Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have

evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Ralph S. Wolfe
Department of Microbiology
University of Illinois at Urbana-Champaign

Preface

In 1962 R. Y. Stanier and C. B. van Niel formulated the view that bacteria represented a definable, biologically coherent group of organisms called the prokaryotes. They pointed out that, up to that time, "the abiding intellectual scandal of bacteriology has been the absence of a clear concept of a bacterium" (Archiv für Mikrobiologie 42:17–35, 1962). In addition to formalizing the distinction between the eukaryotes and the prokaryotes, Stanier and van Niel also emphasized the diversity of the prokaryotes.

The early view of Ferdinand Cohn that bacteria were simply a group of unicellular microorganisms that divide by binary fission had gradually been supplanted, so that by 1962, Stanier and van Niel could point out that bacteria were "photosynthetic or non-photosynthetic; motile by any one of three different mechanisms or permanently immotile; unicellular, multicellular or coenocytic; multiplying by binary transverse fission, or by formation of gonidia or conidia." Although Stanier and van Niel never actually defined the bacteria as a group, their seminal article explicitly emphasized the wide variety of metabolic, physiological, and morphological types among the bacteria, a variety which was reflected in cellular organization, modes of cell division, mechanisms of locomotion, and patterns of energy-yielding metabolism. Nevertheless, the succeeding decades saw a narrowing of the scope of research on the bacteria, since the incredible power and successes of molecular biology required intense study of only a few suitable model organisms. The hypothesis that there was a small group of typical bacteria whose mechanisms and processes were accurately representative of the bacteria as a whole became tacitly accepted. Most areas of human activity have a dialectic quality, and the evolution of scientific ideas is no exception. Thus, the narrow focus on a small group of bacteria is now being broadened to recognize new mechanisms, new strategies for coping with the environment, newly expanded limits to the abilities of the microbe, and new experimental systems. The publication in 1981 of the first edition of *The Prokaryotes* played an important role in this broadening of the perspective of the microbial world. Ten years later, the second edition continues to emphasize the diversity of the prokaryotes while adding the entirely new perspective of prokaryotic phylogeny. As far as possible, in this edition the chapters dealing with individual groups and genera of bacteria are arranged in strictly phylogenetic order.

The pioneering work of Carl Woese in cataloging and sequencing the ribosomal ribonucleic acid of prokaryotes has, for the first time in the history of biology, provided a means of establishing a truly phylogenetic system for living organisms—a goal previously thought to be impossible. The use of the oligonucleotide sequences of 16S rRNA as a molecular/evolutionary chronometer has revealed unsuspected phylogenetic affiliations. Furthermore, it has shown that the uniform concept of the prokaryotes must give way to a dichotomy dividing the prokaryotes into two groups (the archaebacteria, or Archaea, and the eubacteria, or Bacteria) no more closely related to each other than either of them is to the eukaryotes. In essence, the molecular approach has added an entirely new dimension to prokaryotic diversity, providing a fascinating opportunity for gaining insight into the origin of life.

The work of Woese and his coworkers has uncovered so many inconsistencies in classical prokaryotic systematics that an entirely new system for the taxonomy of the prokaryotes will undoubtedly emerge. These phylogenetic conclusions, drawn mainly from 16S rRNA analyses, have been strongly supported by nucleic acid hybridization studies and comparative se-

quence analysis of 23S rRNA, of the beta subunit of adenosine triphosphatase, and of the elongation factor Tu. The phylogenetic relationships of bacteria are also reflected by studies of chemotaxonomic markers such as peptidoglycan and lipid.

A reader familiar with the first edition of *The Prokaryotes* will note that, in the new edition, the subtitle has been changed from "A Handbook on Habitats, Isolation, and Identification of Bacteria" to "A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications." This change reflects developments in bacteriology over the past 10 years as well as the growing awareness of the important role that prokaryotes play in determining and stabilizing the global environment. The term "Habitats" has been changed to "Ecophysiology" to emphasize the interactions of microorganisms both with their habitats and with other organisms that occupy those habitats. In this context, the number of chapters dealing with symbiotic and syntrophic associations of prokaryotes with other prokaryotes and with eukaryotes has been substantially increased in the new edition.

The terms "Isolation" and "Identification" have been maintained because they reflect essential aspects of the second edition of *The Prokaryotes*. However, the individual chapters have undergone considerable change so as to include new techniques for the handling of fastidious anaerobes, for chemotaxonomic analysis, for molecular genetic methods of identification, etc. In addition, the results of another 10 years of experience in preserving and maintaining cultures have been included in many of the chapters. An important addition has been the new key term "Applications." This reflects the conscious move by microbiology into biotechnology. The use of microbes to produce new and useful products and to recycle undesirable products is now of worldwide economic and ecological importance.

But the organization of the second edition of *The Prokaryotes* differs even more fundamentally than the subject matter of the first edition. The decision to organize the Handbook on the basis of phylogenetic relationships generated two problems. First, bacteria have traditionally been divided into groups that share one or more phenotypic properties. Thus, microbiologists are used to dealing with collective entities such as the "gliding bacteria," "the autotrophs," and "the photosynthetic bacteria." These are groups that are similar in their overall physiology, behavior, or metabolism, or that inhabit similar ecological niches. However, the new phylogenetic analyses have made it clear that these groups are not necessarily related to each other in any evolutionary sense. Thus, an organization that reflected the true evolutionary relations among the prokaryotes would necessarily have sacrificed the familiar and intellectually useful associations of phenotypic properties, but retention of the traditional arrangements would have ignored the phylogenetic revolution that has taken place. A second problem is that there are still a number of genera or groups whose position in the phylogenetic scheme have not been determined.

The solution to this dilemma was to divide the present edition of *The Prokaryotes* into six parts. Part I contains introductory essays dealing with the broader aspects of microbiology that underlie the rest of the Handbook. Part II contains general chapters that cover life cycles, prokaryotic behavior, anaerobic growth, syntrophism, and a series of synoptic chapters that describe the familiar phenotypically organized groups. This has allowed us to retain discussions of those useful physiological, metabolic, and ecological generalizations that characterize the bacteria. Parts III and IV of the Handbook consist of phylogenetically arranged chapters devoted to genera, families, and sometimes higher taxa of related prokaryotes. For example, the archaebacteria (Archaea) have been strictly separated from the eubacteria, and within these major groups the individual genera are arranged phylogenetically.

These phylogenetic groupings have generated some phenotypically strange bedfellows. Nevertheless, the editors hope that the juxtaposition of organisms that are phylogenetically related, but appear phenotypically dissimilar, may stimulate microbiologists to seek taxonomically relevant similarities that otherwise would not have been evident. Following the major groups of generic chapters, Part V covers those microorganisms that have established firm symbiotic relationships. Finally, those genera that have not been phylogenetically allocated as yet are dealt with in Part VI. In order to help the reader find a specific genus, an alphabetical listing of genera and other higher taxa follows the Contents.

Microbiology is in the midst of the most significant conceptual revolution it has experi-

enced in the past few decades. We have the privilege of a new way of thinking about the evolution of bacteria that may even help us to understand the origin of life. We also have a set of molecular tools that allow us to probe the innermost details of the workings of the cell and that may also allow us to ask ecological questions, the answers to which have thus far eluded us. Nevertheless, in the final analysis, it is only the ability to isolate and cultivate microbes individually and as consortia that will lead to a full understanding of the strategies, mechanisms, and processes of biodiversity. We dedicate this Handbook to the efforts of those who pursue these goals.

A scientific work of this magnitude requires support, advice, and assistance from many people with a wide range of skills and knowledge. We would be remiss if we failed to express our thanks and appreciation for the suggestions and hard work provided by many secretaries, typists, graphic artists, and photographers who worked with all of the authors of *The Prokaryotes,* second edition. We are indebted to the staff of Springer-Verlag who encouraged and indulged us and demonstrated remarkable patience with us. We are equally grateful to Thomas D. Brock and the staff of Science Tech Publishers, especially Carol Bracewell and Ruth Siegel, whose copyediting expertise and problem-solving capabilities lightened our load considerably. Finally, we are beholden to the more than 300 people throughout the world who gave of their time, knowledge, and experience to serve as authors in this international effort.

Volume I

Part I: Introductory Essays

1. Prokaryote Systematics: The Evolution of a Science 3
CARL R. WOESE

2. Unifying Phylogeny and Phenotypic Diversity 19
ERKO STACKEBRANDT

3. Prokaryotic Diversity 48
MARTIN DWORKIN

4. Prokaryotes and Their Habitats 75
HANS G. SCHLEGEL and HOLGER W. JANNASCH

5. Prokaryote Characterization and Identification 126
HANS G. TRÜPER and KARL-HEINZ SCHLEIFER

6. Principles of Enrichment, Isolation, Cultivation, and Preservation of Bacteria 149
JAN C. GOTTSCHAL, WIM HARDER, and RUDOLF A. PRINS

7. Applications of Prokaryotes 197
LUBBERT DIJKHUIZEN and WIM HARDER

Part II: Ecophysiological and Biochemical Aspects of Phylogenetically Diverse Groups

8. Prokaryotic Life Cycles 209
MARTIN DWORKIN

9. Behavioral Responses in Bacteria 241
JUDITH P. ARMITAGE, R. ELIZABETH SOCKETT, and PHILIP S. POOLE

10. Planktonic Versus Sessile Life of Prokaryotes 262
KEVIN C. MARSHALL

11. Syntrophism among Prokaryotes 276
BERNHARD SCHINK

12. The Anaerobic Way of Life 300
GERHARD GOTTSCHALK and SUSANNE PEINEMANN

13. The Phototrophic Prokaryotes 312
ELENA N. KONDRATIEVA, NORBERT PFENNIG, and HANS G. TRÜPER

14. The Chemolithotrophic Prokaryotes 331
DONOVAN P. KELLY

15. The Mesophilic Hydrogen-Oxidizing (Knallgas) Bacteria 344
MICHEL ARAGNO and HANS G. SCHLEGEL

16. The Colorless Sulfur Bacteria 385
LESLEY A. ROBERTSON and J. GIJS KUENEN

17. Oxidation of Inorganic Nitrogen Compounds as Energy Source 414
EBERHARD BOCK, HANS-PETER KOOPS, BEATE AHLERS, and HEINZ HARMS

18. The Aerobic Methylotrophic Bacteria 431
MARY E. LIDSTROM

19. The Hydrocarbon-Oxidizing Bacteria 446
EUGENE ROSENBERG

122. The Genera *Rickettsia, Rochalimaea, Ehrlichia, Cowdria,* and *Neorickettsia* 2407
GREGORY A. DASCH and EMILIO WEISS

123. The Genera *Coxiella, Wolbachia,* and *Rickettsiella* 2471
J. C. WILLIAMS, E. WEISS, and G. A. DASCH

124. The Genus *Erythrobacter* 2485
TSUNEO SHIBA

125. The Genus *Seliberia* 2490
JEAN M. SCHMIDT and JAMES R. SWAFFORD

Subdivision C2: Beta Subclass

126. The Genus *Neisseria* 2495
STEPHEN A. MORSE and JOAN S. KNAPP

127. The Genus *Bordetella* 2530
ALISON ANN WEISS

128. The Genera *Alcaligenes* and *"Achromobacter"* 2544
HANS-JÜRGEN BUSSE and GEORG AULING

129. The Genera *Rhodocyclus* and *Rubrivivax* 2556
H. G. TRÜPER and J. F. IMHOFF

130. The Genus *Spirillum* 2562
NOEL R. KRIEG

131. The Genus *Aquaspirillum* 2569
BRUNO POT, MONIQUE GILLIS, and JOZEF DE LEY

132. The Genus *Comamonas* 2583
ANNE WILLEMS, PAUL DE VOS, and JOZEF DE LEY

133. The Genera *Chromobacterium* and *Janthinobacterium* 2591
MONIQUE GILLIS and JOZEF DE LEY

134. The Genera *Phyllobacterium* and *Ochrobactrum* 2601
JEAN SWINGS, BART LAMBERT, KAREL KERSTERS, and BARRY HOLMES

135. The Genus *Derxia* 2605
JAN HENDRIK BECKING

136. The Sheathed Bacteria 2612
EPPE GERKE MULDER and MARIA H. DEINEMA

137. The Lithotrophic Ammonia-Oxidizing Bacteria 2625
HANS-PETER KOOPS and UWE CHRISTIAN MÖLLER

138. The Genera *Thiobacillus, Thiomicrospira,* and *Thiosphaera* 2638
J. GIJS KUENEN, LESLEY A. ROBERTSON, and OLLI H. TUOVINEN

139. The Genera *Simonsiella* and *Alysiella* 2658
DAISY A. KUHN

140. *Eikenella corrodens* 2668
PAUL A. GRANATO

Subdivision C3: Gamma Subclass

141. Introduction to the Family Enterobacteriaceae 2673
DON J. BRENNER

142. The Genus *Escherichia* 2696
KARL A. BETTELHEIM

143. The Genus *Edwardsiella* 2737
RIICHI SAKAZAKI and KAZUMICHI TAMURA

144. The Genus *Citrobacter* 2744
WILHELM FREDERIKSEN and PER SØGAARD

145. The Genus *Shigella* 2754
HARUO WATANABE and NOBORU OKAMURA

146. The Genus *Salmonella* 2760
LÉON LE MINOR

147. The Genus *Klebsiella* 2775
FRANCINE GRIMONT, PATRICK A. D. GRIMONT, and CLAUDE RICHARD

148. The Genus *Enterobacter* 2797
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

149. The Genus *Hafnia* 2816
RIICHI SAKAZAKI and KAZUMICHI TAMURA

150. The Genus *Serratia* 2822
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

151. The Genera *Proteus, Providencia,* and *Morganella* 2849
JOHN L. PENNER

152. The Genus *Yersinia* (Excluding *Y. pestis*) 2863
EDWARD J. BOTTONE

153. *Yersinia pestis* 2888
THOMAS J. QUAN

154. The Genus *Erwinia* 2899
MICHEL C. M. PÉROMBELON

155. Additional Genera of Enterobacteriaceae 2922
DON J. BRENNER

156. The Family Vibrionaceae 2938
J. J. FARMER III

157. The Genera *Vibrio* and *Photobacterium* 2952
J. J. FARMER III and F. W. HICKMAN-BRENNER

158. The Genera *Aeromonas* and *Plesiomonas* 3012
J. J. FARMER III, M. J. ARDUINO, and F. W. HICKMAN-BRENNER

159. The Genera *Alteromonas* and *Marinomonas* 3046
MICHEL J. GAUTHIER and VIOLETTE A. BREITTMAYER

160. Introduction to the Family Pseudomonadaceae 3071
NORBERTO J. PALLERONI

161. Human- and Animal-Pathogenic Pseudomonads 3086
NORBERTO J. PALLERONI

162. Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads 3104
MILTON N. SCHROTH, DONALD C. HILDEBRAND, and NICKOLAS PANOPOULOS

Index Volumes I–IV

Volume IV

163. The Genus *Xylophilus* 3133
ANNE WILLEMS, MONIQUE GILLIS, and JOZEF DE LEY

164. The Genus *Acinetobacter* 3137
KEVIN J. TOWNER

165. The Family Azotobacteraceae 3144
JAN HENDRIK BECKING

166. The Genus *Beggiatoa* 3171
DOUGLAS C. NELSON

167. The Family Halomonadaceae 3181
RUSSELL H. VREELAND

168. The Genus *Deleya* 3189
KAREL KERSTERS

169. The Genus *Frateuria* 3198
JEAN SWINGS

170. The Family Chromatiaceae 3200
NORBERT PFENNIG and HANS G. TRÜPER

171. The Family Ectothiorhodospiraceae 3222
JOHANNES F. IMHOFF

172. The Genus *Oceanospirillum* 3230
BRUNO POT, MONIQUE GILLIS, and JOZEF DE LEY

173. *Serpens flexibilis:* An Unusually Flexible Bacterium 3237
ROBERT B. HESPELL

174. The Genus *Psychrobacter* 3241
ELLIOT JUNI

175. The Genus *Leucothrix* 3247
THOMAS D. BROCK

176. The Genus *Lysobacter* 3256
HANS REICHENBACH

177. The *Moraxella* and *Branhamella* Subgenera of the Genus *Moraxella* 3276
GARY V. DOERN

178. The Genus *Legionella* 3281
A. WILLIAM PASCULLE

179. The Genus *Haemophilus* 3304
SUSAN K. HOISETH

180. The Genus *Pasteurella* 3331
REGGIE Y. C. LO and PATRICIA E. SHEWEN

181. The Genus *Cardiobacterium* 3339
SYDNEY M. HARVEY and JAMES R. GREENWOOD

182. The Genus *Actinobacillus* 3342
JAMES E. PHILLIPS

Subdivision C4: Delta Subclass

183. Gram-Negative Mesophilic Sulfate-Reducing Bacteria 3352
FRIEDRICH WIDDEL and FRIEDHELM BAK

184. The Genus *Desulfuromonas* and Other Gram-Negative Sulfur-Reducing Eubacteria 3379
FRIEDRICH WIDDEL and NORBERT PFENNIG

185. The Genus *Thermodesulfobacterium* 3390
FRIEDRICH WIDDEL

186. The Genus *Pelobacter* 3393
BERNHARD SCHINK

187. The Genus *Bdellovibrio* 3400
EDWARD G. RUBY

188. The Myxobacteria 3416
HANS REICHENBACH and MARTIN DWORKIN

Subdivision C5: Epsilon Subclass

189. The Genera *Campylobacter* and *Helicobacter* 3488
FRED C. TENOVER and CYNTHIA L. FENNELL

190. The Genus *Wolinella* 3512
ANNE TANNER and BRUCE J. PASTER

Division D: Spirochetes

191. Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* 3524
ERCOLE CANALE-PAROLA

192. The Genus *Treponema* 3537
JAMES N. MILLER, ROBERT M. SMIBERT, and STEVEN J. NORRIS

193. The Genus *Borrelia* 3560
RUSSELL C. JOHNSON and CARRIE A. NORTON HUGHES

194. The Genus *Leptospira* 3568
SOLLY FAINE

Division E: Chlorobiaceae

195. The Family Chlorobiaceae 3583
HANS G. TRÜPER and NORBERT PFENNIG

Division F: Bacteroides and Cytophaga Group

196. The Genus *Bacteroides* and Related Taxa 3593
HAROUN N. SHAH

197. The Genus *Porphyromonas* 3608
HAROUN N. SHAH

198. The Genera *Flavobacterium, Sphingobacterium,* and *Weeksella* 3620
BARRY HOLMES

199. The Order Cytophagales 3631
HANS REICHENBACH

200. The Genus *Saprospira* 3676
HANS REICHENBACH

201. The Genus *Haliscomenobacter* 3688
EPPE GERKE MULDER and MARIA H. DEINEMA

Division G: Chlamydia

202. The Genus *Chlamydia* 3691
PATRICIA I. FIELDS and ROBERT C. BARNES

Division H: Planctomyces and Related Bacteria

203. The Order Planctomycetales and the Genera *Planctomyces, Pirellula, Gemmata,* and *Isosphaera* 3710
J. T. STALEY, J. A. FUERST, S. GIOVANNONI, and H. SCHLESNER

Division I: Deinococcaceae and Thermus

204. The Family Deinococcaceae 3732
ROBERT G. E. MURRAY

205. The Genus *Thermus* and Related Microorganisms 3745
R. A. D. WILLIAMS and MILTON S. DA COSTA

Division J: Chloroflexaceae and Related Bacteria

206. The Family Chloroflexaceae 3754
BEVERLY K. PIERSON and RICHARD W. CASTENHOLZ

207. The Genus *Thermomicrobium* 3775
JEROME J. PERRY

208. The Genus *Thermoleophilum* 3780
JEROME J. PERRY

209. The Genus *Herpetosiphon* 3785
HANS REICHENBACH

Division K: Verrucomicrobium

210. The Genus *Verrucomicrobium* 3806
HEINZ SCHLESNER

Division L: Thermotogales

211. The Order Thermotogales 3809
ROBERT HUBER and KARL O. STETTER

Part V: Symbiotic Associations

212. Cyanobacterial Symbioses 3819
HAINFRIED E. A. SCHENK

213. Prokaryotic Symbionts of Amoebae and Flagellates 3855
KWANG W. JEON

214. Prokaryotic Symbionts of Ciliates 3865
KLAUS HECKMANN and HANS-DIETER GÖRTZ

215. Prokaryotic Symbionts of Marine Invertebrates 3891
HORST FELBECK and DANIEL L. DISTEL

216. Prokaryotic Symbionts of the Aphid 3907
DAVID L. GUTNICK

Part VI: Phylogenetically Unaffiliated Bacteria

217. Thermophilic, Aerobic, Hydrogen-Oxidizing (Knallgas) Bacteria 3917
MICHEL ARAGNO

218. Morphologically Conspicuous Sulfur-Oxidizing Eubacteria 3934
JAN W. M. LA RIVIÈRE and KARIN SCHMIDT

219. The Genus *Propionigenium* 3948
BERNHARD SCHINK

220. The Genus *Zoogloea* 3952
PATRICK R. DUGAN, DAPHNE L. STONER, and HARVEY M. PICKRUM

221. Large Symbiotic Spirochetes: *Clevelandina, Cristispira, Diplocalyx, Hollandina,* and *Pillotina* 3965
LYNN MARGULIS and GREGORY HINKLE

222. The Genera *Succinivibrio* and *Succinimonas* 3979
ROBERT B. HESPELL

223. The Genus *Leptotrichia* 3983
TOR HOFSTAD

224. The Genus *Francisella* 3987
FRANCIS E. NANO

225. The Hemotrophic Bacteria: The Families Bartonellaceae and Anaplasmataceae 3994
JULIUS P. KREIER, RAINER GOTHE, GARRET M. IHLER, HEINZ E. KRAMPITZ, GLENDA MERNAUGH, and GUY H. PALMER

226. *Streptobacillus moniliformis* 4023
JAMES R. GREENWOOD and SYDNEY M. HARVEY

227. The Genus *Toxothrix* 4026
PETER HIRSCH

228. Fastidious Bacteria of Plant Vascular Tissues and Their Invertebrate Vectors 4030
MICHAEL J. DAVIS

229. Mycoplasma-Like Organisms—Plant and Invertebrate Pathogens 4050
BRUCE C. KIRKPATRICK

230. The L-Forms of Bacteria 4068
SARABELLE MADOFF and JOHN W. LAWSON

231. The Genus *Gallionella* 4082
HANS H. HANERT

232. The Genus *Nevskia* 4089
PETER HIRSCH

233. The Genera *Caulococcus* and *Kusnezovia* 4093
JEAN M. SCHMIDT and GEORGI A. ZAVARZIN

234. The Genus *Brachyarcus* 4095
PETER HIRSCH

235. The Genus *Pelosigma* 4098
PETER HIRSCH

236. The Genus *Siderocapsa* (and Other Iron- or Manganese-Oxidizing Eubacteria) 4102
HANS H. HANERT

237. The Genus *Fusobacterium* 4114
TOR HOFSTAD

Index Volumes I–IV

Alphabetical List of Genera and Groups*

Genus or group	Chapter	Senior author	Page	Volume
Acetoanaerobium	87	Bernhard Schink	1925	II
Acetobacter	111	Jean Swings	2268	III
Acetobacterium	87	Bernhard Schink	1925	II
Acetogenium	87	Bernhard Schink	1925	II
Acetogens	21	Gabriele Diekert	517	I
Acholeplasma	88	Shmuel Razin	1937	II
Achromatium	218	Jan la Rivière	3934	IV
Achromobacter	128	Hans-Jürgen Busse	2544	III
Acinetobacter	164	Kevin J. Towner	3137	IV
Actinobacillus	182	James E. Phillips	3342	IV
Actinomaduraceae	46	R.M. Kroppenstedt	1085	II
Actinomyces	38	K.P. Schaal	850	I
Actinomycetales	35	Jerry Ensign	811	I
Actinoplanaceae	43	Gernot Vobis	1029	II
Aegyptianella	225	Julius P. Kreier	3994	IV
Aerobacter	149	Riichi Sakazaki	2816	III
Aerococcus	68	Norbert Weiss	1502	II
Aeromonas	158	J.J. Farmer III	3012	III
Agarbacterium	168	Karel Kersters	3189	IV
Agrobacterium	108	Allen Kerr	2214	III
Agromyces	62	Matthew D. Collins	1355	II
Alteromonas	159	Michel J. Gauthier	3046	III
Alysiella	139	Daisy Kuhn	2658	III
Ammonia oxidizers	137	Hans-Peter Koops	2625	III
Amoebobacter	170	Norbert Pfennig	3200	IV
Anaerobic Gram-positive cocci	83	Takayuki Ezaki	1879	II
Anaeroplasma	88	Shmuel Razin	1937	II
Anaerorhabdus	196	Haroun N. Shah	3593	IV
Anaplasmataceae	225	Julius P. Kreier	3994	IV
Ancalomicrobium	103	James Staley	2160	III
Aquaspirillum	131	Bruno Pot	2569	III
Arcanobacterium	38	K.P. Schaal	850	I
Archaeoglobus	31	Karl O. Stetter	707	I
Arthrobacter	55	Dorothy Jones	1283	II
Asteroleplasma	88	Shmuel Razin	1937	II
Asticcacaulis	106	Jeanne Poindexter	2176	III
Aureobacterium	62	Matthew D. Collins	1355	II
Azorhizobium	107	Gerald Elkan	2197	III
Azospirillum	109	Johanna Döbereiner	2236	III
Azotobacteraceae	165	Jan H. Becking	3144	IV

*Only the number of the primary chapter is given here; for further information, see the index.

Genus or group	Chapter	Senior author	Page	Volume
Azotomonas	165	Jan H. Becking	3144	IV
Bacillus—insect pathogens	77	Donald P. Stahly	1697	II
Bacillus—medical	78	W. Edmund Farrar	1746	II
Bacillus—nonmedical	76	Ralph Slepecky	1663	II
Bacillus—related genera	79	Dieter Claus	1769	II
Bacteroides	196	Haroun N. Shah	3593	IV
Bartonellaceae	225	Julius P. Kreier	3994	IV
Bdellovibrio	187	Edward Ruby	3400	IV
Beggiatoa	166	Douglas Nelson	3171	IV
Beijerinckia	110	Jan H. Becking	2254	III
Beneckea	156	J.J. Farmer III	2938	III
Bifidobacterium	36	Bruno Biavati	816	I
Blastobacter	105	Peter Hirsch	2171	III
Bordetella	127	Alison Weiss	2530	III
Borrelia	193	Russell C. Johnson	3560	IV
Brachyarcus	234	Peter Hirsch	4095	IV
Brachybacterium	61	Matthew D. Collins	1351	II
Bradyrhizobium	107	Gerald Elkan	2197	III
Branhamella	177	Gary V. Doern	3276	IV
Brevibacterium	61	Matthew D. Collins	1351	II
Brochothrix	72	Dorothy Jones	1617	II
Brucella	120	Nelson Moyer	2384	III
Butyrivibrio	94	Robert B. Hespell	2022	II
Caedibacter	214	Klaus Heckmann	3865	IV
Campylobacter	189	Fred Tenover	3488	IV
Capnocytophaga	199	Hans Reichenbach	3631	IV
Cardiobacterium	181	Sydney M. Harvey	3339	IV
Carnobacterium	70	W.P. Hammes	1535	II
Caryophanon	79	Dieter Claus	1769	II
Caulobacter	106	Jeanne Poindexter	2176	III
Caulococcus	233	Jean M. Schmidt	4093	IV
Cedecea	155	Don J. Brenner	2922	III
Cellulomonadaceae	59	Erko Stackebrandt	1323	II
Cellulose decomposers	20	Michael P. Coughlan	460	I
Chemolithotrophs	14	Donovan P. Kelly	331	I
Chlamydia	202	Patricia I. Fields	3691	IV
Chlorobiaceae	195	H.G. Trüper	3583	IV
Chloroflexaceae	206	Beverly K. Pierson	3754	IV
Chromatiaceae	170	Norbert Pfennig	3200	IV
Chromobacterium	133	Monique Gillis	2591	III
Citrobacter	144	Wilhelm Frederiksen	2744	III
Clavibacter	62	Matthew D. Collins	1355	II
Clevelandina	221	Lynn Margulis	3965	IV
Clostridium—medical	82	Louis D.S. Smith	1867	II
Clostridium—nonmedical	81	Hans Hippe	1800	II
Comamonas	132	Anne Willems	2583	III
Corynebacterium—medical	50	Alexander von Graevenitz	1172	II
Corynebacterium—nonmedical	49	Wolfgang Liebl	1157	II
Cowdria	122	Gregory A. Dasch	2407	III
Coxiella	123	J.C. Williams	2471	III
Cristispira	221	Lynn Margulis	3965	IV
Curtobacterium	62	Matthew D. Collins	1355	II
Cyanobacteria—identification	97	John Waterbury	2058	II
Cyanobacteria—physiology	98	Yehuda Cohen	2079	II

Genus or group	Chapter	Senior author	Page	Volume
Cytophagales	199	Hans Reichenbach	3631	IV
Deinococcaceae	204	Robert G.E. Murray	3732	IV
Deleya	168	Karel Kersters	3189	IV
Denitrifiers	23	Walter G. Zumft	554	I
Dermatophilaceae	60	Erko Stackebrandt	1346	II
Derxia	135	Jan H. Becking	2605	III
Desulfotomaculum	80	Friedrich Widdel	1792	II
Desulfovibrio	183	Friedrich Widdel	3352	IV
Desulfuromonas	184	Friedrich Widdel	3379	IV
Dinitrogen fixers	22	Robert R. Eady	534	I
Diplocalyx	221	Lynn Margulis	3965	IV
Ectothiorhodospiraceae	171	Johannes F. Imhoff	3222	IV
Edwardsiella	143	Riichi Sakazaki	2737	III
Ehrlichia	122	Gregory Dasch	2407	III
Eikenella	140	Paul Granato	2668	III
Enterobacter	148	Francine Grimont	2797	III
Enterobacteriaceae	141	Don Brenner	2673	III
Enterobacteriaceae—additional genera	155	Don Brenner	2922	III
Enterococcus	66	Luc A. Devriese	1465	II
Eperythrozoon	225	Julius P. Kreier	3994	IV
Erwinia	154	Michel C.M. Pérombelon	2899	III
Erysipelothrix	73	Annette Reboli	1629	II
Erythrobacter	124	Tsuneo Shiba	2485	III
Escherichia	142	Karl A. Bettelheim	2696	III
Eubacterium	86	J.R. Andreesen	1914	II
Euplotes	214	Klaus Heckmann	3865	IV
Ewingella	155	Don J. Brenner	2922	III
Fervidobacterium	211	Robert Huber	3809	IV
Filibacter	79	Dieter Claus	1769	II
Flavobacterium	198	Barry Holmes	3620	IV
Flexibacter	199	Hans Reichenbach	3631	IV
Flexithrix	199	Hans Reichenbach	3631	IV
Francisella	224	Francis E. Nano	3987	IV
Frankiaceae	45	Antoon D.L. Akkermans	1069	II
Frateuria	169	Jean Swings	3198	IV
Fusobacterium	237	Tor Hofstad	4114	IV
Gallionella	231	Hans H. Hanert	4082	IV
Gardnerella	40	M.J. Pickett	918	I
Gemella	74	Ulrich Berger	1643	II
Gemmata	203	James Staley	3710	IV
Gluconobacter	111	Jean Swings	2268	III
Grahamella	225	Julius P. Kreier	3994	IV
Haemobartonella	225	Julius P. Kreier	3994	IV
Haemophilus	179	Susan K. Hoiseth	3304	IV
Hafnia	149	Riichi Sakazaki	2816	III
Haliscomenobacter	201	Eppe G. Mulder	3688	IV
Haloanaerobium	84	Aharon Oren	1893	II
Halobacteriaceae	34	Brian J. Tindall	768	I
Halobacteroides	84	Aharon Oren	1893	II
Halomonadaceae	167	Russell H. Vreeland	3181	IV
Helicobacter	189	Fred C. Tenover	3488	IV
Heliobacteriaceae	90	Michael T. Madigan	1981	II
Herbaspirillum	109	Johanna Döbereiner	2236	III

Genus or group	Chapter	Senior author	Page	Volume
Herpetosiphon	209	Hans Reichenbach	3785	IV
Hollandina	221	Lynn Margulis	3965	IV
Hydrocarbon oxidizers	19	Eugene Rosenberg	446	I
Hydrogenobacter	217	Michel Aragno	3917	IV
Hydrogen oxidizers	15, 217	Michel Aragno	344, 3917	I, IV
Hyphomicrobium	106	Jeanne Poindexter	2176	III
Hyphomonas	106	Jeanne Poindexter	2176	III
Isosphaera	203	James Staley	3710	IV
Janthinobacterium	133	Monique Gillis	2591	III
Kingella	126	Stephen A. Morse	2495	III
Klebsiella	147	Francine Grimont	2775	III
Kluyvera	155	Don J. Brenner	2922	III
Kurthia	75	Ronald M. Keddie	1654	II
Kusnezovia	233	Jean M. Schmidt	4093	IV
L-forms	230	Sarabelle Madoff	4068	IV
Lachnospira	94	Robert B. Hespell	2022	II
Lactobacillus	70	W.P. Hammes	1535	II
Lactococcus	67	Michael Teuber	1482	II
Legionella	178	A. William Pasculle	3281	IV
Leptospira	194	Solly Faine	3568	IV
Leptothrix	136	Eppe G. Mulder	2612	III
Leptotrichia	223	Tor Hofstad	3983	IV
Leuconostoc	69	Wilhelm Holzapfel	1508	II
Leucothrix	175	Thomas D. Brock	3247	IV
Listeria	71	Dorothy Jones	1595	II
Luminous bacteria	25	Kenneth H. Nealson	625	I
Lysobacter	176	Hans Reichenbach	3256	IV
Lyticum	214	Klaus Heckmann	3865	IV
Macromonas	218	Jan la Rivière	3934	IV
Maduromycetes	47	Michael Goodfellow	1115	II
Manganese-oxidizing bacteria	114	Kenneth H. Nealson	2310	III
Marinomonas	159	Michel J. Gauthier	3046	III
Megasphaera	91	Auli Haikara	1993	II
Methanobacillus	186	Bernhard Schink	3393	IV
Methanogenic bacteria	33	William B. Whitman	719	I
Methanolomonas	118	Richard Hanson	2350	III
Methylobacterium	117	P.N. Green	2342	III
Methylococcus	118	Richard Hanson	2350	III
Methylomonas	118	Richard Hanson	2350	III
Methylosinus	118	Richard Hanson	2350	III
Methylotrophs	18	Mary E. Lidstrom	431	I
Microbacterium	62	Matthew D. Collins	1355	II
Micrococcus	56	Miloslav Kocur	1300	II
Mobiluncus	39	Carol Spiegel	906	I
Moraxella	177	Gary V. Doern	3276	IV
Morganella	151	John L. Penner	2849	III
Mycobacterium leprae	54	Thomas M. Shinnick	1271	II
Mycobacterium—medical	53	Robert C. Good	1238	II

CHAPTER 163

The Genus *Xylophilus*

ANNE WILLEMS, MONIQUE GILLIS, and JOZEF DE LEY

The genus *Xylophilus* comprises strains pathogenic for the grapevine, *Vitis vinifera. Xylophilus ampelinus,* the only species, is the causal agent of bacterial necrosis and canker of grapevine and is therefore responsible for important economic losses to viticulture in both Europe and South Africa. Although the disease was first described in France in 1895 as "Maladie d'Oléron" (Ravaz, 1895), the causal pathogen was not isolated until 1969.

In 1939 Sarejanni had reported on "Tsilik marasi", a disease of Cretan grapevines which he attributed to a fungus of the family Pythiaceae, and which he considered to be different from the "Maladie d'Oléron", the "Gommose bacillaire" in France and from the "Mal nero" in Italy. The former three diseases of grapevines and the similar South African "Vlamsiekte" were at that time all attributed to *Erwinia vitivora* (Sarejanni, 1939; Du Plessis, 1940). This bacterium (syn. *Erwinia lathyri* and *Erwinia herbicola*) was subsequently shown to be an ordinary saprophyte, commonly isolated from infected plant material (Lelliott, 1974). In 1969, Panagopoulos reported the isolation of a very slow growing yellow-pigmented bacterium from grapevines with "Tsilik marasi" symptoms. This organism proved to be pathogenic upon reinoculation of healthy plants. It was named *Xanthomonas ampelina* (Panagopoulos, 1969) and was shown to be identical to the causal agent of "Maladie d'Oléron" (Prunier et al., 1970), "Vlamsiekte" (Erasmus et al., 1974) and "Mal nero" (Grasso et al., 1979).

The pathogen was originally classified in the genus *Xanthomonas* because it is a Gram-negative, aerobic, nonsporeforming, monotrichously flagellated rod-shaped, plant pathogenic bacterium that produces a yellow water-insoluble pigment and metabolizes sugars oxidatively (Panagopoulos, 1969). Gradually however, it became evident that *Xanthomonas ampelina* was not a genuine *Xanthomonas* (Bradbury, 1984) because of 1) the absence of xanthomonadins in *Xanthomonas ampelina* (Starr et al., 1977); 2) the differences in the regulation pattern of the aromatic amino acid biosynthesis (Byng et al., 1980; Whitaker et al., 1981); and 3) the dissimilarity between the rRNA cistrons of *Xanthomonas ampelina* and the other *Xanthomonas* species (De Vos and De Ley, 1983). By means of hybridizations between a labelled rRNA from the type strain of the vine pathogen and DNA from several reference taxa, it was definitely shown that *Xanthomonas ampelina* is not related to members of the genus *Xanthomonas,* but forms a separate genus in the acidovorans rRNA complex. *Xanthomonas ampelina* was therefore transferred to a new genus as *Xylophilus ampelinus* (Willems et al., 1987).

Habitats

Bacterial Necrosis and Canker of Grapevines

Xylophilus ampelinus strains have been isolated exclusively from different cultivars of *Vitis vinifera,* displaying symptoms of bacterial necrosis and canker. The disease can be detected beginning in early spring, when buds on affected shoots fail to open. The most typical symptoms on affected shoots are longitudinal cracks and cankers that develop from hyperplasiae in the cambial tissue. The underlying vascular tissue shows a brown discoloration and eventually dies. Other parts of the shoot, less severely affected, can survive. Similar cracks can develop on the petioles, flower stalks, and fruit stalks, causing death of leaves, flowers, or fruits. Leaves infected through hydathodes or stomata show reddish-brown lesions. Roots can also be affected, resulting in retarded growth of the shoots. Severity of the symptoms may vary considerably with different varieties (Panagopoulos, 1969; Ridé, 1984; European and Mediterranean Plant Protection Organization data sheets on quarantine organisms, list A2, No. 133, 1984; López et al., 1987b; Grasso et al., 1979).

Agricultural practices and local climatological conditions strongly affect the occurrence of the disease. Since *Xylophilus ampelinus* survives in the vascular tissue, transmission occurs mainly through pruning lesions by the use of contaminated tools and infected grafting material. Wind and rain (and overhead spraying) not only favor the spreading of bacterial ooze from infected leaves, but often cause wounds and thus provide additional access routes for the pathogen. Exceptionally dry seasons may result in partial recovery of infected vineyards (Ridé, 1984; Panagopoulos, 1987; López et al., 1987b).

Geographical Distribution

Xylophilus ampelinus has been isolated from diseased vines in Greece, France, Sardinia, Sicily, Spain and South Africa (Panagopoulos, 1969; Prunier et al., 1970; Garau et al., 1987; Grasso et al., 1979; López et al., 1978; Erasmus et al., 1974). Similar disease symptoms, very likely also caused by *Xylophilus ampelinus,* were reported from Argentina, Austria, Bulgaria, Canary Islands, Portugal, Switzerland, Tunisia, Turkey, Yugoslavia, and the USSR (Bradbury, 1984; Panagopoulos, 1987). According to Panagopoulos, the actual distribution of bacterial necrosis of grape vine is probably much larger, since its symptoms may be confused with those of other diseases (Panagopoulos, 1987). By means of several techniques it was shown that strains from Crete, France, Greece, Spain and South Africa are very similar (Willems et al., 1987).

Isolation

A major problem in the isolation of *Xylophilus ampelinus* strains is the extremely slow and poor growth of these strains on virtually all isolation media (Panagopoulos, 1969). Very often, fast-growing saprophytes, accompanying the pathogen, rapidly overgrow the whole culture. This may partly account for the long time period before *Xylophilus ampelinus* was isolated and characterized.

The most common isolation sources are small pieces of infected wood tissue, taken aseptically from diseased grapevines and soaked for 20 minutes in sterile water. The resulting bacterial suspension is plated on nutrient agar (Panagopoulos, 1969; Erasmus et al., 1974). After five to six days of incubation at 26°C, small pale-yellow colonies appear (0.1 to 0.3 mm diameter). After eight to ten days they can reach a diameter of 0.4 to 0.6 mm. The colony diameter never exceeds 1 mm on nutrient agar (Panagopoulos, 1969). On this medium, colonies are round with an entire margin, semitranslucent, slightly raised, and glistening. According to Panagopoulos, in Greece the pathogen can be isolated from plants the whole year around.

