganese carbonate or manganese acetate agar; brown forest soils and rock crusts.
Siderococcus limoniticus	Cocci (0.2–0.5 μm in diameter) without capsules (recently, capsule-like formations in which iron-oxide deposition takes place have been found by Kutuzova, 1974); in mud horizons and zone growth in culture.
Siderocapsa	Coccus resp. ovoid or short rods, single or in groups in a very thick, slimy iron capsule.
S. treubii	(Including the intermediary form of *S. major* and *S. monoica* found by Hardman and Henrici, 1939 and Drake, 1965.) Coccoid cells of 0.6–1.6 μm in diameter and small rods 0.4–1.0 × 2 μm; single or in groups; most frequently of 6–8 up to 30 cells and more in mucoid capsules averaging about 2 μm by 4.5 μm with round, elliptical, or irregular outer edge surrounded by thick, rust-brown deposits of iron (light microscopic photographs by Hardman and Henrici, 1939).
S. anulata	Single coccus (0.2–0.5 μm in diameter) surrounded by sharply limited ferric iron ring (1.2–1.9 μm), excellent electron microscopic photographs by Kalbe, Keil, and Theile, 1965; planktonic and epilimnetic.
S. coronata	Two to eight cocci (maximal 1.2 μm) in one capsule (up to 24 μm in diameter); aggregating to coenobia of up to 90 capsules and a length of 400 μm (described and pictured by drawings; Redinger, 1931); in alpine lakes.
S. arlbergensis	Cocci (0.4–1.0 μm) normally in pairs in capsules (diameter 6–15 μm); coenobia similar to *S. coronata,* but single capsules not fusing; light-microscopic photographs by Wawrik, 1956; planktonic and neustic in alpine pools.
S. eusphaera	Coccoid to ovoid (1–2 μm) cells up to 60 in large capsules (regular spheres up to 50 μm in diameter); capsules occur singly (drawings by Skuja, 1948); planktonic and hypolimnetic in large lakes.
S. geminata	Ovoid cells (0.5 × 0.8 μm) usually in pairs in round capsules (7–11 μm in diameter); capsules occur singly (drawings by Skuja, 1956); planktonic and hypolimnetic in lakes.

iron oxides in these rust spots consist of tiny, spherical ferric iron particles which are often chainlike in form; these particles correspond to the iron bodies which have been analyzed as ferrihydrite by Tschukrov (1974). These particles consist exclusively of iron, which can easily be demonstrated by X-ray analysis (point-scanning) and dissolving in acids.

Another useful aid in structural analysis in this field is area-scanning electron microscopy in combination with element-specific scanning. The existence of both iron and manganese incorporation in the capsules can be indicated simultaneously (see Fig. 2d-f for *Siderocapsa geminata* and Fig. 2l for *Metallogenium*).

The methodological possibilities for analyzing natural individual development in vivo are represented in Table 4.

In summary, it should be emphasized that an adequate number of identification and culture methods are available for the investigation of Siderocapsaceae, which can be applied to those genera and species (Table 5) whose existence has been made certain. One of these forms is *Siderocystis confervarum,* which forms large, round, iron oxide aggregates on algae, and can be found in profusion in iron-bearing swamp ditches in the vicinity of Braunschweig. The application of the methods described here to this bacterium has resulted in the surprising discovery that this organism lives not only on the surface of the algae but also within it. This bacterium might have a lytic function for this algae, similar to those lytic bacteria which colonize on the hyphae of fungi in natural habitats (e.g., *Phytophthora cinnamomi;* Nesbitt, Malajczuk, and Glenn, 1978).

Acknowledgments

I wish to thank the following organization and persons: The "Deutsche Forschungsgemeinschaft" for financial support; Ilona Koschik, Detlef Herz, and Bernd Hoppe for technical assistance in environmental measurements and preparation of cultures, stains, and photographs.

CHAPTER 237

The Genus *Fusobacterium*

TOR HOFSTAD

The genus *Fusobacterium* includes several species of obligately anaerobic, nonsporeforming, motile or nonmotile, Gram-negative rods. Some are slender, spindle-shaped bacilli, others are pleomorphic rods with parallel sides and rounded ends. Their habitat is the mucous membranes of humans and animals.

During the last decade of the nineteenth century, several authors, among them Miller (1898), Plaut (1894), and Vincent (1896, 1899, 1904), observed spindle-shaped, or fusiform, bacilli in material from both the diseased and the healthy human mouth. Veillon and Zuber (1998), Lewkowicz (1901), and Ellermann (1904) were the first to cultivate fusiform bacilli. Loeffler, in 1884, observed pleomorphic rods in diphtheritic lesions of calves and doves. The same organism, identifiable with the *F. necrophorum* of today, was cultured by Bang (1890–1891) from necrotic lesions of a number of domestic animals, and by Schmorl (1891) from an epizootic in rabbits.

The more pleomorphic fusobacteria without tapering ends have been described under different generic names. Examples are *Bacteroides, Sphaerophorus, Bacterium, Necrobacterium, Pseudobacterium, Bacillus, Actinomyces, Corynebacterium, Ristella,* and *Zuberella.*

The family name Bacteroidaceae was first used by Pribram (1929) for strictly anaerobic rods. Ten years earlier, Castellani and Chalmers (1919) proposed that the genus *Bacteroides* should only contain obligately anaerobic bacilli that did not form spores. Eggerth and Gagnon (1933) and Weiss and Rettger (1937) excluded the Gram-positive rods from the genus. The generic name *Fusobacterium* was proposed by Knorr (1923) for obligately Gram-negative bacilli that were fusiform. Prévot (1938), who argued that the generic name *Fusobacterium* (and also the names Bacteroidaceae and *Bacteroides*) was invalid, used the term *Sphaerophorus* for the nonmotile, pleomorphic fusobacteria, and the term *Fusiformis* for the fusobacteria that had tapered ends. The seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957) divided the family Bacteroidaceae into three genera: *Bacteroides,* defined as rods with rounded ends; *Fusobacterium,* defined as rods with tapering ends; and *Sphaerophorus,* defined as rods with rounded ends that showed a market pleomorphism and where filaments were common.

Cell morphology therefore, had so far been the main criterion for the classification of the nonsporeforming, anaerobic rods. Physiological studies (Beerens et al., 1962; Werner, 1972a; Werner et al., 1971) and studies of DNA base ratios (Sebald, 1962) showed that there was insufficient evidence to separate the genera *Fusobacterium* and *Sphaerophorus.* In the eight edition of *Bergey's Manual* (Moore and Holdeman, 1974a) the genus *Fusobacterium* was restricted to anaerobic, nonsporeforming, Gram-negative rods which form butyric acid as a major endproduct from peptone or glucose (without isobutyric and isovaleric acids). Further, *Leptotrichia* (see Chapter 223) was reestablished as a genus for the saccharolytic fusiform bacilli producing lactic acid as the only major fermentation product.

Up to now, 12 human species of *Fusobacterium* have been adequately described (Table 1). The GC content of these species ranges from 26 to 34 mol%. In addition, *F. prausnitzii,* which has a GC content of 52–57 mol%, has been included in the genus. The species isolated most frequently from humans and animals are *F. nucleatum* and *F. necrophorum,* respectively. *F. simiae* is a new species which has been isolated from the mouth of the stumptailed macaque (*Macaca arctoides*) (Slots and Potts, 1982).

Habitats

As Normal Microbiota of Humans and Animals

All *Fusobacterium* species are parasites of humans and animals. Anaerobic Gram-negative rods with the same morphological and bio-

Table 1. The main human sources of *Fusobacterium* isolates.

Species	Normal flora		Clinical specimens
	Mouth	Gastrointestinal tract

F. necrophorum		+	+
F. alocis	+		
F. gonidiaformans		+	+
F. mortiferum		+	+
F. naviforme	+		+
F. necrogenes		+	
F. periodonticum	+		
F. prausnitzii		+	
F. russii		+	
F. sulci	+		
F. ulcerans			+
F. varium		+	+

Adapted from Moore et al. (1984), Slots et al. (1983), Cato et al. (1985), and Adriaans and Shah (1988).

chemical properties as *Fusobacterium* species have also been isolated from the hindgut of the cockroach *Eublaberus posticus* (Foglesong et al., 1984) and the gastrointestinal tract of the grass carp *Ctenopharyngodon idella* (Trust et al., 1979).

The main human habitats of the different *Fu-sobacterium* species are listed in Table 1.

F. nucleatum is a constant member of the oral microflora of adults, but has also been isolated from the oral cavity of predentate children (Hurst, 1957; McCarthy et al., 1965). The principal habitat of *F. alocis* and *F. sulci* is the human gingival sulcus. The incidence of *F. periodonticum* in the human oral cavity is unknown. Occasionally, *F. naviforme* has been found in the mouth or the upper respiratory tract (Holdeman et al., 1977). The isolation of *F. necrophorum* from pleuropulmonary infections suggests that this organism is also able to live as a parasite on the mucous membranes of the oral cavity and upper respiratory tract of humans. The number of fusobacteria per milliliter of saliva has been estimated to be 5.6×10^4 (Richardson and Jones, 1958). In different surveys, fusobacteria have been found to make up from 0.4 to 7% of the cultivable dental plaque flora (Hardie and Bowden, 1974). There are, however, great individual variations. In patients with different forms of periodontitis, *F. nucleatum* is a predominant member of the subgingival plaque flora (Williams et al., 1976; Moore et al., 1982, 1983). Hadi and Russel (1969) reported a mean viable count of *F. nucleatum* per gram wet weight of gingival plaque material from patients with advanced chronic periodontal disease and acute ulcerative gingivitis of 3.3×10^7 and 9.3×10^7, respectively. In subjects with healthy gingivae, the corresponding figure was 5.7×10^6.

Fusobacterium makes up a small part of the fecal microflora of man, with individual variation ranging from about 7% to less than 1% of the cultivable fecalflora (Finegold et al., 1974; Finegold et al., 1975; Holdeman et al., 1976; Moore and Holdeman, 1974b; van Houte and Gibbons, 1966). The most prevalent species seem to be *F. prausnitzii, F. russii,* and *F. mortiferum.* Both the number of fusobacteria in feces and the relative frequency of the different species are influenced by the diet (Finegold et al., 1974; Maier et al., 1974; Peach et al., 1974). Thus, Japanese on a traditional diet rich in carbohydrate have a relatively high number of *F. necrophorum* in feces (Ohtani, 1970a; Ueno et al., 1974).

The occurrence of fusobacteria on the mucous membranes of the genitourinary tract is virtually unknown. Fusobacteria were not present in the normal microflora of the cervix of 30 healthy females examined by Gorbach et al. (1973), and Hite et al. (1947) found no fusobacteria in the healthy vaginas of pregnant women. Fusobacteria, particularly *F. necrophorum,* were, however, present in the vagina of pregnant women with trichomoniasis and in the postpartum uterus of such women. Spaulding and Rettger (1937) found *F. nucleatum* in the normal vagina but not in the vagina of pregnant women. Davis and Pilot (1922) and Brams et al. (1923) isolated fusiform bacilli (and spirochetes) from the clitoris region in females, and from preputial secretions of 50 out of 100 men.

The habitat of *F. ulcerans* is unknown. The organism has been isolated from tropical ulcers (Adriaans and Drasar, 1987) and from a few specimens of mud (Adriaans and Shah, 1988).