For better growth, the addition of 5% sucrose to nutrient agar is advised. Best growth is reported on yeast extract-galactose-calcium carbonate (YGC) medium containing 1% yeast extract, 2% galactose, 2% $CaCO_3$, and 2% agar (Panagopoulos, 1969; Bradbury, 1973). We have also obtained good growth on glucose-yeast extract-calcium carbonate-agar (GYCA) medium containing 0.5% yeast extract, 1% glucose, 3% $CaCO_3$, and 2% agar (Willems et al., 1987). The presence of calcium carbonate, which prevents the transmission of light, makes the latter two media less suitable for the study of colony morphology. More convenient and also providing good growth, is Yeast Extract/Galactose (YEGAL) medium (Starr et al., 1977).

Composition of YEGAL Medium

Yeast extract	5 g
Galactose	10 g
K_2HPO_4	3.01 g
NaH_2PO_4	4.55 g
NH_4Cl	1 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Ferric ammonium citrate	0.05g
$CaCl_2$	0.005 g
Distilled water	1 liter

Yeast extract and galactose, each dissolved in 100 ml, should be autoclaved separately as concentrated solutions.

On a purely synthetic medium, the addition of 0.1% glutamic acid is required as a growth factor (Bradbury, 1973). In general, the use of a large inoculum is required for good growth. *Xylophilus ampelinus* strains fail to grow on media that have been liquified and sterilized twice (Panagopoulos, 1969).

Xylophilus strains may produce two different stable colony types: one type (t1) producing relatively large yellow colonies (colony diameter 0.8 to 2.0 mm after 15 days on GYCA), the other type (t2) producing smaller, paler colonies that grow more slowly (colony diameter 0.4 to 1.0 mm after 15 days on GYCA). Microscopically, cells of both types look identical. Based on the results of comparative whole-cell protein gel electrophoresis and DNA:DNA hybridizations, it was established that these types are merely morphological colony variants which are phenotypically and genotypically highly similar (Willems et al., 1987).

Cultures can be maintained on screw-capped slants at 4°C; they should be transferred every

two months. For long-term preservation, strains can be lyophilized.

Identification

A few relatively simple bacteriological tests (Table 1) will establish whether strains, isolated from grapevines displaying the typical disease symptoms, belong to the genus *Xylophilus.* Most typical is the extremely slow and poor growth on most media at the optimal growth temperature of 24°C. The tiny yellow colonies, occurring after six to 15 days, produce a brown diffusible pigment on YGC medium. Cells are Gram-negative, straight to slightly curved rods, 0.4 to 0.8 μm by 0.6 to 3.3 μm. They occur singly, in pairs, or short chains, and are motile by means of one polar flagellum. Filamentous cells may occur in older cultures.

Additional features for differentiating *Xylophilus* from most *Xanthomonas* species are: growth on K, Na tartrate, Ca lactate, D-glucose, use of L-glutamine as sole carbon and nitrogen source, and no production of H_2S from L-cysteine (M. Van den Mooter, unpublished observations).

Because of their slow and poor growth, *Xylophilus* strains require relatively long incubation periods in conventional bacteriological tests. We tried to overcome this disadvantage by applying miniaturized API test systems (API Systems S.A., France). The enzymatic tests provided in the API ZYM gallery and in the experimental galleries Osidases, Esterases, and Aminopeptidases AP1 to AP6 (103 tests in total) could be used to distinguish *Xylophilus* from related taxa and from *Xanthomonas* (Willems et al., 1987). The 32 *Xylophilus* strains we tested formed a separate cluster using numerical analysis of the data. For identification purposes, however, these systems are not very suitable because of the large number of negative reactions and the lack of reference data. The auxanographic tests, available from API Systems, could not be used since *Xylophilus* does not grow on the standard medium these tests require.

Table 1. Diagnostic features for *Xylophilus ampelinus.*

Growth at 33°C	−
Mucoid growth	−
Acid from glucose	−
Alkali from Na propionate	−
Alkali from tartrate	+
Urease production	+
Esculin hydrolysis	−
Brown, diffusible pigment on YGC	+

From Panagopoulos, 1987.

Regardless of their geographic origin, *Xylophilus* strains produce a unique pattern in sodium dodecyl sulfate polyacrylamide gel electrophoresis of whole cell proteins and can therefore be identified by means of this technique (Willems et al., 1987).

In specialized phytopathological laboratories, the identity of suspected *Xylophilus ampelinus* strains is verified by techniques such as indirect immunofluorescence and indirect Enzyme-linked immunosorbent assay (ELISA) (López et al., 1987a). Erasmus et al., (1974) used Ouchterlony gel diffusion, Wassermann agglutination, and hemagglutination plate tests to identify the causal agent of the South African "Vlamsiekte" as *Xylophilus ampelinus.* Application of such fast techniques is becoming more and more widespread.

A fast, very reliable, and decisive identification method is based on hybridization of a radioactively labelled rRNA probe of a representative *Xylophilus ampelinus* strain with DNA of the strain to be identified. When rRNA from the type strain is used, *Xylophilus ampelinus* strains have Tm(e) values from 78 to 81°C (Willems et al., 1987). Tm(e) is the temperature at which half of the DNA:rRNA duplex is thermally denatured.

Physiology

Xylophilus strains have a strictly aerobic chemoorganotrophic metabolism. They use only a limited number of carbohydrates, organic acids, and amino acids for growth: on a total of 60 substrates tested, growth could be recorded only on D-glucose, D-galactose, L-glutamic acid, Na succinate, Na fumarate, K, Na tartrate, Na L-malate, Na_3 citrate, and Ca gluconate (M. Van den Mooter and J. Swings, manuscript submitted to Int. J. Syst. Bacteriol.). L-glutamate is required as a growth factor.

Taxonomic Position

Based on rRNA cistron similarities, as determined by DNA-rRNA hybridizations, the genus *Xylophilus* belongs to the acidovorans rRNA complex within rRNA superfamily III (see Chapter 100). Its closest genotypic neighbors are the genera *Comamonas* and *Hydrogenophaga,* several generically misnamed *Pseudomonas, Alcaligenes,* and *Aquaspirillum* species, and several unnamed clinical isolates. The genus *Xylophilus* constitutes a separate rRNA subbranch within this group. It can be

differentiated readily from all these taxa by its slow and poor growth.

CHAPTER 164

The Genus *Acinetobacter*

KEVIN J. TOWNER

Current Taxonomic Status

Members of the genus *Acinetobacter* have previously been classified by various authors under a variety of different names (reviewed by Henriksen, 1973), and, consequently, much of the early literature concerning this group of organisms is difficult to interpret owing to confusion over nomenclature and the lack of a widely accepted classification scheme. The genus *Acinetobacter* originally proposed by Brisou and Prévot (1954) included a heterogenous collection of nonmotile Gram-negative saprophytes that could be distinguished from other similar bacteria by their lack of pigmentation (Ingram and Shewan, 1960). The Subcommittee on the Taxonomy of *Moraxella* and Allied Bacteria subsequently proposed (Lessel, 1971) that the genus *Acinetobacter* should include only the oxidase-negative strains. This division has been supported by the use of transformation tests (Juni, 1972), which now forms the basis for inclusion in the genus. *Acinetobacter* is classified in the family Neisseriaceae, and the current generic description (Juni, 1984) allows unambiguous identification of strains to the genus level.

In contrast, delineation of species within the genus *Acinetobacter* is not satisfactory and is still the subject of much research. Only one species *(A. calcoaceticus)* is included in the current generic description, although it is known that the genus is biochemically and genetically heterogenous (Baumann et al., 1968; Johnson et al., 1970). DNA hybridization studies have identified 12 phenotypically distinct hybridization groups (genospecies) (Bouvet and Grimont, 1986). Species names have been proposed for six of these groups (Table 1), but phenotypic identification can be complex and time-consuming (Bouvet and Grimont, 1986). Five further genospecies have been similarly identified by Bouvet and Jeanjean (1989), but these cannot, as yet, be differentiated solely on the basis of phenotypic properties. There is an urgent need for a simple identification and differentiation scheme suitable for routine taxonomic and epidemiological use.

Table 1. Proposed subdivision of the genus *Acinetobacter* into genospecies.

Genospecies	Proposed species name	Number of strains[a]
1	*Acinetobacter calcoaceticus*	8
2	*Acinetobacter baumannii*	121
3		15
4	*Acinetobacter haemolyticus*	23
5	*Acinetobacter junii*	17
6		3
7	*Acinetobacter johnsonii*	23
8	*Acinetobacter lwoffii*	34[b] (8 and 9)
9		
10		4
11		4
12		3
13–17		20[c]

[a]The number of strains shown is the total of those identified phenotypically in the cited studies and provides an indication of the relative frequencies of the different genospecies.

[b]Genospecies 8 and 9 cannot be differentiated solely on the basis of phenotypic properties (Bouvet and Grimont, 1986).

[c]Genospecies 13–17 are phenotypically distinguishable from genospecies 1–12, but cannot themselves be differentiated phenotypically (Bouvet and Jeanjean, 1989).

Adapted from Bouvet and Grimont (1986) and Bouvet and Jeanjean (1989).

Habitats and Pathogenicity

Acinetobacters are ubiquitous organisms that are present in soil, water, and sewage (Blaise and Armstrong, 1973; Baumann, 1968; Warskow and Juni, 1972). It has been estimated that *Acinetobacter* may constitute as much as 0.001% of the total heterotrophic aerobic population of soil and water (Baumann, 1968). They have been found at densities exceeding 10^4 organisms per 100 ml in freshwater ecosystems and 10^6 organisms per 100 ml in raw sewage (LaCroix and Cabelli, 1982). They can be isolated from

heavily polluted water but are found more frequently near the surface of fresh water and where fresh water flows into the sea (Droop and Jannasch, 1977).

Members of the genus are also found in a variety of foodstuffs, including milk products (Koburger, 1964) and fresh meat (Eribo and Jay, 1985). Acinetobacters have been frequently isolated from eviscerated chicken carcasses and other poultry meats, even following gamma irradiation (Barnes and Thornley, 1966). Lahellec et al. (1975) reported that *Acinetobacter* constituted 22.7% of the total microflora of chicken carcasses. Members of the genus are responsible for spoilage of a number of foods, including chickens, eggs, bacon, and fish, even when the food is stored under refrigerated conditions (Gardner, 1971; Jay, 1982; Shewan et al., 1960; Thornley et al., 1960).

Acinetobacter is a normal inhabitant of human skin and has consequently been implicated as a presumed causal or contributory agent in numerous infectious disease processes, but sometimes is found as a result of sample contamination. They are particularly found in moist skin areas such as toe webs, the groin, and the axilla (Al-Khoja and Darrell, 1979; Noble and Pitcher, 1978; Taplin et al., 1963). Their pathogenicity is generally low but they may cause occasional serious opportunistic infections, including meningitis, septicemia, and pneumonia, particularly in patients with reduced natural resistance (reviewed by Glew et al., 1977). Increasing numbers of nosocomial infections due to *Acinetobacter* are now being reported (Bergogne-Bérézin et al., 1987). Hospital reservoirs of the organism may include waterbaths, disinfectants, room humidifiers, peritoneal dialysis fluid, wet mattresses, respirometers, and the hands of hospital staff (Buxton et al., 1978; Cunha et al., 1980; French et al., 1980; Sherertz and Sullivan, 1985; Smith and Massanari, 1977).

Isolation

Isolation of members of the genus *Acinetobacter* can be accomplished using standard laboratory media such as trypticase soy agar or brain heart infusion agar. A differential medium such as MacConkey agar may be helpful in recognizing colonies of *Acinetobacter* on primary isolation. The optimum growth temperature for most strains is 33–35°C. Although most strains will grow reasonably well at 37°C, some strains have considerably lower optimum growth temperatures and may be unable to grow at 37°C (Breuil and Kushner, 1975).

Selective Enrichment

Most strains of *Acinetobacter* can grow in a simple mineral medium containing a single carbon and energy source such as acetate, lactate, or pyruvate. Baumann (1968) described the use of an enrichment culture procedure for isolating members of the genus from soil and water. Liquid enrichment cultures containing 20 ml of medium (see below) are inoculated with a 5 ml sample of water or of a filtered 10% soil suspension and vigorously aerated at either 30°C or room temperature. Cultures are examined microscopically after 24 or 48 h and streaked onto suitable isolation media. Strains of *Acinetobacter* have a slightly acid pH optimum for growth, and vigorous aeration at a pH of 5.5 to 6.0 favors their enrichment.

Baumann's Enrichment Medium (per liter)

Sodium acetate (trihydrate)	2 g
KNO_3	2 g
$MgSO_4 \cdot 7H_2O$	0.2 g

dissolved in 0.04M KH_2PO_4-Na_2HPO_4 buffer (pH 6.0) containing 20 ml per liter of Hutner's mineral base (Cohen-Bazire et al., 1957).

Differential Selection on Solid Media

Selective liquid enrichment is rarely used in isolation from clinical specimens. For clinical isolation, general-purpose rich media such as blood agar or MacConkey agar are usually preferred because of their broad bacterial coverage. However, Holton (1983) described a selective differential medium (modified from an earlier medium described by Mandel et al., 1964) which may be suitable for the specific isolation and growth of *Acinetobacter* strains from clinical sources.

Holton's Selective Medium (per liter)

Agar	10 g
Casein pancreatic digest	15 g
Peptone	5 g
NaCl	5 g
Desiccated ox-bile	1.5 g
Fructose	5 g
Sucrose	5 g
Mannitol	5 g
Phenylalanine	10 g
Phenol red	0.02 g

Adjust to pH 7.0.

After autoclaving, the medium is cooled to 50°C and the following filter-sterilized ingredients added (final concentration in g per liter):

Vancomycin	0.01 g
Ampicillin	0.016 g
Cefsulodin	0.03 g

Following overnight incubation at 37°C, red colonies on the medium are tested for oxidase reaction and phenylalanine deamination (10% ferric chloride method). Colonies giving a negative reaction with both of these tests are presumptive *Acinetobacter* isolates.

Identification

Morphology

Short, plump, Gram-negative rods, typically 1.0–1.5 by 1.5–2.5 μm in the logarithmic phase of growth, but often becoming more coccoid in the stationary phase. Occasionally difficult to destain. Cells commonly occur in pairs, but also in chains of variable length. No spores formed and flagella absent. Although generally considered to be nonmotile, "twitching" and "gliding" motility has been reported to occur, particularly on semisolid media (Barker and Maxsted, 1975; Henrichsen and Blom, 1975; Mukherji and Bhopale, 1983). Many strains are encapsulated, and the capsule may be readily seen in India ink wet mounts. Colonies are usually nonpigmented, but some strains form white- to cream-colored colonies, which vary in consistency from butyrous to smooth and mucoid and from 1–2 mm in diameter.

Biochemical Identification

All members of the genus *Acinetobacter* are strict aerobes and can grow at a wide range of temperatures. Most strains will grow at 33°C, but some environmental isolates prefer incubation temperatures from 20 to 30°C. Clinical isolates of *Acinetobacter* will normally grow at 37°C and some strains can also grow at 42°C. All strains of *Acinetobacter* are oxidase-negative and catalase-positive. The negative oxidase reaction serves to distinguish the genus from other genera grouped in the family Neisseriaceae. Most strains of *Acinetobacter* can grow in a simple mineral medium containing a single carbon and energy source. A wide variety of organic compounds can be used as carbon sources by particular strains, although relatively few strains can use glucose (Baumann et al., 1968). There is no single biochemical test that enables ready differentiation of this genus from similar bacteria, but the non-fastidious nature and wide biochemical activities of the members of the genus make them readily distinguishable from other bacteria, using the combination of nutritional tests applied for nonfastidious, nonfermentative organisms in general, including commercially available diagnostic devices (Dowda, 1977; Oberhofer et al., 1977; Oberhofer, 1979; Towner and Chopade, 1987). Most strains are unable to reduce nitrate to nitrite in the conventional nitrate reduction assay. A few clinical strains may show hemolysis on blood agar plates due to the production of a phospholipase C (Lehmann, 1971). Most strains are resistant to penicillin due to the production of β-lactamase (Baumann et al., 1968; Gilardi, 1973).

Genetic Identification

Members of the genus are themselves only rarely transformable, but can be easily identified by testing the ability of their isolated DNA to transform a nutritional or antibiotic resistance marker to the naturally competent strain BD413 isolated by Juni (1972). Transformation of this highly competent strain occurs readily either on semi-solid media or in liquid culture and has been used as the basis of a test for the identification of *Acinetobacter* in clinical specimens (Brooks and Sodeman, 1974). DNA samples from unrelated bacteria have consistently failed to transform *Acinetobacter* auxotrophs to prototrophy (Juni, 1972), and this test is consequently believed to allow unambiguous attribution of unknown strains to the *Acinetobacter* genus.

Biochemistry and Physiology

The main identifying biochemical and physiological characteristics of the genus have been outlined earlier in this chapter and only the most significant aspects are therefore reiterated here.

Although rare strains of *Acinetobacter* showing growth factor requirements have been isolated (Baumann et al., 1968; Warskow and Juni, 1972), the vast majority of isolates resemble saprophytic pseudomonads in being able to use any one of a large range of organic compounds as a carbon and energy source in an otherwise mineral medium. Although the utilization of carbohydrates is relatively uncommon, the major biochemical feature of the genus is that many strains are able to metabolize a range of compounds including aliphatic alcohols, some amino acids, decarboxylic and fatty acids, unbranched hydrocarbons, sugars, and many relatively recalcitrant aromatic compounds such as benzoate, mandelate, n-hexadecane, cyclohexanol, and 2,3-butanediol (Juni, 1978). Members of the genus are therefore particularly suitable organisms for studying a variety of unusual biochemical pathways, and they may also have a role to play in degrading a variety of pollutants and industrial products (see "Applications").

As indicated above, most strains are unable to utilize glucose as a carbon source, but occasional rare strains are able to do so via the Entner-Doudoroff pathway (Taylor and Juni, 1961). Many acinetobacters are, however, able to acidify media containing sugars, including glucose, via an aldose dehydrogenase (Hauge, 1960). This property has been previously considered to have major taxonomic significance in the subdivision of the genus, but DNA hybridization studies (Bouvet and Grimont, 1986) now suggest that this is not the case unless considered in combination with other unrelated biochemical properties.

Although most strains of *Acinetobacter* are unable to reduce nitrate to nitrite in the conventional nitrate reduction assay, both nitrate and nitrite can be used as nitrogen sources by means of an assimilatory nitrate reductase (Jyssum and Joner, 1965). All acinetobacters are oxidase-negative, since they lack cytochrome *c*, but they do contain cytochromes *a* and *b* (Whittaker, 1971). All the enzymes of the glyoxylate cycle and the tricarboxylic acid cycle are normally present (Juni, 1978).

One important difference from many other organisms is that *Acinetobacter* cannot incorporate extracellular thymine or thymidine into DNA. Enzyme analysis has revealed that *Acinetobacter* lacks the enzymes thymidine phosphorylase, nucleoside deoxyribosyltransferase, and thymidine kinase, but does contain enzymes for conversion of thymidine-5′-monophosphate to thymidine-5′-triphosphate (Ovrebo and Kleppe, 1973).

Further details of the biochemical pathways mentioned in this section can be found in the detailed review by Juni (1978).

Genetics

All three of the major modes of gene transfer are known to occur in *Acinetobacter* and are discussed briefly below.

Transformation

The transfer of genetic material by transformation in a strain of *Acinetobacter* was first demonstrated by Juni and Janik (1969) and forms the basis of the genetic test for the identification of members of the genus (Juni, 1972). Genetic competence for transformation seems to be a rare trait in *Acinetobacter* (Juni, 1978), but has been used for preliminary genetic mapping of a few genes. Sawula and Crawford (1972) mapped the genes for tryptophan biosynthesis in strain BD413 and showed that they were arranged in a unique pattern consisting of three distinct clusters, as opposed to the single operon found in enteric bacteria. Similarly, Ginther (1977) analyzed proline auxotrophs in strain BD42 and showed that all the mutants belonged to three genetically distinct groups. Cruze et al. (1979) studied the conditions for quantitative transformation in strain BD413 and showed that competence occurred throughout the life cycle, but with a peak early in the exponential growth phase. The highest transformation frequencies (0.5 to 0.7%) were obtained in an aspartate-containing medium which allowed the most rapid growth of strain BD413. Recipient cell concentrations of 1×10^6 to 6×10^6 cells per ml were found to give the highest transformation frequencies, regardless of the DNA concentration. Similar findings were reported by Ahlquist et al. (1980) who demonstrated two peaks of competence for strain NCIB 8250, one during the early stages of batch culture and a second minor peak at the beginning of the stationary phase, and also reported that the presence of cyclic AMP increased the transformation frequencies obtained.

Transduction

A large variety of bacteriophages for various strains of *Acinetobacter* have been isolated from sewage (Blouse and Twarog, 1966; Herman and Juni, 1974; Twarog and Blouse, 1968). Most *Acinetobacter* phages are lytic, but one temperate phage (P78), which lysogenizes its host and is capable of mediating generalized transduction, has been isolated (Herman and Juni, 1974). Phage P78 is specific for its host strain and failed to lysogenize 389 other independently isolated strains of *Acinetobacter,* including the transformation-competent strain BD413. This narrow host specificity may be accounted for by the large number of different surface antigens found in this genus (Marcus et al., 1969). At present, neither P78 nor any other bacteriophage has been used for extensive genetic studies in *Acinetobacter.*

Conjugation

Conjugation in this genus was first reported by Towner and Vivian (1976a) using strain EBF 65/65 and the broad-host-range plasmid RP4 as a mobilizing vector. RP4 is capable of mobilizing the *Acinetobacter* chromosome and transferring chromosomal genes between different mutant derivatives of EBF 65/65. Transfer of the chromosome occurs at detectable frequencies only on solid surfaces (not in liquid matings) and mobilization occurs from at least two different chromosomal locations (Towner and

Vivian, 1976b). This system has been used to map 23 different mutations on a circular linkage group (Towner, 1978), and it has been suggested that the chromosomal organization of *Acinetobacter* differs from enteric bacteria, but is similar to *Pseudomonas,* in that it shows an absence of clustering of functionally related genes. Vakeria et al. (1984) subsequently added several genes concerned with mandelate metabolism to this map using conjugation mediated by RP4 and an indigenous self-transmissible plasmid designated pAV1 (Hinchliffe and Vivian, 1980). A variety of plasmids belonging to different incompatibility groups have now been shown to be capable of transfer by conjugation to *Acinetobacter* from enteric bacteria, although not all are stably maintained (Chopade et al., 1985; Towner and Vivian, 1977). Cloning vectors that are capable of transfer to and maintenance in *Acinetobacter* have also been described (Ditta et al., 1985; Singer et al., 1986).

Applications

Biodegradation of Industrially Relevant Aromatic Compounds

The biodegradation of aromatic compounds produced as industrial pollutants has been reviewed by Fewson (1981). The wide metabolic versatility of *Acinetobacter* means that particular strains have the potential to play an important role in the biodegradation of a wide range of aromatic compounds such as phenols, cresols, toluene, polyethylene glycol, polychlorinated biphenyls, and cyclohexane. Many such degradative pathways are still in the process of being elucidated, but it can already be envisaged that it may also be possible to isolate metabolic intermediates of commercial interest following the construction of mutant strains blocked at appropriate stages in a particular pathway. An important additional advantage is that members of the *Acinetobacter* genus are easy to isolate, cultivate, and manipulate genetically in the laboratory.

Production and Uses of Emulsan

The *Acinetobacter* strain RAG-1 is capable of utilizing a wide variety of hydrophobic growth substrates including crude oil, gas oil, several triglycerides, and middle-chain-length alkanes (Rosenberg et al., 1979a; Shabtai et al., 1985). Emulsan is the extracellular form of a polyanionic, cell-associated heteropolysaccharide produced by strain RAG-1 (Rosenberg et al., 1979b; Zuckerberg et al., 1979). The biopolymer has the property of stabilizing emulsions of hydrocarbons in water and seems to be required in a cell-bound form for growth on crude oil (Pines and Gutnick, 1986). Purified emulsan has a number of potential applications in the petroleum industry, including viscosity reduction during pipeline transport following formation of heavy oil/water emulsions, and production of fuel oil/water emulsions for direct combustion with dewatering (Gutnick and Minas, 1987). However, the affinity of purified emulsan for the oil/water interface also has implications for the stability of oil emulsions during transport and storage, and also for their biodegrability following accidental spillage. The effect of emulsan on the biodegradation of crude oil by pure and mixed bacterial cultures has been investigated in detail by Foght et al. (1989).

Production and Uses of Biodispersan

Most microbial surfactants that have been isolated and characterized act by either lowering the interfacial tension between oil and water or by stabilizing (or destabilizing) hydrocarbon/water emulsions (as described above). Rosenberg et al. (1988a) investigated the possibility that bacteria might also produce surfactants which adhere to the surfaces of inorganic materials. Two strains of *Acinetobacter* were isolated which produced extracellular polymers (termed biodispersans) capable of dispersing limestone in water. The active component of biodispersan has been purified and shown to be an anionic polysaccharide with an average molecular weight of 51,400 (Rosenberg et al., 1988b). Limestone is used in a wide variety of commercial industries, and purified biodispersan may have potential applications in several manufacturing processes producing common products such as paints, ceramics, and paper. It should be noted that whereas the production of hydrocarbon-in-water emulsifiers appears to be widespread among acinetobacters, emulsifying and dispersing activities appear to be due to different materials, with production of dispersants apparently restricted to a relatively small number of *Acinetobacter* strains (Rosenberg et al., 1988a).

CHAPTER 165

The Family Azotobacteraceae

JAN HENDRIK BECKING

The family Azotobacteraceae is represented by two genera, *Azotobacter* (Beijerinck, 1901a, 1901b) and *Azomonas* (Winogradsky, 1938). The removal of the genera *Beijerinckia* and *Derxia* from the Azotobacteraceae was based on rRNA cistron analysis (De Smedt et al., 1980) and rRNA cistron similarities as observed in DNA-rRNA hybridization experiments (De Vos et al., 1985). Such experiments showed that *Beijerinckia* and *Derxia* are not closely related to the genera *Azotobacter* and *Azomonas,* but that they belong to other subdivisions or groups, i.e., the alpha and the beta subclasses, respectively of the Proteobacteria (see Chapter 100). On the other hand, investigations on rRNA similarities of various Gram-negative bacteria based on $T_{m(e)}$ values of DNA-rRNA hybrids showed that *Azotobacter* and *Azomonas* are closely related to one another and to the *Pseudomonas fluorescens* rRNA branch. The latter branch or group belongs to the Superfamily I in the nomenclature of De Ley and coworkers (see Chapter 100; De Smedt et al., 1980; and De Vos et al., 1985) or the gamma group/subdivision or subclass of the purple bacteria as defined by Woese et al. (1985a, 1985b) or the Proteobacteria, as defined by Stackebrandt et al. (1988).

Members of the Azotobacteraceae are primarily characterized as nonsymbiotic (i.e., free-living), aerobic, heterotrophic bacteria whose main property is the ability to fix molecular (atmospheric) nitrogen in a nitrogen-free or nitrogen-poor medium with an organic carbon compound (preferentially sugars, alcohols, or organic acids) as energy source. However, dinitrogen fixation is not unique to this family, as this property can be observed in quite a number of other unrelated bacteria (see Chapters 107 and 109). Moreover, some representatives of this family can produce associative growth (which is different from symbiotic growth) with higher plants. For these reasons, representatives of this family are usually called nonsymbiotic nitrogen-fixers.

General Habitats

Representatives of the Azotobacteraceae are regular inhabitants of soil, including aerially transported dust, of water habitats, and of plant surfaces such as the external environment of roots (rhizosphere) and leaves (phyllosphere). *Azotobacter chroococcum* and *A. vinelandii* also occur in marine habitats. Some species occur in much larger numbers in the rhizosphere of higher plants than in the soil itself, and it has been shown in some cases that this associative growth is beneficial for the plant because fixed nitrogen becomes available to the plant (Döereiner, 1966, 1968). Some investigators (see "Applications") report the same for *Azotobacter chroococcum* and a number of agricultural crops in India.

For *Azotobacter paspali* and the grass *Paspalum notatum,* the association seems to be species-specific (Döbereiner, 1966, 1970). Also, on leaf surfaces, members of this group (especially, *Azotobacter chroococcum*) often occur as nonpathogenic epiphytic flora, particularly on older or aged leaves. The bacteria probably proliferate at the expense of the sugar-rich and nitrogen-poor exudates of the plant; the exudates act as a kind of enrichment medium (see below). For the phyllosphere, it has been suggested that the fixed nitrogen becomes available to the plant (Ruinen, 1961), but an unambiguous proof using $^{15}N_2$ has not yet been presented.

Most species of this family occur in soil as well in water, but two *Azomonas* species, *A. agilis* and *A. insignis,* have so far only been isolated from water habitats. The pH value of the soil or water environment often governs the occurrence of a certain species. Therefore, the pH of the medium, in combination with selective carbohydrate utilization, are important factors for selective isolation of the various species in enrichment media.

General Identification

Morphological and physiological properties are both very important for the identification of Azotobacteraceae. All representatives have the ability to fix nitrogen in simple media. Cells are usually large, blunt to oval in shape, 2 μm or more in diameter. The morphology may change with various growth conditions. The cells are normally in pairs, but single cells or short chains may also occur. Motile by peritrichous or polar flagella or nonmotile. Intracellular poly-β-hydroxybutyrate is produced (Fig. 1). Cells are Gram-negative to Gram-variable (rarely). Endospores are not formed. Microcysts are formed in one genus *(Azotobacter).* They are chemoheterotrophic, preferentially utilizing sugars, alcohols, and salts of organic acids. Cultures are obligately aerobic and catalase-positive. They fix molecular nitrogen in a nitrogen-free or nitrogen-poor medium in air, but also under reduced oxygen pressure. Organic growth factors are not required. Trace elements (e.g., molybdenum or vanadium) are required because they are involved in nitrogenase activity. Normally, cells fix 10 mg of nitrogen per g of a suitable carbohydrate (usually glucose) in synthetic media containing 1–2% carbohydrate. However, the efficiency of dinitrogen fixation can be markedly increased (sometimes doubled up to 20–25 mg N/g carbohydrate) by lowering the carbohydrate levels (Becking, 1971), to levels such as usually occur in soils, or when under low oxygen tension (Meyerhof and Burk, 1928; J. H. Becking, unpublished observations; see also "Physiological and Biochemical Aspects").

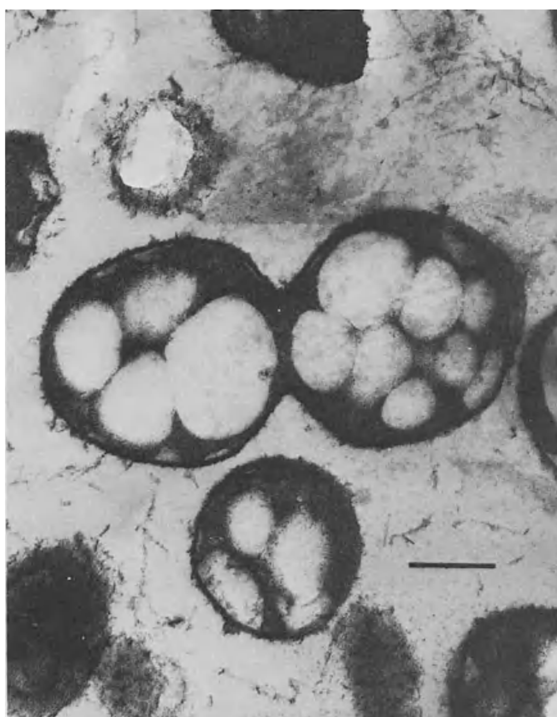

Fig. 1. *Azotobacter chroococcum.* Thin section through cells demonstrating the presence of large, poly-β-hydroxybutyrate globules as reserve material. Many cells occur in pairs in the so-called diplococcus stage. Transmission electron micrograph. Bar = 0.5 μm.

They can utilize various sources of combined nitrogen, but some species utilize nitrate poorly or not at all. Water-insoluble and water-soluble pigments or fluorescent pigments are produced by some species.

In the genus *Azotobacter,* microcysts are formed in older cultures grown with sugar as carbon source. In some species, a medium containing butan-1-ol as organic substrate (0.1–0.2 ml is added prior to pouring of the agar plates) enhances cyst formation (Tchan and New, 1984). A microcyst can be distinguished from an endospore by its characteristic structure: a central body surrounded by a cyst coat, consisting of an exocystorium and an exine. In contrast to a spore, the cell inside the cyst is similar to the vegetative form and there are no cytological changes in the cell prior to its germination (Socolofsky and Wyss, 1961; Tchan et al., 1962). The primary habitat is soil, water, and the plant rhizosphere and phyllosphere. In this family, the GC content of the DNA ranges from 52–67.5 mol%. The type genus is *Azotobacter* Beijerinck 1901b, 567.

Differentiation from Other Nitrogen-Fixing Bacteria

Although some rhizobia may fix nitrogen nonsymbiotically, unlike *Azotobacter,* they can only do so under reduced oxygen tension. Furthermore, their cells are generally smaller than *Azotobacter* cells (*A. paspali* excepted). Moreover rhizobia need a more complex medium (supplemented with growth substances, etc.) for growth. Other nonsymbiotic nitrogen-fixing organisms have a different cell morphology and widely different physiological and nutritional requirements depending on the taxonomic group of the Prokaryote class to which they belong.

Genus Differentiation of Azotobacteraceae

Azotobacter: Microcysts formed; GC content is 63–67.5 mol% (T_m).
Azomonas: Microcysts not formed; GC content is 52–59 mol% (T_m).

Isolation

Species of the Azotobacteraceae are typical aerobic, chemoheterotrophic, dinitrogen-fixing bacteria. Therefore, any medium of suitable pH value that contains an organic carbon source, minerals (especially phosphate), some trace elements (in particular, molybdenum and/or vanadium), and no combined nitrogen is suitable for enrichment, since only organisms that can grow at the expense of atmospheric nitrogen are able to develop.

Members of this group fix dinitrogen better at low oxygen tension, probably because fixation is a reductive process (i.e., nitrogenase is inhibited or inactivated by oxygen). However, in enrichment cultures, care should be taken to provide sufficient aeration of the medium, in order to suppress the development of anaerobic or facultatively anaerobic bacteria (evident by a characteristic butyric acid smell of the enrichment culture), which may develop when the oxygen pressure is low or when the oxygen is totally exhausted. Therefore, thin-liquid layers in Erlenmeyer flasks or petri dishes are recommended to allow sufficient oxygen access. This precaution is not absolutely obligatory for enrichment of most *Azotobacter* species, since in static culture, they usually form a pellicle on the liquid surface. It is advisable to leave this pellicle undisturbed, because careless handling or shaking of the enrichment culture may rupture the pellicle and cause the cells to precipitate as a sediment, which stimulates the development of the above-mentioned anaerobic or facultative anaerobic contaminating bacteria always present in enrichment cultures.

General Enrichment Procedures

Members of the family Azotobacteraceae can be enriched from soil or water by adding phosphate (0.1%) and an organic carbon source, usually 1–2% sugar or a calcium (or sodium) salt of an organic acid, to one of the above substrates as will be described below. Usually, an organic carbon source and phosphate are the minimum nutrients that must be added to obtain the development of Azotobacteraceae under natural conditions in soil or water. Using this principle, a number of simple enrichment procedures can be designed for the successful isolation of members of this group.

ISOLATION OF AZOTOBACTERACEAE BY THE SOIL-PASTE PLATE METHOD. A small amount of soil (about 30–50 g) is mixed in a porcelain mortar with about 0.5–1.0 g of organic carbon (e.g., sucrose, glucose, or mannitol), about 0.5 g of chalk ($CaCO_3$) to assure an alkaline reaction, 4 drops (0.12 ml) of a 10% aqueous K_2HPO_4 solution, and 4 drops of a 10% aqueous $MgSO_4$ solution. When the water content of the soil is low, some extra distilled water is also added in order to obtain a soil paste. If the soil is too sandy, or is difficult to make into paste for other reasons, sterile clay mineral (kaolinite) is added. The soil paste is transferred with a sterile knifepoint or spatula to a small, low-rimmed container, watch glass, or hollow gypsum block, and the soil is firmly pressed into the hollow surface. With the aid of a knife or spatula, preferentially sterile, the surface of the soil is neatly smoothed. The small container with the soil is subsequently placed in a petri dish containing a wet piece of filter paper and incubated at 27–30°C. Care should be taken that the top of the soil does not touch the upper lid of the petri dish, thus causing anaerobic conditions. After 3–7 days incubation, glistening, slimy *Azotobacter* colonies develop on the smooth soil surface. Colonies of *A. chroococcum* turn brown in a few days.

ISOLATION OF AZOTOBACTERACEAE BY THE SIEVED-SOIL PLATE METHOD. In this method (Winogradsky, 1932), silica-gel plates are prepared by treating a sodium-silicate solution with acid to have a complete inorganic substrate. The plates are impregnated with nitrogen-free, carbohydrate-containing nutrient solution suitable for the cultivation of Azotobacteraceae. Before impregnation, the excess salt (NaCl, when HCl is used for gel preparation) is washed out in running tap water, and then the plates are rinsed with sterile, distilled water. The solid medium is allowed to dry in an incubator. Subsequently, the plates are impregnated with medium, the superfluous medium is poured off, and the remaining water is evaporated in an incubator. The dry plates are seeded with soil crumbs; sieved soil is used preferentially (either sieved directly over the plate or distributed on the plate with a spatula) in order to obtain small soil particles and an even distribution. After incubation at 27–30°C, colonies of members of soil-inhabiting Azotobacteraceae develop on the gel around the soil particles.

The preparation of silica gel is rather laborious, but good quality agar can also be used, i.e., agar low in combined nitrogen. Other agars can also made sufficiently low in combined nitrogen by some preparations, i.e., by fermentation of the agar in distilled water and by repeated removal and renewal of the rinsing solution. The treated agar (10–20 g/l) can be made up with Azotobacteraceae nitrogen-free medium (see below), and the nutrient agar plates inoculated with sieved soil particles in

the manner mentioned above for the silica plates. As Azotobacteraceae medium, Winogradsky's nitrogen-free medium can be used. It has the following composition (g/l): KH_2PO_4 50.0; $MgSO_4 \cdot 7\ H_2O$, 25.0; NaCl, 25.0; $FeSO_4 \cdot 7H_2O$, 1.0; $Na_2MoO_4 \cdot 2\ H_2O$, 1.0; and $MnSO_4 \cdot 4H_2O$, 1.0; the pH is adjusted to 7.2 with NaOH. This is a stock solution, which can be stored indefinitely at room temperature; the medium is prepared by using 5.0 ml of stock solution and 0.1 g $CaCO_3$ per liter of distilled water (see Tchan and New, 1984). The medium is sterilized at 120°C for 20 min. The organic substrate (10–20 g/l) is added to this organic medium. Some sugars, including glucose, must be sterilized separately before addition to the sterilized mineral medium. The medium is usually solidified with 15.0 g agar/per liter.

ISOLATION OF AZOTOBACTERACEAE BY THE NUTRIENT SOLUTION METHOD. A complete nutrient medium is used (see e.g., Winogradsky's nitrogen-free mineral medium supplemented with a carbohydrate source as mentioned above). This medium is preferably sterilized in order to eliminate contamination from other sources. The liquid medium is usually placed in shallow layers in Erlenmeyer flasks or in petri dishes, and about 0.3–0.5 g of wet soil of the sample to be tested is used to inoculate 100–150 ml of enrichment medium.

For the investigation of distribution of members of Azotobacteraceae in water samples, usually an organic carbon source (5–20 g/l) is added to the water sample itself. Sometimes the sample is supplemented with some inorganic nutrients (particularly phosphate and molybdenum). The water sample can also be mixed with an equal volume of sterile nutrient solution of double strength. These two methods, in general, gave better results than the inoculation of a complete medium with a small amount of the water sample (e.g., 1–5 ml water sample added to 100–150 ml medium), probably because of the lower density of Azotobacteraceae in normal natural water sources compared to soil.

As already mentioned with use of nutrient solutions, the depth of the liquid layer employed should not be too high; if the liquid layers are too thick, anaerobic conditions may occur at the bottom of the flasks, resulting in growth of contaminants which inhibit the growth of Azotobacteraceae.

Representatives of the Genus *Azotobacter*

These are soil, water, plant rhizosphere, and phyllosphere organisms; therefore, all these substrates can be used as inoculum. Many members of this genus produce copious amounts of capsular slime (polysaccharide). No endospores are formed, but some form thick-walled microcysts, which, unlike spores, are encysted vegetative cells without cytological changes prior to their germination. The cells show motility by peritrichous flagella (Fig. 2) or they are nonmotile. The cells are Gram-negative. Although some species appear to be Gram-variable (e.g., Jensen and Peterson, 1954; Kirakosyan and Melkonyan, 1964; Norris and Kingham, 1968; Johnstone, 1974), but Thompson and Skerman (1979) attribute these results to incomplete decolorization of thick smears.

Identification of *Azotobacter* Species

Cells are motile in *Azotobacter chroococcum, A. vinelandii, A. armeniacus,* and *A. paspali,* but motility is absent in *A. beijerickii* and *A. nigricans.*

Nonmotile variants have been described in *A. vinelandii.*

Excretion of water-soluble, yellow-green, fluorescent pigment occurs in *A. vinelandii* and *A. paspali* and that of red-violet or brownish-black pigment in *A. nigricans, A. armeniacus,* and sometimes *A. paspali* under certain conditions.

Rhamnose as the sole source of carbon can only be utilized by *A. vinelandii* and not by any other species. For a list of other specific carbon compounds and inhibitory substances, see the specific enrichment media given below for the various species.