Tropical ulcer is a form of skin ulceration predominantly affecting children and is most commonly in the tropics (Robinson and Hay, 1985)

F. necrophorum is a normal inhabitant of the alimentary tract of cattle, horses, sheep, and pigs. Fuller and Lev (1964), in a study of the Gram-negative bacteria of the pig alimentary tract, found *F. necrophorum* to be present from the age of 43 days. Aalbæk (1972) isolated the organism from the colon of pigs in numbers up to 10^3 per gram of wet material, but in considerably higher number in the ileus, cecum, and colon of pigs with experimental enteritis. *F. necrophorum* has also been found in infections and in feces of other animals, such as mules (Nolechek, 1918), goats (Jensen, 1913), reindeer (Horne, 1898–1899), antelope (Mettam and Carmichael, 1933), macropods (Bang, 1890–1891; Samuel, 1983), wildebeest (Grainer, 1983), dogs (Jensen, 1913), rabbits (Cameron and Williams, 1926; Schmorl, 1891), rats (Lewis and Rettger, 1940), chickens (Jensen, 1913), and apes (Dack et al., 1935; Dack et al., 1937). It has also been reported in buffaloes, cats, guinea pigs, mice, snakes, tortoises, and fowl (Simon and Stovell, 1969; Weinberg et al., 1937).

Less is known about the presence in animals of the other *Fusobacterium* species. Fusiform bacilli, probably *F. nucleatum,* have been isolated from the alimentary tract of pigs (Aalbæk, 1977) and mice (Syed, 1972), and from the oral cavity and the throat of monkeys (Krygier et al., 1973; Pratt, 1927; Slanetz and Rettger, 1933), dogs (Slanetz and Rettger, 1933), cats (Prèvot et al., 1951), rabbits (Pratt, 1927; Slanetz and Rettger, 1933), and guinea pigs (Pratt, 1927; Spaulding and Rettger, 1937). Terada et al. (1976) isolated *F. necrogenes* and *F. mortiferum* from pig feces, and *F. perfoetens* has been found in piglet feces (van Assche and Wilssens, 1977). *F. necrogenes* is a member of the cecal flora of poultry (Holdeman et al., 1977). *F. russii* is a member of the normal oral flora of cats (Love et al., 1987) and has been mentioned as being part of the normal microflora of mice and pigs, as well as of the rumen flora of cattle (Smith, 1975).

As Pathogens of Humans and Animals

Next to members of the "*Bacteroides fragilis* group" and the black-pigmented bacteroides, *F. nucleatum* is the Gram-negative anaerobic organism most often encountered in human infections. Also, *F. necrophorum* is clearly pathogenic in humans. Before the advent of antibiotics and other antimicrobial drugs, this organism was frequently isolated from suppurative infections of the oral cavity and the upper respiratory tract, and from pleuropulmonary infections. Reviewing the literature concerning anaerobic pleuropulmonary infections, Finegold (1977) found that *F. necrophorum* accounted for 24% of all anaerobic bacteria isolated from 358 cases. Today the organism is less commonly isolated from human infections. *F. nucleatum* is usually found associated with other anaerobic and/or facultative organisms. On a percentage basis, *F. nucleatum* and *F. necrophorum* have been isolated in pure culture from pyogenic infections more frequently than have other anaerobic bacteria (Beerens and Tahon-Castel, 1965; Werner and Pulverer, 1971; Bartlett et al., 1974). However, when in mixture with other organisms the recovery of fastidious strains of *F. nucleatum* and *F. necrophorum* may fail. Other species of *Fusobacterium* are occasionally isolated from clinical specimens, and nearly always in mixed culture.

Pathogenic fusobacteria are in particular isolated from inflammatory processes accompanied by necrosis and ulceration. They are most frequently found in head and neck infections, pleuropulmonary infections, abscesses of the brain and the liver, and in infections following human and animal bites. *Fusobacterium* species are also recovered from subcutaneous and soft-tissue abscesses, obstetrical and gynecological infections, and abdominal abscesses. Because of variations in nomenclature and anaerobic culture technique, the incidence of *Fusobacterium* infections is difficult to determine from the literature. In a series of 15,844 clinical specimens submitted over 12 years (1973–1985) to the microbiological laboratories in two military hospitals, *Fusobacterium* species accounted for 4% of all anaerobic isolates (Brook, 1988). *F. nucleatum* was the most common *Fusobacterium* species (47% of all *Fusobacterium* species). The incidence of fusobacteria was somewhat higher in a 10-year series of anaerobic isolates from hospital patients (Sutter et al., 1985). *F. nucleatum* and *F. necrophorum* may also be encountered in blood cultures, particularly when the upper respiratory and the female genital tract are the portals of entry (Felner and Dowell, 1971; Henry et al. 1983). *Fusobacterium* species may be a cause of chorioamnionitis (Altshuler and Hyde, 1985). *F. nucleatum* is invariably present in Plaut-Vincent's angina (fusospirochetal angina) and in acute necrotizing ulcerative gingivitis.

F. necrophorum is the cause of human necrobacillosis. This is a rare, but life-threatening septicemia which predominantly affects healthy young adults. The infection is characterized by sore throat, followed by rigor and the formation

of abscesses, usually involving the lung (Lemierre, 1936; Moore-Gillon et al., 1984).

F. necrophorum is an animal pathogen that is frequently isolated from necrotic and gangrenous lesions in cattle, sheep, and pigs, and less frequently from other animals. Carnivorous animals appear to be resistant. The most common manifestations of diseases associated with *F. necrophorum* are liver abscess (hepatic necrobacillosis) and footrot.

Liver abscesses are especially encountered in heavily fattened cattle. Ninety % or more of such abscesses contain *F. necrophorum* as the only organism or in combination with other organisms (Hussein and Shigidi, 1974; Kanoe et al., 1976; Newsom, 1938; Simon and Stovell, 1971; Berg and Scanlan, 1982). The disease is associated with inflammation of the forestomach, presumably caused by irritating substances produced by fermentation of the high-caloric feed or by foreign bodies (Jensen and Mackay, 1965). *F. necrophorum* present in the stomach contents is thought to gain entry to the vascular system through the injured mucosa. Liver abscesses have thus been produced experimentally in cattle and sheep by intraportal injections of viable cells of a bovine isolate of *F. necrophorum* (Jensen, et al., 1954). Hepatic necrobacillosis in feedlot cattle may present an economic problem in meat-producing countries (Langworth, 1977; Panel report, 1973). Footrot is frequently encountered in sheep and cattle. The disease affects the epidermal tissues of the interdigital skin and hoof and leads to separation of the hoof from the soft tissues. Lameness and morbidity from infection lead to a reduction in productivity and economic losses. Footrot in sheep is caused by *Bacteroides nodosus* in combination with *Fusobacterium necrophorum*. *B. nodosus* is the principal causative agent transmitting the disease from one animal to another (Beveridge, 1941), whereas *F. necrophorum* is essential for the later inflammatory destruction of tissue (Egerton et al. 1969; Roberts and Egerton, 1969). Injury to the foot and damp soil are predisposing factors (Graham and Egerton, 1968). Effective protection against ovine footrot is achieved through immunization with killed, fimbriated *B. nodosus* cells (Egerton and Roberts, 1971; Stewart et al., 1982).