Azotobacter chroococcum

Cells of *A. chroococcum* are pleiomorphic, bluntly rod-, oval-ovoid-, or coccus-shaped. Mean dimensions are 3.0–7.0 μm long × 1.5–2.3 μm wide. The cell shape changes dramatically in time or with changes in growth (medium) conditions. Cells are often in pairs. Young cells are motile by peritrichous flagella. Microcysts and capsular slime are formed. Colonies are moderately slimy, turning black or black-brown on aging. The pigment produced is not water-diffusible.

SOIL-PASTE METHOD FOR ISOLATION OF *AZOTOBACTER CHROOCOCCUM.* The soil-paste method described under the general techniques is a quick and easy method to obtain this species from soil. Also the sieved-soil plate method and the nutrient solution method are adequate for obtaining *A. chroococcum* from soil. Appar-

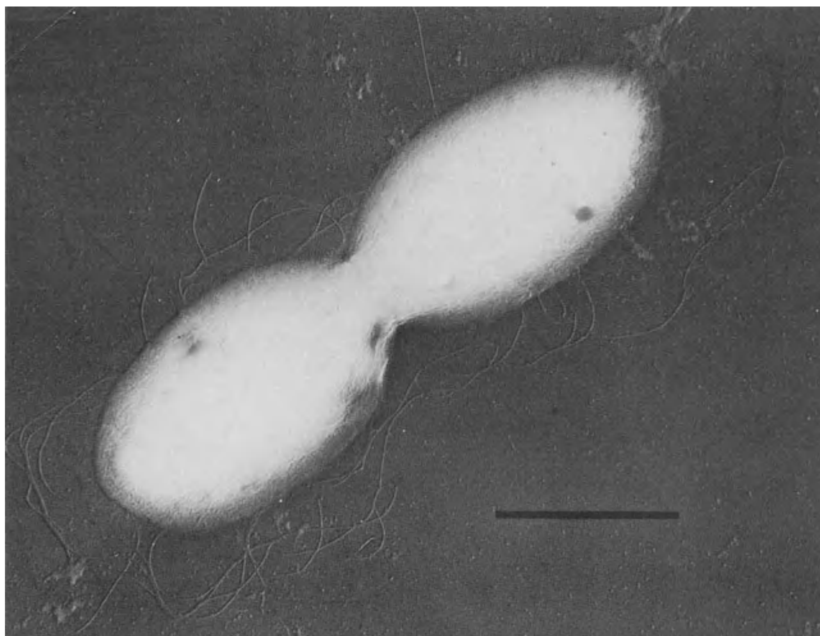

Fig. 2. *Azotobacter chroococcum.* Two cells in a pair ("diplococcus" stage) showing peritrichous flagella. Preparation shadowed with an alloy of gold and manganese. Transmission electron micrograph. Bar = 2.0 μm.

ently, because *A. chroococcum* is the most common and predominant *Azotobacter* in soil, no special enrichment techniques are necessary to make it selectively dominant.

NUTRIENT SOLUTION FOR ISOLATION OF *AZOTOBACTER CHROOCOCCUM.* The nutrient solution method, originally described by Beijerinck (1901a, 1901b) for the isolation of *A. chroococcum,* is also a good and well-established method for enrichment and isolation of *A. chroococcum* from soil and water samples.

Nutrient Solution Method

To a 500-ml Erlenmeyer flask, about 100 ml of nitrogen-free nutrient solution of the following composition is added:

Distilled water	1 liter
Glucose	20.0 g
$CaCO_3$	20.0 g
K_2HPO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g

Adjust to pH 7.2-7.6.

In some cases it is advisable to also add trace elements, especially molybdenum ($NaMoO_4 \cdot 2\ H_2O$, 0.005 g/l), to the medium. The medium is inoculated with about 0.3–0.5 g of soil; for water samples, the distilled water of the prescription is replaced by the surface water tested. After 1–3 days, an *Azotobacter* pellicle forms on the liquid surface.

Due to anaerobic conditions below the pellicle, nitrogen-fixing butyric acid bacteria (e.g., *Clostridium pasteurianum*) may develop later at the bottom of the flask, and eventually throughout the medium. It is therefore advisable to subculture the *Azotobacter* pellicle according to the normal procedures (by applying appropriate dilutions in sterile tap water) as soon as possible to nitrogen-free agar plates in order to reduce contamination. Such subculturing is also advisable because combined nitrogen produced by *Azotobacter* development may make it possible for non-dinitrogen-fixing contaminants to develop.

The following agar medium can be used for the isolation, purification, and further subcultivation of *Azotobacter chroococcum* found in the enrichment cultures:

Agar Medium for *Azotobacter chroococcum*

Distilled water	1 liter
Glucose	20.0 g
K_2HPO_4	0.8 g
KH_2PO_4	0.2 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$FeCl_3 \cdot 6H_2O$	0.10 g (or 0.05 g)
$CaCl_2 \cdot 2H_2O$	0.05 g
or $CaCO_3$	20.0 g
$NaMoO_4 \cdot 2H_2O$	0.05 g
Agar	20.0 g

Adjust to pH 7.4–7.6.

With $CaCl_2$, the agar medium is translucent; with $CaCO_3$ it is opaque white. The latter substance is, however, in some cases an advantage for detecting *Azotobacter* colonies, because they do not produce acid on it. Acid-producing colonies, as evident by the dissolution of the calcium carbonate around the colony, are certainly not *Azotobacter* species. A further advantage for

adding $CaCO_3$ to the medium is that it has a good buffering capacity at the alkaline side; an alkaline reaction is necessary for the development of *Azotobacter chroococcum.*

The presence of *A. chroococcum* in soil or water is strongly governed by the pH value of these substrates. In an environment below pH 6.0, *Azotobacter* is generally rare or totally absent (see Becking, 1961). H. L. Jensen (1965) tested 264 Danish soils and found that practically all of the soils above pH 7.5 contained *Azotobacter* (predominantly *A. chroococcum*) varying in numbers between 10^2 and 10^4 per gram of soil. Of the 148 tropical soils tested by Becking (1961), all soils above pH 7.5 (pH range 7.5–9.0) contained *Azotobacter* (also mainly *A. chroococcum*) and, in the pH ranges of 7.0–7.4, 6.5–6.9, and 6.0–6.4, the percentage of *Azotobacter*-positive soils was 89, 57, and 32%, respectively. In nitrogen-free nutrient media, the lower pH limit for growth of *A. chroococcum* strains in pure culture is between pH 5.5 and 6.0 (Jensen and Petersen, 1955).

As already mentioned earlier (Becking, 1962, 1981), according to the author's experience, not all *Azotobacter* strains that produce a brown or brown-black pigment on aging (Fig. 3) belong to one species, because *Azotobacter chroococcum* strains are very pleomorphic (see Fig. 4). It was therefore likely that this species comprises a more complex group consisting of several species, whose delimitations have not yet been sorted out. The latter is confirmed by Thompson and Skerman (1979) who examined 151 strains of Azotobacteraceae of different provenance in 230 variant tests and analyzed the data according to numerical methods in a hierarchical classification of groups. They obtained evidence that at least two distinct black-brown-pigmented *Azotobacter* species occur next to *A. chroococcum,* i.e., *A. nigricans* and *A. armeniacus* (see below).

Azotobacter nigricans

This species, originally isolated by Krasil 'nikow (1949), possesses, in contrast to *A. chroococcum* (but like strains of *A. beijerinckii*), nonmotile cells. Cells are bluntly rounded rods in shape, occurring singly or in pairs. Mean cell dimensions are 4.1–4.9 μm long $\times$ 1.5–2.7 μm wide. Moreover, they differ from *A. chroococcum* in a number of nutritional properties, such as the inability to utilize ethanol, pentan-1-ol, propionate, caproate, and benzoate and to produce brown-black or red-violet diffusible pigments. They differ from *Azotobacter armeniacus* by the inability to utilize caprylate, which compound can be used as carbon source by the

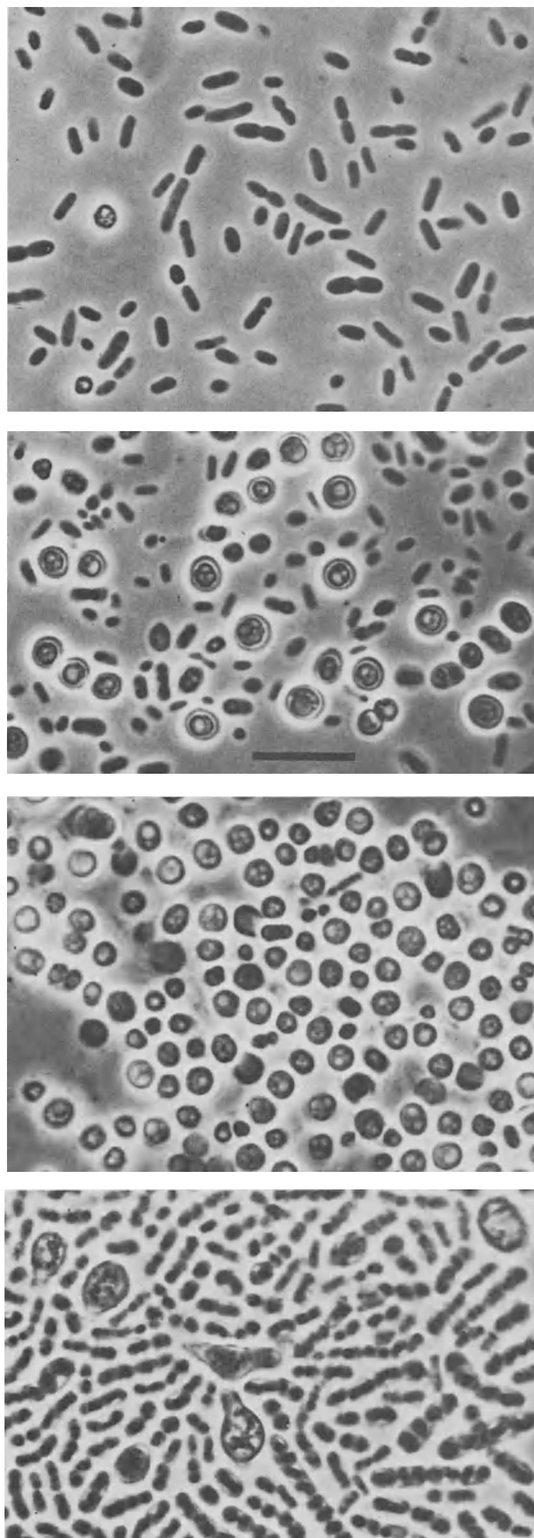

Fig. 3. *Azotobacter chroococcum* cells. Four different strains of the same age growing on an identical medium (nitrogen-free, mineral glucose agar with 2% calcium carbonate). Note the presence of lipoid-filled cells, cysts, and germinating cysts in some of the strains. Living preparations; phase contrast micrographs. Bar = 10 μm.

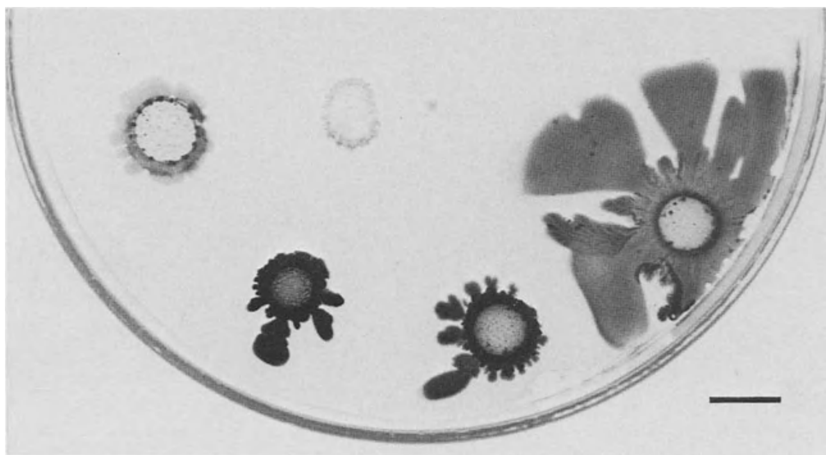

Fig. 4. *Azotobacter chroococcum* colonies. Strains growing on the same medium (nitrogen-free, mineral glucose agar with calcium carbonate) and of the same age, showing the variation of the chromogenesis of the colonies. Bar = 1 cm.

latter species. In *A. nigricans,* the production of agar-diffusible homopolysaccharides from sucrose or raffinose is strain variable, but no strain produces any colony-retained homopolysaccharide. On aging, colonies of *A. nigricans* turn black-brown due to the same diffusible pigment, but a variant formerly called *A. beierinckii* subsp. *achromogenes* Jensen and Petersen 1954, but now proposed to be *A. nigricans* subsp. *achromogenes* (Thompson and Skerman, 1979) produces only a yellow nondiffusible pigment within the colony and no diffusible pigment.

Strains of this species has been isolated from European soils, particularly from East European soils.

There is no species-specific selective enrichment method for isolating *A. nigricans.*

Azotobacter armeniacus

This is a poorly understood species that has been described by Thompson and Skerman (1981). Cells are bluntly rounded rods, occurring singly or in pairs. Mean cell dimensions are 5.0–5.7 μm × 1.7–2.0 μm. Strains of this species differ from *A. nigricans* by having motile cells, but they have in common with the latter species the production of a diffusible brown-black or red-violet pigment into the medium. In contrast to *A. nigricans,* they are able to use citrate or D-galacturonate as sole carbon source and most strains also can use *n*-valerate and caprylate, but like *A. nigricans,* capronate is not utilized. All *Azotobacter* species, including *A. nigricans,* can utilize ammonium and nitrate as sole source of nitrogen, and these N-sources are assimilated in preference to molecular nitrogen, *A. armeniacus* is unable to use ammonium, nitrate, or glutamate as sole source of nitrogen for growth (Thompson and Skerman, 1979).

There is no special enrichment medium for *A. armeniacus,* but probably it can be enriched with caprylate as sole source of carbon, but *A. vinelandii* also can be grown on this medium. Further isolation, however, will differentiate between these two species.

Azotobacter beijerinckii

Formerly, this organism was not regarded as a distinct species, but merely as a nonpigmented variant of *A. chroococcum.* In the eighth edition of *Bergey's Manual* (Buchanan and Gibbons, 1974), it has, however, been restored to the species level. Cells are bluntly ended rods or ellipsoidal, occurring singly or in pairs, sometimes in short chains. Mean cell dimensions are 3.2–5.3 μm long × 1.7–2.7 μm wide.

The main differences between *Azotobacter beijerinckii* and *A. chroococcum* are that colonies of *A. beijerinckii* produce, on aging, a yellowish or cinnamon pigment (in *A. chroococcum,* it is brown or blackish-brown) and its cells are nonmotile (motile in *A. chroococcum*). Moreover, it invariably lacks the ability (in contrast to *A. chroococcum*) to utilize starch as the sole source of carbon. Sometimes the inability to utilize mannitol is also mentioned as a determinative character (see Johnstone, 1974), but 9 out of 10 strains tested by Jensen and Petersen (1955) showed good growth on this carbon source. Thompson and Skerman (1979) mentioned in addition, that caproate is utilized by *A. chroococcum,* but not by its satellite species, *A. nigricans* and *A. armeniacus.* The differences between *A. nigricans,* which is also a species with nonmotile cells, and *A. beijerinckii* are not so clear with respect to carbon source utilization, except that malonate is used by all strains of *A. beijerinckii,* but only by a minority of strains of *A. nigricans,* and that D-glucuronate, D-galacturonate, and benzoate are utilized by *A. beijerinckii* but not by *A. nigricans*

(Thompson and Skerman, 1979). The main difference remaining is the pigment, which in *A. nigricans* is black-brown to red-violet, whereas the excretion of any water-soluble pigment into the substrate is completely absent in *A. beijerinckii.* The physiological differences between *A. chroococcum* and *A. nigricans* or *A. armeniacus* are already outlined under the headings of the latter two species.

Tchan (1953) described a variant of *A. beijerinckii,* named *A. beijerinckii* subsp. *acido-tolerans,* which could grow and fix dinitrogen at a pH of 4.75. Later, Tchan and New (1984) delineated this characteristic more in detail and distinguished two subgroups. An acid-tolerant subgroup and another subgroup distinguished by its sensitivity to 0.05% phenol or 40 μg/ml diamond fuchsin, its inability to utilize sorbitol or aconitate, and its failure to produce diffusible homopolysaccharides. V. Jensen and Petersen (1954) have also described another form of *A. beijerinckii, A. beijerinckii* subsp. *achromogenes,* in which under the cultural conditions applied, no pigment ever was produced. The latter strains were isolated from Danish calcareous forest soils in a survey including all types of Danish soils (see later).

Jensen and Petersen (1954) also showed that acid tolerance is a rather common characteristic of *A. beijerinckii,* since all strains isolated could grow and fix dinitrogen to a pH of 5.1. The nitrogen-fixation data published by Jensen and Petersen (1955) showed, however, that considerably more atmospheric nitrogen was fixed under alkaline than under acidic conditions.

For selective enrichment of *A. beijerinckii* and elimination of *A. chroococcum,* a selective nitrogen-free medium of the same composition as used for *A. chroococcum,* but with $CaCl_2$ (instead of $CaCO_3$) and with a slightly acid pH (pH 4.9–5.5), can be employed. So far, no experience has been gained with such a medium since all *A. beijerinckii* strains so far known are casual isolates coming from *A. chroococcum* plates. It might be surmised that *A. beijerinckii* would favor somewhat acidic soils. In this respect it is remarkable that, in the above-mentioned survey of Danish forest soils by V. Jensen and Petersen (1954), *A. beijerinckii* was found predominantly in soil samples of two localities with beech *(Fagus sylvatica)* forest on calcareous soil with pH values of 7.0–8.0 and 7.8–8.0, respectively. In these and nearly all other forest soils tested, *A. chroococcum* was absent or nearly absent. These observations indicate that some calcareous forest soils are a favorable and probably selective habitat for *A. beijerinckii* and that the occurrence of *A. chroococcum* is confined to the more alkaline agricultural soils.

Azotobacter vinelandii

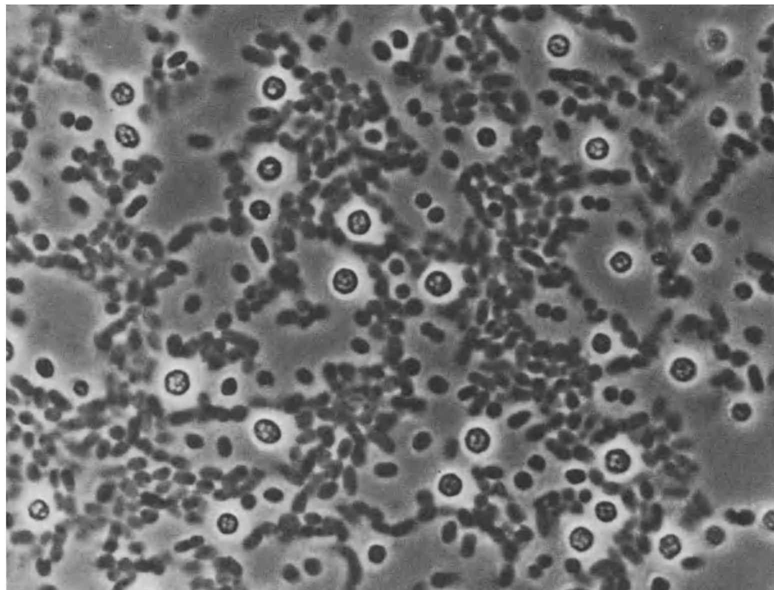
Cells are rounded-ended rods, occurring singly or in pairs. Mean cell dimensions are 3.0–4.5 μm long × 1.5–2.4 μm wide (Fig. 5). Cells are motile with numerous peritrichous flagella; very rarely, some are nonmotile. Colonies are nonpigmented. They excrete a yellow-green, fluorescent, water-soluble pigment into medium.

Fewer strains of *Azotobacter vinelandii* have been isolated in comparison with strains of *A. chroococcum* and *A. beijerinckii.* Most of the strains were casual isolates obtained from soil, such as the original strain of Lipman (1903a) from New Jersey (USA) soil (pH unknown). Wilson's strain O(P), used for many physiological and biochemical studies (e.g., Wilson and Knight, 1947; Shutter and Wilson, 1955), is probably a subculture of this strain. Bortels (1930) isolated another strain from German soil (originally described as *Azotobacter agile*), and Winogradsky (1932) obtained one strain from soil in France. Later, Winogradsky (1938) also underlined the relative rarity of this species.

The present author has obtained a number of strains—often in association with *A. chroococcum*—from Dutch soil, but also from freshwater samples using the nutrient solution method for *A. chroococcum* (preferentially with ethanol as carbon source) for enrichment (J. H. Becking, unpublished observations). *A. vinelandii* was obtained mostly from rather alkaline Dutch and European soils, such as calcareous soils and soil derived from marine sediments, sea sludge, or sea muds that had been pumped up for leveling land. The latter soils, usually also rather rich in sodium chloride, showed pH values of 8.0–9.5.

The water samples from which this organism was obtained were pond, lake, or marsh water of alkaline reaction (pH 7.5–8.0). This species was also numerous in some tropical soils, such as alkaline sea muds and mainly calcareous soils of Indonesia and certain very alkaline soils of Bolivia and other localities in South America (Becking, 1961; J. H. Becking, unpublished observations). Clearly, alkaline conditions are favorable for the occurrence of *A. vinelandii* and probably selective for its distribution. Further, this species may be halophilic to some degree, or at least resistant to salinity, in view of isolation from alkaline sea muds. The presumed halophilic properties need, however, experimental confirmation.

Derx (1951b) designed a method for selective isolation of this species from soil and water sources. The underlying principles of this method were the addition to the enrichment medium of sodium benzoate (1.0%) as an inhibitor in order to suppress the development of



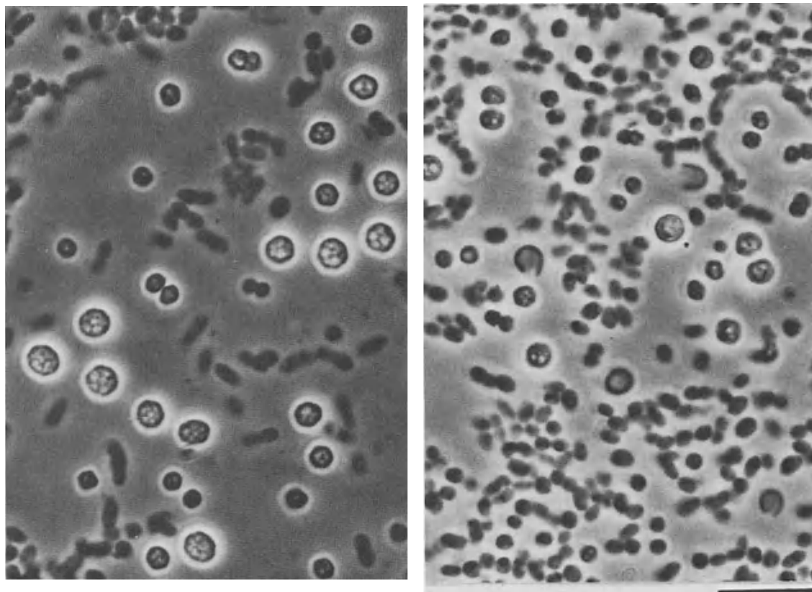


Fig. 5. *Azotobacter vinelandii* cells. Three different strains growing on the same medium (nitrogen-free, mineral glucose agar) showing some variation in the cell size of the strains and in the number of lipoid-filled cells, cysts, and germinating cysts. Living preparation, phase contrast micrographs. Bar = 10 μm.

A. chroococcum, and the use of a special carbon source, such as mannitol or ethanol, which is very readily assimilated by *A. vinelandii.* Derx's method was a further extension of earlier work of Reuszer (1939), who observed that by applying benzoate, benzoic acid, or another phenolic compound to soil, the normal population of *Azotobacter chroococcum* and *A. beijerinckii* was replaced completely by a green-pigment-producing form of *Azotobacter,* which had not been found before in the soil.

Derx's Medium for Selective Enrichment of *Azotobacter vinelandii* (Derx, 1951b)

Distilled water	100 ml
Mannitol	0.5 g
or ethanol	1.0 ml
K_2HPO_4	0.5 g
Sodium benzoate	1.0 g
Adjust to pH 7.5–8.0.	

For the isolation of this species from soil, ethanol is preferentially used as carbon source; for its isolation from water samples, the use of mannitol as carbon source is recommended since *Azomonas agilis* (see "Representatives of the Genus *Azomonas*") is usually unable to assimilate this compound. According to the present author, the rather alkaline reaction induced by the addition of sodium benzoate may also

be responsible for the selective properties of this medium for the enrichment of *A. vinelandii.*

Numerous strains of *A. vinelandii* were obtained by the present author from Dutch water habitats, such as the Rhine River, and pond and lake water (usually of pH 7.0–7.5) by using Derx's medium with mannitol as carbon source and the supplement of sodium benzoate. In all cases, the enrichment medium was adjusted to pH 8.0–9.0. Use was made of 300-ml Erlenmeyer flasks with 50 ml of medium or 100-ml Erlenmeyer flasks with 20 ml of medium. For the water samples, the sample itself, instead of distilled water, was used as liquid to which the carbon source and salts were added.

V. Jensen (1961) mentioned that L-rhamnose (1.0%) could be used as a carbon source for the selective enrichment of *A. vinelandii,* since only a very small fraction of the strains of the other *Azotobacter* and *Azomonas* species tested could utilize this compound. When grown in pure culture on L-rhamnose, *A. vinelandii* develops profusely within 3–5 days at 25°C, while the other *Azotobacter* species that can utilize this compound only produce some development after 1–2 weeks. Therefore, in spite of the presence of other *Azotobacter* species, *A. vinelandii* soon becomes dominant in such an enrichment medium.

Using the L-rhamnose enrichment medium, V. Jensen (1961) observed *A. vinelandii* to be sparsely distributed in normal soil. It was only present in a very few garden soils and seemed to be restricted to the most fertile soils. Although Johnstone (1974) reported that *A. chroococcum* and *A. beijerinckii* do not utilize L-rhamnose as sole source of carbon, according to the present author, this is not always true. Utilization of L-rhamnose is not a common feature of strains of these species, when these are obtained as random isolates with the more common sugars, but some strains utilizing this carbon source can be secured in enrichment media by using L-rhamnose as sole source of carbon. Also, Thompson and Skerman (1979) observed that one of the 19 *A. chroococcum* strains tested could utilize L-rhamnose, while Claus and Hempel (1970) isolated both *A. chroococcum* and *A. beijerinckii* from soil and water samples with L-rhamnose as sole substrate.

Claus and Hempel (1970) observed that resorcin, ethylene glycol, or glutarate, all in 0.1 or 0.2% (wt/vol) concentration, are very selective carbon sources for *A. vinelandii,* and that a number of strains could be isolated from soil by using these compounds as sole source of carbon in enrichment media. The above-mentioned carbon compounds apparently cannot be utilized by the more common *Azotobacter* species.

A. vinelandii strains have numerous peritrichous flagella, in general, but Derx (1951b) isolated nonflagellated strains of *A. vinelandii* for which he proposed the name *Azotobacter non-vinelandii,* which name is, however, considered not to be validly published under Rule 23 of the Bacteriological Code (Lapage et al., 1975). Another characteristic of these strains, which distinguishes them from typically flagellated strains of *A. vinelandii,* is the ability to produce a black pigment in the presence of benzoate (Derx, 1951b).

In multiple tests for numerical analysis, Thompson and Skerman (1979) confirmed that all *A. vinelandii* strains tested could readily utilize rhamnose as sole source of carbon, in contrast to most strains of other species. Moreover, they observed that *A. vinelandii* could utilize caproate, caprylate, and *meso*-inositol, compounds which generally are not utilized by the other *Azotobacter* species. Furthermore, 0.1% phenol can be used in enrichment cultures to inhibit the growth of other *Azotobacter* species, and incubation at 37°C particularly favors the development of this species. According to these authors, the nonmotile *Azotobacter non-vinelandii* strains may be regarded as a special subgroup that differs from typical *A. vinelandii* strains by the inability to utilize raffinose and by the utilization of pimelate, suberate, and sebacate as sole sources of carbon. In addition, in contrast to typical *A. vinelandii,* these strains were resistant to brilliant green at a concentration of 10 μg/ml.

The presence of *A. vinelandii* in enrichment media can be detected by a color change of the medium, which turns yellow, green, or violet. On nitrogen-free, mineral agar plates, a water-soluble yellow, green, or violet fluorescent pigment is excreted into the medium, but they do not produce any nondiffusible pigment. Pigment production into the substrate is stimulated by low-iron concentration or iron deficiency of the medium (Becking, 1962). As shown by Johnstone (1955, 1957b) and Johnstone and Fishbein (1956), the fluorescence of the pigment under ultraviolet light shifts with pH changes, and different fluorescence curves are obtained with the diffusible pigments of *A. vinelandii* and *Azomonas agilis.* Thus, fluorescence measurements also have diagnostic value in distinguishing between both species.

Azotobacter paspali

Cells are long, bluntly ended rods. Mean cell dimensions are 7.0–10.9 μm long × 1.3–1.7 μm

wide; sometimes shorter rods of 3.2–4.2 μm long × 1.6–1.9 μm wide are seen. Cells in young cultures often form long filaments. A yellow-green, fluorescent or red-violet, water-soluble pigment is excreted into the medium.

This species, described by Döbereiner (1966), was originally isolated on Winogradsky's silica-gel plates impregnated with a mineral salt solution (see sieved-soil plate method) with a pH of 6.5 and calcium citrate as sole source of carbon. Later (Döbereiner, 1970), a N-free, mineral sucrose agar (a modification of Lipman's [1903b, 1905] medium) was recommended, because it gave satisfactory results and it was much easier to prepare.

Nitrogen-free, Mineral Sucrose Agar for Isolation of *Azotobacter paspali* (Döbereiner, 1970)

Distilled water	1 liter
K_2HPO_4	0.05 g
KH_2PO_4	0.15 g
$MgSO_4 \cdot 7H_2O$	0.20 g
$CaCl_2$	0.02 g
$CaCO_3$	1.0 g
$Na_2MoO_4 \cdot 2H_2O$	0.002 g
$FeCl_3$ (10%, aqueous solution)	1 drop
Bromthymol blue (0.5%, ethanol solution)	10 ml
Sucrose	20 g
Agar	20 g

Adjust the pH to ca. 7.0.

Plates with this medium were inoculated with root-surface (socalled rhizoplan) soil of a grass species, *Paspalum notatum.* The soil (about 20–50 mg per plate) was usually scattered directly from the roots on the plates. However, the soil also can first be passed through a sieve (0.5-mm mesh), and then 50 mg can be weighed out and scattered over the plates for quantitative tests. The plates were incubated at 35°C.

Differentiation of *A. paspali* from the other *Azotobacter* species on silica-gel plates with calcium citrate as carbon source is relatively easy. Colonies appear 4–5 days after inoculation and these produce an intense yellow pigment, which diffuses into the silica gel below the colony. The colonies are relatively small and raised and readily solubilize the opaque white calcium citrate layer at the top of the silica gel, giving the appearance of many little holes. Later, the colonies spread rapidly and become flat.

On the above-mentioned agar medium, *A. paspali* colonies appear 2–3 days after inoculation and incubation at 37°C. The colonies are dense, raised, and yellow in color due to acid production, because bromthymol blue is added as an indicator to the medium.

The acid-producing ability of this species is not found in any other *Azotobacter* species. Moreover, the ability of *A. paspali* to use organic compounds (only 17 out of 159 tested by Thompson and Skerman, 1979) is much more limited than that of other *Azotobacter* species. *A. paspali* cells are usually 7–12 μm long and 1.3–1.7 μm wide, but occasionally exceptionally long rods (up to 60 μm × about 2.0 μm) are seen. These are typical for this species and are a significant morphological feature, which is not seen in any other *Azotobacter* species. A further characteristic of this species is that cells of the microcolonies are often dimorphic, some colonies possess cells 7–11 μm long, whereas other colonies have cells 3–4 μm in length (Thompson and Skerman, 1979). Cells of older colonies on nitrogen-free agar may reach a length of 60 μm (see above).

From numerical analysis, Thompson and Skerman (1979), concluded that *A. paspali* is not closely related to other *Azotobacter* species. Moreover, they observed an antagonism toward Gram-positive bacteria in this species. In addition, their very restricted habitat—they occur solely in the plant rhizosphere—is unique among all the other *Azotobacter* species. In view of these differences, these authors proposed a new genus for this species, *Azorhizophilus* (Thompson and Skerman 1981). This opinion is, however, opposed by De Smedt et al. (1980), who found that the rRNA cistron of *A. paspali* is almost identical with those of *A. chroococcum, A. beijerinckii, A. vinelandii,* and *A. nigricans.* Moreover, Tchan et al. (1983), using rocket-line immunoelectrophoresis, showed that *A. paspali* is not immunologically separable from other members of this genus. In view of this, it is not desirable to place *A. paspali* in a separate genus.

Strains of *A. paspali* excrete a diffusible, yellow green, in UV-light fluorescent pigment into the substrate, particularly on iron-deficient media.

The association between *Azotobacter paspali* and the grass, *Paspalum notatum,* is highly species-specific; this association is found only in a few other *Paspalum* species (i.e., *P. plicatulum, P. dilatatum,* and *P. virgatum*) of 16 other *Paspalum* species tested for this bacterium (Döbereiner, 1970). It was never found in other Gramineae examined and in some Leguminosae and other dicots tested.

The original isolate came from a broad-leaved and hairy *Paspalum notatum* variety "Batatais" (common Bahia grass) in Brazil, but it was later also found in the same and other *Paspalum* species and varieties in Florida (USA) and Puerto Rico, but not in rhizosphere soil of *Paspalum* from Argentina, Paraguay, and South Africa (Döbereiner, 1970). However, according to the present author, no definite conclusion from its absence in the latter three regions can be made,

because only a very restricted number of rhizosphere soil samples (one to five) of these localities have actually been examined.

Representatives of the Genus *Azomonas*

Members of the genus *Azomonas* are primarily aquatic. *Azomonas agilis* and *A. insignis* are obligately aquatic organisms, since so far they have only been isolated from freshwater habitats. The only exception is *A. macrocytogenes*, which has been isolated from soil. The latter species was first isolated and described by H. L. Jensen (1955). For a long time, it was only known from a single strain and two variants derived from it, but according to Thompson and Skerman (1979) a total of 7 strains is now available. However, probably all, except one strain, are derivatives or subcultures of Jensen's original strain!

Azomonas species differ from those of the genus *Azotobacter* by a number of morphological and physiological characteristics. They all possess relatively large cells, which frequently occur singly and which have a special type of flagellation that gives the cells a high motility. Microcysts are never formed. Colonies on agar are generally opaque, glistening, smooth, and without insoluble pigment. On iron-deficient agar media, a yellow-green diffusible pigment is formed; and in some other media, often more red-violet or purple diffusible pigments are produced. Usually pigment production is very pronounced in liquid media and less pronounced on solid media. In *A. agilis* and *A. macrocytogenes*, the pigments are fluorescent in UV light; *A. insignis* has a nonfluorescent pigment.

Identification of *Azomonas* Species

Apart from cell shape and dimensions, which will be covered later in the descriptions of the separate species, *A. macrocytogenes* can readily be distinguished by the formation of enlarged filamentous cells in media with ethanol, a phenomenon absent in *A. agilis* and *A. insignis*. Moreover, flagellation is peritrichous in *A. agilis*, lophotrichous in *A. insignis*, and usually monotrichous (sometimes, however, two flagella at one pole) in *A. macrocytogenes*. With regard to carbon sources as sole source of carbon. It has been observed that mannitol is utilized by *A. macrocytogenes* and not by *A. agilis* and *A. insignis*, and malonate gives just the reverse outcome, i.e., it is utilized by *A. agilis* and *A. insignis*, but not by *A. macrocytogenes*. Finally, maltose is readily utilized by *A. macrocytogenes*, but not by *A. insignis* and only by a minority of the *A. agilis* strains. All species produce water-diffusible pigments, but in contrast to the pigments of *A. agilis* and *A. macrocytogenes*, the pigment of *A. insignis* does not produce fluorescence in UV light.

Azomonas agilis

This species has large, ovoid, ellipsoidal or coccoid cells, often giving it a protist-like appearance (Fig. 6). Cells are seldom found in pairs. Cells are usually 2.5–6.4 μm long and 2.0–2.8 μm wide; sometimes giant cells up to 10.0–13.5 μm long have been observed (Fig. 6). The cells are motile by means of peritrichous flagella. No microcysts are formed. A nondiffusible pigment is not produced, but a diffusible yellow-green or red-violet pigment, particularly on iron-deficient media. In UV light, the pigment gives a bluish-white fluorescence.

This species was first isolated and described by Beijerinck (1901a, 1901b), who obtained it from Dutch (Delft) canal water. Beijerinck used the following enrichment medium:

Enrichment Medium for *Azomonas agilis* (Beijerinck, 1901a, 1901b)

Canal water	100 ml
Mannitol	2.0 g
K_2HPO_4	0.02 g

The incubation temperature is 25–30°C.

Later, Kluyver and van Reenen (1933) and Kluyver and van den Bout (1936) obtained other strains with the same method. A strain isolated by the latter authors from Delft canal water (ATCC 7494) is now the neotype, because Beijerinck's original strain has been lost. It is remarkable that *A. agilis* in pure culture cannot utilize mannitol, so this carbon source must first be degraded by other microbes before it can become available to *A. agilis*. It is also possible that immediately after isolation, the strains can actually utilize mannitol, but that this ability is later lost during purification and therefore absent in pure cultures. Kluyver and van Reenen (1933) observed that, when cultures were streaked immediately from the enrichment medium on plates containing tap water, 2% mannitol, 0.02% K_2HPO_4, and 1.5% agar, and incubated at 20°C, *A. agilis* develops in 2–3 days to very small colonies about 1 mm in diameter. Growth on agar plates that contain glucose (2%) instead of mannitol as source of carbon was luxurious and with much slime production, but isolation from these plates was not recom-

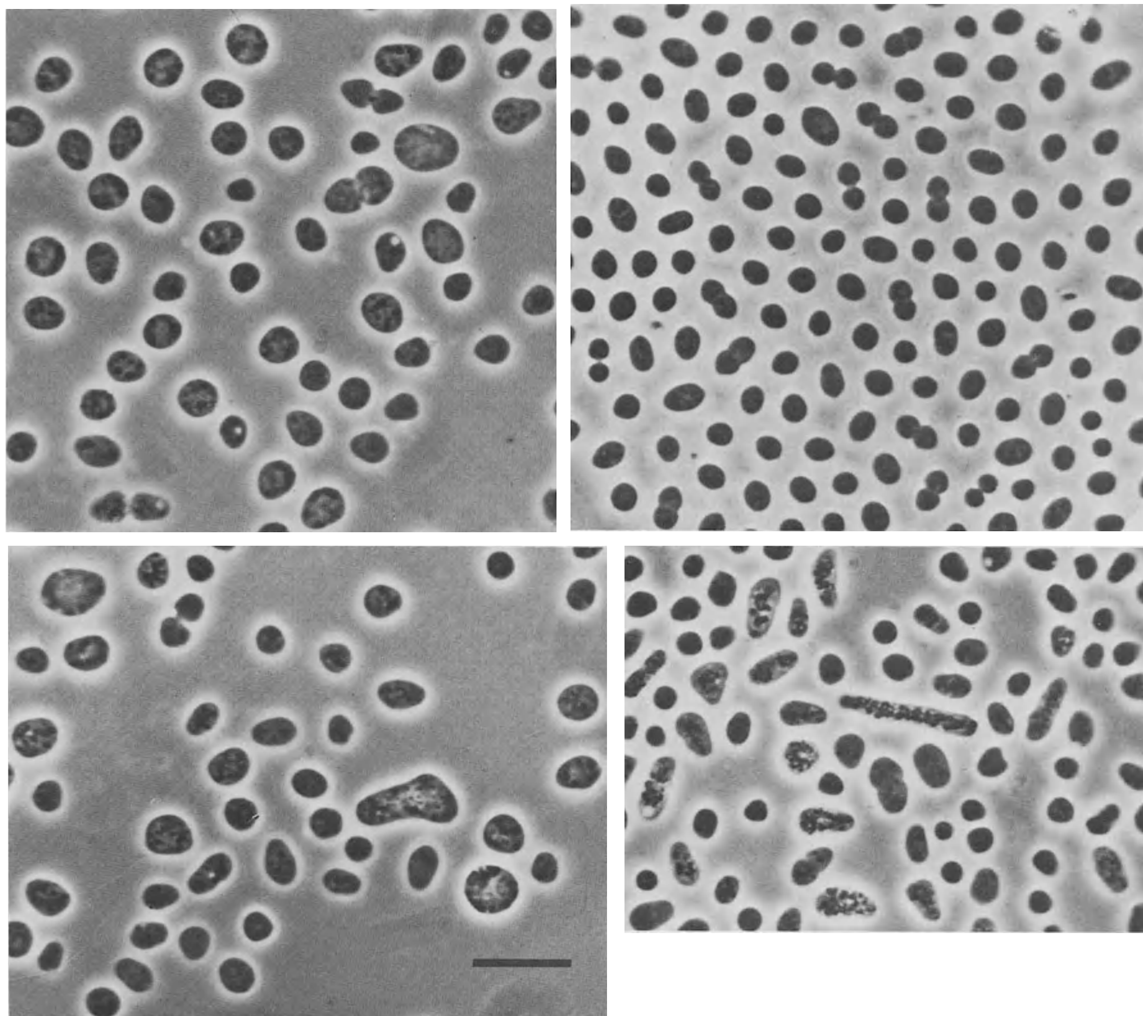

Fig. 6. *Azomonas agilis.* Cells of two strains demonstrating the large, protist-like appearance of the cells and the sporadic occurrence of aberrantly shaped, pleomorphic cells. Living preparations, phase contrast micrographs. Bar = 10 μm.

mended because many accompanying contaminants may develop in the capsular slime produced.