The primary cause of epizootic footrot in cattle has not been found. *F. necrophorum* is present in the lesions as a concurrent pathogen or a secondary invader. Typical lesion have ben produced in cattle by the intradigital or intradermal inoculation of *F. necrophorum* alone or in combination with black-pigmented bacteroides (Berg and Loan, 1975; Clark et al., 1985).

Another disease associated with *F. necrophorum* is calf "diphtheria," which is necrotic laryngitis that occurs in calves up to 2 years of age. *F. necrophorum* is also involved in several other suppurative or gangrenous processes in domestic animals, such as interdigital dermatitis and heel abscess in sheep (Parsonson, et al., 1967; Roberts et al., 1968), neonatal bacteremias in calves and lambs, necrotic enteritis of pigs, necrotic rhinitis of growing pigs, and oral infections in several animals.

Necrobacillosis have long been known as a serious cause of death of macropods, mainly in zoological collections, but also in wild habitats. The body sites most commonly affected are the face, the stomach wall, and the hind limbs. There is good evidence that *F. necrophorum* is the main etiological agent of the disease, but other organisms, especially *Bacteroides* species, are often also present in the lesions in high numbers (Oliphant et al., 1984; Samuel, 1983). *Fusobacterium* species are the predominant species of the mixed flora in soft tissue infections of cats caused by contamination from the oral flora (Love et al., 1980).

Virulence Determinants

The natural infections have verified the infectivity and invasiveness in animals of *F. necrophorum* and in man of *F. nucleatum* and *F. necrophorum*. Experimental investigations in animals have shown that synergistic mechanisms may be of importance in the pathogenesis of mixed infections involving fusobacteria (Brook and Walker, 1986; Hamp and Mergenhagen, 1963; Hill et al., 1974; Kaufman et al., 1972; Onderdonk et al., 1976; Roberts, 1967a, b).

Our current knowledge of virulence determinants is cursory. Fimbriation has been seen in *F. necrophorum* (Shinjo and Kiyoyma, 1986), but not in *F. nucleatum* or other *Fusobacterium* species. Encapsulation has been observed in *F. nucleatum* and *F. necrophorum* (Brook, 1986; Emery 1988).

F. necrophorum isolates from cattle and sheep have been assigned to biovars A and B, and to an intermediate type, AB, on the basis of cultural characteristics (Fievez, 1963). A and AB biovars are frequently isolated from lesions, are highly virulent in mice, hemolytic, and produce a hemagglutinin. B biovars are of low virulence in mice and nonhemolytic. The agglutinin is associated with the cell wall, has a subunit molecular weight of 19,000, and is heat labile (Nagai et al. 1984). Certain strains of *F. necrophorum* produce a leukocidin which is also destructive for erythrocytes and a variety of cul-

tivated cells (Coyle-Dennis and Lauerman, 1978; Fales et al., 1977; Garcia et al., 1975a; Ishii et al., 1988; Roberts, 1967a, b; Scanlan et al., 1982). The toxin is possibly a phospholipase (Abe et al., 1979). High amounts of leukocidin is produced by A and AB biovars of *F. necrophorum,* indicating a correlation between toxin production and virulence. (Coyle-Dennis and Lauerman, 1979; Emery and Vaughan, 1986; Scanlan et al. 1982).

A hemagglutinin is also produced by *F. nucleatum* (Dehazya and Coles, 1980; Falkler and Hawley, 1977). *F. nucleatum* and *F. necrophorum,* as well as other *Fusobacterium* species, posses a cell wall lipopolysaccharide with the characteristics of an endotoxin (Garcia et al., 1975; Hofstad and Kristoffersen, 1971; Sveen et al., 1977; Warner et al., 1975).

Physiology

Fusobacterium species are not particularly demanding with regard to a low oxidation-reduction potential. The maximum E_h value permitting growth varies, depending on the species, the size of inoculum, and the medium. Stock strains of *F. nucleatum* were able to grow in an oxygen tension of up to 6% (Loesche, 1969). Fusobacteria are, however, fairly readily killed by exposure to air. This is possibly due to their susceptibility to hydrogen peroxide and is especially noticeable when thioglycolate or cysteine HC1 is incorporated into media that are exposed to air before inoculation and incubation.

Fusobacteria grow readily on ordinary solid media, such as Brucella blood agar and brain heart infusion agar, and in fluid media with a base of peptone and yeast extract. Proteose peptone, tryptone, and trypticase have better growth-promoting effects than casamino acids (Gharbia and Shah, 1988a).

Energy is obtained from peptides and amino acids, which are fermented to give a mixture of butyric and acetic acids. Peptides represent the most important energy source (Gharbia et al., 1989). Lysine is likely catabolized by the 3-keto, 5-aminohexanoate pathway (Barker et al., 1982). Glutamate may be degraded through different pathways (Gharbia, 1987). *F. necrophorum* has an absolute need for protein-containing polypeptides (Wahren and Holme, 1973). Most *Fusobacterium* species convert threonine to proprionate. Lactate is converted to proprionate by *F. necrophorum.*

All the *Fusobacterium* species are either nonfermentative or only weakly fermentative. All species examined are able to utilize glucose, which is incorporated into cellular components (Robrish et al., 1987; Gharbia and Shah, 1988a). The accumulation of glucose is dependent upon energy supplied by fermentation of amino acids (Robrish et al., 1987). A low terminal pH (seldom lower than pH 5.5) in glucose-containing media indicate that, in at least a few species, some glucose is fermented.