Derx (1951b) designed specific methods for the enrichment of *Azomonas agilis* by eliminating, so far as possible, the development of the more common *Azotobacter* species and of other *Azomonas* species. The underlying principle of Derx's method is that *Azomonas agilis,* in contrast to the more common *Azotobacter* species, is remarkably tolerant to the presence of 1% sodium benzoate in the medium, although it cannot utilize this compound as a carbon source. Derx also added a carbon compound readily utilizable by *A. agilis.* Mannitol cannot be used as the carbon source because it is normally not utilized by *A. agilis,* but it is assimilated by *Azotobacter vinelandii.* The latter organism is frequently also present in water samples and, moreover, is resistant to 1% sodium benzoate. Therefore, Derx recommended the use of ethanol as sole source of carbon for the isolation of *Azomonas agilis.* The following enrichment medium gave good results.

Selective Medium for *Azomonas agilis* (Derx, 1951b)

Water sample (canal, river, or lake water)	100 ml
Ethanol	1 ml
K_2HPO_4	0.05 g
Sodium benzoate	1.0 g

The enrichment medium is placed in relatively thin layers in Erlenmeyer flasks to allow good oxygen access, e.g., 10–15 ml of medium in 100-ml flasks, or 50 ml medium in 250-ml flasks.

Following Derx's method, the author was able to isolate a large number of *Azomonas agilis*

strains from various water sources. The organism proved to be particularly common in strawboard factory wastewater, as already observed by K. T. Wieringa (personal communication; see also Smit, 1954) and by Johnstone (1957a), and in some heavily polluted waters. In clear and clean water of rivers, lakes, and turbulent or rapidly moving, oxygen-rich, mountain brooks and rivulets, it was rarely present and frequently totally absent. In this habitat, it is entirely replaced by *Azomonas insignis.*

The tolerance of *A. agilis* strains to salt concentration up to 1.0% suggest that they are able to live in contaminated waters where concentrations of organic matter and mineral salts can be relatively high. Also its resistance to iodoacetate (1 μM) points in this direction, and this compound could be used for the selective enrichment and isolation of this species (Thompson and Skerman, 1979).

In agreement with this general pattern of being able to survive in polluted environment, nitrate is never or rarely reduced to nitrite by strains of *A. agilis* in contrast to strains of *A. insignis.* Growth experiments using *A. agilis* strains on nitrate-containing media incubated in air revealed that nitrate is an inert, nonutilizable compound for them, and thus they are able to fix molecular nitrogen in the presence of nitrate in the medium (Becking, 1962). In 19 out of 20 *A. agilis* strains tested, vanadium was unable to replace molydenum in nitrogen fixation (Becking, 1962), indicating that they predominantly have only a molybdenum-activated nitrogenase system.

Azomonas insignis

Colonies on nitrogen-free media are usually small, smooth, translucent, and low convex. They show a low proportion of extracellular polysaccharides. Cells are round or ellipsoidal and are usually 2.5–3.9 μm in length and 1.7–2.6 μm in width. On average, they measure 3.1 × 1.9 μm (Derx, 1951a). The cells have lophotrichous flagella. No microcysts are formed. On iron-deficient media, a yellow-green, red-purple, or violet pigment may be produced. The pigments are, however, not UV fluorescent.

As will be shown in the enrichment methods for this species, ethanol and salts of organic acids are preferential carbon sources for the isolation of *A. insignis.* On the whole, the utilization of organic carbon compounds as sole source of carbon for growth and energy is very restricted in this species (see later). The type strain of Derx (1951a), which is no longer extant, could not utilize glucose as sole source of carbon. It was probably lost by subcultivation on glucose-containing agar slants. New isolates (see V. Jensen, 1955) could utilize glucose, but with regard to carbohydrate utilization, in all strains tested, it is limited to only two, D-glucose and D-fructose (Thompson and Skerman, 1979).

This species was first isolated and described by Derx (1951a). It was obtained from water of clear, rapidly flowing mountain streams and small rivulets of the Cibodas Nature Reserve, Western Java, Indonesia (ca. 1,400 m altitude). These rather turbulent streams have limpid, oxygen-rich water, which contains much soluble calcium. *Azomonas agilis* could never be isolated from these sources (see above).

Derx (1951a) recommended the following medium for the specific enrichment of *A. insignis* from these water sources:

Selective Medium for *Azomonas insignis* (Derx, 1951a)

Water sample	100 ml
Calcium formate	0.5 g
Ethanol	1.00 ml

The enrichment medium is placed in rather thin layers in Erlenmeyer flasks, i.e., 20–25 ml in 100-ml flasks or 50 ml in 250-ml flasks. Incubation is at 25–30°C. Calcium formate is added to the medium to inhibit the development of various other microbes, including *Azotobacter* species and other *Azomonas* species. *A. insignis* does not utilize calcium formate but is rather resistant to it. Ethanol is added as sole source of carbon because it is a preferential carbon source for *A. insignis.* According to Derx (1951a), his strains of *A. insignis* could not utilize glucose or mannitol. A nonvolatile carbon source, which also gives good growth and can be used for maintenance in pure culture on agar slants is calcium malate or calcium succinate. Therefore, the use of nitrogen-free, mineral agar plates with calcium malate (0.5%) or calcium succinate (0.5%) as sole carbon source can also be recommended for isolation of *A. insignis* from enrichment cultures.

Pure cultures can also be grown in liquid medium: tap water (for trace element supply), to which is added K_2HPO_4 (0.05%) and ethanol (0.5–1.0%, or about 0.5–1.0 ml per 100 ml medium). Growth is obtained in 24 h at 25–30°C. After several days, the medium turns milky white, later blue-gray, and after about a week sometimes to violet (see above).

V. Jensen (1955) isolated six strains of *A. insignis* from surface water of fast-flowing brooklets and streams with very limpid fresh water in Denmark, but occasionally also from stagnant and somewhat polluted water (e.g., his strains 7 and 9). None of his isolates could utilize mannitol but, in contrast to Derx's strains, all the Danish strains could utilize glucose as sole source of carbon. Two of Jensen's strains were also able to grow in a medium that contained sodium benzoate (1.0%).

Enrichment Medium for *Azomonas insignis* (V. Jensen, 1955)

Water sample	25 ml
K_2HPO_4	0.02%
Ethanol	1.0% (or about 0.25 ml)
or	
Water sample	25 ml
K_2HPO_4	0.02%
Ethanol	1.0% (or about 0.25 ml)
Sodium benzoate	1.0%

The water samples are placed in 100-ml Erlenmeyer flasks.

Thompson (see Thompson and Skerman, 1979) isolated *A. insignis* from a rusty-brown, probably iron-oxide-rich water of a slow-flowing Australian creek with a pH of 6.7, using an enrichment medium recommended by V. Jensen (1955), by adding to the water sample 0.02% K_2HPO_4 and 1% ethanol. The strain isolated (WR-51) was very similar to Derx's type strain as this strain also could not utilize glucose and excretes a violet diffusible pigment into the medium. In this respect it can be regarded as a neotype of Derx's original strain.

The acid tolerance of *Azomonas insignis* was also tested by V. Jensen (1955) in the strains isolated by him and compared to that of the other *Azomonas* and *Azotobacter* species. Most *A. insignis* strains could not grow in a medium with a pH lower than 5.7–5.9, although a few could produce faint growth at pH 5.5. Of the two *Azomonas agilis* strains tested, one could produce faint growth at pH 5.3, and one *Azotobacter beijerinckii* strain could even grow normally at pH 5.2. The one *Azotobacter chroococcum* strain tested in the survey could not grow below pH 6.1.

Other experiments also showed that *Azomonas insignis* strains have, in general, a preference for slightly alkaline conditions for optimal growth and nitrogen fixation. Of nine strains tested, three could grow at pH 6.0, but all strains grew at pH 10.0 (Thompson and Skerman, 1979). With respect to temperature requirements for growth, *A. insignis* strains seems to be able to grow at relatively lower temperature in comparison to other Azotobacteraceae. Nine of the 10 *A. insignis* strains tested by Thompson and Skerman (1979) could grow at 9°C, while the maximum growth temperature was 32°C.

A considerable reduction of the capacity to utilize carbon compounds by *A. insignis* compared to other *Azomonas* and *Azotobacter* species was first noted by V. Jensen (1955). Of the 26 compounds studied, *Azotobacter chroococcum* could utilize 16, *Azotobacter beijerinckii* on the average about 14, *Azomonas agilis* 11, and *Azomonas insignis* only 8. In a general survey, Thompson and Skerman (1979) tested 161 organic carbon compounds as sole source of carbon for *A. insignis.* Of these, 21 compounds could be utilized by nearly all *A. insignis* strains, 9 compounds could be utilized by a few strains, and no strain could utilize any of the 131 other organic carbon compounds tested.

Azomonas macrocytogenes

In contrast to the two previous *Azomonas* species, *A. macrocytogenes* is isolated from soil. The species is primarily known from one isolate, called strain O (original), and two variants derived later, strains M (mutant) and I (intermediate). Although Thompson and Skerman (1979) described seven strains, most of them are subcultures or derivatives of the original strains, and only one, a strain designated as the cotype of *Azotobacter agilis* subsp. *jakutiae* Krasil'nikov (1949), had another origin.

The original strain was isolated by H. L. Jensen (1955) in an attempt to isolate *Beijerinckia* from Danish soil. The isolate appeared on a nitrogen-free, mineral sucrose agar of about pH 5.5, seeded with garden soil (a fertile loam, pH 7.5) of the State Laboratory of Plant Culture, Lyngby, Denmark.

As could be anticipated from its isolation procedure, the type strain (type O and its variants) can produced good growth and nitrogen fixation in a nitrogen-free medium in the pH range of 4.6–6.9; one variant grew also at pH 4.3. This species is therefore even more acid tolerant than Tchan's (1953) and Jensen and Petersen's (1955) strains of *Azotobacter beijerinckii.*

Apart from morphological properties, such as ellipsoidal or rod-shaped cells, usually 2.5–3.5 μm in length and 1.6–2.1 μm wide, occurring singly or in pairs and occasionally forming short chains, and on media containing ethanol, the formation of very large coccoid, spindle-shaped or filamentous (up to 100 μm) cells, also physiological properties are important. The type strain showed no utilization of starch and rhamnose, but mannitol is utilized. Moreover, *A. macrocytogenes* strains can be differentiated from other *Azomonas* species by the utilization of mannitol (negative in *A. agilis* and *A. insignis*) and maltose (not utilized by *A. insignis* and most strains of *A. agilis*), and by its nonutilization of malonate (utilized by both *A. agilis* and *A. insignis*). In addition, *A. macrocytogenes,* being a soil organism, is more resistent to desiccation than *A. agilis* and *A. insignis,* which generally do not survive on silica gel for more than 2 days (Thompson and Skerman,

1979). However, no microcysts are formed, although microcyst-like structures occasionally are produced. These structures are more like capsules lacking the characteristic exine layer of a microcyst. Moreover, the cells sometimes have the tendency to become Gram-variable, i.e., to change from Gram-negative to Gram-positive.

The cells bear monotrichous flagella, but sometimes there are two flagella at one pole. Colonies do not produce a nondiffusible pigment, but on iron-deficient media, yellow-green or red-violet diffusible pigments are produced, which give a blue-white fluorescence in UV light.

In a numerical analysis and in the constructed dendrogram of relationships, Thompson and Skerman (1979) showed that *Azomonas macrocytogenes* fused at a low hierarchical level with *Azotobacter paspali*. At a higher level, the *Azomonas macrocytogenes–Azotobacter paspali* group fused with the two other *Azomonas* species before fusing with *Azotobacter*. This was a motive for these authors to propose a new genus, *Azomonotrichon* (Thompson and Skerman 1979) for *Azotomonas macrocytogenes*. However, De Smedt et al. (1980) showed that the rRNA cistrons of *Azomonas insignis* and *A. agilis* differ as much from each other as they do from *Azomonas macrocytogenes* and from *Azotobacter*. Therefore, there is no reason to create a new genus for *Azomonas macrocytogenes*, although more genome comparisons of the various members of the Azotobacteraceae would probably be useful in clarifying its exact taxonomic position. It is noteworthy that Rubenchik (1959) transferred *Azomonas macrocytogenes* to the genus *Beijerinckia* as *B. macrocytogenes* because it fixed nitrogen at pH values of 4.5–5.0 and produced acid from certain carbohydrates. In support of this, Thompson and Skerman (1979) noted that *Azomonas macrocytogenes* produces colony-retained homopolysaccharides from sucrose and saccharose, and this is only found in this group and in most strains of the group containing the *Beijerinckia* species.

Preservation of Cultures

For routine maintenance, *Azotobacter* and *Azomonas* cultures should be subcultured at monthly or bimonthly intervals on nitrogen-free mineral agar containing glucose or sucrose (1 or 2%). For those strains which cannot assimilate glucose (e.g., *Azomonas insignis*), another appropriate carbon source (e.g., an organic acid such as calcium malate or calcium succinate) can be chosen.

Poor results were obtained by lyophilization in skim milk or dextran-sodium glutaminate solution on filter paper in small glass vials under vacuum with storage of the closed vials at room temperature in the dark. Antheunisse (1972, 1973) compared this method with storage of cultures on the usual agar media in normal culture tubes, plugged with sterile rubber seals, and stored in the dark at room temperature. Tests for viability of the cultures were made after periods of 1 to 10 years. The outcome showed that lyophilization of *Azotobacter* and *Azomonas* gave very poor results. Only 32% of the cultures were viable after 6 years. The rate of survival of *Azotobacter vinelandii* was relatively high, but that of *A. chroococcum* was low and that of *Azomonas agilis* was nil. In contrast, the 65 *Azotobacter* and *Azomonas* strains kept on sealed agar slants for 3–10 years gave an average viability of 60%. In this case, both *Azotobacter vinelandii* and *Azomonas agilis* gave good survival rates (86 and 78%, respectively).

In the author's laboratory, *Azotobacter* and *Azomonas* cultures are usually kept in normal culture tubes (with cotton plugs) under a seal of sterile liquid paraffin or mineral oil at room temperature (sometimes also at 4°C); such cultures generally survive for at least 3–5 years (J. H. Becking, unpublished observations). Care should be taken that the oil completely covers the agar slant, because if the agar medium remains in contact with air, the agar will dry out and the culture may die.

Physiological and Biochemical Aspects

Azotobacteraceae are aerobic, heterotrophic, nitrogen-fixing organisms and therefore possess all oxidative enzymes for the degradation of the numerous organic carbon compounds utilizable by the various species as sole source of carbon and energy. Many of these enzymes are constitutive, but some are induced by the particular carbon substrate involved. Many publications have appeared on these enzymes, including some on the kinetics of their induction, beginning with the Wisconsin school (Stone and Wilson, 1952a, 1952b; Repaske and Wilson, 1953; Repaske, 1954; Williams and Wilson, 1954; Wilson and Wilson, 1955; Shutter and Wilson, 1955; Alexander and Wilson, 1956; Marr and Marcus, 1962), but they will not be discussed here in view of space limitations. Only some characteristic enzymes associated with nitrogen-fixation in Azotobacteraceae and the relation between the oxidative pathway and nitrogen fixation will be discussed.

The oxidative pathway in Azotobacteraceae as source of energy (ATP) follows the TCA cycle. It has been studied in many investigations (see above) using whole-cell suspensions or cell-free extracts to test the various intermediates of the TCA cycle, such as acetate, malate, succinate, α-ketoglutarate, and citrate. Also, the effect of oxygen on nitrogen fixation and the high respiratory activity of Azotobacteraceae have received special attention, since Meyerhof and Burk (1928) and Burk (1930), first oberved it, and it was the subject of many later studies (Tschapek and Giambiagi, 1955; Parker and Scutt, 1958, 1960; Dilworth and Parker, 1961). All the studies found that high oxygen levels, even atmospheric levels of oxygen, inhibited the nitrogen fixation activity in *Azotobacter*. Moreover, the exceptionally high respiratory quotients of *Azotobacter* species obtained by manometric methods were remarkable; Q_{O_2} values of 20,000 μl O_2/h or 4,000–5,000 μl O_2/mg dry wt/h have regularly been measured (Williams and Wilson, 1954; Shutter and Wilson, 1955). Both observations have led to detailed investigations on the role of oxygen in the nitrogenase complex. Experiments revealed that in *Azotobacter* a special mechanism operates which protects the oxygen-sensitive nitrogenase from oxygen damage. The high respiration rate of Azotobacteraceae was explained as a mechanism which scavenges oxygen from the dinitrogen-fixing site of nitrogenase (Dalton and Postgate, 1969a). This process, called the "respiratory protection" of nitrogenase, is coupled with a multitude of cytochromes and redox proteins (Haddock and Jones, 1977), thus maintaining the nitrogenase in an essentially anoxic environment inside cells that nevertheless derive energy from aerobic metabolism.

The significance of respiratory protection has been argued, and alternative mechanisms have been suggested. A prominent argument was that the nitrogenase complex, which consists of two components (see later), was extremely sensitive to oxygen, being rapidly and irreversibly inactivated upon exposure to air, but nitrogenase in cell-free extracts of *Azotobacter* is relatively oxygen stable (Bulen et al., 1964; Kelly, 1969). The Brighton, England nitrogen-fixation school also suggested that if O_2 enters the cell more rapidly than it can be removed by respiration (i.e., by "respiratory protection"), an alternative control mechanism operates for which they proposed the name "conformational state protection," i.e., a protection by some steric arrangement of the components (Dalton and Postgate, 1969a). In the latter mechanism, during O_2 stress, nitrogenase binds to a 2Fe-2S protective protein, also called Fe/S II, to give an O_2-stable complex that is protected from O_2 damage, but that is inert to nitrogenase substrates. When the oxygen stress is low or lowered by excessive respiration, the protected complex dissociates to give active nitrogenase. Such protective proteins have been isolated and characterized for *A. chroococcum* (Robson, 1979) and for *A. vinelandii* (Scherings et al., 1983).

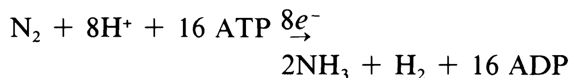
However, some alternative mechanisms have been proposed. Oppenheim et al. (1970a, 1970b) suggested that protection against oxygen was due to a major cytoplasmic membrane component that appears in these organisms when grown in nitrogen-free medium, while Yates (1970) suggested a form of respiratory control by nucleotides (ATP) operating in *Azotobacter*. Also, Kuhla and Oelze (1989) found a dependence of nitrogenase switch-off upon oxygen stress on the nitrogenase activity in *Azotobacter vinelandii*. Their results suggested that the flux of electrons to the nitrogenase complex, rather than cellular oxygen consumption (qO_2), stabilizes nitrogenase activity against O_2 inactivation in aerobically growing *A. vinelandii*.

From the observations mentioned above, it may be concluded that the mechanism of O_2 control and the absence of a serious inhibition of functioning nitrogenase by O_2 is a rather complex process, which may involve several different systems.

Although nitrogenase is the most important enzyme for aerobic nitrogen-fixing bacteria like the Azotobacteraceae, this enzyme is also found in a great number of other microorganisms belonging to quite-different taxonomic groups and affiliations. The main properties of nitrogenase (i.e., of the main species of nitrogenase, see later) can be summarized as follows: it consists of two proteins; it is sensitive to oxygen or it can be destroyed by oxygen; it contains the transition metals Fe and Mo; it needs Mg^{2+} ions to be active; it converts ATP to ADP when functioning; it is inhibited by ADP; it reduces nitrogen and several other small triply bonded molecules (such as C_2H_2 and CN); and it reduces H^+ ions to gaseous H_2 even when N_2 is present. The two proteins forming this nitrogenase are a large one (MW of about 220,000) and a smaller one (MW of about 60,000). Both proteins contain Fe (amounts variable), and this metal is essentially accompanied by S atoms. The large protein contains in addition two atoms of Mo and is therefore usually called the molybdoprotein. The proteins of the nitrogenase complex are often also called component I and component II. Furthermore, it is interesting that the two proteins are very similar in different nitrogen-fixing organisms. Their similarity is so great that it is possible to inter-

change these proteins with the proteins of other nitrogen-fixing microbes, regardless of their origin (e.g., *Klebsiella pneumoniae, Bacillus polymyxa,* and *Clostridium pasteurianum*) yielding fully active preparations (Bulen et al., 1966; Detroy et al., 1968; Dahlen et al., 1969).

Nitrogenase reduces N_2 to NH_3 and, for this function, it needs adenosine triphosphate (ATP). In vitro, 16 ATP molecules are consumed to convert one N_2 to two NH_3 molecules, and eight electrons are also involved:



$$N_2 + 8H^+ + 16\ ATP \xrightarrow{8e^-} 2NH_3 + H_2 + 16\ ADP$$

Actually, the reduction of N_2 to two NH_3 requires six electrons, equivalent to 12 ATP molecules. It has been shown that two electrons or four ATPs are used for the formation of one molecule of H_2. In growth experiments with *Azotobacter chroococcum* in continuous culture, Dalton and Postgate (1969b) demonstrated that nitrogen fixation entrained a maintenance coefficient of 1.06 g substrate/g organism/h compared with about 0.40 for ammonia assimilation. Assuming that most of this maintenance was directed to respiratory protection of nitrogenase, an extrapolated maximum requirement of 4 moles ATP/mole N_2 fixed was observed.

In other growth experiments, Dalton and Postgate (1969a) observed that, at 0.03 atm O_2, nitrogen-limited, continuous cultures of *A. chroococcum* fixed about twice as much N_2/g carbon source utilized than at atmospheric pressure (i.e., 0.20 atm O_2), confirming earlier growth experiments by other authors (Becking, 1971). The specific effects of different O_2 levels on nitrogen-fixation efficiency of *Azotobacter* have already been discussed (see "General Identification").

As noted before, the nitrogenase system in *Azotobacter* consists of two nonheme iron proteins, i.e., a MoFe protein called Component I, which has been crystallized (Burns et al., 1970; Shah and Brill, 1973) and was shown to be a tetramer of 245,000 daltons (Swisher et al., 1977; Shah and Brill, 1977) containing two Mo atoms per molecule, and a protein called Component II, which is a Fe protein, a dimer of two identical subunits of 31,200 daltons, containing 289 amino acids (Hausinger and Howard, 1980). Thus, apart from Fe, the uptake of Mo by the organism is essential and a prerequisite for active functioning of the nitrogenase complex. Particularly, Mo defiency or Mo depletion of the medium of Azotobacteraceae cultures limit their growth under nitrogen-fixing conditions. In growth experiments, it was shown by Becking (1962) that the Mo requirements of various *Azotobacter* and *Azomonas* species differ. Half-maximal nitrogen fixation was obtained in *A. chroococcum* at about 0.05 ppm Mo and in *A. vinelandii* at 0.0004 ppm Mo, whereas the same half-maximal growth value is reached in *Azomonas agilis* at 0.0002 ppm Mo. In these growth experiments, Becking (1962) further observed that in the majority of *Azotobacter chroococcum* and *A. vinelandii* strains, vanadium could replace molybdenum under nitrogen-fixing conditions. Of the 10 *A. chroococcum* strains tested, only three were unable to utilize vanadium as a substitute for molybdenum in nitrogenase and, in 19 out of the 20 *A. vinelandii* strains tested, vanadium was able to replace molybdenum in the nitrogen-fixation process. However, in all except one of 20 *Azomonas agilis* strains simultaneously tested, vanadium was unable to replace molybdenum in nitrogen fixation. Moreover, nitrogen fixation with vanadium was reduced to two-thirds of that produced by molybdenum. Experiments also demonstrated that for nitrate assimilation, molybdenum was also required in those species, which could assimilate nitrate (most *Azomonas agilis* strains are unable to utilize nitrate). But in the nitrate reductase system, molybdenum could not be replaced by vanadium. Finally for ammonium assimilation, neither of the two metals is required (Becking, 1962).

In this context, it is of interest that an alternative nitrogenase system lacking molybdenum has been discovered and its existence proved biochemically and genetically. First evidence of such an alternative nitrogen-fixing system came from the genetic studies of Bishop et al. (1980, 1982), who obtained Nif^+ pseudorevertants of the Nif^- strains UW6 and UW10 (see Shah et al., 1973) of *A. vinelandii.* These pseudorevertants displayed growth on nitrogen-free medium at a lower growth rate than the wild type and fixed nitrogen at a rate of 3–4% of the Nif^+ control. Moreover, phenotypic reversion of Nif^- mutants to Nif^+ occurred when they were grown on media lacking molybdenum but containing tungsten, vanadium, or rhenium salts (Bishop et al., 1980, 1982). Under these conditions, there was nitrogen fixation at a low rate although the cells lacked the typical EPR signal of the MoFe protein. These observations led Bishop et al. (1980, 1982, 1986) to propose an alternative pathway for nitrogen fixation in *A. vinelandii,* whose functioning was independent of molybdenum.

Following this, Eady et al. (1987) and Dilworth et al. (1988) demonstrated the existence of a vanadium nitrogenase in *A. chroococcum.* Miller and Eady (1988) showed that, for both the Mo and V nitrogenases present in *A. chroo-*

coccum, low temperature favors the nitrogen reduction by the V nitrogenase. The vanadium nitrogenase of *A. chroococcum* was purified and the properties of the VFe protein were studied (Eady et al., 1987). These authors demonstrated that the VFe protein of the vanadium nitrogenase contained an iron-vanadium cofactor forming the substrate-reducing site (Smith et al., 1988). Also, the Fe protein of the vanadium nitrogenase was purified and characterized (Eady et al., 1988). Raina et al. (1988) characterized the gene for the iron-protein of the vanadium-dependent alternative nitrogenase of *A. vinelandii* and constructed a Tn*5* mutant. Finally, the structural genes for the vanadium nitrogenase from *A. chroococcum* have been cloned and the nucleotides have been sequenced (Robson et al., 1989). There is also genetic evidence obtained using deletion mutant analysis that shows that at least in *Azotobacter vinelandii,* there is also a third nitrogenase that lacks both Mo and V (Pau et al., 1989). This has been independently verified, and the existence of an FeFe protein has been demonstrated (Smith, 1989; B.E. Smith, personal communication). Thus, in conclusion, three distinct nitrogenases are now known, each with its own, genetically distinct, Fe protein which acts as an electron transfer agent to either a MoFe, VFe, or FeFe protein in an ATP-hydrolyzing reaction. The MoFe and VFe proteins have been shown to contain cofactors (FeMoco and FeVco) that form the substrate-reducing sites.

Besides oxygen, hydrogen has also been intensively studied in relation to nitrogenase (Robson and Postgate, 1980). Hydrogen evolution has received attention in the context of the efficiency of the nitrogen-fixing system (Schubert and Evans, 1976; Schubert et al., 1977). It was suggested that in a fully efficient system, all electrons would be used for ammonia production and no hydrogen would be evolved. All Azotobacteraceae have very powerful hydrogenases and therefore, in these organisms, the role of hydrogen in nitrogen fixation was of particular interest. Hydrogen-dependent mixotrophic growth of *A. vinelandii* has been observed (Wong and Maier, 1985). Moreover, hydrogen-mediated enhancement of hydrogenase expression (Prosser et al., 1988) and hydrogen-mediated mannose uptake (Maier and Prosser, 1988) have both been reported for *A. vinelandii.* Recently, competition studies in continuous culture between a Hup$^-$ (= Hydrogen-uptake$^-$) mutant of *A. chroococcum* and its presumed isogenic Hup$^+$ recombinant showed that Hup activity benefitted the organism under nitrogen-fixing and sucrose- or phosphate-limiting conditions, but it was ineffective or disadvantageous under O_2, sulfate, or iron limitation (Yates and Campbell, 1989). The physiological aspects as well as the genetics of the hydrogen-uptake hydrogenase has been lately reviewed by Yates (1988) and Yates et al. (1988).

With regard to the assimilation of combined nitrogen such as ammonia, the usual enzymes, including glutamate dehydrogenase (GDH), glutamine synthetase (GS), and glutamate synthase (GOGAT), have been reported for *A. chroococcum* (Drozd et al., 1972), and some have also been demonstrated in other *Azotobacter* species. GOGAT was found in both soluble and membrane-bound forms in *A. vinelandii.* Assimilatory nitrate and nitrite reductases have been characterized for *A. chroococcum* and *A. vinelandii* (Guerrero et al., 1973; Spencer et al., 1957; Taniguchi and Ohmachi, 1960; Vega et al., 1973).

Genetic Aspects

The first metabolic mutants of Azotobacter were described for *Azotobacter vinelandii* by Karlsson and Barker (1948), and shortly afterwards mutants of the same species which do not fix nitrogen were reported by Wyss and Wyss (1950). The first DNA-mediated transformation in *Azotobacter* was observed by Sen and Sen (1965), who described an interspecific transformation of pigment production between *A. chroococcum* and *A. vinelandii.* Transformation of Nif$^-$ strains of *A. vinelandii* with *Rhizobium* DNA have also been described (Page, 1977), together with some other intergeneric transformations between *Rhizobium* and *Azotobacter* (Sen et al., 1969; Bishop et al., 1977a; Maier et al., 1978). Although phages (azotophages) of *Azotobacter vinelandii* and *A. chroococcum* have been isolated (Monsour et al., 1955; Chuml et al., 1980), these phages had limited host ranges and apparently had no transducing ability (Bishop et al., 1977b). An earlier positive report (Wyss and Nimeck, 1962) mentioning interspecific transduction in *Azotobacter* could not be confirmed.

Most studies on mutants of *Azotobacter* have involved the *nif* genes. The first stable *nif*$^-$ mutants of *Azotobacter* were described for *A. vinelandii* by Fisher and Brill (1969). These mutants were biochemically analyzed by these authors for the activity of the two nitrogenase components (Shah et al., 1973; Bishop and Brill, 1977).

Regulatory mutants of *Azotobacter* that fix nitrogen in the presence of ammonium have also been isolated and described by Sorger (1968), Gordon and Brill (1972), Bishop and

Brill (1977), and Terzaghi (1980b). Such mutants were found particularly among strains resistant to methylalanine. Ammonia-exporting mutants may be important in industry for ammonia production (see "Applications").

Bishop et al. (1980) obtained *nif*⁺ pseudorevertants of some particular *nif*⁻ mutants (UW 6 and UW 10), which could fix nitrogen at a rate of 2–4% of the *nif*⁺ control. From these observations, they inferred the existence of an alternative pathway for nitrogen fixation functioning independentally of Mo (see "Physiological and Biochemical Aspects"). Moreover, drug-resistant mutants (Page and Sadoff, 1976; Bishop and Brill, 1977) and amino acid and vitamin autotrophs (Leach and Battikhi, 1978) of *A. vinelandii* have regularly been obtained by mutagenesis and the application of selective media.

On the whole, *Azotobacter* species and, in particular, *Azomonas* species seem to be difficult to mutate or the selection procedures used so far have been inadequate. Sadoff et al. (1979) argued that *A. vinelandii* contains 40 chromosomes per cell, and therefore failure to isolate mutants could result from difficulties in segregation rather than mutagenesis. In view of these difficulties, most information on the *nif* genes comes from *Klebsiella pneumoniae.* It has a good transduction system and a plasmid (pRD1) that carries the entire *nif* cluster of *K. pneumoniae.* The plasmid has been isolated and this system was most useful in the development of the *Azotobacter nif* genetics, e.g., by the expression of *Klebsiella nif* genes in *Azotobacter* (Cannon and Postgate, 1976).

At the moment, the homology of *nif* genes of *Azotobacter* and other bacteria species is well established, and the genes encoding the two nitrogenase systems in two species *(A. vinelandii* and *A. chroococcum)* have been identified.

A group of genes spanning 25–30 kb of DNA was characterized in *A. chroococcum* after being cloned and their expression studied in *Klebsiella pneumoniae* (Jones et al., 1984). Hybridization to *nif* gene probes from *K. pneumoniae,* coupled with DNA sequencing and complementation analysis, revealed that the *nif* genes *FMVSUNEKDH* are present in this region (Evans et al., 1985). The genes best characterized for structure and function in *A. vinelandii* and *A. chroococcum* are *nifKDH.* A restriction map for a region of the *A. chroococcum* genome carrying *nif* genes (Jones et al., 1984) confirms close linkage and expression of *nifKDH* as a single transcript, and places *nifV* 15 kb away from *nifKDH.*

The promotors of *nif* genes were observed to share common nucleotide sequences in two regions upstream from the site at which transcription begins in a number of different organisms such as *Azotobacter, Klebsiella, Rhizobium, Thiobacillus,* and *Desulfovibrio.* The structural genes, including that of the VFe protein of the vanadium nitrogenase from *A. chroococcum* (Robson et al., 1989), have been cloned, and nucleotide sequences were determined as already reported. Activator proteins are needed for *nif* gene expression, and genes encoding activator genes have diverged to control expression of the three different enzyme systems responsible for nitrogen fixation. Regulation of *nif* genes in *Azotobacter* is therefore rather complicated.

Similarity of *nif* regulation among *K. pneumoniae* and *A. vinelandii* and *A. chroococcum* has been demonstrated (Kennedy and Robson, 1983). Introduction of the *nifA* gene from *K. pneumoniae* into *Azotobacter* mutants deficient in both components I and II restored the Nif⁺ phenotype to the presumed regulatory mutants but not to a nitrogenase-structural-gene mutant. The results are interpreted to suggest that *nifA* activation of *nif* genes might also be conserved among diazotrophs. Two nitrogen fixation regulatory regions, *nifA* and *nfrX,* in *Azotobacter vinelandii* and *A. chroococcum* have also been identified and characterized (Santero et al., 1988). These investigations are too numerous to cite here fully, but most of them are cited in recent reviews on the genetics of *Azotobacter* and related organisms by Elmerich (1984), Kennedy and Toukdarian (1987), and Kennedy (1989).

Applications

Associative growth of one *Azotobacter* species, *A. paspali,* has been reported to produce growth responses, apparently giving an increase in nitrogen, in forage grasses (Döbereiner, 1970; Döbereiner and Day, 1976).

However, *Azotobacter* inoculants (mainly *A. chroococcum*) also may produce crop responses. Especially in the USRR in the years 1958–1960, numerous field experiments were conducted with *Azotobacter* inoculants (named "Azotobacterin" or "Nitragin") with agricultural crops like spring wheat, winter wheat, barley, oats, and maize. Mishustin and Shilnikova (1969, 1971) have summarized these results, showing that in some trials, significant yield increases were obtained with a beneficial effect varying from 7–12%. Later, however, this practice was no longer recommended and it has now been abandoned.

However, some workers still claim that *Azotobacter* has a positive effect on crops, e.g., *Azotobacter* inoculation of seeds or seedlings of wheat, rice, onion, tomato, brinjal *(Solanum aestivum),* and cabbage. Significant responses with increases that average 10–20% are reported for such crops (Sundara Rao et al., 1963; Lehri and Mehrotra, 1968, 1972; Mehrotra and Lehri, 1971; Joi and Shinde, 1976; Shende et al., 1977).

Some other workers (Vančura and Macura, 1959, 1961; Brown et al., 1962, 1964) performed field and pot experiments in which artificial inoculation produces increases in the yield of crops. They attributed the beneficial responses in addition to fixed nitrogen made available to the plants by the production of phytohormones such as gibberellins, auxins, and some phenolic compounds (Jackson et al., 1964; Hennequin and Blachère, 1966), giving the plants a better health condition. Also, the production of antifungal antibiotics by *Azotobacter* may play a rôle in these yield increases (Mishustin and Shilnikova, 1969, 1971; Laksmi Kumari et al., 1975).

For instance, Meshram and Jager (1983) mentioned an antagonism of isolates of *Azotobacter chroococcum* to *Rhizoctonia solani* on agar plates and *Azotobacter* isolates were tested for their ability to control *R. solani* infection of potato sprouts in sterilized and unsterilized soil. The degree of antagonism exhibited varied strongly among the isolates and was found to be temperature-dependent. Following this, Azad and Aslam (1985) observed that *Azotobacter chroococcum* inoculation increased the yield and the protein content of potato *(Solanum tuberosum)* tubers. Analyses showed that the inoculum increased substantially the population of *A. chroococcum* present in the rhizosphere soil in these experiments.

Bagyaraj and Menge (1978) showed that larger populations of bacteria and actinomycetes were recovered from the rhizospheres of tomato *(Lycopersicon esculentum)* plants inoculated with the mycorrhizal fungus *Glomus fasciculatus* and *Azotobacter chroococcum,* either individually or together, than from those of non-inoculated plants. The dry weights of the tomato plants inoculated with both *G. fasciculatus* and *A. chroococcum* were significantly (62%) greater than non-inoculated plants. These results suggest a synergistic or additive interaction between *Glomus fasciculatus* and *Azotobacter chroococcum.*

Although the practice of using *Azotobacter* inoculants was often unsatisfactory and has been abandoned in many countries, in India a constant stream of publications continues to appear on the beneficial effects of *Azotobacter* on various crops such as sorghum, pearl millet, maize, rize, sesame, wheat, and barley (Ghonsikar et al., 1986; Prasad, 1986; Konde and Shinde, 1986; Shende et al., 1986; Subbian and Chamy, 1984; Rai and Gaur, 1988; Kavimandan et al., 1978; Tiwari et al., 1989). In India, it is also suggested that *Azotobacter* inoculation gives positive growth responses in oak seedlings used in forestry (Pandey et al., 1986).

Outside India, there are now only sporadic reports on the beneficial effects of *Azotobacter* inoculations, and these refer mainly to subtropical regions. Some Egyptian authors have obtained positive results on the growth of the castor oil plant, *Ricinus communis* (Monib et al., 1984), or of wheat (Emam et al., 1986) with *Azotobacter* inoculation.

Monib et al. (1979) also studied the effect of bacterization of barley *(Hordium vulgare)* grains with a selected strain of *Azotobacter chroococcum.* In N-deficient sand, seed inoculation increased plant length, dry weight, nitrogen content in addition to a significant increase in soil nitrogen. In the presence of a mixed soil microflora the beneficial effect of bacterization was less than in monobacterial cultures. Azotobacters naturally present in soil also colonized in heavy densities the rhizoplane (rhizosphere) of the barley plants, but their effect on plant growth and soil nitrogen were less as compared with that of bacterization.

In Spain, the beneficial effects of *Azotobacter chroococcum* on root colonization and grain production of maize have been reported (Martinez-Toledo et al., 1988a, 1988b), and in *Sorghum bicolor,* a specific root association with *A. chroococcum* was demonstrated, but there was no interaction influencing the nitrogenase activity in the rhizosphere, probably due to the lack of excretion of a carbon and energy source by the plant (De La Rubia et al., 1989). In addition, in Israel, positive responses of *Azotobacter* inoculation on the growth of *Setaria italica* have been reported (Yahalom et al., 1984). In Pakistan, Hussain et al. (1985) studied in field experiments the seed inoculation of wheat *(Triticum aestivum)* on the yield in relation to the application of farm yard manure and some N-P-K levels, in which N was given in the form of urea. The results indicated that *Azotobacter* inoculation was more effective as regards to grain yield in the trials where no nitrogen was added, next was farm yard manure and the lowest response was with urea application.

From all these investigations it is clear that, with regard to beneficial effects, the supply of fixed N might not be the sole factor involved or it is only a minor factor and that growth-promoting substances may be involved. In par-

ticular, it appears that plant root colonization by bacteria is favorable, probably due to biological control of plant diseases (see e.g., Kloepper et al., 1989).

Some *Azotobacter* mutants may be important for biotechnology and industrial application. Mutants of *A. vinelandii* have been obtained that fix molecular nitrogen in the presence of excess NH_4^+ excretion into the medium (Gordon and Brill, 1972; Shaw et al., 1973). Terzaghi (1980a, 1980b) tried to produce such mutants in a variety of *Azotobacter/Azomonas* species, i.e., mutants which could excrete excess ammonia in addition to being able to reduce N_2 in the presence of excess NH_4^+. She isolated nitrogenase-derepressed (Nif-Drd) mutants of *Azotobacter* in the two *Azotobacter* species *(A. vinelandii* and *A. beijerinckii)* and the two *Azomonas* species *(A. agilis* and *A. macrocytogenes)* tested. Such mutants could only be obtained in *Azotobacter vinelandii* and to a much lesser degree in one strain of *Azomonas agilis.* These mutants, having up to 100% nitrogenase activity and excreting NH_4^+ into the medium without inhibiting the nitrogenase activity, are of industrial significance, for instance by immobilization in Alginate beads, because they offer the opportunity to produce ammonia (which can be used as plant fertilizer) using *Azotobacter* in a biotechnological process.

CHAPTER 166

The Genus *Beggiatoa*

DOUGLAS C. NELSON

The genus *Beggiatoa* is currently represented by a single defined species *Beggiatoa alba* (Strohl, 1989). However, this species designation is commonly used for any colorless, filamentous, gliding bacterium that deposits internal globules of elemental sulfur but does not form bundles of trichomes within a common sheath. Organisms with a variety of filament widths, ranging from 1–120 μm, have been observed in native material and are assumed to belong to this genus (Jørgensen, 1977; Klas, 1937; Nelson et al., 1989b), but a single phylogenetic affinity group is by no means proven. *Beggiatoa* is of historical importance because Winogradsky's (1887) earliest experiments, which ultimately led to development of the concept of bacterial chemoautotrophy, were performed with natural enrichments of this organism (see Brock and Schlegel, 1989).

Habitats

Beggiatoa is worldwide in its distribution. Macroscopically visible assemblages dominated by members of this genus can be observed in a variety of environments, all of which are characterized by the presence of a detectable level of hydrogen sulfide. Freshwater environments such as sulfur springs and a variety of eutrophic lakes and ponds contain benthic mats rich in *Beggiatoa* spp. (Keil, 1912; Lackey et al., 1965; Winogradsky, 1887). However, in the lighted region of these water bodies the dominance of this organism is often overlooked. This is because its pattern of daily migration typically brings it to the sediment-water interface only after dark (Jørgensen, 1982a; Nelson and Castenholz, 1982).

Marine environments are especially conducive to massive enrichment for *Beggiatoa* due to the greater abundance of sulfate, which channels a major portion of the anaerobic mineralization of organic matter into the production of hydrogen sulfide (Jørgensen, 1982b). The surface sediments of shallow seas, brackish fjords, salt marshes and intertidal sand flats may be covered by mats rich in *Beggiatoa* spp. (Ankar and Jansson, 1973; Grant and Bathmann, 1987, Jørgensen, 1977; Lackey, et al., 1965). Highly localized regions of anaerobic decomposition, ranging from a whale carcass on the ocean floor (Smith et al., 1989) to oil-soaked heads of coral (Chet and Mitchell, 1975), can also lead to enrichment of *Beggiatoa.* Some deep-sea hydrothermal vents (2,000–2,500 m depth) rich in geothermally produced hydrogen sulfide are also locally dominated by representatives of this genus (Nelson et al., 1989b).

In the examples above, the *Beggiatoa*-dominated assemblage is proven or presumed to exist at a very narrow interface between oxygen and hydrogen sulfide (Jørgensen and Revsbech, 1983). A different sort of environment, characterized as being without oxygen but oxidized in its redox potential (i.e., no free hydrogen sulfide), can also harbor a more diffuse distribution of *Beggiatoa* (Jørgensen, 1977). This "oxidized-anoxic" region of marine sediments is more globally extensive than the rich environments that produce luxurious sediment surface "blooms" of *Beggiatoa* spp. (Jørgensen, 1989). Therefore, it should be possible to enrich for this bacterium from a very wide variety of marine habitats.

Isolation

Selective Enrichments

The most consistently successful enrichments for *Beggiatoa* spp. have been made as follows: The bottom of a shallow pan or aquarium (approximately 30 × 30 × 12 cm) is covered with a few centimeters of sand. $CaSO_4$ (approximately 20 g) and K_2HPO_4 (a few grams) are then added, along with a source of complex organic polymers such as seaweed or shredded paper. This is covered with several centimeters of sulfide-rich marine mud, and then enough seawater to cover the entire enrichment to a depth

of 1–2 cm is added. Covering the pan with aluminum foil or incubating in a dark place minimizes competition with phototrophic bacteria. The enrichment is certain to contain the proper sulfide-oxygen interface somewhere in the vessel if air is introduced near the sediment surface using an airstone. Water lost by evaporation should be replaced with distilled water. Alternatively, a slow steady flow of freshly aerated seawater, with a drain maintaining a constant level, will provide the necessary O_2. A similar freshwater enrichment inoculated with mud from a sulfur spring and maintained on a light-dark cycle (10 h:14 h) provided viable tufts of *Beggiatoa* spp. for almost a year (Nelson and Castenholz, 1982).

Sewage treatment plants are also an excellent source of enrichment material (Burton and Lee, 1978; Williams and Unz, 1985). A predictably successful enrichment is achieved using activated sludge freshly collected from an aeration basin of a treatment plant (W. Pfeiffer, personal communication). Approximately 500 ml of this "mixed liquor" is incubated in a 1-liter Erlenmeyer flask at room temperature in the dark. After 5 to 15 days the surface of the settled flocculant material is typically covered with tufts or sheets of *Beggiatoa.*

Another type of enrichment has a long historical association with *Beggiatoa* and is based on the use of extensively extracted dried grasses or hay in an otherwise mineral medium (Cataldi, 1940). The complex polymers such as cellulose residues in the material presumably fuel sulfate reduction localized near the surface of the grasses. This, in turn, provides the hydrogen sulfide necessary to enrich for *Beggiatoa.* The grasses also serve as a physical substrate for these gliding bacteria. Inclusion of soil extract and the enzyme catalase appear to enhance the rate and success of this enrichment (Joshi and Hollis, 1976; Strohl and Larkin, 1978a).

Isolation Procedures

The various enrichments described above are considered successful when they yield "tufts" or "puff balls" comprised mainly of intertwined *Beggiatoa* filaments. The nature and size of these aggregates is similar to that obtained in aerobic growth of certain freshwater strains (Fig. 1d). Several tufts are collected from the sediment-water interface with a Pasteur pipette or pointed forceps and are passed through several rinses in sterile water. These rinses may contain sodium azide to help reduce contamination (Burton and Lee, 1978), and inclusion of sodium sulfide (250–500 μM) has also been suggested. Tufts are then inoculated into the center of well-dried plates (0.8–1.2% agar) of an appropriate medium. After a period of time individual filaments will have moved far enough from the inoculation site so that they can be transferred (along with a small block of agar) using finely pointed watchmakers' forceps. The procedure described by Castenholz (1988) has produced excellent results. Depending on the source of inoculum these single filament isolations can be best accomplished several hours to a few days after inoculation. With practice, up to a half of the filaments isolated are without contaminants and success is greatly facilitated by lightly prescoring the surface of the medium to guide the gliding filaments (Burton and Lee, 1978).

Media for Isolation

As will be discussed later, the marine isolates characterized to date have a different physiology from freshwater *Beggiatoa* strains examined. It is suggested, but not proven, that this is because they have been isolated under very different conditions. All recently studied strains of freshwater *Beggiatoa* were isolated in the presence of full air (O_2 partial pressure approximately 20 kPa) typically using media that contained a low concentration (0.02 to 5 mM) of a single organic compound, principally acetate, lactate, or glucose (Strohl and Larkin, 1978a; Williams and Unz, 1985). Such media sometimes, but by no means always, contained Na_2S or $Na_2S_2O_3$. Successful isolations and sustained maintenance have also been accomplished using agar-gelled but otherwise unsupplemented thiosulfate-mineral medium (Nelson and Castenholz, 1981b). In this instance, trace organic impurities in the agar presumably acted as the carbon source for these nonautotrophic strains. All freshwater isolates currently available are capable of growth in the presence of full air.

By contrast, the half-dozen known strains of marine *Beggiatoa* are obligate microaerophiles that were isolated under microoxic conditions (4 kPa O_2) on medium supplemented with sodium sulfide and sodium acetate. Subsequently it was realized that all strains will grow luxuriantly in sulfide-gradient medium (described below) in the absence of added organics.

Isolation of Lithoautotrophic Marine Strains

The following procedure ensures a Marine Basal Medium (J3) free of precipitates.

Solution 1:

Aged natural seawater (salinity 3.2–3.5%); prefiltered (Whatman #1 or Gelman GF/F) and filtered (0.45 μm)	500 ml

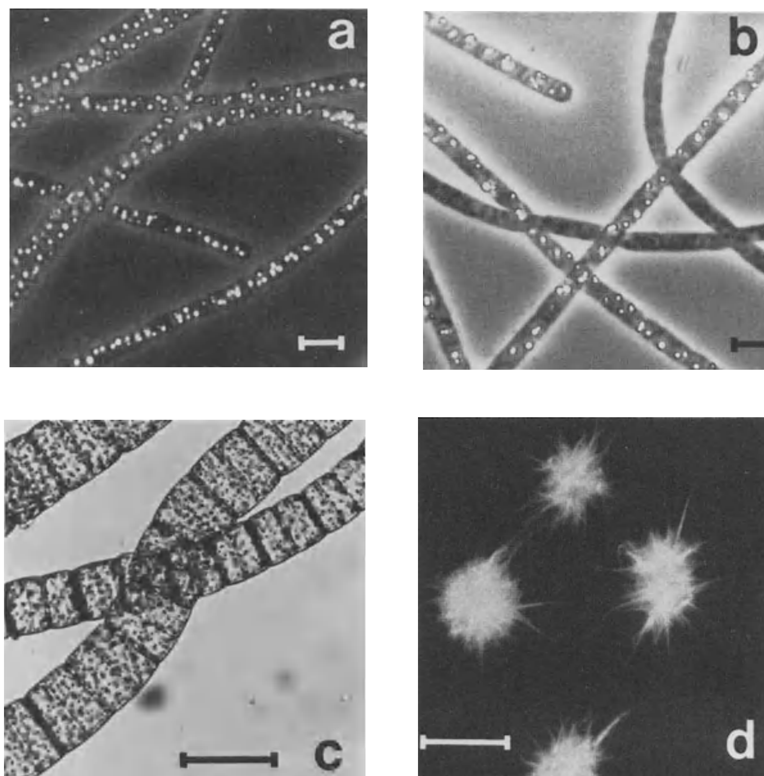

Fig. 1. Light micrographs of pure cultures and natural samples of *Beggiatoa* spp. Part (a) and part (b) are phase contrast; part (c) bright field; part (d) employed reflected illumination and a dissecting microscope. (a) Marine strain MS-81-1c, chemoautotrophic growth, gradient medium. Note refractile S^0 globules. Bar = 5 μm. (b) Freshwater strain OH-75-2a (similar to *B. alba*), stationary phase, liquid DTA medium. Some filaments are devoid of refractile S^0 globules. Nonrefractile inclusions are probably PHB (see Fig. 4). Bar = 5 μm. (c) *Beggiatoa* sp. collected at a deep-sea vent of the Guaymas Basin, Gulf of California. These "hollow," chemoautotrophic filaments (Nelson et al. 1989b) are representative of the wider material frequently found in natural samples. Bar = 50 μm. (Micrograph courtesy of H. W. Jannasch and C. O. Wirsen.) (d) Freshwater strain OH-75-2a aggregated in tufts typical of its aerated growth. Bar = 1 mm.

Solution 2:	
Distilled water	200 ml
Agar	9.0 g
Solution 3:	
NH_4NO_3	0.06 g
Trace elements (SL8, Pfennig and Biebl, 1981)	0.75 ml
Mineral stock	50 ml

The mineral stock contains (per liter): K_2HPO_4, 0.52g; Na_2MoO_4, 0.05 g; $FeCl_3{\cdot}6H_2O$, 0.29 g; $Na_2S_2O_5$ (sodium pyrosulfite), 0.75 g; phenol red, 10 ml of a sterile solution (0.5%, Gibco).

Autoclave solutions 1, 2, and 3 separately in Erlenmeyer flasks. After cooling to 50°C, aseptically combine in the solution 2 vessel (volume > 750 ml). Then supplement with 0.2 ml of Va vitamin solution, which contains (in mg per liter): B_{12}, 1; thiamine, 200; biotin, 1; folic acid, 1; paraaminobenzoic acid, 10; nicotinic acid, 100; inositol, 1; calcium pantothenate, 100.

J3 Basal Medium is amended to produce an Isolation Medium (J-TS) by adding the following sterile stocks (final concentrations in parentheses): 1) 7.5 ml of 200 mM $Na_2S_2O_3$ (2 mM). 2) 3.75 ml of freshly neutralized 200 mM Na_2S (1 mM). This is autoclaved as a basic solution, which is quite stable against autooxidation, and then neutralized with an equimolar quantity of sterile HCl just prior to use. 3) 15 ml of 1 M $NaHCO_3$ (20 mM). To make this stock autoclave 8.4 g of $NaHCO_3$ (dry) and add 100 ml of sterile distilled water when cool.

Immediately after solidification, plates were incubated in a bell jar for 24 h or more under anoxic conditions (99.5% N_2, 0.5% CO_2), with desiccant present to absorb water evaporating from the surface of the medium. The medium is buffered by the bicarbonate in conjunction with the level of atmospheric CO_2. After inoculation with a tuft of *Beggiatoa* spp., plates were placed in a microoxic atmosphere (0.5% CO_2; 0.2% O_2; balance N_2). Exposing the medium and bacteria to full air for approximately 20 min every day or two, as needed for inoculation or single-filament isolations, posed no problem to the success of the technique. Pure cultures resulting from repeated single-filament isolations were maintained in sulfide-oxygen gradient media (see below).

Construction of Gradient Medium

Marine gradient medium (JG8) was constructed as follows: First a 4 ml quantity of J3 Medium (pH 8.4; 1.5% agar; $NaHCO_3$ concentration lowered to 2.0 mM) supplemented with freshly neutralized Na_2S was solidified in the bottom of a 16 × 150 mm screw-capped tube. An initial sulfide concentration of 8 mM in this butt has proven satisfactory for all isolates tested. (The thiosulfate present in the isolation medium need not be included because the tube geometry [Fig. 2] provides a sustained flux of sulfide for several weeks.) This butt was then overlayed with 8.0 ml of semisolid J3 Medium (0.25% agar; $NaHCO_3$ lowered to 2.0 mM; no sulfide or thiosulfate). At this point the gradient of sol-

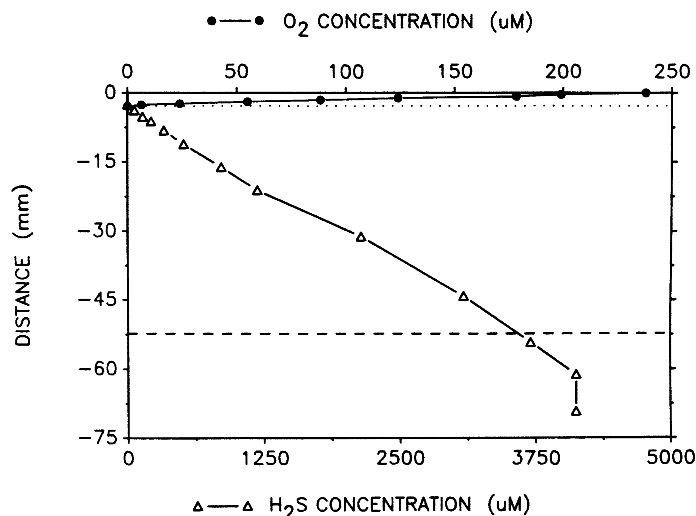

Fig. 2. Microelectrode profiles of O_2 and H_2S in a gradient culture after 47 h of growth at 25°C. The medium was cured 41 h prior to inoculation. Dotted line, location of *Beggiatoa* plate (300 μm vertical thickness). Dashed line, top of initial H_2S butt (8.5 mM). Depth represents distance below air-agar interface. Note different concentration scales. "H_2S" designates sum of soluble sulfide species (e.g., $[H_2S] + [HS^-] + [S^=]$).

uble sulfide (neglecting convective mixing) is theoretically a "step-gradient," i.e., all of the sulfide would be below the dashed line of Fig. 2. The air headspace in the top 8 ml of the tube constitutes an oxygen reservoir. Molecular diffusion and nonbiological reaction between sulfide and oxygen both gradually alter the gradient shapes as described in more detail elsewhere (Nelson et al., 1986a, 1986b).

Aging new gradient media for 2 to 3 days prior to inoculation establishes a sulfide-oxygen interface that is quite stable in both position and rates of nutrient flux. The interface is located approximately as shown in Fig. 2, but the extent of sulfide and oxygen overlap is roughly 6–7 mm in uninoculated medium (Nelson et al., 1986a) as compared with 200μm or less in the cultures (Fig. 3). Whether inoculated at the surface of this medium or stabbed throughout the upper few centimeters, the filaments rapidly proliferate at the sulfide-oxygen interface, forming a marked layer or "plate," which attains a maximum thickness of approximately 1 mm (Fig. 3b). Gliding motility and negative chemotactic responses (discussed later) allow these bacteria to track this interface as it slowly descends due to gradual depletion of the sulfide reservoir.

Isolation of Freshwater Strains

For the freshwater strains currently available, isolations were performed under oxic conditions (air atmosphere) on a variety of media (Nelson and Castenholz, 1981b; Strohl and Larkin, 1978a; Williams and Unz, 1985). A representative medium is shown here:

DTA Medium

ND stock solution (Castenholz, 1988)	50 ml
$(NH_4)_2SO_4$	0.13 g
Sodium acetate	0.68 g
K_2HPO_4	0.027 g
$Na_2S_2O_3 \cdot 5H_2O$	0.50 g
$CaCl_2$	0.10 g
Distilled water	950 ml
Agar	8–12 g

ND stock solution

Distilled Water	1,000 ml
NTA (nitrilotriacetic acid)	2.0 g
Micronutrient solution	10 ml
$FeCl_3$ solution (0.29 g/liter)	20 ml
$CaSO_4 \cdot 2H_2O$	1.2 g
$MgSO_4 \cdot 7H_2O$	2.0 g
NaCl	0.16 g
Na_2HPO_4	1.4 g
KH_2PO_4	0.72 g

Micronutrient solution

Distilled water	1,000 ml
H_2SO_4 (concentrated)	0.5 ml
$MnSO_4 \cdot H_2O$	2.28 g
$ZnSO_4 \cdot 7H_2O$	0.50 g
H_3BO_3	0.50 g
$CuSO_4 \cdot 5H_2O$	0.025 g
$Na_2MoO_4 \cdot 2H_2O$	0.025 g
$CoCl_2 \cdot 6H_2O$	0.045 g

The pH is adusted to 7.0 prior to autoclaving. As in the marine isolations, it is important that the surface of the agar is dry. For purification of single filaments from enrichment-derived tufts, lowering the acetate concentration to 0.5 mM for the initial dispersal of filaments may minimize contamination.

A sulfide-oxygen gradient medium based on DTA Medium has proved effective for maintaining freshwater strains because they require infrequent transfer. The sulfide concentration of the butt should be reduced to 3–4 mM, and thiosulfate can be deleted from the top agar.

Preservation of Cultures

Marine gradient stock cultures require transfer every 3 weeks (25°C) into fresh gradient me-

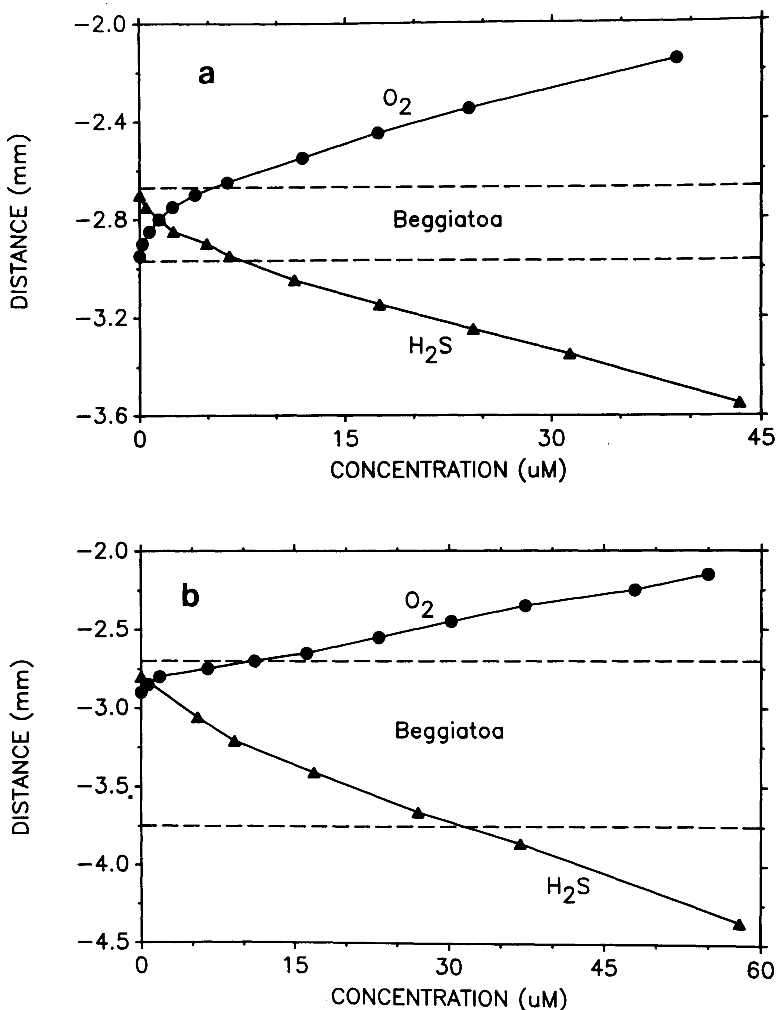

Fig. 3. Fine-scale details of H_2S and O_2 gradients in immediate vicinity of *Beggiatoa* plate. These and other data summarized in Nelson et al. (1986b). (a) Details corresponding to Fig. 2. H_2S flux = 4.8 nmol·mg prot^{-1}·sec^{-1}; O_2 flux = 5.1 nmol·mg prot^{-1}·sec^{-1}. (b) Culture which is a duplicate of part (a) but after 176 h of growth. H_2S flux = 0.46 nmol·mg prot^{-1}·sec^{-1}; O_2 flux = 0.91 nmol·mg prot^{-1}·sec^{-1}.

dium, while freshwater stocks need only be transferred approximately every 6 weeks. Transfers into gradient media aged several weeks will not survive as long as those into freshly prepared media. Stock cultures grown for 1 week at room temperature and then transferred to 10°C maintain viability for 2 to 4 months. Both marine and freshwater strains have been recovered from storage at −80°C for 2 years by inoculating into gradient media. Glycerol (25%) as a cryoprotectant was used along with rapid freezing (solid CO_2-methanol bath).

Identification

Members of the genus *Beggiatoa* are colorless, gliding filaments that contain internal globules of elemental sulfur (S^0). S^0 globules in virtually pure natural assemblages were shown to contain principally S_8 with a small percentage of S_7 (Nelson et al., 1989b). Whenever examined, the S^0 globules were located in the periplasm, surrounded by a nonunit membrane (Strohl et. al., 1982). *Beggiatoa* spp. can be differentiated from other S^0-containing genera as follows: 1) Their lack of photosynthetic pigment and filamentous morphology differentiate them from the purple sulfur bacteria. 2) The other colorless filamentous genera, *Thiothrix* (holdfasts, nonmotile except in the hormogonial stage) and *Thioploca* (common sheath around a bundle of gliding filaments), can also be readily differentiated.

Based on macroscopically visible natural collections, *Beggiatoa* filaments ranging in diameter from 1 μm to approximately 120 μm have been recognized (Strohl, 1989; Nelson et al., 1989b). As summarized elsewhere (Nelson et al., 1989b), it is clear that discrete width classes of this organism exist. Only narrow strains averaging approximately 2 and 4 μm have been isolated in pure culture, and width is aparently an invariant property of these strains.

In the past, different species designations were associated with the various width classes (Leadbetter, 1974); however currently only a

single species, *B. alba,* is recognized (Strohl, 1989). This is a 2–3 μm wide freshwater strain, which, based on 5S rRNA analysis, belongs to the gamma subgroup of the purple bacteria (Stahl et al., 1987). An analysis of the type strain (ATCC #33555) and of a very similar independent isolate (OH-75-2a) indicated a GC content of 37–40 mol% (Nelson, 1989; Mezzino et al., 1984). Although not reported as such, OH-75-2a is the *Beggiatoa* strain tested by Woese et al. (1985), which was found to belong to the gamma group of the purple bacteria based on 16SrRNA oligonucleotide catalogs (J. Gibson, personal communication). Since bulk liquid cultivation of autotrophic marine strains has just become possible (K. Diggs, unpublished observations), the evolutionary relationship of these to the freshwater strains has yet to be established. To date, there have been no studies of DNA homology within this genus.

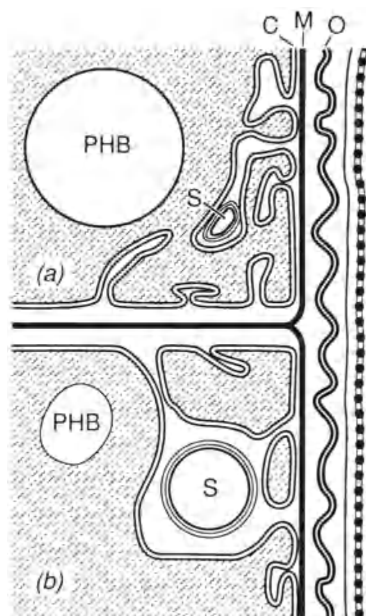

Fig. 4. Schematic of *Beggiatoa alba* strain B15LD (ATCC #33554). Symbols: C, cell membrane; M, presumed murein layer; O, presumed outer membrane layer; S, globule of S^0; PHB, poly-β-hydroxybutyrate granule. (a) Note large PHB inclusion and rudimentary S^0 globule typical of cells grown in acetate-supplemented mineral medium. (b) Note small PHB inclusion and large S^0 globule typical of cell grown in the presence of sulfide or thiosulfate and a low concentrate of acetate. (Figure adapted from Strohl et al. [1982]; by permission of Society for General Microbiology and the author.)

Cell Structure

Narrow *Beggiatoa* filaments examined in pure culture (2–5 μm width) are typically composed of cylindrical cells (length ranging from 1.5–8 × width (Faust and Wolfe, 1961; D. Nelson, unpublished observations; Scotten and Stokes, 1962). However, crosswalls are rarely visible in cultured cells filled with poly-β-hydroxybutyrate (PHB) or S^0 (Figs. 1a and b). Trichomes may exceed 1 cm in length when actively growing in semisolid medium. Terminal cells are rounded in all cultured strains. Exhausting of nutrients results in trichome breakage at necridia or "sacrificial" cells (Pringsheim, 1964; Strohl and Larkin 1978b) to produce trichomes as short as 3 to 10 cells in length. The wider filaments (15–120 μm; Klas, 1937; Jørgensen, 1977; Nelson et al., 1989b) are disk-shaped with cell lengths (5–25 μm) ranging from 0.10–0.90 × cell width (see Fig. 1c). At least some of the wider filaments (e.g., Fig. 1c) are hollow, i.e., composed of a thin cylinder of cytoplasm surrounding a large central vacuole (Nelson et al., 1989b).

The few *Beggiatoa* strains tested are Gram-negative both phylogenetically and by staining; however, they have unusual cell wall structures. Figure 4 shows a schematic diagram that indicates that only the inner layer of the cell wall (presumably murein) plus the cell membrane participate in septation. The outer envelope layers do not participate in cross-wall formation but are apparently continuous over the entire filament length (Strohl et al., 1982).

Three types of inclusions have been reported for various *Beggiatoa* strains: PHB (Pringsheim, 1964; Strohl and Larkin, 1978a; Strohl et al., 1982), polyphosphate (Strohol and Larkin 1878a; Maier and Murray, 1965), and sulfur (Strohl et al., 1981b, 1982; Winogradsky, 1887). The reports of polyphosphate should be regarded as tentative because the staining technique employed is nonspecific (Krieg and Hylemon, 1976). Production of PHB appears, on the other hand, to be a universal feature of the freshwater strains examined. Interestingly, PHB deposition seems to correlate primarily with high aeration (Pringsheim, 1964) and it can account for up to 50% of total dry weight under these conditions in the absence of sulfide (Güde et al., 1981).

The sulfur inclusions of *Beggiatoa* are periplasmic in location, being enclosed in invaginations of the cell membrane (Fig. 4). The S^0 globules in the specific strain diagramed here are enclosed within a multiayered sulfur inclusion envelope of 12–14 nm thickness (Strohl et al., 1982) while in other strains the S^0-globule envelope appears to be composed of a single protein layer 4–5 nm thick (Strohl et al., 1981b). The extraction of S^0 globules with solvents such as pyridine and their refractile appearance when intact cells are viewed under phase contrast mi-

croscopy have proven very useful in confirming their presence (Skerman et al., 1957). As shown schematically (Fig. 4), *Beggiatoa* cells grown in the absence of reduced sulfur compounds apparently contained small, "rudimentary" S^0-inclusion envelopes (Strohl et al., 1982). Since dehydration solvents (e.g., ethanol) necessary for preparation of the electron microscopy specimens dissolve the S^0, it is difficult to determine whether the rudimentary inclusions completely lack S^0.

Physiological Properties

Freshwater Strains

All freshwater strains tested to date could be grown as areobic chemoheterotrophs, and those investigated appear to posses a functional tricarboxylic acid (TCA) cycle with glyoxylate bypass. A very limited number of organic acids, alcohols, and TCA cycle intermediates could serve as the sole source of carbon and energy, with the most universal among these being lactate, acetate, pyruvate, and ethanol. Strain-specific differences are summarized elsewhere (Nelson, 1989; Strohl, 1989).

The earliest studies of freshwater strains reported what we would now interpret as chemoautotrophic growth (Winogradsky, 1887; Keil, 1912). Since that time, repeated attempts to obtain growth of freshwater *Beggiatoa* strains in completely inorganic media have met with failure (Pringsheim, 1967; Strohl, 1989; Nelson, 1989). However, two enzymes diagnostic for the Calvin cycle, ribulose-1,5-bisphosphate carboxylase and phosphoribulokinase, were detected in two of these strains. Demonstration of enzyme activity has also sometimes been confirmed by hybridization with appropriate gene probes (Nelson et al., 1989a). Curiously, the enzyme activities observed were one or more orders of magnitude below those deemed minimally necessary for autotrophic growth. A plasmid location was suggested for the ribulose-1,5-bisphosphate carboxylase/oxygenase gene (Nelson et al. 1989a).

Under the imprecise label of "mixotrophy," lithoheterotrophy has been repeatedly postulated for various freshwater strains (Güde et al., 1981; Strohl and Schmidt, 1984; Pringsheim, 1967). At this time, as discussed in detail elsewhere (Nelson, 1989), there is no clear proof of lithoheterotrophic growth of any freshwater strain.

In gradient media a significant portion of the niche of *Beggiatoa* is anoxic, but microoxic conditions prevail a few hundred micrometers away in another portion of the bacterial plate. A demonstration of this is included here for a marine strain (Fig. 3) and presented elsewhere for freshwater strains (Nelson et al., 1986b). Constant gliding in this medium, which simulates the gradients of this bacterium's natural environment, presumably exposes filaments to alternating anoxic and microoxic conditions. Individual cells will spend on the order of a few seconds to a few minutes in one microniche before passing to the other. Although O_2 is the only electron acceptor proven to sustain growth of *Beggiatoa,* there is evidence that other acceptors are of importance under anoxic conditions, at the very least for sustaining motility. Stored S^0 globules, nitrate, and nitrite are all reduced by some strains under these conditions (Nelson and Castenholz, 1981a; Schmidt et al., 1987; Vargas and Strohl, 1985b). The participation of acetate oxidation in this process has sometimes been demonstrated, but the role of stored PHB has not been carefully addressed. Whether biomass increase occurs under these conditions is not known.

Virtually all freshwater strains tested are capable of fixation of dinitrogen under microoxic conditions (Nelson et al., 1982; Polman and Larkin, 1986). Ammonia, nitrate, nitrite, a few amino acids, and urea are also useful sources of combined nitrogen for some or all strains (Nelson et al., 1982; Vargas and Strohl, 1985a, 1985b). Based on repeated growth in media that contain sulfate as the only sulfur source, there is no evidence of an assimilatory need for reduced-sulfur compounds in freshwater strains.

Marine Strains

Our limited knowledge of the physiology of marine strains is based largely on studies in gradient media. The half-dozen isolates tested to date all grew as chemoautotrophs in a seawater-based medium that contained oppositely sloped gradients of O_2 and H_2S (Fig. 2 and 3) and was devoid of added organic compounds except vitamins (Nelson and Jannasch, 1983; Nelson et al., 1986b). Quantitative insights into this type of growth were obtained using microelectrodes to measure the shapes of O_2 and H_2S gradients and the respective fluxes of these nutrients. Representative data indicate that the "plate" or "lens" formed by an actively growing *Beggiatoa* culture can completely consume H_2S and O_2 fluxes within a vertical distance of 300μm or less (Figs. 3a and b). It has been further demonstrated that bacterially mediated consumption of these two nutrients in their zone of overlap is at least three orders of magnitude more rapid than the purely chemical oxidation of H_2S

in uninoculated control medium (Nelson et al., 1986a). Given also the values for diffusion coefficients, instantaneous rates of H_2S and O_2 consumption can be calculated from the slopes of these gradients immediately below or above the *Beggiatoa* plate, respectively. As cultivation in gradient medium continues, depletion of the H_2S reservoir results in a diminished flux until the rate of transfer is only sufficient to provide maintenance energy of the enlarged *Beggiatoa* population (Fig. 3b). At this point the bacterial plate is considerably thicker, the zone of H_2S and O_2 overlap extremely small, and the cells are, on average, predominantly in an anoxic environment.

Of the two strains studied in detail, one (MS-81-6) is also capable of organoheterotrophic growth with acetate as the sole carbon and energy source in liquid medium under microoxic conditions (Nelson and Jannasch, 1983). This strain also responds to a limited number of organic compounds if they are added singly to sulfide-limited gradient medium. These compounds can augment both O_2 consumption and total biomass production (Nelson, 1989). By contrast, the other strain (MS-81-1c) appears to be an obligate chemoautotroph (Nelson, unpublished observations).

Appropriately high activities of ribulose-1,5-bisphosphate carboxylase/oxygenase and phosphoribulokinase are taken as evidence of a functional Calvin cycle in all of these marine strains (Nelson et al., 1989a; Nelson, unpublished observations). Likewise, all strains demonstrated the capacity for nitrogen fixation (Nelson et al., 1982). Determination of the enzymes involved in sulfur-based energy metabolism is currently in progress for these strains. Interestingly, extremely high concentrations of an unusual *c*-type cytochrome have been implicated in H_2S oxidation in very pure natural assemblages of *Beggiatoa* sp. collected from deep-sea hydrothermal vents (Prince et al., 1988).

The sharp upper boundary of a *Beggiatoa* plate (e.g., Fig. 3a and 3b) is almost certainly the result of the negative chemotactic response to O_2 demonstrated by Møller et al. (1985). Likewise, the sharp lower boundary of these plates is taken as presumptive evidence of a negative chemotactic response to excess H_2S. Thus, *Beggiatoa* appears to find its interface niche, somewhat paradoxically, by avoiding high concentrations of its two major nutrients. There is also evidence (Nelson and Castenholz, 1982; Møller et al., 1985) that a negative response to blue light is common. Furthermore, it appears that this response is of ecological importance in helping *Beggiatoa* sp. to locate the H_2S-O_2 interface if it must pass down through a cyanobacterially produced O_2-maximum to do so.

Applications

When growing at or below the sediment-water interface, *Beggiatoa* serves the extremely important function of preventing the aerobic phase of an ecosystem from becoming anaerobic (Kuenen, 1975) as long as it has the capacity to quantitatively harvest the H_2S flux (cf. Figs. 2 and 3). The organisms thus protected can be marine fauna of sediments or the overlying water (Ankar and Jansson, 1973) or rice plants in flooded soils (Joshi and Hollis, 1977). *Beggiatoa* also may channel some of the potential energy of the H_2S flux into dinitrogen fixation. The agricultural importance of this process may have been underestimated due to the difficulty of culturing this organism.

CHAPTER 167

The Family Halomonadaceae

RUSSELL H. VREELAND

The Halomonadaceae (Franzmann et al., 1988) presently contains representatives of two genera, the type genus *Halomonas* and at least one species of the genus *Deleya (D. aesta)* (see Chapter 168). The establishment of the family was suggested because S_{ab} values obtained from 16S rRNA catalogs show that *Halomonas* and *Deleya* are phylogenetically isolated from all other major groups of the gamma subdivision of the Proteobacteria (Stackebrandt et al., 1988 Woese et al., 1985), forming an internally coherent cluster at an S_{ab} of 0.60. Internally, the family contains two subgroups composed of the type species of *Halomonas, H. elongata* and *Halomonas halmophilum* (formerly *Flavobacterium halmophilum*). This cluster forms at an S_{ab} of 0.66. The companion cluster contains *H. subglaciescola* and *D. aesta* and forms at an S_{ab} of 0.67. The position of the other halomonads (Table 1) within the phylogeny is not presently known.

The Genus *Halomonas*

The genus *Halomonas* presently contains four recognized species and two closely related but as yet unnamed strains (Table 1). The type species of the genus is *Halomonas elongata* (ATCC 33173), which has one biotype (ATCC 33174) (Vreeland et al., 1980; Vreeland, 1984; Hebert and Vreeland, 1987). All of the members of this genus are Gram-negative rods that exhibit extreme tolerance to NaCl. These bacteria are rather nonfastidious, being able to grow on a wide variety of sole carbon compounds.

Taxonomy

Vreeland et al. (1980) originally placed these organisms into the family Vibrionaceae based largely upon the fact that the type species produced acid from glucose under anaerobic conditions, indicating some fermentative ability. In addition, the organisms produced numerous curved, highly motile cells. However, since this fermentative ability appeared to be restricted to a single unique situation, the genus was given separate status among the Gram-negative aerobic rods and cocci in the most recent edition of *Bergey's Manual* (Vreeland, 1984). Woese et al. (1985) studied the 165 rRNA and suggested that these bacteria belong to group 3 of the gamma subdivision of the Proteobacteria (Stackebrandt et al., 1988). The genus *Halomonas* possesses seven unique RNA signature sequences, CCUAACUUCG, UUAAUACCCG, AUAAC-

Table 1. Currently recognized species of the genus *Halomonas* and closely related strains.[a]

Species name	Type strain	Biotype	Reference
Halomonas species			
H. elongata[T]	ATCC 33173	ATCC 33174	Vreeland et al., 1980
H. halodurans	ATCC 29686	DSM 30433	Hebert and Vreeland, 1987
H. subglasciescola	UQM 2926	UQM 2927	Franzmann et al., 1987
H. halmophilum	NCMB 1971, ATCC 19717	–	Franzmann et al., 1988
Closely related strains			
Ba1	ATCC 43985	–	Rafaeli-Eshkol, 1968; Huval et al., unpublished observations
Strain NRCC 41227	ATCC 43984		Matheson et al., 1976; Huval et al., unpublished observations

[a]Abbreviations: T, type species of the genus; ATCC, American Type Culture Collection; DSM, Deutsche Sammlung für Microorganismen; UQM, University of Queensland Microbial Culture Collection; NRCC, National Research Council of Canada Culture Collection.

UUG, CCCUCG, UCUCAG, and UUAACG. (Woese et al. 1985) Phylogenetically, the *Halomonas* species and *Deleya aesta* are isolated from the other sublines of the gamma subclass, including such well-defined families as Enterobacteriaceae, Aeromonadaceae, Vibrionaceae, Ectothiorhodopiraceae, and Chromatiaceae (Franzmann et al., 1988). How many other members of the genus *Deleya* also belong to the Halomonadaceae must still be determined. However, in view of the close rRNA similarities known to exist among many of the organisms now contained within the genus *Deleya,* it would seem logical to expect that a significant number will ultimately be shown to belong to the Halomonadaceae.

Habitats

The *Halomonas* were first isolated from a solar saltern on the island of Bonaire in the Netherlands Antilles (Vreeland et al., 1980). The organisms were originally isolated from the saturation ponds and crystallizers in the facility, and were in close association with extremely halophilic archaebacteria. Their extreme salt tolerance and the fact that they are able to survive and prosper with very little NaCl suggests that they are present in virtually any saline environment (Vreeland, 1984).

Halomonas-like strains have been isolated in Canada (J. H. Huval, D. J. Kushner, and R. H. Vreeland, unpublished observations; Matheson et al., 1976), from an American estuary (Hebert and Vreeland, 1987; Rosenberg, 1983), the Dead Sea (J. H. Huval, D. J. Kushner, R. H. Vreeland, unpublished observations; Rafaeli-Eshkol, 1968), manganese nodules in the Pacific Ocean (Hebert and Vreeland, 1987), and from the Antarctic (Franzmann et al., 1988). In addition, several *Halomonas*-like bacteria have been isolated from underground salt formations in the United States (Vreeland and Huval, 1990). As of this writing, no *Halomonas* have been isolated from saline soils, soda lakes, or naturally occurring saline lakes, although several of the moderately halophilic soil isolates described by Quesada et al. (1983) and Ventosa et al. (1982) have properties similar to the *Halomonas.*

Isolation

Due to their wide-ranging biochemical ability, the *Halomonas* are relatively easy to isolate. They can be grown on complex or defined media having a variety of formulations. (See Table 2 and "Laboratory Cultivation"). Because of their salt tolerance, *Halomonas* will grow on these media regardless of the NaCl content used. These organisms have been successfully cultured in NaCl concentrations ranging from 0.016 to 5.5 M in complex media and 0.05 to 3.4 M in defined media (Vreeland et al., 1980; Vreeland and Martin, 1980). The *Halomonas* species actually require the Na^+ cation but not the Cl^- anion, consequently sodium can be supplied as NaBr, $NaNO_3$, Na_2SO_4, Na acetate, or Na glutamate (Vreeland and Martin, 1980; Vreeland et al., 1984). In addition to laboratory media, *Halomonas* strains have been successfully isolated using media prepared by supplementing water taken from the environment. This technique was successfully employed by Franzmann et al. (1987) to isolate *H. subglasciescola.*

While there is no particular technique that can be used to selectively enrich for *Halomonas,* some degree of selection can be obtained by taking advantage of the salt tolerance of the organism. This can be done with relative ease by inoculating samples containing small amounts of NaCl onto media with a high NaCl concentration, or vice versa. The *Halomonas* strains are able to survive sudden NaCl fluctuations of as much as 200-fold (0.2 to 20% w/v NaCl) without experiencing large-scale mortality (Martin et al., 1983), while shocks of this magnitude will quickly kill nonhalotolerant or halophilic bacteria.