Glutamate dehydrogenase is produced by all *Fusobacterium* species. The activity at different pH values and the electrophoretic mobility of the enzyme differ between species or groups of species (Gharbia and Shah, 1988b). Possibly all fusobacteria produce deoxyribonuclease (Porschen and Sonntag, 1974). *F. necrophorum* is able to deconjugate bile salts (Shimada et al., 1969).

The fusobacteria are susceptible to many of the commonly used antibiotics, including penicillins and cephalosporins. They are, however, resistant or relatively resistant to vancomycin, neomycin, and erythromycin. *F. nucleatum* may produce beta-lactamase. *F. varium* and *F. mortiferum* are resistant to rifampicin (rifampin). The growth of these two organisms is not inhibited by bile, to which other species of *Fusobacterium* are susceptible. Along with several other Gram-negative bacteria, the fusobacteria will grow in the presence of low concentrations of various dyes.

Isolation

Sampling

Fusobacterium nucleatum is best isolated from saliva or centrifuged salivary deposits, or from the crevice or pocket that exists between the gingiva and the tooth surface. Sampling from the crevice area is performed by the use of sterile filter paper points (absorbent dental points), which are gently inserted into the crevice. Saliva or salivary deposits may be inoculated into the medium either directly or after being resuspended in a reducing diluent, such as the serum-containing diluent of Bowden and Hardie (1971) or in prereduced anaerobically sterilized (PRAS) one-fourth-strength Ringer solution (Sutter et al., 1985). The inoculated tapering end of the paper point is streaked on a small area of the solid medium, and further spreading of the deposited material is carried out by a wire loop. Because of their presence in small numbers, isolation of other *Fusobacterium* species from their natural habitat in man can be difficult. Detailed directions for collection, transport, and processing of fecal specimens have been given by Sutter et al. (1985). It is essential

that the specimens are thoroughly homogenized and adequately diluted in a reducing diluent before inoculation. This applies also to the isolation of *F. necrophorum* from the intestinal tract of animals.

Isolation Under Nonselective Conditions

When present in clinical specimens, *Fusobacterium nucleatum* and *F. necrophorum* and the less commonly isolated *Fusobacterium* species are usually recovered on solid nonselective media. If the colonies are carefully inspected, the Gram stain is properly used and if subculturing is performed promptly, isolation is usually straight forward.

Nonselective isolation of fusobacteria from their natural habitats on the mucous membranes in man and animals is laborious and time-consuming. Such isolation attempts should be avoided in those instances where isolation on selective media is possible. However, isolation under nonselective conditions seems to be the most reliable method for examination and quantitation of viable cells in normal flora specimens. For this purpose the roll tube method (Holdeman et al., 1977; Moore, 1966) or the use of a glove box (Aranki et al., 1969) is to be recommended. By inoculating roll tubes with 1 ml each of 10^8, 10^9, and 10^{10} dilutions of homogenized feces, bacterial species—including fusobacteria—present in numbers as low as 3×10^{10} per gram of fecal dry matter (0.06% of the fecal bacterial population), were counted (Moore and Holdeman, 1974).

Selective Isolation

Media formulations have been developed and evaluated for selective isolation of fusobacteria from human (Baird-Parker, 1957; Morgenstein et al., 1981; Ohtani, 1970b; Omata and Disraely, 1956; Sutter et al., 1971; Walker et al., 1979) and animal (Fales and Teresa, 1972a) sources.

The following medium of Morgenstein et al., (1981) is recommended for the isolation of *Fusobacterium* species from their natural habitats and from clinical specimens.

Fusobacterium Egg Yolk Agar (FEA) Medium
(Morgenstein et al., 1981; Sutter et al., 1985)

Brucella agar base	37 g
Disodium phosphate	5 g
Monopotassium phosphate	1 g
Magnesium sulfate	0.1 g
Hemin solution (5 mg/ml)	1 ml
Polysorbate 80	1 ml
Neomycin solution (100 mg/ml)	1 ml
Distilled water	1,000 ml
Vancomycin solution (7.5 mg/ml)	0.67 ml
Josamycin (Yamanouchi Pharmaceuticals)	3 mg
Egg yolk emulsion (Difco)	50 ml
(or Egg yolk emulsion) (Oxoid)	74 ml

The vancomycin, the josamycin and the egg yolk emulsion are added to the medium after adjustment of pH to 7.6, dissolving by boiling, autoclaving at 121°C for 15 min, and cooling to 50°C.

The FEA medium is selective because of its content of antibiotics. Addition of egg yolk makes it differential for *F. necrophorum,* which is lipase positive. All species of *Fusobacterium* grow on the medium with only minimal inhibition. The typical colonial morphology is translucent to white, convex, round, and entire colonies. *Leptotrichia* grows with white, raised, and granular colonies, and *Veillonella* forms small and translucent colonies. The growth of a majority of facultative Gram-negative organisms is inhibited. Gram-positive organisms do not grow on the medium.

The CVE medium of Walker et al. (1979) may be used in addition to the FEA medium for isolation of *F. nucleatum* from the oral cavity.

Crystal Violet Erythromycin Agar (CVE) Medium
(Walker et al., 1979)

Trypticase	10 g
Yeast extract	5 g
Sodium chloride	5 g
Glucose	2 g
Tryptophane	0.2 g
Agar	15 g
Crystal violet	5 mg
Distilled water	1,000 ml
Sterile defibrinated sheep blood	50 ml
Erythromycin (dissolved in small volume of 95% ethanol)	4 mg

The blood and the erythromycin are added to the medium after adjustment of the pH to 7.0–7.2, autoclaving at 121°C for 20 min, and cooling to 50°C.