Isolation Procedures

In general the *Halomonas* can be isolated using standard bacteriological techniques such as surface inoculation of samples, followed by single colony purification using quadrant streak plates. Some care should be exercised when attempting to isolate these bacteria using plates containing high salt concentrations. First, such plates tend to dry out rapidly, resulting in crystallization of the NaCl. Therefore, high-salt plates should be incubated in high humidity or sealed in plastic bags. Second, plates containing salt concentrations in excess of 25% NaCl have too little free water to support adequate colony growth. Under such conditions, *Halomonas* colonies will be very small and perhaps even transparent, necessitating the use of dissecting microscopes for isolation.

Laboratory Cultivation

Halomonas can be cultivated in any type of glassware, using a rotary or reciprocating shaker to provide oxygenation. Most of the available *Halomonas* strains will grow well on the chem-

Table 2. Recipes for complex media used to grow species of the genus *Halomonas*.[a]

Ingredient	Rosenberg (1984)	Franzmann et al. (1987)	Vreeland et al. (1980)
Casamino acids			7.5
Proteose peptone #3			5.0
Peptone	1.0		
Yeast extract	1.0		1.0
NaCl	0–178.2		80
$MgSO_4 \cdot 7H_2O$			20
K_2HPO_4			0.5
Na citrate			3.0
ASW[b]	26.0		
Agar	15	15	20
pH	7.0	7.0	7.2
Organic lake water (Antarctic)		1 liter	
Distilled water	1 liter		1 liter

[a]All values in grams per liter of final medium.
[b]ASW, artificial sea water.

ically defined medium described by Martin et al. (1983) or Vreeland et al. (1984). Although this medium can be used with virtually any NaCl concentration or carbon source, when low NaCl concentrations are being used growth is more reproducible if the medium is supplemented with 1.0 mM $CaCl_2$ (Vreeland et al., 1984). The basal defined medium has the following composition:

Basal Defined Medium

$MgCl_2 \cdot 6H_2O$	0.026 M
KCl	0.01 M
$(NH_4)_2SO_4$	0.031 M

This basal salts solution is made as a 10× stock for use in both medium and wash solutions. The completed medium also contains:

$CaCl_2$	0.001 M
K_2HPO_4	0.0029 M
Carbon source	0.01 M
NaCl	Variable

The carbon source and NaCl can be added directly to the diluted basal salts solution, the pH adjusted to 7.0 and the solution sterilized by autoclaving. The calcium and phosphate salts must be made as separate solutions (100× is convenient) and sterilized separately from the other components. These latter solutions must not be added until the medium has cooled to room temperature. If they are added to hot medium they will precipitate making the medium unless.

The above medium works well for strains of *H. elongata, H. halodurans,* and Bal, but it must be supplemented with 0.01% yeast extract for NRCC 41227; *H. subglasciecola* and *H. halomophilum* have not yet been grown on this medium. *H. subglasciescola* has been grown on a defined medium described by Franzmann et al. (1987). This defined medium contains:

Medium of Franzmann et al. (1987)

NaCl	80 g
$MgSO_4 \cdot 7H_2O$	9.5 g
KCl	5.0 g
$CaCl_2$	0.2 g
$(NH_4)_2SO_4$	0.1 g
KNO_3	0.1 g
Yeast extract	1.0 g
Distilled water	960 ml

The pH of this solution is adjusted to 7.0 and the solution is sterilized by autoclaving. When the medium is cool, it is supplemented with 20 ml of phosphate solution and 1.0 ml of vitamin mix, which have the following composition:

Phosphate solution

K_2HPO_4	50 mg
KH_2PO_4	50 mg
Distilled water	20 ml

Vitamin mix (filter-sterilized):

Cyanocobalamin	10 mg
Biotin	2.0 mg
Thiamine	10 mg
Ca pantothenate	5.0 mg
Folic acid	2.0 mg
Nicotinamide	5.0 mg
Pyridoxine HCl	10 mg
Distilled water	100 ml

In addition, Franzmann et al. (1987) added 20 ml of Hutner salts solution to the final medium (Staley, 1981). This solution contains:

Distilled water	1 liter
Nitriloacetic acid	10.0 g
$MgSO_4 \cdot 7H_2O$	29.7 g
$CaCl_2 \cdot 2H_2O$	3.3 g
$NaMoO_4 \cdot 2H_2O$	12.7 mg
$FeSO_4 \cdot 2H_2O$	99.0 mg
EDTA*	130 mg
$ZnSO_4 \cdot H_2O$*	550 mg
$FeSO_4 \cdot 7H_2O$*	250 mg
$MnSO_4 \cdot H_2O$*	80 mg

$CuSO_4 \cdot 5H_2O$*	20 mg
$CoCl_2 \cdot 6H_2O$*	10 mg
$Na_2B_4O_7 \cdot 10H_2O$*	9 mg

The nitriloacetic acid must be neturalized with KOH prior to adding the remaining ingredients. In addition, the items marked * can be combined in a separate 1-liter solution (multiply all above weights by 20); then, 50 ml of this solution is added to the Hutner salts.

CULTURE PRESERVATION. *Halomonas* cultures have been stored at 4°C in sealed screw-capped tubes on slants of complex media for up to 3 years without noticeable loss of viability. Cultures can also be stored under liquid nitrogen or frozen using the Protect® system (Pro-Labs, Houston) in which the organisms are adsorbed to ceramic beads.

Halomonas cultures have been lyophilized, although this method is less effective than those listed above. If the cultures are lyophilized, the lyophilization vials should be flame-sealed.

Identification

In order to differentiate between the *Halomonas* and other genera, it is important to consider a wide range of morphological and physiological characteristics. There is no single test that will unequivocally differentiate the *Halomonas* from other eubacteria. Rather, they are differentiated from other genera on the basis of several phenotypic characteristics or by the presence of their rRNA signature sequences. The most useful phenetic characters are extreme salt tolerance, presence of both catalase and oxidase, presence of both lateral and polar flagella on the same cell (giving rise to a helical type of movement), and formation of rather elongated, flexible cells during some portion of their growth cycle (Vreeland et al., 1980; Franzmann et al., 1987; Vreeland and Huval 1990).

The *Halomonas* are Gram-negative and rod-shaped when grown at all salt concentrations. All known species grow in NaCl concentrations from 0.2 to 25% NaCl, depending on the type of medium used. Complex media tend to support growth over a wider range of NaCl concentrations than do defined media. The colonies formed by these organisms are white to yellow in color, although the yellow tends to become more pronounced as the cultures age. *Halomonas* reduces nitrate to nitrite, and most of the species can grow under anaerobic conditions in the presence of nitrate.

H. elongata, H. halodurans, NRCC 41227, and Bal are rather nonfastidious organisms, able to utilize a wide variety of carbon compounds as the sole source of carbon. *H. subglasciescola* tends to have a somewhat more restricted metabolic ability and grows on fewer carbon compounds than do the other *Halomonas* species. The metabolic abilities of *H. halmophilum* have not been tested. The GC content of the *Halomonas* DNA is between 59 to 63 mol% when measured by both buoyant density and thermal denaturation methods.

The fatty acid patterns of several *Halomonas* organisms (*H. elongata, H. halodurans,* NRCC 41227, and Bal) have been studied (J. H. Huval, D. J. Kushner, and R. H. Vreeland, unpublished observations). These four organisms possess dodecanoate ($C_{12:0}$), 3-hydroxydodecanoate (3-OH $C_{12:0}$), *cis*-9-hexadecanoate ($C_{16:1^9}$), hexadecanoate ($C_{16:0}$), heptadecanoate ($C_{17:0}$), 13-methyltetradecanoate (Me + $C_{14:0}$), and *trans*-9-octadecanoate ($C_{18:1^{9t}}$) as their major fatty acids.

Finally, recently completed studies (Hebert and Vreeland, 1987; Huval and Vreeland, unpublished observations) of the effect of NaCl on the phenotype of *Halomonas* species, and salt-tolerant bacteria in general, point to the need to establish optimum growth conditions prior to performing a taxonomic study of these bacteria. During this study, a group of salt-tolerant strains, including *Halomonas,* were subjected to the same testing regime at three different NaCl concentrations. The results showed that, if these bacteria are tested under nonoptimal conditions, identical strains can be mistakenly identified as members of different genera! If, however, the phenotype is established under optimal growth conditions, the similarities between the species are still the same after over 12 years in culture.

Physiology

The physiological properties of salt-tolerant bacteria, including the genus *Halomonas,* has recently been reviewed in some detail (Vreeland, 1987). There are, however, certain unresolved issues that relate to the uniqueness of *Halomonas.* The first issue deals with the mechanisms for osmoregulation in these organisms. The internal ion and amino acid concentration of *H. elongata* following growth in different NaCl concentrations are significantly lower than in its external environment (Vreeland et al., 1983). In short, while the internal Na^+ and glutamate concentrations of the cells do rise in high salts, the increase *is not sufficient* to balance the external osmotic pressures. A similar situation appears to be true for the halotolerant strain NRCC 41227, as well as other salt-tol-

erant organisms (Matheson et al., 1976; Vreeland et al., 1983; Vreeland, 1987).

A significant portion of the physiology of *H. elongata* can be correlated with these cytoplasmic conditions. For instance, in order to utilize electron microscopy to examine the cell walls of cells grown in different NaCl concentrations, it is necessary to use a fixation buffer composed of the ions and amino acid concentrations found by Vreeland et al (1983). Attempts to use buffers not containing NaCl or even to use the growth medium itself cause extensive plasmolysis or shrinkage of the cells. Second, recent work on several enzymes isolated from *Halomonas elongata* has shown that the conditions needed for optimal enzyme activity always correspond to the cytoplasmic conditions predicted by Vreeland et al. (1983) (M. Bylund, J. K. Dyer and E. L. Martin, personal communication). Further, these enzymes are actually inhibited by the KCl or polyol concentrations needed to provide osmotic balance to the cells during growth.

Nuclear magnetic resonance studies with ^{13}C by Wohlfarth et al. (1990) have shown that several *Halomonas* possess high internal concentrations of the novel cyclic amino acid ectoine (1,4,5,6-tetrahydro-2-methyl-4-pyrimidine carbonic acid; Galinski et al., 1985). This unique compound is present in molar quantities in the cell, it is a zwitterion, so it is charge-neutral for the cells, and it cannot be detected by any of the amino, acid detection techniques used by previous workers (Vreeland et al., 1983, 1984). These properties fit the criteria predicted by Vreeland (1987) during his discussion of osmoregulation in halotolerant bacteria and the possible existence of a previously undetected osmoregulatory compound. Thus it would appear that ectoine provides *Halomonas* with effective osmoregulation (Wohlfarth et al., 1990), obviating the need to postulate the existence of a hypoosmotic lifestyle for salt-tolerant bacteria as discussed by Vreeland (1987). The biosynthesis of ectoine in *Halomonas elongata* has been elucidated (Peters et al., 1990).

Overall, knowledge of the physiological properties of *Halomonas* species is rather sketchy at present. This is probably due to the fact that the studies conducted to date have been directed at trying to develop an explanation for the salt tolerance of these bacteria, rather than strict physiological examination. Two members of the *Halomonas—H. elongata* and strain Ba1—have actually been examined rather extensively. However, their close taxonomic relationship was not recognized until very recently, so no comparative studies have been performed as yet. Most of the work performed on *H. elongata* has been directed toward an examination of how various anatomical features are affected by salt. Work on strain Ba1 on the other hand has been aimed at studies of the salt resistance of the cells' respiratory system and bioenergetics.

From an anatomical perspective, *H. elongata* makes a variety of NaCl-related adaptations (Vreeland et al., 1990). Vreeland et al. (1984) have shown that cells growing in low salt (0.05 M) continuously produce a large number of blebs from their cell wall, while in higher salts (1.37 to 3.4 M), these blebs disappear. Further, freeze-fracture patterns show that the walls of cells grown in low salt contain fracture faces which are not present in high-salt-grown cells (Vreeland et al., 1984). These data indicate that the cell walls tighten up and are more stable in high salt than in low. The tightening of the cell wall is also indicated by recent data on the sensitivity of *Halomonas* species to antibiotics. The experiments, conducted in both my and Dr. E. L. Martin's laboratories, show that low-salt-grown *Halomonas* are susceptible to a variety of cytoplasmically active antibiotics (i.e., chloramphenicol, streptomycin, and tetracyclines). Yet, when the same strains are grown in higher salt concentrations (1.37 M and up), they are resistant to these antibacterials. Subsequent analyses using labeled antibiotics indicated that the inhibitory compounds were simply unable to enter the cells.

The peptidoglycan of *H. elongata,* while not changing in response to NaCl, is unique for

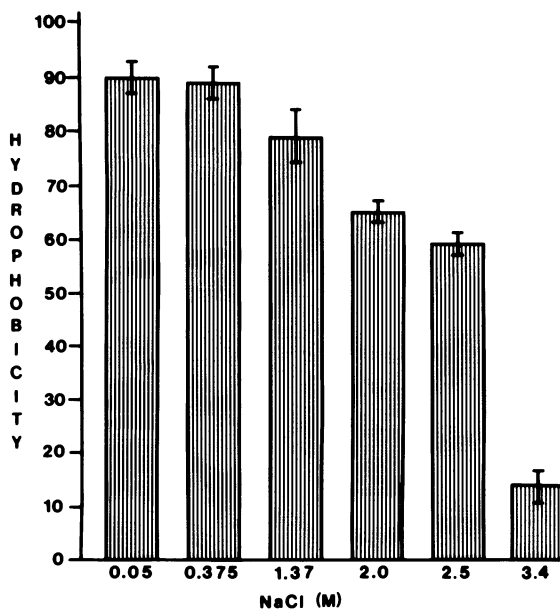

Fig. 1. Differences in the surface hydrophobicity of lag-phase cells of *H. elongata* following growth in different NaCl concentrations. (From Hart and Vreeland, 1988; with permission.)

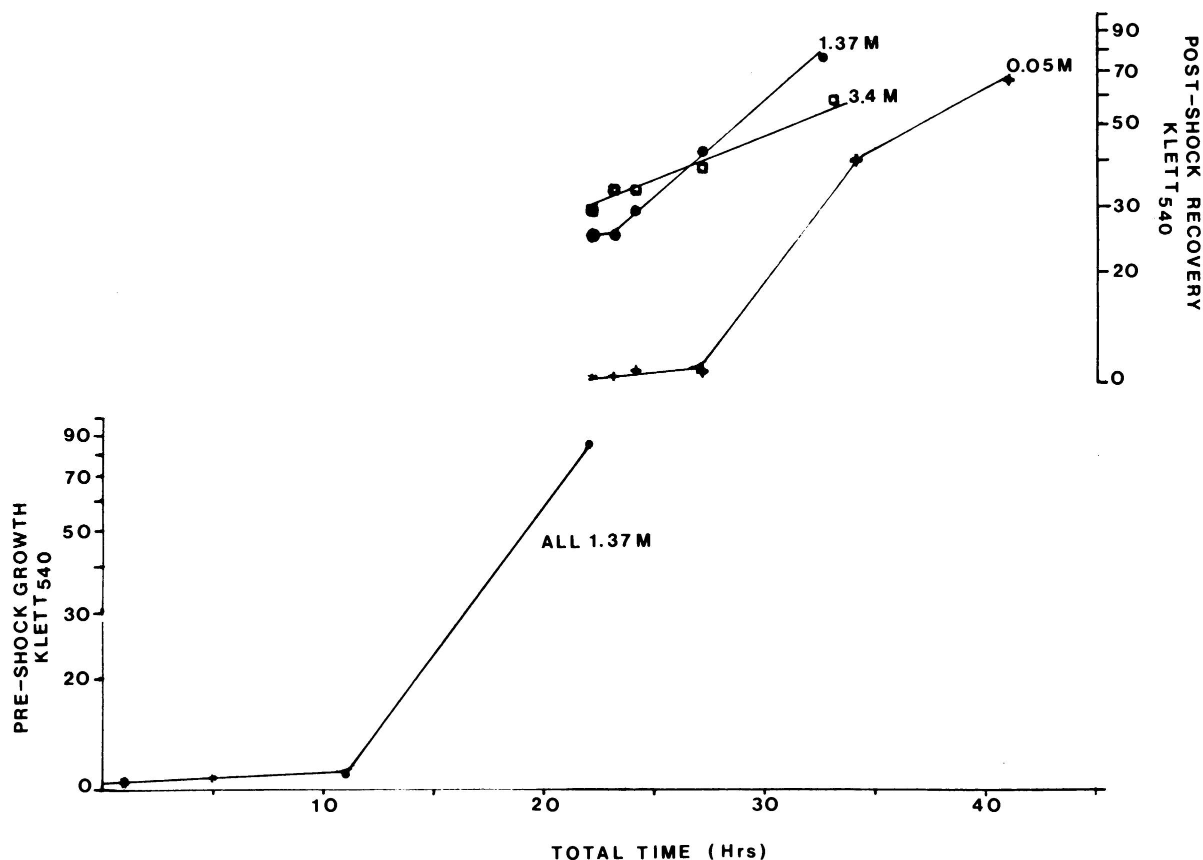

Fig. 2. Growth of *H. elongata* before (pre-shock) and after sudden resuspension (post-shock) in different concentrations of NaCl.

Gram-negative bacteria because it contains a significant amount of leucine. This hydrophobic moiety may be important in the cell wall tightening mentioned above since the strength of hydrophobic bonds increases in high salts. Finally, Vreeland et al. (1984) demonstrated that the phospholipid components were composed of phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and cardiolipin (C). In low-salt-grown cells, PE makes up 50% of the total phospholipid while PG and C represent 42% and 3% respectively. In high-salt-grown cells, the same ratios are PE, 36%; PG, 44%; and C, 13%. This suggests that as the cells adapt to the high salt, the increased amounts of phosphatidyglycerol and cardiolipin would tend to make the cell surface more negatively charged and hydrophilic. This idea has been confirmed by Hart and Vreeland (1988) (Fig. 1), who demonstrated that high-salt-grown cells were less adherent to hexadecane and therefore more hydrophilic than were low-salt-grown cells (Hart and Vreeland, 1988). The pattern of increased hydrophilicity in high salts does not however, appear to be a wide spread phenomena amongst halotolerant bacteria (D. J. Hart and R. H. Vreeland, unpublished observations).

The salt-related adaptations of *H. elgonata* are physiological in nature (Vreeland et al 1990) and require an adaptation period. When *H. elongata* is grown in 1.37 M NaCl, harvested, and then rapidly resuspended in identical media with low 0.05 M or high 3.4 M NaCl, the cells reenter a lag period (Fig. 2). This lag period may last for up to 12 hours, depending upon the size of the NaCl shock. This sudden shock does not cause a severe noticeable loss of viability (Martin et al., 1983), nor does it cause immediately-detectable changes in the cells' surface hydrophobicity (Hart and Vreeland, 1988). This does not mean however, that the cells are not affected. Electron microscopic studies of cells during a salt-induced lag period (Fig. 3) show that the organisms are definitely subjected to severe stresses, during which water loss causes extensive plasmolysis (Fig. 3, top). After approximately 3 hours, the cells are still plasmolyzed but have a more organized appearance (Fig. 3, middle). Toward the end of the lag period (Fig. 3, bottom), the cells once again ex-

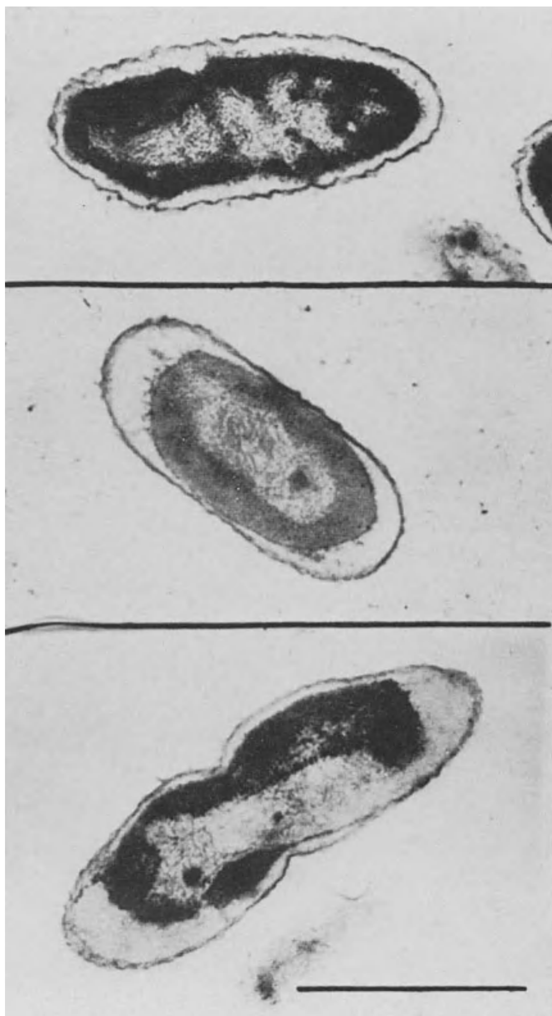

Fig. 3. Plasmolysis stages of cells of *H. elongata* grown in 0.05 M NaCl that have been suddenly exposed to 3.4 M NaCl. Top, immediately after NaCl shock; middle, middle of NaCl-induced lag; bottom, end of NaCl-induced lag just prior to resumption of growth. Bar = 5 μm.

pand to reach the wall, although they still show some level of disruption. During this lag period, cellular protein profiles are also altered and take on the profile of the salt concentration in which the cells are suspended (R. H. Vreeland and R. G. E. Murray, unpublished observations).

The only organism other than *H. elongata* that has been studied at all is strain Ba1. As stated earlier, much of the work on this organism has centered upon the salt resistance of the respiratory chain and on membrane transport systems. As one might expect, the rate of oxygen uptake in Ba1 is significantly affected by the amount of NaCl present in the suspending solution (Rafaeli-Eshkol, 1968). Rafaeli-Eshkol and Avi-Dor (1968) have demonstrated that both choline and its breakdown product, betaine, increased the salt resistance of the respiratory chain. Shkedy-Vinkler and Avi-Dor (1975) have subsequently shown that this stimulatory effect is exerted from outside the cell membrane.

The uptake and extrusion of ions and proline by Ba1 has in fact received some specific attention. Peleg et al. (1980) found that NaCl stimulated the uptake of proline two- to three fold. The K_m and V_{max} data obtained during this study indicated that the same permeases were present in both high- and low-salt-grown cells. Thus the stimulation by Na^+ was not due to an alteration of the cellular transport machinery but to an intrinsic property of the cell permeases.

Recently, Ken-Dror et al. (1986b) demonstrated that the primary site for sodium-mediated respiratory stimulation was the NADH quinone oxidoreductase. In this regard, Bal appears to be similar to *V. alginolyticus.* Further, the sodium transport systems of these bacteria are not linked to the proton motive force. Instead, the electrogenic extrusion of sodium is driven by redox reactions occurring in the respiratory chain (Ken-Dror et al., 1984).

The involvement of Na^+-stimulated respiration in this organism may in fact help Ba1 regulate its internal salt content. Avi-Dor and Schnaiderman (1981) demonstrated that Na^+ stimulation of respiration caused a concomitant increase in the rates of extrusion of Na^+, K^+, and Rb by the cells. Subsequently, Ken-Dror et al. (1986a) showed that the Na^+ pump in these bacteria is not sensitive to uncouplers such as carbonylcyanide-*p*-trifluro-methoxyphenyl-hydrozone, or *N'N'*-dicyclohexyl-carbodimide. As a corollary, Ken-Dror et al. (1986a) noted a distinct volume change in cells adapting to new NaCl concentrations. This suggests that in Bal, and perhaps in *H. elongata* where similar changes have been noted (Vreeland and Martin, 1980), the Na^+ pumps may play a dual role by regulating cell volume (and water?) as well as the cytoplasmic ion content.

Application

At present, *Halomonas species,* like other halophiles, have not been extensively used in biotechnology. Their wide-ranging biochemical ability suggests that they might be useful in the biodegradation of organics in saline areas such as salt marshes, estuaries, and oceans. Some preliminary experiments in the author's laboratory indicate that they may be able to concentrate toxic heavy metals from the environment, particularly in saline regions. Accord-

ingly, *Halomonas* may prove useful for cleaning waste streams contaminated with organic compounds and heavy metals.

CHAPTER 168

The Genus *Deleya*

KAREL KERSTERS

The genus *Deleya,* along with the genus *Halomonas,* comprises the family Halomonadaceae (Franzmann et al., 1988). This family encompasses various halotolerant and moderately halophilic rod-like Gram-negative nonfermentative, chemoorganotrophs that require 75 mM to 200 mM NaCl for growth. However, some *Deleya* strains grow optimally only in media containing at least 7.5% salts (1.3 M NaCl). "Salt-loving" is a universal feature of all strains belonging to the genera *Deleya* and *Halomonas,* and *Deleya* strains have been isolated from marine environments, solar salterns, saline soils, and salted food.

Within the Proteobacteria, the family Halomonadaceae belongs to the rRNA superfamily II sensu De Ley (1978) (see Chapter 100), i.e., part of the gamma subclass sensu Stackebrandt et al. (1988). The genus *Deleya* consists of six validly published species: *D. aesta, D. cupida, D. halophila, D. marina, D. pacifica,* and *D. venusta* (Baumann et al., 1983; Quesada et al., 1984). The genus is both genotypically and phenotypically heterogeneous; the GC content of the DNA ranges from 52 to 68 mol%. Good evidence exists (see below) that these six *Deleya* species, together with the *Halomonas* species, are part of a single evolutionary lineage. DNA-rRNA hybridizations (De Vos et al., 1989, and this chapter) and chemotaxonomic analyses (Akagawa and Yamasato, 1989; Franzmann and Tindall, 1990) revealed that various organisms misnamed as members of the genera *Pseudomonas, Alcaligenes,* and *Achromobacter* are authentic members of the genus *Deleya.* In the text below, misnamed taxa are enclosed by brackets, [ ], and invalid taxon names are in quotation marks," ".

Intra- and Suprageneric Relationships of *Deleya* Species and Allied Bacteria

In a taxonomic study of more than 200 Gram-negative, nonfermentative, marine eubacterial strains, Baumann et al. (1972) assigned peritrichously flagellated strains of four different phena to four new species of the genus *Alcaligenes ([A.] aestus, [A.] cupidus, [A.] pacificus,* and *[A.] venustus,* respectively). Hendrie et al. (1974) considered *[Achromobacter] aquamarinus* (ZoBell and Upham, 1944) as an acceptable species within the genus *Alcaligenes.* However, it is now well established that all these marine *[Alcaligenes]* strains are genotypically and phenotypically very different from the type species *Alcaligenes faecalis.* The latter species belongs, together with some other *Alcaligenes* taxa and all *Bordetella* species, in the family Alcaligenaceae (De Ley et al., 1986) within the rRNA superfamily III (beta subclass) of the Proteobacteria (see also Chapter 100). On the other hand, all marine *[Alcaligenes]* species are members of the rRNA superfamily II (part of the gamma subclass) (De Ley, 1978; Kersters and De Ley, 1980) and are phylogenetically more related to the authentic *Pseudomonas* species (i.e., *Pseudomonas* section I of Palleroni, 1984). In *Bergey's Manual of Systematic Bacteriology,* the marine *[Alcaligenes]* species were therefore considered as species incertae sedis (Kersters and De Ley, 1984). Evolutionary studies on pathways of carbohydrate metabolism (Sawyer et al., 1977) and on patterns of regulation of aspartokinase activities (Baumann and Baumann, 1974), immunological studies on superoxide dismutases and glutamine synthetases (Baumann and Baumann, 1978; DeLong et al., 1984) as well as chemotaxonomic data (Akagawa and Yamasato, 1989; Franzmann and Tindall, 1990), also yielded strong evidence that the peritrichously flagellated marine *[Alcaligenes]* species constitute a single evolutionary lineage, together with the polarly flagellated species *[Pseudomonas] marina.* This group of bacteria is unrelated to the authentic *Alcaligenes* species and is also distinct from the fluorescent pseudomonads, which are their close relatives. On the basis of all these arguments Baumann et al. (1983) proposed a new genus called *Deleya* to accommodate the marine *[Alcaligenes]* species together with *[P.] marina. D. halophila* was de-

scribed by Quesada et al. (1984) for strains isolated from hypersaline soils in Spain. On the basis of cellular fatty acid profiles, biochemical and physiological features and DNA-DNA hybridizations, Akagawa and Yamasato (1989) proposed that *[Alcaligenes] aquamarinus* was synonymous with *Deleya aesta* and *Deleya aquamarina* be recognized as the type species of the genus *Deleya*. DNA-rRNA hybridizations were performed in order to unravel the inter- and intrageneric relationships of the species of the genus *Deleya*. Fig. 1 summarizes our present knowledge of the position of various taxa and strains on the *Deleya* rRNA branch. All hybridizations were carried out versus labeled rRNA of *Deleya aquamarina* NCMB 557^T (the former *[Alcaligenes] aquamarinus*). The branching point of the genus *Halomonas* at a Tm(e) value of 76°C agrees very well with data from 16S rRNA cataloging (Franzmann et al., 1988). With the latter method, four halophilic species, *Halomonas elongata, H. subglaciescola, H. halmophila* (ex *[Flavobacterium] halmophilum;* Franzmann et al., 1988) and *D. aesta,* form a fairly coherent cluster phylogenetically, with a lowest branching at S_{AB} 0.60 (Franzmann et al., 1988). In the Tm(e) dendrograms, the family Halomonadaceae at 70°C is closest to the authentic *Pseudomonas* group and to *Marinomonas* (Fig. 1).

On the basis of Tm(e) values of DNA-rRNA hybrids versus *D. aquamarina* NCMB 557^T, two groups of strains can be recognized on the *Deleya* rRNA branch (Fig. 1):

1. Strains located in the top 3°C ΔTm(e), including *D. aquamarina* (the type species), *D. aesta* (synonym of *D. aquamarina*), *D. venusta, [A. faecalis]* subsp. *homari* isolated from lobsters, *"[P.] bathycetes," "Agarbacterium*

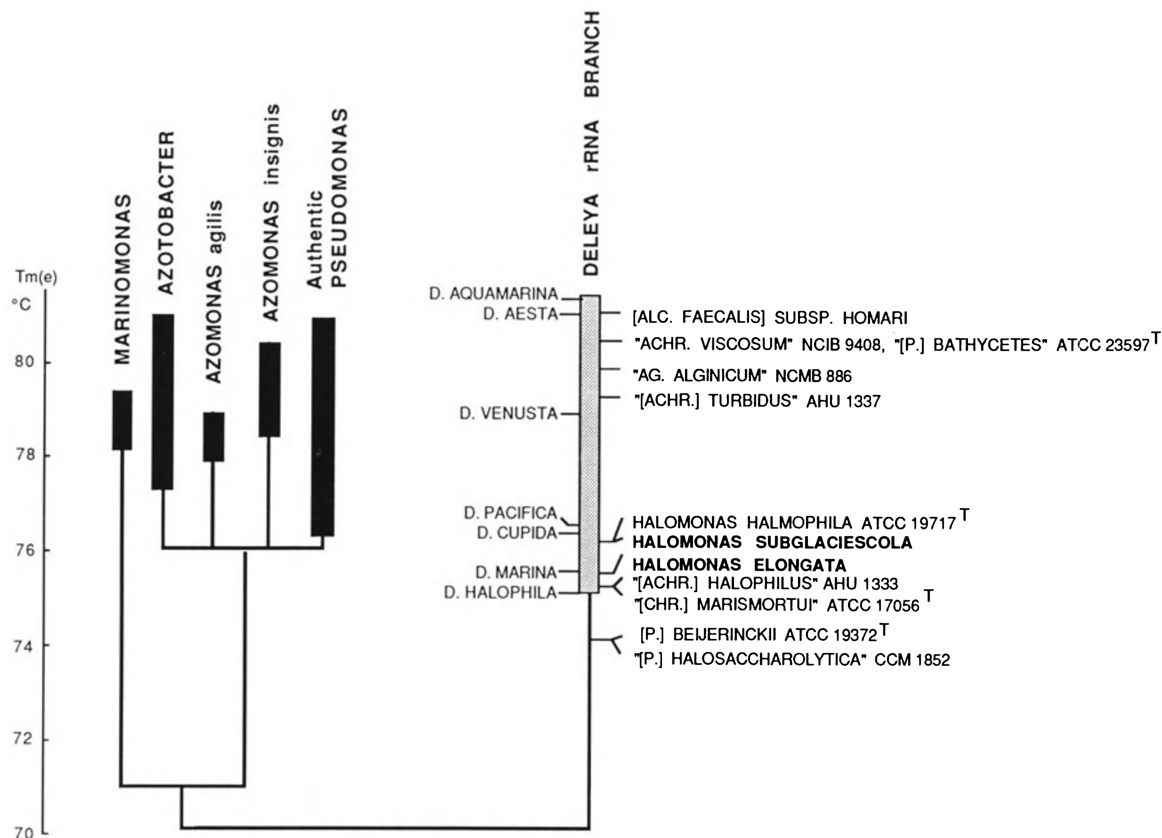

Fig. 1. Simplified rRNA cistron-similarity dendrogram of *Deleya* and related taxa. Tm(e) is the temperature at which 50% of the DNA-rRNA hybrid is eluted. The black bars at the top of the branches represent the ranges of the Tm(e) values of the reference taxa. The position of all validly published *Deleya* species is indicated at the left side of the *Deleya* rRNA branch, whereas three species of *Halomonas* and various generically misnamed taxa and strains are on the right side of this rRNA branch. Abbreviations: ACHR., *Achromobacter,* AG., *"Agarbacterium";* ALC., *Alcaligenes;* CHR., *Chromobacterium;* D., *Deleya;* F., *Flavobacterium;* P., *Pseudomonas.* The position of this group of bacteria within rRNA superfamily II (part of the gamma subclass) of the Proteobacteria can be found in Fig. 5 of Chapter 100. Tm(e) values were taken from De Vos and De Ley (1983), De Vos et al. (1989), Van Landschoot and De Ley (1983), and P. Segers (unpublished observations).

alginicum," and some misnamed *Achromobacter* strains; all these strains possess DNA with a GC content of 52–61 mol%. Akagawa and Yamasato (1989) found that *[A. faecalis]* subsp. *homari* is highly similar to *D. aquamarina.* When more data on their phenotype and genotype will be available, the other misnamed strains will very likely be allocated to the genus *Deleya* either as synonyms of existing species or as separate species.

2. Strains located at the bottom 5–7°C ΔTm(e), including *D. cupida, D. halophila, D. marina, D. pacifica, H. elongata* (type species of the genus *Halomonas*), *H. subglaciescola,* and various misnamed strains (see Fig. 1); the GC content of their DNA ranges from 59 to 68 mol%. More detailed rRNA comparisons are required to elucidate the exact relationships between the different members of this group. In particular, the relationships among this group of strains and all members of the genus *Halomonas* need to be investigated.

Generically Misnamed Taxa and Strains of the *Deleya* rRNA Branch

Genomic and phenotypic studies have indicated that a great number of generically misnamed taxa and strains are authentic members of the *Deleya* rRNA branch (P. Segers and K. Kersters, unpublished observations). The position of these taxa and individual strains is indicated in Fig. 1; additional information on the habitats of these organisms can be found in Table 1.

"[Pseudomonas] bathycetes" originates from deep-sea sediments (Quigley and Colwell, 1968); *"Agarbacterium alginicum"* was isolated from the surface of brown algae and *[Alcaligenes faecalis]* subsp. *homari* is pathogenic for lobsters (Austin et al., 1981). The immunological data of DeLong et al. (1984) on glutamine synthetases indicate that *[Alcaligenes faecalis]* subsp. *homari* is not related to *Alcaligenes,* but it is highly similar to *Deleya.* DNA-rRNA hybridizations (Fig. 1) show that these taxa, together with strains *"[Achr.] viscosum"* NCIB 9408 and *"[Achr.] turbidus"* AHU 1337, belong to the genus *Deleya.* Some misnamed *[Pseudomonas]* and *[Achromobacter]* strains were isolated from salted food, whereas *"[Chromobacterium] marismortui"* originates from water of the Dead Sea.

Intrageneric Relationships of Species of *Deleya*

Data on the finer internal taxonomic relationships of the genus *Deleya* are scarce. Most of the well-established *Deleya* species have been delineated on the basis of numerical taxonomic studies of phenotypic features (Baumann et al., 1972; Marquez et al., 1987; Quesada et al., 1983). DNA-DNA hybridizations revealed that the following taxa are highly related (more than 75% homology): *D. aesta, D. aquamarina,* the lobster isolates (*[A. faecalis]* subsp. *homari*), and *"[Achromobacter] viscosum"* strain NCIB 9408 (P. Segers and B. Hoste, unpublished observations). They are all located in the top 1°C ΔTm(e) of the *Deleya* rRNA branch (Fig. 1), and the GC content of their DNA ranges from 57 to 61 mol%. No significant DNA homologies were detected between *D. aquamarina* and the type strains of the other *Deleya* species (Akagawa and Yamasato, 1989).

Habitats

One common characteristic of all the strains belonging to the *Deleya* rRNA branch is their isolation from salt-containing materials. Table 1 gives an overview of the various habitats where strains of the *Deleya* rRNA branch have been found. Many *Deleya* strains are from marine origin and grow optimally at salt concentrations of 0.4% to 1.2% NaCl (Baumann et al., 1983), but others such as *D. halophila* are moderate halophiles because they display optimal growth at 7.5% NaCl (Ferrer et al., 1987). *D. halophila* strains were usually isolated from hypersaline soils and solar salterns (Quesada et al., 1982; 1983). *Deleya* strains have also been isolated from ponds of an inland Spanish saltern which was supplied with water from a subterranean inland saline well (del Moral et al., 1987, 1988).

Some strains—previously assigned to the ill-defined genus *Achromobacter*—were isolated from various salt-containing foods (Table 1). Austin et al. (1981) isolated *[Alcaligenes faecalis]* subsp. *homari* strains from the hemolymph of moribund and dead lobsters. These lobsters were reared in tanks containing seawater; their death occurred after the water in the tanks accidently reached a temperature of 26°C for three days. The isolated bacteria were found to be pathogenic for lobsters. It has been proven (see above) that three of these isolates (including the type strain) were phenotypically and genomically highly related to *D. aesta* (type species) and *D. aquamarina* (Fig. 1).

Isolation

The following media and isolation procedures were used by several authors for the isolation of strains belonging to the *Deleya* rRNA branch.

More details can be found in Baumann and Baumann (1981).

Media For the Isolation of *Deleya* Species

Artificial Seawater (ASW) (MacLeod, 1968)

NaCl	400 mM
$MgSO_4 \cdot 7H_2O$	100 mM
KCl	20 mM
$CaCl_2 \cdot 2H_2O$	20 mM

Dissolve the salts separately in distilled water and combine.

Basal Medium (BM)

TrisHCl (pH 7.5)	50 or 100 mM
NH_4Cl	19 mM
$K_2HPO_4 \cdot 3H_2O$	0.33 mM
$FeSO_4 \cdot 7H_2O$	0.1 mM
Half-strength ASW	

The carbon source is usually supplied at a concentration of 0.1–0.2% (w/v for solids and v/v for liquids). Labile compounds should be filter-sterilized.

Basal Medium Agar (BMA)

Prepare equal volumes of double-strength BM and double-strength agar in distilled water (40 g agar per liter), sterilize by autoclaving, and combine before pouring plates. Carbon and energy sources can be added to double-strength BM prior to autoclaving. Labile compounds should be filter-sterilized and added to BMA, which has been cooled to about 42°C prior to pouring of plates.

Marine Agar (MA)

Marine agar 2216E is available from Difco Laboratories, Detroit, Mich., USA.

Medium for Moderately Halophilic Bacteria (MH Medium) (Quesada et al., 1983)

5 g proteose peptone, 10 g yeast extract, and 1 g glucose are dissolved in 10% (w/v) marine salts solution. Marine salts solution contains, in one liter of distilled water:

NaCl	81 g
$MgCl_2 \cdot 6H_2O$	7 g
$MgSO_4 \cdot 7H_2O$	9.6 g
$CaCl_2 \cdot 2H_2O$	0.36 g
KCl	2 g
$NaHCO_3$	0.06 g
NaBr	0.026 g

The pH is adjusted to 7.2 with 1 M KOH, and agar (20 g/liter) is added.

MH medium with e.g., 20% marine salts, is prepared by doubling the amount of inorganic salts in the above medium. Lowering the concentration of Mg^{2+} (to 1 g $MgSO_4 \cdot 7H_2O$/liter) increases the selectivity of the MH medium for moderate halophiles, because growth of extreme halophiles is suppressed (Marquez et al., 1987).

Isolation Procedures

ISOLATION FROM SEAWATER (BAUMANN ET AL., 1972). The enrichment culture methods have been described by Baumann et al. (1971) and Baumann and Baumann (1981). Various amino acids (L-lysine, L-glutamate, L-histidine), amines (e.g., histamine) and organic acids (glycolate, *o*-hydroxybenzoate) have been used as sole carbon source for enrichment of *Deleya* strains (Baumann et al., 1972). The strains are purified on BMA containing 0.1% of the same carbon compound as used in the enrichment, or on BMA containing 0.1% Na succinate, 0.1% Na lactate and 0.1% Na acetate.

For direct isolation, samples of sea water are filtered through 0.22- or 0.45-μm pore size nitrocellulose filters, which are placed in petri dishes containing Marine Agar or Basal Medium Agar with 0.1% organic substrates (e.g., *meso*-inositol, D-galactose, adipate, L-valine, etc.) (Baumann et al., 1972).

ISOLATION FROM HYPERSALINE SOILS (QUESADA ET AL., 1983, 1984). *D. halophila* was isolated from hypersaline soils in Spain by suspending one soil sample in 10 ml of 10% marine salts solution (see above); 10-fold dilutions were made (always keeping the same balanced salt concentrations), and 0.1 ml of each dilution was plated on MH medium.

ISOLATION FROM THE HEMOLYMPH OF LOBSTERS (AUSTIN ET AL., 1981). Drops of aseptically collected hemolymph from moribund lobsters *(Homarus americanus)* were inoculated on Marine Agar medium for the isolation of *[Alcaligenes faecalis]* subsp. *homari.* Plates were incubated at 19°C for 7 days.

Preservation of Cultures

Baumann and Baumann (1981) recommended maintenance of *Deleya* strains on MA slants. After each monthly transfer, cultures were allowed to grow at 25°C for 1–2 days and stored at 18°C. Quesada et al. (1983) maintained their strains on slants of MH medium. We maintained *Deleya* strains at 4°C on slants of the following medium: 1% peptone, 0.8% beef extract powder, 3% NaCl, and agar in tap water. Lyophilization is recommended for long-term preservation.

Identification

The range of GC content of the DNAs of members of the genus *Deleya* is very broad (52–68 mol%) and is reflected in 1) the fairly great span of ΔTm(e) values of their DNA-rRNA hybrids versus labeled rRNA of *D. aquamarina* (see Fig. 1); and 2) considerable phenotypic and geno-

Table 1. Sources and geographical distribution of taxa and strains belonging to the *Deleya* rRNA branch.

Species or strain[a]	Source of isolation	Geographical origin	Reference
Deleya aesta	Seawater (at 100–600 m deep)	Hawaii, USA	Baumann et al. (1972)
Deleya aquamarina (ex *[Alcaligenes] aquamarinus*)	Seawater		ZoBell and Upham (1944)
Deleya cupida	Seawater (surface)	Hawaii, USA	Baumann et al. (1972)
Deleya halophila	Hypersaline soil	Spain	Quesada et al. (1983, 1984)
Deleya marina	Seawater (surface)	Hawaii, USA	Baumann et al. (1972)
Deleya pacifica	Seawater (surface)	Hawaii, USA	Baumann et al. (1972)
Deleya venusta	Seawater (surface)	Hawaii, USA	Baumann et al. (1972)
Halomonas elongata	Solar saltern	Netherlands Antilles	Vreeland et al. (1980)
Halomonas subglaciescola	Hypersaline lake	Organic Lake, Antarctica	Franzmann et al. (1987)
Halomonas halmophila ATCC 19717^T (ex *"[Flavobacterium] halmophilum"*)	Hypersaline lake	Dead Sea, Israel	Elazari-Volcani (1940)
"[Achromobacter] halophilus" AHU 1333	Salted salmon	Japan	Bergey et al. (1930)
"[Achromobacter] turbidus" AHU 1337	Salted eggplant	Japan	
"[Achromobacter] viscosum" NCIB 9408			Bergey et al. (1925)
"Agarbacterium alginicum" NCMB 886	Mass of brown algae	Georgia, USA	Adams et al. (1961), Eller and Payne (1960)
[Alcaligenes faecalis] subsp. *homari*	Hemolymph of moribund lobsters	Mass., USA	Austin et al. (1981)
"[Chromobacterium] marismortui" ATCC 17056^T	Hypersaline lake	Dead Sea, Israel	Elazari-Volcani (1940)
"[Pseudomonas] bathycetes" ATCC 23597^T	Deep-sea sediments (at > 9,000 m)	Pacific Ocean	Quigley and Colwell (1968)
[Pseudomonas] beijerinckii ATCC 19372^T	Salted French beans		Hof (1935), Breed et al. (1957)
"[Pseudomonas] halosaccharolytica" CCM 2851	Rock salt	Japan?	Ohno et al. (1979), Yamada and Shiio (1953)

[a]Abbreviations: AHU, Department of Agricultural Chemistry, Faculty of Agriculture, Hokkaido University, Sapporo, Japan; ATCC, American Type Culture Collection, Rockville, Md., USA; CCM, Czechoslovak Collection of Microorganisms, Brno, Czechoslovakia; NCIB, National Collection of Industrial Bacteria, Torry Research Station, Aberdeen, Scotland; NCMB, National Collection of Marine Bacteria, Torry Research Station, Aberdeen, Scotland.

typic heterogeneity within the genus. An important common feature for all *Deleya* species is their absolute requirement for at least 75–200 mM NaCl for optimal growth. This feature differentiates *Deleya* from terrestrial *Pseudomonas* and *Alcaligenes* species (Baumann and Baumann, 1981).

Deleya species can be differentiated from other marine eubacteria by four important features: absence of fermentation of D-glucose, accumulation of poly-β-hydroxybutyrate, peritrichously flagellated cells (except *D. marina*), and by the parameters of their DNA-rRNA hybrids. Differentiation of *Deleya* from *Halomonas* spe-

cies is difficult because no comprehensive phenotypic or genomic studies have been performed using standardized procedures. Species of *Deleya* can best be differentiated from each other by carbon assimilation tests (Table 2).

Deleya strains are Gram-negative straight rods, 0.8 to 1.1 μm wide and 1.5 to 3.0 μm long. They accumulate poly-β-hydroxybutyrate as an intracellular reserve product. Involution forms may occur in old cultures or under adverse conditions of cultivation. Endospores are not formed. Motile by four to twelve peritrichous flagella, except *D. marina* which is motile by two to five polar flagella. They are obligately aerobic, possessing a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Colonies are nonpigmented. They do not denitrify or fix molecular nitrogen and do not grow chemolithotrophically with hydrogen gas and CO_2. All species are chemoorganotrophs able to grow on a mineral medium containing sea water base, D-glucose and NH_4Cl. Na^+ is an absolute requirement for all species; the minimal concentration for optimal growth ranges from 75 to 200 mM (or even 1.3 M for *D. halophila*). All species utilize acetate, succinate, DL-β-hydroxybutyrate, DL-lactate, glycerol, and L-α-alanine. All *Deleya* (and *Halomonas*) strains contain ubiquinone 9 as the major respiratory quinone with traces of Q8, and 16:1 *cis* 9, 16:0, 17:0 cyclo, 18:1 and 19:1 cyclo 11–12 as major fatty acids (Franzmann and Tindall, 1990). The GC content of the DNA ranges from 52 to 68 mol%. The type species is *D. aquamarina* (type strain ATCC 14400, NCMB 557, DSM 30161, LMG 2853, IAM 12550).

Table 2 lists the diagnostic features for the differentiation of species of the genus *Deleya*. The original publications should be consulted for full descriptions (see references in footnotes of Table 2). The type strains of the species are also listed at the bottom of Table 2. Akagawa and Yamasato (1989) give a few other biochemical and physiological features to differentiate the type strains of the *Deleya* species.

Physiological Properties

Species of *Deleya* have no organic growth factor requirements and utilize a great variety of organic compounds as sole sources of carbon and energy. They can assimilate pentoses, hexoses, disaccharides, sugar alcohols, sugar acids, fatty acids, dicarboxylic acids, tricarboxylic acid cycle intermediates, amino acids, amines, and some aromatic substances. The latter compounds are metabolized via the β-ketoadipate pathway involving the *ortho*-cleavage of diphenolic compounds (Baumann et al., 1972). D-Glucose and D-fructose are metabolized via the Entner-Doudoroff pathway (Baumann and Baumann, 1973; De Ley et al., 1970; Sawyer et al., 1977).

Growth characteristics of the type strain of *Deleya halophila* have been studied in more detail by the research group of A. Ramos-Cormanzana. *D. halophila* displays a specific requirement for Na^+, which cannot be replaced by other cations (Quesada et al., 1987). Optimal growth of *D. halophila* occurs at 7.5% total salts, when incubated at 32 or 42°C. However, when the incubation temperature is lowered to 22°C, its optimal growth occurs at 5% total salts. *D. halophila* is able to grow at salt concentrations varying from 2.5% to 25% (Ferrer et al., 1987). Such characteristics are typical of moderately halophilic bacteria isolated from hypersaline soils, where salt content can vary considerably in space and time.

Investigations have been performed on the effects of growth temperature and salt concentration on the cellular fatty acid composition of *D. halophila*, *"[Pseudomonas] halosaccharolytica,"* and *Halomonas halmophila* (ex *[Flavobacterium] halmophilum;* Franzmann et al., 1988) (Monteoliva-Sanchez and Ramos-Cormenzana, 1986, 1987; Monteoliva-Sanchez et al., 1988; Ohno et al., 1979). Increasing the salt concentration in the medium resulted in an increase of cyclopropanoic acids with a concomitant decrease in the monounsaturated fatty acids. *[Pseudomonas] beijerinckii* and *Halomonas halmophila* mainly contained ubiquinone Q-9 (Collins et al., 1981).

"Agarbacterium alginicum" hydrolyzes agar, a property which can be lost upon continued laboratory culture. The alginase of this bacterium has been studied in some detail (Williams and Eagon, 1962).

Calvo et al. (1988) were the first authors to report the existence of bacteriophages active against moderately halophilic bacteria. They demonstrated the existence of temperate phages in 52% of their *D. halophila* strains. Phage F9–11 (isolated from *D. halophila* strain F9–11) was studied in more detail and possessed an isometric head and a noncontractile tail. The phage could replicate at a wide range of marine salt concentrations, from 2.5% to 15%. Its stability seemed to be influenced by the osmolarity of the medium rather than by the NaCl concentration (Calvo et al., 1988).

CHAPTER 169

The Genus *Frateuria*

JEAN SWINGS

The genus *Frateuria* comprises bacteria formerly classified as *Acetobacter aurantius* (Kondo and Ameyama, 1958). These are strains isolated from the plant *Lilium auratum,* which are brown, pigment-producing, polarly-flagellated, acetic acid-like bacteria. They were thought by Asai (1968) to be an evolutionary "intermediate" between *Pseudomonas* and *Gluconobacter,* and the position of these "intermediate" strains was discussed in a separate chapter. Within the acetic acid bacteria, their assignment either to *Gluconobacter* or *Acetobacter* has been difficult (Swings et al., 1980; Yamada et al., 1976). Since DNA-rRNA hybridization studies showed that these isolates are quite removed from the family *Acetobacteraceae,* the new genus *Frateuria* was created for them (Swings et al., 1980). *Frateuria* belongs in the Proteobacteria in subclass gamma sensu Stackebrandt et al. (1988) (see Chapter 100). In *Bergey's Manual of Systematic Bacteriology, Frateuria* was treated as a separate genus (Swings et al., 1984).

Habitats

Only two habitats of *Frateuria* are known, *Lilium auratum* (Kondo and Ameyama, 1958) and the fruit of the raspberry *Rubus parvifolius* (Yamada et al., 1976). Only 14 strains are known and described in the literature.

Isolation

Isolation from Raspberries *(Rubus parvifolius)* (Yamada et al., 1976)

> The picked raspberries were incubated at 30°C in a medium containing glucose, 10 g; ethanol, 5 ml; yeast extract, 5 g; peptone, 3 g; and acetic acid 0.3 ml, per liter of 10% potato extract adjusted to pH 4.5. After the enrichment culture, typical acetic acid-like bacteria were selected on $CaCO_3$ plates, (see Chapter 111), where they dissolved the calcium carbonate.

Identification

As *Frateuria* possesses the phenotypical features of the family Acetobacteraceae (see Chapter 111), it was initially classified as an acetic acid bacterium. The minimal phenotypic description is as follows: Gram-negative, strictly aerobic, polarly flagellated rods when motile, requiring no growth factors, producing a water-soluble brown pigment on glucose-yeast extract-$CaCO_3$ agar, producing ubiquinone (menaquinone) with eight isoprenoid units (MK-8) and H_2S, able to grow at pH 3.6 and on Frateur's Hoyer mannitol medium; producing acid from ethanol, glucose, and xylose; lacking oxidase and gelatinase; not reducing nitrates; not hydrolyzing starch.

Frateuria presents another example of the unreliability of using solely phenotypic characterizations at the inter- and suprageneric levels in bacteriology. The production of acetic acid from ethanol and the growth at pH 3.6 suggest a relationship with the acetic acid bacteria which is not justified by more detailed phenotyphic analysis. Additional methods are necessary in order to identify the genus *Frateuria* unambiguously, e.g., the types of ubiquinones formed, cellular fatty acid composition and DNA-rRNA hybridization analysis. *Frateuria* typically produces the ubiquinone MK-8, whereas *Gluconobacter* produces MK-10 and *Acetobacter* MK-9 or MK-10 (Yamada et al., 1976). *Frateuria* has an unusual fatty acid profile, consisting of the iso-branched-chain acid of $C_{15:0}$, which is different from those of *Acetobacter* or *Gluconobacter* (Yamada et al., 1981) and which is more closely related to *Xanthomonas maltophilia.* The application of DNA-rRNA hybridizations constituted the ultimate proof that *Frateuria* is not related to the acetic acid bacteria (subclass alpha of the Proteobacteria), but constituted a separate genus within subclass gamma. The acid-tolerant, nitrogen-fixing bacterium isolates from sugarcane resembled *Frateuria* by its production of a brown diffusible pigment and of H_2S, its lack of growth factor requirements, and

its growth on 30% glucose (Cavalcante and Döbereiner, 1988), but it could be assigned unambiguously to the genus *Acetobacter* by DNA-rRNA hybridizations (Gillis et al., 1989) (see Chapter 111). The genus *Frateuria* currently comprises only one species, *Frateuria aurantia* (Swings et al., 1980, 1984).

Physiological Properties

Good growth occurs on glucose-yeast extract-$CaCO_3$ agar and in beer wort. In peptone broth, yeast extract broth, and Hoyer's mannitol medium, growth is faint. In Hoyer's medium, NH_4^+ is used as a nitrogen source in the presence of mannitol as a carbon source. All *Frateuria* strains grow well on casamino acids, in contrast with the acetic acid bacteria. Growth factors are not required.

The oxidation of lactate was demonstrated on oxydograms. In an oxydogram (Frateur, 1950), several strains are streaked on 2% agar plus 2% Ca lactate. Lactate oxidation is shown by the precipitation of $CaCO_3$. The ketogenic activity on polyalcohols was weak or doubtful. From glucose, 2-keto-, and 2,5-diketogluconic acids were formed but not 5-ketogluconic acid. The production of acid from D-glucose and D-xylose was marked, and the pH always dropped below 4. Ethanol, glycerol, D-arabinose, D-ribose, D-fructose, D-galactose, and D-mannose were also acidified (Swings et al., 1980). Ethanol concentrations above 5% were not tolerated. The majority of the strains still grew in 25 to 30% glucose concentrations, and, in this respect, they also resemble the acetic acid bacteria.

The Family Chromatiaceae

NORBERT PFENNIG and HANS G. TRÜPER

The Family Chromatiaceae (purple sulfur bacteria) comprises physiologically and genetically closely related species and genera (Fowler et al., 1984) that carry out anoxygenic photosynthesis. The most important and selective environmental factors in their aquatic habitats are anoxic conditions, the presence of hydrogen sulfide, and illumination. The only other groups of phototrophic bacteria that thrive under similar environmental conditions are the Ectothiorhodospiraceae (see Chapter 171) and the Chlorobiaceae (green sulfur bacteria; see Chapter 195). Because they live in the same types of habitats, some discussion of the Chlorobiaceae must be included in this chapter. However, since the Chlorobiaceae are not phylogenetically related to the other anoxygenic phototrophic bacteria (Stackebrandt et al., 1984), they are treated in a separate chapter, Chapter 195.

Ever since the first experimental studies of purple sulfur bacteria by Winogradsky (1888), it has been customary to grow these bacteria in the laboratory in raw enrichment cultures. These well-known Winogradsky columns are set up in tall glass cylinders with plant residues, $CaSO_4$, and anaerobic mud and water of a natural habitat and incubated in dim light at a north window. The preparation and development, as well as the advantages and limitations, of the different types of such long-lasting raw cultures are well described by Winogradsky (1888), Buder (1915), Schrammeck (1934), Schlegel and Pfennig (1961), and van Niel (1971). These raw-culture methods are not described in the present article, since nearly all the different genera and species of purple and green sulfur bacteria that thrive in Winogradsky columns can be grown and isolated today by direct methods in synthetic media.

The first rational enrichment and isolation procedures for certain species of purple and green sulfur bacteria were developed by van Niel (1931). Further attempts to grow in pure culture the large-celled purple sulfur bacteria *Chromatium okenii* and *Thiospirillum jenense* led to the elaboration of another synthetic medium that contains vitamin B_{12} (Pfennig, 1965; Pfennig and Lippert, 1966; also given by van Niel, 1971). With slight modification, this culture medium (see below, medium 1) provides rather nonselective growth conditions and allows the cultivation of most purple and green sulfur bacteria that occur in freshwater, estuarine, and marine habitats. Therefore, this medium will be described first in the present article. In addition, a second culture medium is given (medium 2; Biebl and Pfennig, 1978), which is more simple to prepare and which allows the cultivation of most common green and purple sulfur bacteria. A number of other media that were successfully used for the cultivation of certain species of phototrophic bacteria are described by Bose (1963).

Habitats

Freshwater Habitats

Pink to purple-red mass accumulations of purple sulfur bacteria in the water and on the mud of shallow, freshwater ponds or ditches were described during the last century by Ehrenberg (1838), Lankester (1873), Cohn (1875), Kützing (1883), Winogradsky (1888), and Miyoshi (1897). Winogradsky's publications marked a turning point; he gave the most comprehensive species and genus descriptions of the different morphological types of purple sulfur bacteria that he observed in samples from nature and raw cultures. As a result, later investigators of visible enrichments in natural habitats performed more detailed studies and used Winogradski's descriptions for identification (e.g., Bavendamm, 1924; Kolkwitz, 1909; Lauterborn, 1915; Molisch, 1907; Strzeszewski, 1913; Szafer, 1910). In his monograph on the colorless and purple sulfur bacteria, Bavendamm (1924) reviewed the older literature and gave, together with his own observations, the first detailed ac-

count on their ecology. More recent comprehensive reviews of the literature on the distribution of green and purple sulfur bacteria in nature have been given by Kondratieva (1965); Gorlenko et al. (1983); van Gemerden and Beeftink (1983); Tindall and Grant (1986); Lindholm (1987); and Pfennig (1989).

Sulfur springs create aquatic habitats with relatively constant sulfide concentrations (Winogradsky, 1888). Szafer (1910) and Strzeszewski (1913) in Poland first reported visible mass accumulations of green and purple sulfur bacteria in the effluents of such habitats exposed to light (40–100 mg H_2S/liter). Green sulfur bacteria, at that time often described as yellowish green forms of the cyanobacteria, occurred as the predominant forms at highest sulfide concentrations, followed downstream by different species of purple sulfur bacteria. Miyoshi (1897) reported the presence of purple sulfur bacteria in warm sulfur springs (35–44°C) in Japan. While growth temperatures up to 43°C are not uncommon for *Chromatium vinosum* strains, the optimum growth temperature of 48–50°C with *C. tepidum* is exceptional. This first moderately thermophilic purple sulfur bacterium was isolated from carbonaceous sinter in the Stygian Springs of Yellowstone Park (Madigan, 1986). No purple sulfur bacteria that tolerate higher temperatures of hot sulfur springs have been reported.

Visible accumulations of phototrophic sulfur bacteria occur temporarily in the anaerobic parts of small, freshwater environments, such as shallow ditches, ponds, and stagnant bodies of water in forests, botanical gardens, or near lakes or rivers. In such habitats, development usually proceeds during summer or fall when hydrogen sulfide is formed by sulfate-reducing bacteria from decaying plant material or from organic pollution. Pink to purple-red or yellowish-green blooms are often detected within the water itself or in the form of more-or-less profuse patches that cover the upper or lower side of dead leaves or the mud surface. Even if no accumulations are apparent, enrichment cultures usually yield positive results when hydrogen sulfide is present in the sediment (Bavendamm, 1924; Kaiser, 1966; Pfennig, 1967).

Certainly the largest and most significant freshwater environments of the phototrophic bacteria are lakes, because these habitats have remained more constant over longer periods of time. In these habitats, the blooms of green and purple sulfur bacteria are not directly visible; they are detected only by sampling the water from different depths. The most intensive development is usually found in summer and early fall. Depending on the location and depth of the anaerobic, sulfide-containing zone, three major types of lakes may be differentiated (Biebl and Pfennig, 1979):

1. Lakes with a maximum depth of 15 m, in which the anaerobic, sulfide-containing zone is primarily confined to the mud sediment and does not significantly extend into the adjacent water layers, show mass developments of purple sulfur bacteria on and above the mud. Examples of this type of lake are: the Kolksee and Edebergsee (northern Germany) with blooms of *Thiopedia* and *Pelochromatium* consortium (Utermöhl, 1925); Lunzer Mittersee (Austria) with *Chromatium okenii* and *Lamprocystis* blooms (Ruttner, 1962); Mulizne Lake (Poland) with *Thiopedia* bloom (Czeczuga, 1968a); and Haruna Lake (Japan) with a *Chromatium* bloom (Takahashi and Ichimura, 1968).
2. In holomictic lakes (lakes that undergo spring and fall mixing) during summer stratification, the anaerobic, sulfide-containing, stagnant water (hypolimnion) reaches the highest level and, hence, the best illumination condition. Blooms of phototrophic bacteria develop in the uppermost part of the hypolimnion in green- or red-colored water layers or plates. In certain lakes, the layer is dominated by green sulfur bacteria. In other lakes, green and purple bacteria occur either in mixed populations *(Ancalochloris, Pelochromatium, Lamprocystis),* as in the Pluss-See (northern Germany; Anagnostidis and Overbeck, 1966), or develop separated in different layers, as in Wintergreen Lake (USA; Caldwell and Tiedje, 1975), in which populations of gas-vacuolated, green sulfur bacteria thrive below the layers of *Thiopedia* and *Thiocystis.* The Lunzer Obersee (Austria; Ruttner, 1962), the Rotsee (Switzerland; Schegg, 1971), and Lake Vechten (Netherlands; Steenbergen and Korthals, 1982) are examples of holomictic lakes in which populations of *Chromatium okenii, Thiopedia rosea,* and *Lamprocystis roseopersicina* are the dominant species in purple-red layers. In the Banyoles karstic area of nontheastern Spain, several small lakes with mass developments of purple sulfur bacteria exist (Guerrero et al., 1987); Lake Cisó with blooms of *Chromatium minus* has been studied in detail (van Gemerden et al., 1985).
3. In the permanently stratified meromictic lakes, the anaerobic, sulfide-containing hypolimnion often consists of salt or sea water. Although the phototrophic bacteria can thrive in a layer at a more-or-less fixed depth,

major fluctuations in the population density occur in response to seasonal differences in the intensity of sunlight and the associated consequences. In 1913, the first purple-red layer (bloom of *Chromatium okenii*) was discovered at a depth of 12.6 m in the meromictic Ritomsee (Switzerland; Düggeli, 1924). In the famous, well-studied Belovod Lake (USSR; Kusnetzov, 1970; Sorokin, 1970), the purple-red layer also consisted predominantly of *Chromatium okenii*. Mixed populations of *Chromatium* and *Chlorobium* were reported for Suigetsu Lake and Kisaratsu Reservoir (Japan; Takahashi and Ichimura, 1968).

The last group of habitats for phototrophic sulfur bacteria are artificial: the anaerobic waste-stabilization ponds (Gloyna, 1971). Cooper et al. (1975) described an intensively pink to purple-red lagoon (2.17 ha) which received sulfide-containing fellmongery effluent in which *Thiocapsa roseopersicina* was the dominant sulfide-oxidizing bacterium. As a rule, conditions for the development of purple sulphur bacteria in waste-treatment lagoons are created when wastewater with a high organic load (e.g., sewage or slaughterhouse wastewater) is treated in fairly deep ponds (1–2 m in depth) which favor development of anaerobic conditions and the formation of sulfide by sulfate-reducing bacteria (Gloyna, 1971; Holm and Vennes, 1970; Sletten and Singer, 1971). In such ponds, blooms of purple sulfur bacteria are visible in spring and fall; during summer, the ponds are often turned green by unicellular algae. The most common purple sulfur bacteria in waste-treatment systems are *Thiocapsa roseopersicina, Amoebobacter roseus, A. pendens,* and *A. pedioformis* (Eichler and Pfennig, 1986). In addition to these, small *Chromatium* species and *Thiocystis violacea* were often present in small numbers.

Marine Habitats

The most abundant and conspicuous developments of phototrophic bacteria are found in seawater pools of salt marshes, in closed bays, and in estuaries (Baas Becking and Kaplan, 1956; Baas Becking and Wood, 1955), as well as on sand beaches ("Farbstreifensandwatt"; Schulz, 1937). These habitats have also been named "beach sulfureta" (Suckow, 1966), because they house a complete sulfur cycle that consists of bacterial sulfate reduction and the consequent anaerobic sulfide oxidation by phototrophic bacteria. Bacterial sulfate reduction in turn is facilitated by decaying plant and microbial materials that supply the sulfate-reducing bacteria see Chapter 24) with the necessary carbon sources (and electron donors). The food chain in such beach sulfureta has been the subject of a careful and excellent study by Fenchel (1969). Since Warming (1875) described mass developments of purple sulfur bacteria on the coasts of Denmark, they have been found and studied on the coasts of Germany (Gietzen, 1931; Hauser and Michaelis, 1975; Hoffmann, 1942; Schulz, 1937; Schulz and Meyer, 1939; Suckow, 1966; Stal et al., 1985), the Netherlands (Imhoff, 1976), the eastern United States (Trüper, 1970; Nicholson et al., 1987), mediterranean France (Matheron, 1976; Matheron and Baulaigue, 1972), and the Black Sea (Gorlenko, 1968; consult Kondratieva, 1965, for the older Russian literature; Yegunov, 1895).

"Red water" caused by phototrophic sulfur bacteria (Chromatiaceae as well as Chlorobiaceae) has been described and studied in many coastal lakes and lagoons: Lake Faro in Sicily (Genovese, 1963; Puchkova and Gorlenko, 1976; Trüper and Genovese, 1968); the Mar Piccolo near Tarento (Cerruti, 1938); Veliko and Malo Jezero on the Dalmatian island of Mljet (Cviic, 1955; 1960, Imhoff, 1976); the Bay of Tunis (Heldt, 1952; Stirn, 1971) and Bietri Bay of the Ebrie Lagoon, Ivory Coast (Caumette, 1984); the Etang du Prevost near Montpellier, France (Caumette 1986); lagoons at Messolonghi and Aitolikon in Greece (Hatzikakidis, 1952; 1953); the Solar Lake on the Sinai Peninsula (Cohen et al., 1977); and Lake Mogilnoye on the Arctic island of Kildin (Isachenko, 1914; Gorlenko et al. 1978). Typical splash water ponds on rocky coasts have been successfully studied in Japan (Taga, 1967), Helgoland, Germany, and Yugoslavia (Imhoff, 1976).

In contrast to estuarine or nearshore marine habitats, the oxygenated waters of the open seas have been found to be devoid of phototrophic sulfur bacteria. Only the Black Sea, a large, meromictic enclosed basin that is not part of the open ocean, contains phototrophic sulfur bacteria as was shown first by Kriss and Rukina (1953) and, after an initial unsuccessful attempt (Jannasch et al., 1974), as was confirmed by Hashwa and Trüper (1978). In recent studies, evidence was obtained for the development of brown Chlorobiaceae in areas where the chemocline is at depths of 68 to 90 m.

So far, there is only one type of habitat within well-oxygenated sea water where the anaerobic phototrophic sulfur bacteria can be regularly encountered: Eimhjellen (1967) found them in the North Sea sponge, *Halichondrium panicea*. Imhoff and Trüper (1976) investigated several Mediterranean sponges and isolated seven dif-

ferent species of Chromatiaceae and even some purple nonsulfur bacteria from *Euspongia officinalis* and *Ircinia* species. Marine sponges, although strictly aerobic, obviously contain anaerobic pockets that receive enough light to allow the growth of phototrophic bacteria.

Isolation

Preparation of Culture Media

The composition and preparation of two different culture media are described below for the cultivation of purple and green sulfur bacteria. Medium 1 is suitable for almost all green and purple bacteria presently in laboratory culture, including those species that are most difficult to grow (e.g., *Thiopedia rosea, Thiospirillum jenense, Chromatium okenii,* and *Thiodictyon elegans*). With minor modifications, this culture medium was published by Pfennig (1965), Pfennig and Lippert (1966), Trüper (1970), van Niel (1971), and Eichler and Pfennig (1988). Medium 2 (Biebl and Pfennig, 1978) is easier to prepare and can be successfully used for the cultivation of the most common purple and green sulfur bacteria.

Medium 1 for Cultivation of Purple and Green Sulfur Bacteria (Eichler and Pfennig, 1988)

The medium is prepared in a 5-liter bottle (or flask) with four openings at the top. Two openings for tubes are in the central, silicon rubber stopper: a short, gas-inlet tube with a sterile cotton filter; and an outlet tube for medium, which reaches the bottom of the vessel at one end and has, at the other end, a silicon rubber tube with a pinchcock and a bell for aseptic dispensing of the medium into bottles. The other two openings have gas-tight screw caps; one of these openings is for the addition of sterile solutions and the other serves as a gas outlet.

The composition of medium 1 is given below for a total of 5 liters of culture medium. A number of different solutions are required to prepare the medium.

Solution 1:

Distilled water	4,900 ml
KH_2PO_4	1.7 g
NH_4Cl	1.7 g
KCl	1.7 g
$MgSO_4 \cdot 7H_2O$	2.5 g
$CaCl_2 \cdot 2H_2O$	1.25 g

For enrichment cultures or pure cultures from marine or estuarine habitats, add 100 g NaCl to solution 1 and increase the $MgSO_4 \cdot 7H_2O$ to 15 g.

Solution 1 is autoclaved for 45 min at 121°C in the 5-liter bottle, together with a teflon-coated magnetic bar. It is cooled to room temperature under an N_2 atmosphere with a positive pressure of 0.05–0.1 atm (a manometer for low pressures is required). The cold medium is then saturated with CO_2 by magnetic stirring for 30 min under a CO_2 atmosphere of 0.05–0.1 atm. The sterile solutions 2 through 6 (see below) are then added through one of the screw-cap openings against a stream of either N_2 gas or, better, a mixture of 95% N_2 and 5% CO_2, while the medium is magnetically stirred.

Solution 2: Vitamin B_{12} solution
Prepare a sterile filtered stock solution containing 2 mg vitamin B_{12} in 100 ml distilled water. Add 5 ml to Solution 1.

Solution 3: Trace element solution SL 12
Prepare the following stock solution:

Distilled water	1 liter
Ethylenediamine-tetraacetate-di-Na-salt	3.0 g
$FeSO_4 \cdot 7H_2O$	1.1 g
H_3BO_3	300 mg
$CoCl_2 \cdot 6H_2O$	190 mg
$MnCl_2 \cdot 4H_2O$	50 mg
$ZnCl_2$	42 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$Na_2MoO_4 \cdot 2H_2O$	18 mg
$CuCl_2 \cdot 2H_2O$	2 mg

The salts are dissolved in the order given and the solution is autoclaved in a screw-cap bottle. Add 5 ml to solution 1.

Solution 4: Na bicarbonate solution
Prepare a solution of 7.5% Na bicarbonate. The solution is saturated with CO_2 and autoclaved under a CO_2 atmosphere. Add 100 ml to solution 1.

Solution 5: Sodium sulfide solution
Add 20 ml of a sterile, 10% $Na_2S \cdot 9H_2O$ solution to solution 1 for purple sulfur bacteria, or 30 ml for green sulfur bacteria. The sulfide solution is prepared in a screw-cap bottle; after replacement of the air by N_2, the bottle is tightly closed and autoclaved.

After combining and mixing solutions 1 through 5, the pH of the medium is adjusted with sterile 2M HCl or Na_2CO_3 solution to pH 7.2 for purple sulfur bacteria or to pH 6.8 for green sulfur bacteria. The medium is then distributed aseptically through the medium outlet tube into sterile, 100-ml bottles with metal caps and autoclavable rubber seals, using the positive gas pressure (0.05–0.1 atm) of the N_2/CO_2 gas mixture. A small air bubble is left in each bottle to meet possible pressure changes. The tightly sealed, screw-cap bottles can be stored for several weeks and months in the dark. During the first 24 h, some iron of the medium precipitates in the form of black flocks. No other sediment should arise in the otherwise clear medium.

SUPPLEMENT SOLUTION. The amount of $Na_2S \cdot 9H_2O$ initially added to medium 1 (higher initial amounts may be inhibitory for some species) will only produce very limited growth. After the sulfide and sulfur are completely photooxidized, the bacteria stop growing and will be damaged by further illumination. In order

to keep the cultures growing and to obtain high cell yields it is necessary to feed the cultures several times with sterile, partially neutralized sulfide solution, which is prepared from solution 6.

Neutralized Sulfide Solution for Feeding Cultures of Green and Purple Sulfur Bacteria:

Solution 6:

Distilled water	100 ml
$Na_2S{\cdot}9H_2O$	3.6 g

The 0.15 M solution is prepared in a 250-ml screw-cap bottle; after replacement of the air by N_2, the bottle is tightly closed and autoclaved.

To prepare the neutralized feeding solution, a measured amount of sterile solution 6 is added to a sterile Erlenmeyer flask containing a magnetic bar. The solution is brought to about pH 7.3 by dropwise addition of sterile 2 M H_2SO_4 on a magnetic stirrer. If too much acid is added, the sulfide solution becomes turbid due to precipitation of elemental sulfur. The nearly neutralized solution is immediately used for feeding 100-ml-bottle cultures. Depending on the population density, 1–2 ml are used for Chromatiaceae. Before the addition, an equivalent amount of culture medium is aseptically removed from the bottle culture.

Alternatively the method of Siefert and Pfennig (1984) can be used to prepare neutralized feeding solution.

Cultures of purple and green sulfur bacteria that can use thiosulfate as an electron donor can be supplemented with 0.1% of this compound from stock solution 7.

Thiosulfate Solution for Cultivation of Purple and Green Sulfur Bacteria

Solution 7:

Distilled water	95 ml
$Na_2S_2O_3{\cdot}5H_2O$	10 g

The solution is prepared in a 200-ml screw-cap bottle and autoclaved. One ml of solution is aseptically added to 100 ml of culture medium.

Growth yields of purple and green sulfur bacteria can be increased by the addition of acetate as a readily assimilated carbon source; 0.03% or 0.05% acetate (from solution 8) is added to deep agar dilution cultures. Acetate can be added to liquid cultures only if they are free of purple nonsulfur bacteria. The ammonium and magnesium salts of acetate are used to avoid strong pH changes during growth.

Acetate Solution for Cultivation of Green and Purple Sulfur Bacteria

Solution 8:

Distilled water	100 ml
Ammonium acetate	2.5 g
Magnesium acetate	2.5 g

The solution is prepared in a 200 ml screw-cap bottle and autoclaved. Application is 1 ml added aseptically to 100 ml of culture medium.

Medium 2 for Cultivation of Purple and Green Sulfur Bacteria (Biebl and Pfennig, 1978)

This medium is prepared in a 2-liter Erlenmeyer flask with an outlet near the bottom. A silicon rubber tube (about 30 cm long) with a pinchcock and a bell for aseptic distribution of the medium into bottles is connected to the outlet. A magnetic bar is put into the flask.

Solution 1:

Distilled water	950 ml
Solution 2 (SL 12)	1 ml
KH_2PO_4	1 g
NH_4Cl	0.5 g
$MgSO_4{\cdot}7H_2O$	0.4 g
$CaCl_2{\cdot}2H_2O$	0.05 g

For marine strains, add 20 g NaCl to solution 1 and increase the $MgSO_47H_2O$ to 3 g. The solution is autoclaved in the cotton-plugged, 2-liter Erlenmeyer flask.

Solution 2:

Trace element solution SL 12 (see medium 1). Application is 1 ml for 1 liter of medium.

When the autoclaved solution 1 (including solution 2) is cold, the following sterile solutions 3 through 5 are aseptically added while magnetically stirring the medium:

Solution 3: Vitamin B_{12} solution

The solution is prepared as a sterile filtered stock solution containing 2 mg vitamin B_{12} in 100 ml distilled water. Add 1 ml of solution 1.

Solution 4: Na bicarbonate solution

The 5% solution is prepared in distilled water and is filter-sterilized. Add 30 ml to solution 1.

Solution 5: Sodium sulfide solution

A freshly autoclaved 6% solution is prepared in distilled water; 6 ml is added to medium for purple sulfur bacteria, or 10 ml to medium for green sulfur bacteria.

After additions from solutions 1 through 5, the pH of the medium is adjusted with sterile 2M H_2SO_4 or Na_2CO_3 solution to pH 7.3 for purple sulfur bacteria or to pH 6.8 for green sulfur bacteria. The medium is then dispensed aseptically into sterile, 50- or 100-ml bottles with metal screw caps containing autoclavable rubber seals. A small air bubble is left in each bottle to meet possible pressure changes.

Methods for Pure Culture Isolation

Irrespective of the source of the inoculum, e.g., sample from nature, enrichment culture, or suspension of a colony, the deep agar dilution method is the most convenient and reliable method for preparing pure cultures of phototrophic purple and green sulfur bacteria (Larsen, 1952; Pfennig, 1978; van Niel, 1931). For motile species that do not form colonies in agar media (e.g., *Thiospirillum*) Giesberger's (1947) "Pasteur pipette" method (see later) is recom-

mended. For nonmotile species, the well-known dilution method in liquid media should be applied.

Preparation of Pure Cultures of Phototrophic Purple and Green Sulfur Bacteria by Dilution in Deep Agar Tubes

Granular agar is thoroughly washed several times with distilled water, and a 3% solution is prepared in distilled water (for marine samples, 2% NaCl is added) and liquefied by autoclaving. While kept in a hot-water bath, the agar is dispensed in 3-ml portions into standard test tubes (16 or 18 mm × 200 mm), which are then plugged with cotton and autoclaved.

The molten agar is kept in a water bath at 60°C, and a 50- or 100-ml screw-cap bottle, containing complete medium 1 (or medium 2), is kept with a loosened screw cap in a water bath at 40°C. For one dilution series, eight tubes are supplied with 6 ml of the prewarmed medium and kept in the 40°C water bath. At the same time, the cotton plugs are replaced by rubber stoppers. No mixing is required at this stage.

One of the tubes is inoculated with one to three drops from the suspension of the phototrophic bacteria; the contents are immediately mixed by inverting the tube once. Of this culture, 0.5–1.0 ml are then transferred into a second tube that contains the agar medium, mixed immediately by inverting as with the first tube, and so on. This dilution series is continued over eight steps. After transfer to the next tube, each tube is set into a water bath with tap water (about +10°C) to harden the agar. After hardening, the air above the agar is replaced by gassing with sterile N_2 and 5% CO_2 and the tubes are tightly closed with the rubber stoppers. The agar dilution cultures are incubated at 20–28°C (depending on the previous treatment of the inoculum) at a light intensity of 200–500 lux.

After the cultures have developed, individual colonies are isolated from the highest dilution step that shows pigmented colonies. For this purpose, a single colony is removed through the open end of the test tube by suction, using a fine Pasteur pipette attached to a rubber tubing. The procedure is best carried out under a dissecting microscope. The contents of the colony are suspended in 0.5 ml of sterile medium in a test tube, the suspension is microscopically checked for purity, and the whole dilution series in deep agar tubes is repeated. In order to obtain a pure culture, it may be necessary to repeat the whole process again. When pure cultures and colonies are achieved, individual colonies are inoculated into liquid medium. It is advisable to start with small-sized bottles or screw-cap tubes (10 or 25 ml) and then to scale up to the regularly used sizes.

Purity is checked by use of A-C medium (Difco) and *Desulfovibrio* medium (after Postgate; See Chapter 183), adjusted to the respective salinities. As long as no growth in these media occurs and the culture is morphologically uniform, it can be considered pure.

Motile purple sulfur bacteria that do not grow well in agar media, e.g., *Thiospirillum jenense* (Pfennig, 1965), may be isolated by the method described by Giesberger (see below) for the isolation of heterotrophic spirilla or rhodospirilla (Giesberger, 1947).