The selectivity of the CVE medium depends on its content of erythromycin and crystal violet. Strains of *F. nucleatum* exhibit one of two different colony types on CVE. Some strains form transparent, smooth, round, blue colonies having an entire edge with a darker blue center. Other strains form transparent, rounded or irregular, blue colonies with a speckled internal appearance. Several species of Gram-positive and Gram-negative organisms grow on the medium, but with a colonial morphology distinguishable from those of *F. nucleatum.*

The medium of Sutter et al. (1971) is selective for *F. varium* and *F. mortiferum* and can be used for isolation of these species from feces or from other sources. The selectivity of this medium

depends on the addition of rifampin to standard blood agar.

Rifampin Blood Agar (Sutter et al. 1971; Sutter et al., 1985)

A total of 50 μg/ml of rifampin is added to Brucella blood agar just before the plates are poured. Rifampin stock solution: 0.1 g of rifampin is dissolved in 20 ml of absolute ethyl alcohol, and 80 ml of sterile distilled water is added. This gives a final concentration of 1,000 μg/ml. The solution can be stored at 4°C for up to 2 months.

F. varium and *F. mortiferum* grow freely on this medium, while the growth of *Bacteroides* and most other organisms present in human feces in high numbers is inhibited.

A medium selective for the isolation of *F. necrophorum* from bovine liver abscesses was reported by Fales and Teresa (1972a). The medium is based on the trypticase and egg yolk medium of McClung and Toabe (1947) and contains crystal violet and phenethyl alcohol as selective agents.

Isolation Medium for *Fusobacterium necrophorum* (Fales and Teresa, 1972a)

To 415.0 ml of distilled water add the following:

Trypticase	16.0 g
Biosate	4.0 g
Thiotone	2.0 g
Glucose	0.5 g
$MgSO_4$ (5% solution)	0.1 ml
Na_2HPO_4	2.5 g
Agar	8.3 g

Adjust to pH 7.3.

After autoclaving, the basal medium is cooled to 50°C, and 1.35 ml (0.27% vol/vol) of phenethyl alcohol is added. One egg yolk mixed with an equal volume of a 0.9% sterile saline solution (total volume, approximately 45.0 ml) and blended with the basal medium, and then 11.5 mg of crystal violet dissolved in 25.0 ml of sterile distilled water is added. Finally, the volume is adjusted to 500 ml with sterile distilled water.

Small colonies of *Proteus* species appearing on the medium are easily distinguished from the larger colonies (1.5–1.7 mm in diameter after 48 h of incubation) of *F. necrophorum.*

As previously mentioned, the various selective media designed for isolation of *Fusobacterium* species allow other organisms to grow to a varying extent. In order to gain experience with these media it is important, therefore, to check the different colony types by Gram-staining.

Axenic Cultivation and Maintenance

Fusobacterium strains can be maintained by weekly serial subcultures on blood agar. Viable cells can be stored at −70°C in Greave's solution. Stock cultures can also be prepared in skim milk (Sutter et al., 1985).

Greave's Solution

Bovine serum albumin	50 g
Sodium glutamate	50 g
Glycerol	100 g
Distilled water	1,000 ml

Batch cultivation is best performed in a nutrient broth with a tryptone base, which is supplemented with yeast extract (0.3%), glucose (0.25%), and cysteine HCl (0.1%), or in the selective media bases. If narrow-necked, well-filled containers are used, PRAS media are usually not necessary.

F. necrophorum has been grown in continuous culture with glucose as the growth-limiting factor (Wahren et al., 1971). Maximal cell yields (3.5 mg/ml dry weight) were achieved at dilution rates between 0.19 h^{-1} and 0.40 h^{-1}, at a pH of 6.8, and at temperatures of 33–36°C.

Identification

All *Fusobacterium* species are susceptible to colistin and kanamycin, resistant to vancomycin, and produce butyric acid without isobutyric or isovaleric acids. In the clinical diagnostic laboratory identification is based on both cell and colony morphology and on biochemical properties. Chemotaxonomic methods, such as DNA-DNA hybridization, lipid analysis, electrophoretic mobility of glutamate dehydrogenase, outer membrane protein patterns, and peptidoglycan composition, are useful for taxonomical purposes.

Morphology

Fusobacterium nucleatum has a characteristic cell morphology that makes presumptive identification relatively easy. The cells are Gram-negative, slender, spindle-shaped bacilli with sharply pointed ends, often appearing in pairs and end-to-end. Most cells are 5–10 μm long, but both shorter and longer rod forms may be seen. *F. periodonticum* has a similar cell morphology. This organism has, however, not been isolated from clinical specimens. The fusiform cells of *Capnocytophaga* species are generally smaller than those of *F. nucleatum.* Those of *Leptotrichia buccalis* are thicker and usually larger (distinguishing characters are given in Table 1 of Chapter 223). The cells of *F. necrophorum* are pleomorphic, often curved, and may have spherical enlargements. Free coccoid bod-

Table 2. Differential characteristics of *Fusobacterium* species encountered in clinical specimens.

Characteristic	*F. nucleatum*	*F. necrophorum*	*F. gonidiaformans*	*F. naviforme*	*F. mortiferum*	*F. russi*	*F. varium*

ies and, especially, filaments are common. *F. naviforme* strains may have boat-shaped cells. Gonidial forms may be seen in old cultures of *F. gonidiaformans*. The other *Fusobacterium* species have no distinctive cellular morphology.

Colonies of *F. nucleatum* on blood agar are low convex, glistening, and slightly irregular in form. Those of *F. necrophorum* are circular, rough, and often β-hemolytic. The other *Fusobacterium* species form smooth, small- to-punctiform colonies on blood agar after incubation for two days.

Biochemical Properties

Differential characteristics of the most common *Fusobacterium* species are shown in Table 2. In addition, *F. periodonticum* hydrolyzes hippurate; nitrate is reduced by *F. ulcerans;* the pH may be slightly lowered in cultures of *Fusobacterium* species grown in carbohydrate-containing media, but also in cultures grown without added carbohydrate. This makes the interpretation of fermentation reactions difficult.

Commercial multitest systems for identification of bacteria are generally associated with a percentage of misidentifications, which may be either system or laboratory dependent. Experience is limited with respect to identifications of *Fusobacterium* species.

DNA probes for identification of *Fusobacterium* species are not available. The fluorescent antibody technique has been used for identification of fusobacteria in clinical specimens from man (Griffin, 1970; Stauffer et al., 1975) and for *F. necrophorum* in bovine liver abscesses (Fales and Teresa, 1972b). Simon (1975) has described a hemagglutination inhibition test for rapid identification of *F. necrophorum.*

Clostridium pectinovorum, 535
Clostridium perenne, see Clostridium barati
Clostridium perfringens, 88, 302, 644, 1801, 1804–1807, 1810, 1815, 1818–1821, 1831, 1839, 1873–1875, 2011
Clostridium pfennigii, 517–518, 1805, 1814–1815, 1831, 1925
"Clostridium plagarum," see Clostridium perfringens
Clostridium polysaccharolyticum, 1805, 1815, 1831
Clostridium populeti, 1805, 1815, 1831–1832
Clostridium propionicum, 301, 834, 1801, 1804–1805, 1812, 1814, 1831–1832
Clostridium proteolyticum, 1805–1806, 1815, 1832
"Clostridium pseudotetanicum," see Clostridium butyricum
Clostridium puniceum, 1805, 1815, 1832
Clostridium purinolyticum, 1804–1806, 1812–1816, 1832
Clostridium putrefaciens, 1805, 1807, 1818, 1832
Clostridium putrificum, 1805–1806, 1815
Clostridium quercicolum, 1805, 1814–1815, 1832
Clostridium ramosum, 1800–1802, 1805, 1807, 1815, 1819, 1826, 1832–1833, 1944–1945, 1962
Clostridium rectum, 1805, 1815, 1821
Clostridium roseum, 1805, 1832–1833
"Clostridium rubrum," see Clostridium beijerinckii
Clostridium saccharolyticum, 1805, 1815, 1820, 1833
Clostridium sardiniensi, 1805
Clostridium sartagoforme, 1805, 1815, 1833
Clostridium scatologenes, 1805, 1814–1815, 1833
Clostridium scindens, 1805, 1815, 1833, 1839
Clostridium septicum, 1805, 1815, 1875–1876
Clostridium sordellii, 1804–1805, 1815, 1834, 1867, 1871, 1876
Clostridium sphenoides, 1805, 1810–1812, 1816, 1821, 1833
Clostridium spiroforme, 1805, 1815, 1826, 1829, 1833–1834, 1876
Clostridium sporogenes, 88, 290, 1801–1802, 1804–1806, 1812, 1815, 1818, 1821, 1825, 1833–1834
Clostridium sporosphaeroides, 1805, 1815, 1834
Clostridium stercorarium, 479, 481, 484, 1805, 1815, 1834
Clostridium sticklandii, 82, 1801, 1805, 1815, 1834–1835
Clostridium subterminale, 1805, 1812, 1815, 1829, 1835
Clostridium symbiosum, 306, 1805, 1815, 1835
"Clostridium tartarivorum," see Clostridium thermosaccharolyticum
Clostridium tertium, 1801, 1805–1806, 1814–1815, 1839
Clostridium tetani, 88, 132, 1804–1805, 1815, 1876–1877
Clostridium tetanomorphum, 82, 301–302, 1801–1802, 1805, 1810, 1812, 1815, 1826, 1835–1836
Clostridium thermoaceticum, 307, 517–518, 521–529, 749, 1801, 1805–1806, 1815–1820, 1827, 1836, 1925, 1927, 1933
Clostridium thermoautotrophicum, 517–518, 1805, 1815–1816, 1818–1820, 1836
Clostridium thermobutyricum, 1805, 1815, 1836
Clostridium thermocellum, 78, 103, 166–167, 461, 466–481, 484–485, 489, 491, 493, 1802, 1805–1806, 1810, 1815, 1818–1821, 1836–1837, 1901–1911
Clostridium thermocopriae, 479, 481, 1805, 1815, 1837
Clostridium thermohydrosulfuricum, 461, 1805, 1815, 1818–1820, 1837, 1901–1911
Clostridium thermolacticum, 1805, 1815, 1818, 1837
Clostridium thermosaccharolyticum, 461, 536, 1805, 1807, 1818–1821, 1837–1838
Clostridium thermosulfurogenes, 1805, 1818–1821, 1838, 1901–1911
Clostridium tyrobutyricum, 535, 1805, 1810, 1819, 1821, 1838
Clostridium villosum, 1805
Clostridium welchii, see Clostridium perfringens
Clove, Sumatra disease, 4031, 4034, 4037, 4041
Clover
- club leaf disease, 4035, 4043
- nitrogen-fixing bacteria, 541

pathogen, 661
phloem-inhabiting bacteria, 4031
rhizobia, 2198

Starch-casein-sulfate agar, actinoplanetes, 1040–1041, 1051
Starch-manganese carbonate medium, Siderocapsaceae, 4104, 4106
Star-shaped aggregate, *Seliberia*, 2490–2493
Star-shaped bacteria, *Stella*, 2167–2169
Starter culture
  citrate-fermenting bacteria, 1486
  Lactobacillus, 1546–1548, 1552–1553, 1558
  Lactococcus, 1482–1483, 1487, 1493–1496
  Leuconostoc, 1513–1514, 1517–1518, 1527
  Pediococcus, 1504
  phage contamination, 1494–1496
  production and preservation, 1487–1488
Starvation, 89, 255
Starvation-survival form, 267–269
Starvation-survival strategy, *Spirochaeta*, 3528
State (taxonomic definition), 129
Stationary fixed-film reactor, downflow, 759
Stationary growth phase, 158
Stearate utilization
  sulfate-reducing bacteria, 3363
  syntrophic bacteria, 2049
Steel pipe corrosion, 406
Stella, 27, 2132, 2167–2169, 3806
Stella humosa, 2167, 2169
Stella maintenance medium, 2168–2169
Stella vacuolata, 2167, 2169
Stellate structure, manganese-oxidizing bacteria, 2312
Stem canker, *Curtobacterium*, 1363
Stem nodule, 541, 2198–2199
Stentor multiformis, 3876
Stentor polymorphus, 3876
Sterile cabinet, 169
Sterile room, 169
Sterilization
  arthropod, 2423
  Bacillus spores as indicators, 1687
  equipment, 171–173
  with heat, 171–172
  indicators, 171
  medium, 170–173
  nodule surface, 2205
  plant surface, 4035–4037
  seed surface, 2206
  without heat, 172–173
Steroid production, myxobacteria, 3448, 3467
Steroid transformation
  Clostridium, 1821, 1833, 1839
  Comamonas, 2588
  Eubacterium, 1914–1915, 1918–1921
  Mycobacterium, 1231
  Nocardiaceae, 1203–1205
Sterol, aphid symbiont, 3910
Sterol requirement
  mycoplasma, 1938, 1949
  Spiroplasma, 1974
Sterol surrogate, 134
Stewart's disease, maize, 2910
STG medium, myxobacteria, 3437
Stickland reaction, 290, 302, 1801, 1834–1835
Stigmatella, 29, 68, 3426, 3432, 3442, 3448, 3452–3453, 3463, 3471–3472
Stigmatella aurantiaca, 70–71, 224–227, 2134, 3416–3422, 3426, 3432–3437, 3440, 3447–3450, 3454–3464, 3467–3468, 3472
Stigmatella cellulosum, 3467
Stigmatella erecta, 66, 3418–3419, 3421–3422, 3426, 3454–3455, 3458–3459, 3461, 3463, 3472
Stigmatellin, 3475–3476
Stigonema, 538, 2076, 3822, 3827
Stigonematalean cyanobacteria, 326, 328
Stigonematales, 2059, 2069, 2073–2076, 3827
STK2 agar
  Cytophagales, 3646–3647
  myxobacteria, 3432
Stock culture, preservation, 182–183
Stockhausen, F., 153
Stokes' medium, *Sphaerotilus*, 2615
Stolbur mycoplasma-like organism, 4057–4060
Stomach
  Helicobacter, 3491
  Lactobacillus, 1538–1540, 1542
Stomatitis
  Aeromonas, 3020
  diphtheroid, *see* Diphtheroid stomatitis
Stomatococcus, 24, 51, 1320–1321, 1323, 1450
Stomatococcus mucilaginosus, 52, 1320–1321
Stool, *see* Feces
Storage granule, homoacetogens, 1931
Strain GraIval, 279, 281
Strain HQGöl, 279
Strain improvement, 197–203

Yersinia enterocolitica, 142, 652, 2385, 2675, 2678–2679, 2689, 2745, 2863–2880, 2895, 3027
Yersinia frederiksenii, 2675, 2688–2689, 2864, 2866, 2871, 2874
Yersinia intermedia, 2675, 2688–2689, 2864–2866, 2869, 2871, 2878
Yersinia kristensenii, 2675, 2688–2689, 2864–2865, 2871
Yersinia mollaretii, 2675, 2688–2689, 2865, 2872–2873
Yersinia pestis, 142, 178, 640, 646, 652, 2540, 2675, 2679, 2687–2688, 2863–2864, 2870, 2874, 2888–2896
Yersinia philomiragia, see Francisella philomiragia
Yersinia pseudotuberculosis, 142, 652, 2116, 2540, 2675, 2677, 2679, 2687–2688, 2863–2879, 2893–2895, 2912
Yersinia rhodei, 2675, 2688–2689, 2865
Yersinia ruckeri, 2675, 2677, 2688–2689, 2865
Y-form, *Promicromonospora*, 1337
YGC broth, *see* Yeast extract-glucose-citrate broth
YGC medium, *see* Yeast extract-galactose-calcium carbonate medium
YGLM medium, *see* Yeast glucose litmus milk medium
YGPB medium, *Leuconostoc*, 1516
YNA medium, *Kurthia*, 1657
YNB medium, *Kurthia*, 1657
YNG medium, *Kurthia*, 1657
Yogurt
Lactobacillus, 1542, 1547, 1567, 1571–1572
Lactococcus, 1486, 1492
Yokenella, 28, 2934–2935
Yokenella regensburgei, 2675, 2683, 2819, 2923–2924, 2934–2935
yopK gene, *Yersinia pestis*, 646
YOPP medium, cyanobacteria, 2065, 2067
Yops, 2868–2869, 2895–2896

Z

Z value, 171–172
ZanI, 2297
Zeaxanthin
  Cytophagales, 3655
  Erythrobacter, 2486–2487
  Flavobacterium, 3627
  Herpetosiphon, 3802
  Prochlorales, 2105
Zeaxanthin dirhamnoside
  assay, 2375
  Xanthobacter, 2372–2373, 2375
Zein medium, myxobacteria, 3437
Zeta toxin, *Clostridium novyi,* 1873
Ziehl-Neelsen stain, 136
  Mycobacterium, 1214, 1219–1220, 1251, 1274
Zinc binding, *Zoogloea,* 3962
Zobell's marine broth, dimorphic prosthecate bacteria, 2185, 2190
Zoogleal stage, *Seliberia,* 2490, 2493
Zoogloea, 3071–3075, 3079, 3952–3962
Zoogloea filipendula, 3952–3962
Zoogloea ramigera, 91, 562, 3072–3073, 3079, 3952–3962
Zoogloeal matrix, 3952–3956, 3958
Zooplankton, grazing, 270
Zoospore
  Actinoplanetes, 216
  Dermatophilus, 1347
  Geodermatophilus, 1069
Zoothamnium pelagicum, 3876
Zopfius, see Kurthia
Zuberella, 4114
Zymogenous microorganism, *see* Allochthonous microorganism
Zymomonas, 27, 1997, 2128–2129, 2133, 2254, 2269, 2271, 2287–2298
Zymomonas anaerobia, 1833
Zymomonas congolensis, 2288
Zymomonas mobilis, 82, 201, 495, 2273, 2287–2298, 2725