Pasteur Pipette Technique for Isolating Motile Purple Sulfur Bacteria (Giesberger, 1947)

The wide part of a sterile Pasteur pipette is heated in a Bunsen burner not far from the onset of the capillary part; the softened glass is then squeezed to a flat tube using pliers with parallel movement of the jaws. The flat part is again heated and carefully pulled out to a flat capillary. The whole Pasteur pipette is then filled with sterile liquid medium and placed horizontally under a dissecting microscope so that the flat capillary part can be observed. The cell suspension with the thiospirilla is then introduced into the wide part of the Pasteur pipette not far from the capillary part. Some of the very fast and straight-moving thiospirilla soon leave their original position and swim through the flat capillary; this movement can be followed readily under the microscope. When a few cells have reached the other end, the capillary is aseptically cut in the middle of the capillary part, and the drop of medium with the cells is inoculated into a screw-cap test tube with sterile medium. When many parallel tubes of these capillary separations are set up, chances are good that one of the culture tubes will give rise to a pure culture.

Cultivation on Agar Plates in Anaerobic Jars

A useful method for cultivating phototrophic sulfur bacteria was introduced by Irgens (1983). It is based upon the release of hydrogen sulfide, ammonia, and acetic acid from decomposing thioacetamide.

The medium including agar is prepared without any sulfide and poured into Petri dishes. After inoculation, these are placed in anaerobic jars (for instance, the Gas-Pak system of Becton Dickinson, Cockeysville, MD. Before the jars are closed, they are supplemented with a test tube containing 0.05–0.1 g thioacetamide dissolved in 1.0 ml of 0.2 N or 0.5 N HCl. Irgens (1983) demonstrated that hydrogen sulfide is released over a period of at least one week. Also included in the jars are the methylene blue redox indicator and a strip of lead acetate-sulfide indicator. This method is also a convenient method for obtaining viable counts. The technique has been successfully used for the isolation of *Amoebobacter, Chromatium, Lamprocystis, Thiocapsa, Thiocystis* and *Ectothiorhodospira* strains with an illumination by a 60-W incandescent light bulb at a distance of 60 cm from the jars (Irgens, 1983).

Although less oxygen- tolerant species might not survive the short inoculation or transfer period between incubations, this is an easy way to grow the more oxygen-tolerant species. However, in general, it cannot replace the isolation by agar shake dilution series as described above.

Methods for Enrichment Culture

Van Niel's (1931) original observation that green sulfur bacteria have a lower pH optimum than purple sulfur bacteria has been corroborated by all later studies and forms the basis for the enrichment culture of the two groups. How-

ever, since the pH ranges of the groups overlap, the use of different pH values in the media is not sufficient to assure the selective enrichment of each group. In particular, enrichments for purple sulfur bacteria can readily be outgrown by Chlorobiaceae, in which case the use of light filters is helpful (see below, "Application of Light Filters in Enrichment of Purple Sulfur Bacteria").

The concentration of sulfide is critical for a number of species in both groups that are inhibited by higher concentrations (e.g., 0.1% $Na_2S \cdot 9H_2O$). Therefore, the sulfide concentrations for media 1 and 2 given earlier are low enough so that the cultivation of sensitive forms is not excluded. *Thiopedia rosea* is exceptional in being inhibited by sulfide concentrations above 0.6 mM. For cultivation of *Thiopedia*, the addition of sodium dithionite (50 mg for 1 liter) is required (see Overmann and Pfennig, 1989). High population densities can be achieved only by repeated addition of sulfide ("feeding") during growth (see the recipe for "Partially Neutralized Sulfide Solution").

The salinity of the culture medium is usually adjusted according to the salinity of the inoculum. For marine isolations, it is sufficient to raise the NaCl concentration to 2–3%. However, some isolates also require the addition of increased concentrations of magnesium (e.g., 0.3% $MgSO_4 \cdot 7H_2O$) and sometimes also of calcium (Biebl and Pfennig, 1978). It should be taken into account that the salinity of a natural habitat may not always be optimal for a particular isolate from that habitat. Therefore, use of enrichment media of different salinities may be useful for the isolation of a variety of species.

The incubation temperature is very important for the enrichment culture of several species of purple and green sulfur bacteria. As a rule, at high incubation temperatures (28–35°C) a wide variety of different species are outgrown by single, fast-growing species. At low temperatures (15–22°C), the enrichment cultures develop more slowly and a larger number of different species may be present simultaneously.

Selective Enrichment of Purple Sulfur Bacteria

For the successful enrichment of many characteristic species of purple sulfur bacteria, it is important to realize that they occur very irregularly in different aquatic habitats. The source and species composition of the inoculum is, therefore, of primary importance for the outcome of enrichment experiments. When the desired species is detected microscopically in reasonable numbers in a given sample, deep agar dilution series should be prepared directly from the sample without trying further enrichment in liquid culture. Even in this case, however, the incubation conditions for the agar cultures should closely resemble the conditions used for liquid enrichment cultures of the particular species.

APPLICATION OF LIGHT FILTERS IN ENRICHMENTS OF PURPLE SULFUR BACTERIA. Medium 1 with a pH value between 7.2 and 7.4 is used for the selective enrichment of purple sulfur bacteria from freshwater or marine habitats. The use of specific light filters can be of value in two cases: 1) in the presence of established populations of green sulfur bacteria (Pfennig, 1965, 1967); and 2) for the enrichment of purple sulfur bacteria that contain bacteriochlorophyll *b*, such as *Thiocapsa pfennigii* (Eimhjellen, 1970; Eimhjellen et al., 1967). Development of green sulfur bacteria (long-wavelength absorption maxima between 705 and 750 nm) can be prevented when the enrichments are illuminated behind an infrared filter that transmits light only above 800 nm (e.g., gelatin filter No. 530, Göttinger Farbfilter; or interference filter plus prefilter for light transmission at around 850 nm). The selective enrichment of *Thiocapsa pfennigii* is achieved with an infrared filter that transmits radiation only above 900–1,000 nm) (e.g., gelatin filter No. 533, Göttinger Farbfilter; or interference filter plus prefilter for light transmission at around 1,020 nm).

The various species of the purple sulfur bacteria differ with respect to the selective advantage they exhibit under different kinds of illumination. These differences can be exploited for the selective enrichment of certain groups of species in medium 1 (Pfennig, 1967). Two extremes of different illumination with incandescent light are recommended here.

CONTROL OF LIGHT INTENSITY AND ILLUMINATION IN SELECTIVE ENRICHMENT OF PURPLE SULFUR BACTERIA. If continuous illumination at high light intensities of 1,000–2,000 lux, and an incubation temperature of about 30°C is used, the small and fast-growing Chromatiaceae can be expected to enrich: *Chromatium vinosum, C. minus, C. violascens, C. gracile, C. minutissimum, Thiocystis violacea,* and *Thiocapsa roseopersicina.*

Results may be different with intermittent illumination at low light intensities of 50–300 lux and an incubation temperature of about 20°C. The light and dark phases may be either 12 h light and 12 h dark (or 6 h light and 6 h dark) or, according to van Gemerden (1974), 4 h light and 8 h dark. After inoculation from the natural

habitat, the bottle cultures should not be shaken until they are fed with more sulfide. Depending on the inoculum, the large and flagellated and the gas-vacuole-containing Chromatiaceae can be expected to enrich: *Thiospirillum jenense, Chromatium okenii, C. weissei, C. warmingii, C. buderi, Thiocystis gelatinosa, Lamprocystis roseopersicina, Thiodictyon elegans, Amoebobacter roseus,*, and *Thiopedia rosea.* The flagellated forms keep swarming in the whole bottle (Pfennig, 1962) and can be further enriched by carefully pipetting the inoculum for subsequent enrichment cultures from the upper part of the bottle culture. At first, the nonmotile forms enrich in the sediment at the bottom of the bottles; later, the gas-vacuole-containing cells tend to accumulate at the surface under the screw cap. This process can be accelerated by keeping the enrichment for a few days in a refrigerator at +4°C. For further enrichment, the floating cell mass is carefully pipetted from the surface and transferred to fresh medium.

Alternatively, enriched cell populations may be removed by a Pasteur pipette and directly used as inoculum for deep agar dilution series. Medium 1 for deep agar cultures is supplemented with 0.05% acetate (supplement solution 8). The deep agar cultures are incubated at room temperature and a light intensity of 200 lux. An illumination regimen of 16 h light and 8 h dark is the most favorable.

Pure cultures of most species of the purple and green sulfur bacteria have been successfully maintained by the authors for many years (30 year for some strains) in liquid cultures with medium 1, preferentially using 100-ml screw-cap bottles as culture vessels.

Maintenance and Preservation of Pure Cultures of Purple and Green Sulfur Bacteria

After transfer to fresh medium, stock cultures of green sulfur bacteria are incubated at room temperature and a light intensity of 200–500 lux; they are grown until the initially formed elemental sulfur has just disappeared. Then the stock cultures are stored in the dark in a refrigerator at +4°C to +6°C. Before transfer into fresh medium after 3–4 months of storage, the stock cultures are fed with 1 ml neutral sulfide solution (supplement solution 6) to a final sulfide concentration of 1.5 mM and incubated in dim incandescent light (100–200 lux) at room temperature. The stock cultures are transferred after the cells have formed elemental sulfur (milky appearance of the culture) and have started to grow.

Stock cultures of purple sulfur bacteria may be maintained in a similar way; however, the freshly grown cultures have to be fed with 1 ml neutral sulfide solution (supplement solution 6) and kept in the light for a few hours until the cells have formed intracellular globules of elemental sulfur. At this stage, the stock cultures can be stored in a refrigerator at +4°C to +6°C for several months. The cultures keep well when they are put back into dim light at room temperature after 4–6 weeks of storage in the dark. Cultures with sulfur-free cells are then fed with 1 ml neutral sulfide solution and, after formation of elemental sulfur, put back into the refrigerator.

Long-term preservation of purple and green sulfur bacteria is also possible by storage in liquid nitrogen (Biebl and Malik, 1976). Not all strains could be lyophilized (Malik 1990a, 1990b). For liquid-nitrogen preservation, heavy cell suspensions of liquid cultures with 5% dimethylsulfoxide (DMSO) as a protective agent were placed in 2-ml plastic ampules, sealed, and freeze-stored.

Most type strains of the Chromatiaceae are presently maintained in liquid nitrogen by the German Collection of Microorganisms and Cell Cultures, (DSM), Braunschweig, Germany (Claus and Schaab-Engels, 1977).

Identification

The properties of the species of the Chromatiaceae are listed in Table 1. Cells of all species multiply by binary fission. All motile cells carry polar or sub-polar flagella. Growth is influenced by environmental conditions; therefore, only pure cultures allow reliable identification. Fig. 1 shows the morphology of some typical species of the Chromatiaceae.

All species are able to photometabolize a number of simple organic carbon compounds, at least acetate and pyruvate. The large-cell species, *Chromatium okenii, C. weisseei, C. warmingii, C. buderi,* and *Thiospirillum jenense,* differ from the other species not only in size but in their requirement for vitamin B_{12}, inability to utilize organic compounds other than acetate and pyruvate, and lack of assimilatory sulfate reduction. Vitamin B_{12} is also required by *Amoebobacter roseus* and *C. salexigens.*

The majority of enrichment techniques for anoxygenic phototrophic bacteria select for certain physiological groups, but are not species specific. Therefore, reliable and rapid methods for identification are important.

A preliminary but relatively good differentiation between sulfur and nonsulfur bacteria is already given by the enrichment or isolation medium. Medium that contains H_2S and bi-

carbonate is selective for sulfide-oxidizing bacteria, such as the Chromatiaceae and Chlorobiaceae, but *Rhodobacter sulfidophilus* (and perhaps others) will also grow (or survive) in sulfide-containing medium. If phototrophic bacteria are isolated from a sulfide-free medium with organic compounds as electron donors, no species of the Chlorobiaceae will grow, and only those species of the Chromatiaceae that are able to assimilate (and reduce) sulfate will grow.

For a quick differentiation of the Chromatiaceae from other purple bacteria that may prevail under these conditions, the following method is recommended:

Differentiation of Chromatiaceae from Ectothiorhodospiraceae and Purple Nonsulfur Bacteria

Place a drop of the cell suspension under the microscope and allow a drop of neutralized Na_2S solution to run in from besides the cover slip. If the bacteria form *intracellular sulfur globules* in the light (usually in less than 20 min), they belong to the Chromatiaceae.

Great attention should be paid to the microscopic appearance of a newly isolated strain. Width (diameter), length, shape of cells, type of flagellation, mode of division, and the presence or absence of slime capsules, sulfur globules, and gas vacuoles should be recorded (Fig. 1). Further, an absorption spectrum of a cell suspension should be taken to identify the predominant bacteriochlorophyll and the carotenoid composition. Some methods for the measurement of such absorption spectra follow.

Sucrose Method for Measuring Absorption Spectra

Mix 5 g of sucrose with 3.5 ml of cell suspension until the former is completely dissolved. Then record the spectrum against a blank of 5 g of sucrose in 3.5 ml of water (or medium) in an appropriate spectrophotometer.

Trüper and Yentsch (1967) described another method in which the cells are precipitated on glass fiber filters and the spectrum is measured through the wet filter. The most accurate method to date for directly measuring pure absorbance spectra of living phototrophic microorganisms was published by Göbel (1978). For the purpose of identification alone, however, the sucrose method given above is the simplest and quickest.

The characteristic absorption maxima of the bacteriochlorophyll (bchl) in living cells are: for bchl *a;* 375, 590, 805, and 830–890 nm; and for bchl *b;* 400, 605, 840, and 1020–1040 nm.

The only species of the Chromatiaceae containing bchl *b* rather than *a* is *Thiocapsa pfennigii.* This species also possesses a unique ultrastructure, i.e., bundles of tubes as the intracytoplasmic membrane system.

All other species of the Chromatiaceae contain membrane vesicles.

Fig. 2 shows a number of absorption spectra of living cell suspensions of Chromatiaceae. The in vivo absorption characteristics of bchls *a* and *b* as well as of the most common carotenoids are shown.

After the physiological group, morphology, and pigments of a newly isolated strain have been determined, identification with a known species is possible in most cases and, if not, further properties of the new strain must be studied. We recommend the determination of the GC content of the DNA and a study of ultrathin sections under the electron microscope in order to determine the fine structure, in particular the type of intracytoplasmic membranes present.

The description of a new species of the anoxygenic phototrophic bacteria should be based on pure cultures and, if possible, on more than one strain. Besides nomenclatural items, a new description should contain detailed information about cell morphology (color, size, shape, flagellation, mode of division, presence of gas vacuoles, slime capsules, sheaths, etc.); occurrence of cell aggregates; fine structure (membrane systems, storage materials, cell wall, flagellation); photosynthetic pigments (color of cell suspensions, types of bchl and carotenoids); and GC content. The following physiological data should be given: oxygen tolerance; sulfide tolerance; salinity requirements; optimum growth temperature and pH; sulfur, nitrogen, and carbon sources utilized; vitamins or other growth factors required; and capacity for: photo- versus chemotrophy, organo- versus lithotrophy, and hetero- versus autotrophy. An indication of natural habitats is also necessary.

Finally, a type strain must be designated and deposited in one of the recognized national type culture collections, preferably either ATCC, DSM, NCIB, or NTHC, as required by the International Code of Nomenclature of Bacteria (Lapage et al., 1975).

Physiology and Biochemistry

While the energy yield from lithotrophic metabolism is usually low, phototrophic organisms are able to produce large amounts of ATP as long as light is present. In their natural environments, however, this is only the case in the daytime. Therefore, all phototrophic organisms must in addition possess other energy-yielding

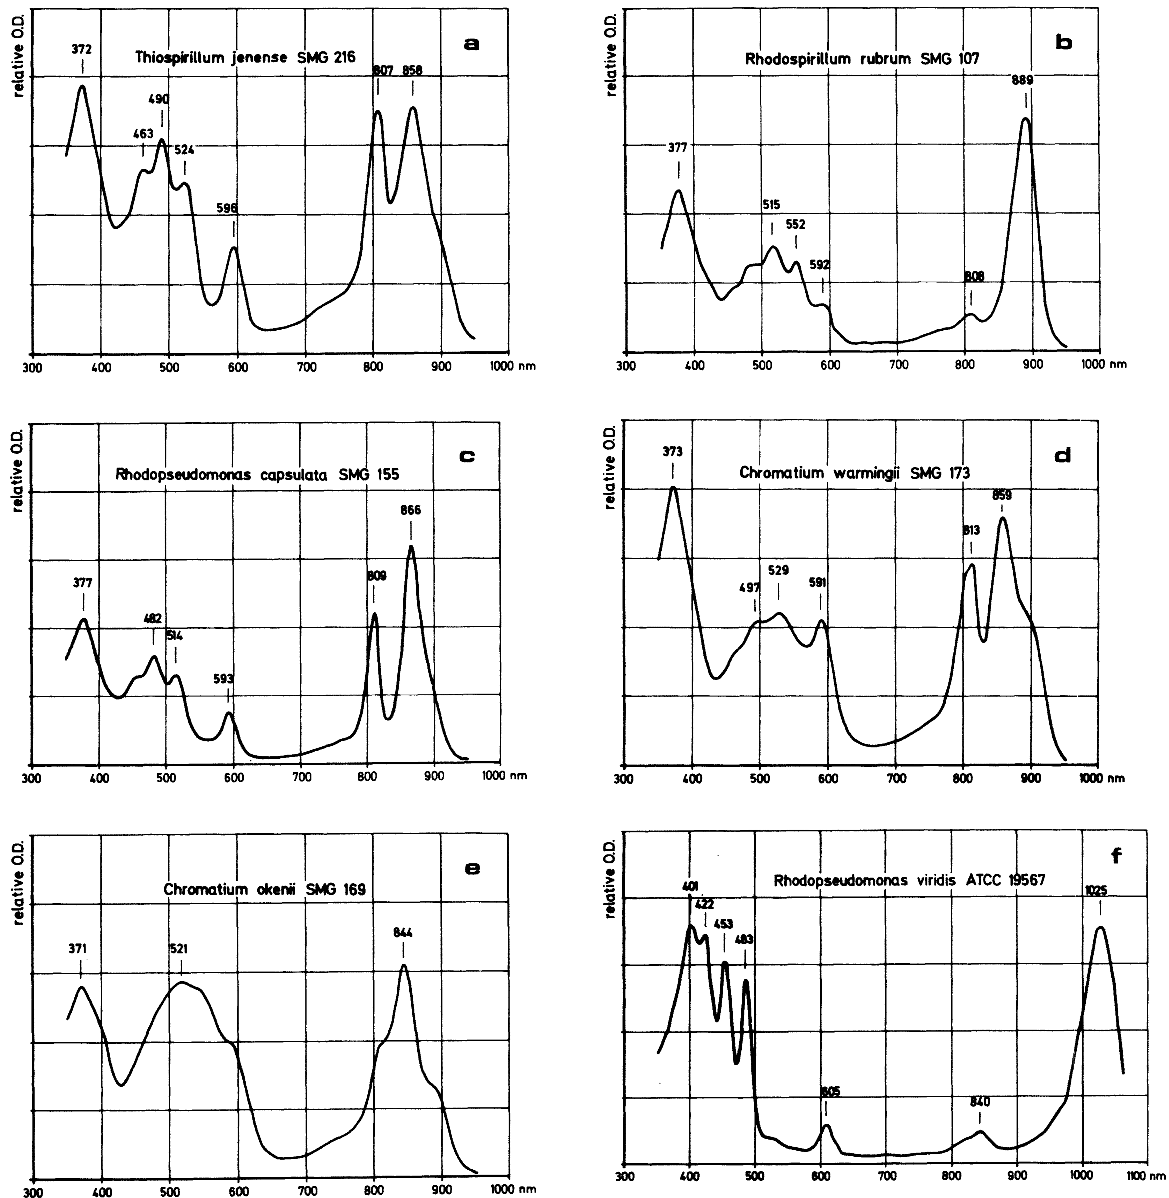

Fig. 2. Absorption spectra of living cell suspensions of Chromatiaceae (and some purple nonsulfur bacteria) containing bacteriochlorophyll *a* (a-e) or *b* (f). Typical carotenoids seen and their approximate absorption maxima: (a) lycopene and rhodopin (463, 490, 524 nm); (b) spirilloxanthin (486, 515, 552 nm); (c) spheroidene (450, 482, 514 nm) (this organism is now called *Rhodobacter capsulatus*); (d) rhodopinal (497, 529 nm); (e) okenone (521 nm); (f) 1,2-dihydro-derivatives of lycopene and neurosporene (422, 453, 483 nm).

metabolic processes, i.e., respiration and/or fermentation, which function during periods of darkness. In the light, ATP is produced by cyclic photophosphorylation. This term characterizes a process during which electrons are circled between reaction-center bacteriochlorophyll, a primary acceptor, and several electron carriers such as quinones, nonheme iron-sulfur proteins, and cytochromes, all associated with the photosynthetic membrane system. Light is harvested by antenna pigments (bacteriochlorophylls and carotenoids bound to proteins). From the light-harvesting pigments, the energy is transferred to the reaction centers. In purple bacteria, the reaction center consists of four molecules of bacteriochlorophyll, two of bacteriophaeophytin, and a protein consisting of several sub-units. Closely associated with the reaction center is an iron-ubiquinone complex which bridges the gap between the inner mem-

brane surface and the reaction center; the latter is located in the membrane toward the outer surface. Another biochemical complex stretching through the membrane contains a cytochrome *b*, a cytochrome c_1, and an iron-sulfur protein. Ubiquinone acts as a mobile carrier within the membrane, whereas cytochrome c_2 can change its site on the outside of the cytoplasmic membrane. When light energy is transferred from the antenna complex to the reaction center, one electron per light quantum is translocated from bacteriochlorophyll to bacteriopheophytin and further to the iron-ubiquinone complex. At the reaction center bacteriochlorophyll, the missing electron is immediately replaced by an electron from cytochrome c_2. From the reduced iron-ubiquinone complex, the electron enters the intramembraneous ubiquinone pool together with two protons (per quinone molecule and electron) from the cytoplasm. The reduced ubiquinone travels to the bc_1 complex, where the electron is donated to cytochrome c_2, and the two protons to the topological outside of the cell. Cytochrome c_2 acts as a mobile electron carrier between the bc_1 complex and the reaction center complex. The proton gradient created this way between outside and inside drives ATP synthase, thus forming ATP in the cytoplasm (For details, see Drews, 1989).

For the generation of NADH, anoxygenic lithoautotrophic bacteria require external electron donors such as H_2 or reduced sulfur compounds. In the Chromatiaceae, the Ectothiorhodaceae, and the facultatively photolithoautotrophic Rhodospirillaceae, NADH formation is not possible by direct reduction of NAD^+ via the primary acceptor but requires reverse electron flow. Reverse electron transfer is driven by the proton motive force provided by the light reaction mechanism described above, i.e., by cyclic photosynthetic electron flow. The electrons required for NAD^+ reduction are donated at less electronegative sites via *c*-type cytochromes. These electrons are derived from the oxidation of reduced sulfur compounds or molecular hydrogen.

Many phototrophic bacteria can grow using molecular hydrogen as the photosynthetic electron donor. This capability was detected more than 55 years ago in *Chromatium vinosum* strain D and other purple sulfur bacteria (Roelofsen, 1935; Gaffron, 1935).

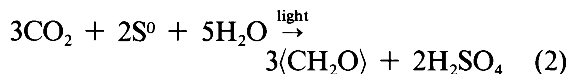
Hydrogen utilization depends upon the presence of the enzyme hydrogenase, and several "uptake" hydrogenases of phototrophic bacteria have been studied in much detail in *Chromatium vinosum* (Gitlitz and Krasna, 1975; Strekus et al., 1980) and *Thiocapsa roseopersicina* (Kondratieva and Gogotov, 1981, 1983; see also Vignais et al., 1985; Gogotov, 1978, 1984, 1986; Schlegel and Schneider, 1978). In general, the enzymes appear to be membrane-bound and probably contain nickel and iron-sulfur clusters. The natural electron acceptors of these hydrogenases are cytochromes of the *c*- or *b*-type in purple bacteria (Gogotov, 1986).

The use of reduced sulfur compounds as electron donors for anoxygenic photosynthesis has been found in all groups of phototrophic purple bacteria (Trüper, 1981a, 1984, 1989; Trüper and Fischer, 1982). In the Chromatiaceae, all species oxidize sulfide and elemental sulfur, and some also oxidize thiosulfate and sulfite.

As first shown by van Niel (1931), photosynthetic carbon dioxide fixation and sulfide (or thiosulfate) oxidation are stoichiometrically linked (in equations 1–6 below, $\langle CH_2O \rangle$ stands for organic matter at the oxidation level of carbohydrate).

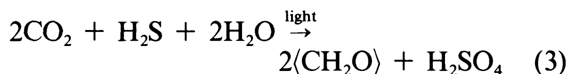
For sulfide:

$$CO_2 + 2H_2S \xrightarrow{\text{light}} \langle CH_2O \rangle + H_2O + 2S^0 \quad (1)$$



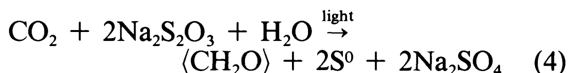
$$3CO_2 + 2S^0 + 5H_2O \xrightarrow{\text{light}} 3\langle CH_2O \rangle + 2H_2SO_4 \quad (2)$$

The sum of equations 1 and 2 gives the ratio of CO_2 to sulfide:

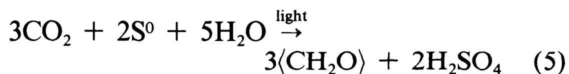


$$2CO_2 + H_2S + 2H_2O \xrightarrow{\text{light}} 2\langle CH_2O \rangle + H_2SO_4 \quad (3)$$

For thiosulfate:

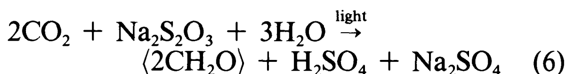


$$CO_2 + 2Na_2S_2O_3 + H_2O \xrightarrow{\text{light}} \langle CH_2O \rangle + 2S^0 + 2Na_2SO_4 \quad (4)$$



$$3CO_2 + 2S^0 + 5H_2O \xrightarrow{\text{light}} 3\langle CH_2O \rangle + 2H_2SO_4 \quad (5)$$

The sum of equations 4 and 5 gives the ratio of CO_2 to thiosulfate:



$$2CO_2 + Na_2S_2O_3 + 3H_2O \xrightarrow{\text{light}} \langle 2CH_2O \rangle + H_2SO_4 + Na_2SO_4 \quad (6)$$

A great deal of information about the action of reduced sulfur compounds as photosynthetic electron donors has been derived from experiments with whole cell suspensions, in contrast to work with cell extracts or purified enzymes.

Most species of phototrophic bacteria depend on or are at least capable of utilizing reduced sulfur compounds as electron donors. All organisms with this capacity utilize sulfide. Elemental sulfur is readily utilized by all Chromatiaceae. The utilization of thiosulfate is rather common in Chromatiaceae, but only

very few species oxidize sulfite or tetrathionate (Trüper, 1981a).

During oxidation of sulfide, sulfur usually appears in the form of globules inside the bacterial cells. Presumably, the elemental sulfur originating from sulfide reacts immediately with surplus sulfide, thus forming polysulfide. As soon as the sulfide is exhausted, the bacteria start to oxidize the polysulfides. Although the pH inside the cells and the optimal pH of media for the Chromatiaceae is rather close to 7.0, at which pH polysulfides are rather unstable, the formation of intracellular "sulfur globules" may follow this scheme. The formation of elemental sulfur is discussed in detail by Steudel (1989). Evidence is accumulating that these "sulfur globules" are not really elemental sulfur but rather are large globular agglomerates of long-chain polythionates. This idea is supported by activation energy measurements during cyanolysis (Then and Trüper, 1983, 1984; Then, 1984), the demonstration that only traces of sulfur ring molecules are present (Steudel, 1985), the hydrophilic properties of the globules (Then and Trüper, 1983, 1984), and density measurements (Guerrero et al., 1984). A detailed investigation of comparable "sulfur" globules of the chemolitho-autotrophic species *Thiobacillus ferrooxidans* by Steudel et al. (1987) revealed that these consisted of an inner core of S_8, S_7, S_9, and S_{12}, and an outer layer of long-chain polythionates (with more than 19 sulfur atoms) which render the globules hydrophilic, so that they are covered by a hydration shell. This structure has yet to be proven for the anaerobic phototrophic sulfur bacteria.

During growth of Chromatiaceae on thiosulfate, sulfur globules appear inside the cells, derived entirely from the sulfane group of thiosulfate (Smith, 1965; Trüper and Pfennig, 1966).

In Chromatiaceae, sulfate is the end product of sulfur oxidations. All sulfur compounds oxidized to sulfate have to pass through sulfite. The enzymatic pathways of dissimilatory sulfur metabolism in Chromatiaceae can be divided into three sections with a group of enzymes each:

1. oxidation of sulfide and elemental sulfur;
2. utilization of thiosulfate; and
3. oxidation of sulfite.

Sulfide may be utilized by three different enzymes, leading to polysulfides, thiosulfate, or sulfite, respectively. The enzymatic step from sulfide to polysulfides and "sulfur" clearly involves cytochromes of the *c* type (Fischer and Trüper, 1977) as biocatalysts, and electron acceptors. The formation of thiosulfate from sulfide is catalyzed by flavocytochrome *c* as it occurs in *Chromatium* (Fischer, 1977). A "reverse" siroheme-containing sulfite reductase is responsible for sulfite formation from sulfide directly as well as from polysulfides and/or "elemental sulfur." This enzyme has been purified from *Chromatium vinosum* and characterized (Schedel et al., 1979). Thiosulfate is split to elemental sulfur and sulfite by an enzyme that may be measured by its thiosulfate-sulfur transferase (rhodanese) activity. *Chromatium vinosum* (Smith, 1966) contains thiosulfate:acceptor oxidoreductase, earlier called tetrathionase, which forms tetrathionate from thiosulfate. An enzyme oxidizing or splitting tetrathionate has not as yet been found in phototrophic bacteria. Under natural environmental conditions, however, a chemical reduction of tetrathionate by sulfide may readily occur. The enzyme adenylyl sulfate (APS) reductase, an essential enzyme in dissimilatory sulfate-reducing bacteria and in two *Thiobacillus* species was found to occur also in Chromatiaceae (Thiele, 1968; Trüper and Peck, 1970). The enzyme was purified from *Thiocapsa roseopersicina* (Trüper and Rogers, 1971). In *Chromatium vinosum* (Schwenn and Biere, 1979) and *Chromatium warmingii* (Leyendecker, 1983) it is firmly membrane-bound and cannot be solubilized. *Chromatium purpuratum* and *Chromatium gracile* lack this enzyme (Trüper and Fischer, 1982; Ulbricht, 1984). The intermediary formation of APS demands an additional enzyme to split off the sulfate moiety. This step allows conservation of the high-energy phosphate bond energy contained in APS. The enzyme ADP sulfurylase replaces the sulfate moiety of APS by inorganic phosphate, thus producing adenosine diphosphate (equation 7):

$$APS + (P_i) \rightarrow ADP + SO_4^{2-} \quad (7)$$

ADP then can be disproportionated by the enzyme adenylate kinase, leading to the formation of 1 ATP and 1 AMP per 2 ADP. This pathway has been found in six species of the Chromatiaceae (Trüper and Fischer, 1982; Ulbricht, 1984).

Another pathway that conserves the energy of APS is the replacement of its sulfate moiety by inorganic pyrophosphate, catalyzed by the action of ATP sulfurylase. Inorganic pyrophosphate is a common product of biosynthetic reactions, especially of protein biosynthesis, and therefore is readily available during the exponential growth phase of cells. An enzyme bypassing the formation of APS in phototrophic bacteria is sulfite:acceptor oxidoreductase (Trüper, 1981a; Trüper and Fischer, 1982):

$$SO_3^{2-} + H_2O \rightarrow SO_4^{2-} + 2e^- + 2H^+ \quad (8)$$

This enzyme occurs in most Chromatiaceae in addition to the APS pathway; in a few cases, instead of the latter (Ulbricht, 1984): sulfite:acceptor oxidoreductase has been partly purified and characterized from *Chromatium vinosum* (Ulbricht, 1984). Dahl and Trüper (1989) showed that the activity considered by other authors in some strains as sulfite:acceptor oxidoreductase in *Thiocapsa roseopersicina* is a nonenzymatic property of cell-free extracts. Some strains of *T. roseopersicina* are devoid of this enzyme.

The flow of electrons from reduced sulfur compounds to the photosynthetic-reaction-center bacteriochlorophyll is, in all species of the Chromatiaceae studied, mediated by *c*-type cytochromes in its final step. The nature of the direct electron acceptors (and, perhaps intermediate electron carriers) of the sulfur-oxidizing enzymes is far from being resolved in all cases. The *c*- and *b*-type cytochromes, flavocytochromes *c*, and high-potential nonheme iron-sulfur proteins are all possible candidates (Fischer, 1984).

In the Chromatiaceae, autotrophic CO_2 fixation is performed by the reductive ribulosebisphosphate cycle (Calvin cycle) with ribulosebisphosphate carboxylase and phosphoribulokinase as the key enzymes. Although not all species have been studied in detail, there is enzymological proof for the Calvin cycle in *Chromatium vinosum* (Fuller et al., 1961), *C. okenii* (Trüper, 1964), *Thiocapsa roseopersicina* (Kondratieva et al., 1976; Zhukov, 1976), and *T. pfennigii* (Sahl and Trüper, 1977). Undoubtedly all species of the family posses the Calvin cycle when they are growing photolithoautotrophically (Kondratieva, 1979).

The enzymatic equipment necessary to make use of the assimilated carbon in phototrophic bacteria does not substantially differ from that of other prokaryotes. Versatility in carbon metabolism is higher in those Chromatiaceae with small cells (e.g., *C. vinosum, Thiocapsa roseopersicina*), than in the Chromatiaceae with large cells (e.g., *C. okenii, Thiospirillum jenense*) (Trüper, 1981b). The latter group is obligately photolithoautotrophic, however, with a certain mixotrophic potential, i.e., these species depend strictly on a supply of CO_2 and sulfide even when they are also utilizing acetate or pyruvate.

In principle, assimilatory nitrogen and sulfur metabolism is not different from that of nonphototrophic bacteria. The majority of photolithoautotrophic bacteria are able to fix dinitrogen, although in some species this capability is found only in certain strains. As dinitrogen fixation is linked with hydrogen (gas) production, this field has received much attention in research (for reviews, see Vignais et al., 1985; Hallenbeck, 1987).

Ammonia is used as the preferred nitrogen source by all species of phototrophic bacteria. As in other bacteria, it is assimilated via glutamine synthetase and further distributed via transamination (the "GOGAT" system). Nitrate is not utilized by Chromatiaceae.

In their natural environments, Chromatiaceae usually have access to abundant concentrations of reduced sulfur compounds—predominantly sulfide—for assimilation as well as for energy metabolism. Sulfur is bound to the carbon skeleton via *O*-acetylserine sulfhydrylase, forming cysteine (Hensel and Trüper, 1981). From cysteine, most of the other organic sulfur compounds needed can be synthesized. Assimilatory sulfate reduction is lacking in the large-cell species of Chromatiaceae, whereas all other species are able to assimilate sulfate and reduce it to the sulfhydryl level as nonphototrophic bacteria do.

Although several species of the Chromatiaceae are relatively oxygen tolerant, only *Thiocapsa roseopersicina* can also grow under fully aerobic conditions, either chemoorganoheterotrophically (Pfennig, 1970), or chemolithotrophically by the oxidation of reduced sulfur compounds (Kondratieva et al., 1976). Chemolithotrophic growth in the dark at low oxygen tension has been found in *Amoebobacter roseus* (Gorlenko, 1974), *Thiocapsa roseopersicina* (Kondratieva et al., 1975), *C. minus, C. vinosum, C. gracile, C. violascens,* and *Thiocystis violacea* (Kämpf and Pfennig, 1980). No growth under such conditions was found in *Thiospirillum jenense, C. okenii, C. weissei, C. warmingii, Thiocapsa pfennigii, Lamprocystis roseopersicina, Thiodictyon elegans, Thiodictyon bacillosum, Amoebobacter pendens,* and *Thiopedia rosea* (Kämpf and Pfennig, 1980). In *Thiocapsa roseopersicina,* the same pathway of sulfide oxidation to sulfate is used as under anaerobic conditions in the light (Dahl and Trüper, 1989).

Anaerobic growth in the dark is very poor in Chromatiaceae; several species have been found to possess a fermentative metabolism (Krasilnikova, 1976; Krasilnikova et al., 1975, 1983; van Gemerden 1968a, 1968b) that at least guarantees survival in the absence of light and oxygen. During fermentation of storage carbohydrate, the intracellular "sulfur" globules serve as an electron sink, and sulfide is excreted (van Gemerden, 1968a, 1968b, 1974).

Applications

The use of phototrophic sulfur bacteria in large-scale processes has the advantages that light is a clean energy source and oxygen is not required. The disadvantages are, however, the technical problems of illumination and corrosive effects of sulfide-containing media upon metal parts.

Nevertheless, these bacteria have been and are being used in a number of biotechnological processes (Mitsui, 1979), including:

production of single cell protein (biomass),
sewage and effluent treatment,
sulfide removal and S^0 production,
production of molecular hydrogen, and
production of organic molecules.

M. Kobayashi and coworkers (e.g., Kobayashi and Tchan, 1973; Kobayashi and Kurata, 1978, Kobayashi et al. 1971) developed a sewage-treatment plant working with mixed natural enrichments of phototrophic sulfur and nonsulfur bacteria. They showed that the biomass could be used as fish and chicken feed as well as fertilizer in citrus fruit cultivation. In addition to the organic and sulfide contents of a variety of sewages, phototrophic bacteria completely removed bad-smelling substances, such as putrescine, cadaverine, and mercaptans, as well as the carcinogen dimethylnitrosamine (Kobayashi and Tchan, 1978).

A laboratory-scale tube system for the degradation of poultry and cattle manure was described by Ensign (1977).

A simple but effective system for effluent treatment is lagooning, where liquid wastes from food industries or communities are fed into large shallow open lagoons. Such systems have been studied several times with respect to the abundance of phototrophic bacteria in them: *Chromatium* sp. in petroleum refinery waste, *Thiopedia rosea* in animal-fat-rendering waste (Cooper, 1963, 1965; Cooper et al., 1975), Chromatiaceae in municipal sewage (May and Stahl, 1967), *Thiocapsa roseopersicina* and *C. vinosum* in potato waste (Holm and Vennes, 1970), *Thiopedia rosea* in feedlot manure (Wenke and Vogt, 1981), and *Thiocapsa roseopersicina* in sugar-factory effluents (N. Pfennig and H. G. Trüper, unpublished observations).

Bharati et al. (1982) showed complete degradation of cellulose by mixed cultures of sulfate-reducing bacteria, anaerobic cellulose decomposers, and *C. vinosum.*

So far, species of the Chromatiaceae have not been used specifically for sulfide removal and sulfur production from H_2S-containing fluids and gases.

Bollinger et al. (1985) developed a system to produce hydrogen gas by phototrophic bacteria growing in sugar-refinery waste water. Immobilized purified hydrogenase of *Thiocapsa roseopersicina* has been used in biofuel cells (Yarapolov et al., 1982).

Chromatiaceae can be used for the production of vitamin B_{12} (Toohey, 1971; Koppenhagen, 1981; Koppenhagen et al., 1981) and biotin (Filippi and Vennes, 1971).

It is surprising that so far no use has been made of the wide spectrum of colorful carotenoids produced by purple sulfur bacteria.

CHAPTER 171

The Family Ectothiorhodospiraceae

JOHANNES F. IMHOFF

The family Ectothiorhodospiraceae at present contains a single genus, *Ectothiorhodospira.* All species of this genus have rod- to spiral-shaped cells, with intracytoplasmic membranes as lamellar stacks (Cherni et al., 1969; Holt et al., 1968; Imhoff and Trüper, 1977, 1981; Imhoff et al., 1981; Raymond and Sistrom, 1967, 1969; Remsen et al., 1968; Oren et al., 1989). Species of this genus form two subgroups, one containing extremely halophilic species, the other containing species with lower salt requirements. The division into two subgroups is supported by the type of flagellation, the quinone content, and the similarity coefficients of the 16S rRNA (Imhoff, 1984b; Stackebrandt et al., 1984).

The position of *Ectothiorhodospira* species among the phototrophic purple bacteria has been disputed since their discovery by Pelsh (1936). He distinguished these bacteria, which he called "Ectothiorhodaceae," from those purple bacteria with elemental sulfur inside their cells, which he called "Endothiorhodaceae" (Pelsh, 1937). Pelsh's isolates were poorly characterized and were lost soon after their isolation. Trüper (1968) reisolated *Ectothiorhodospira mobilis,* and Pfennig and Trüper (1971) included *Ectothiorhodospira* as an exceptional genus into the Chromatiaceae because of its ability to perform a dissimilatory sulfur metabolism. With the isolation of new species and the availability of chemotaxonomic data, additional properties of *Ectothiorhodospira* species became apparent that clearly separate this genus from those of the Chromatiaceae. Therefore, the reassignment of the genus *Ectothiorhodospira* to the new family Ectothiorhodospiraceae has been proposed (Imhoff, 1984a).

Habitats

In comparison with Chromatiaceae and purple nonsulfur bacteria, Ectothiorhodospiraceae are more restricted in their natural distribution because of their growth requirements for alkalinity and salinity. Like other phototrophic sulfur bacteria, they may develop in the presence of anoxic conditions, soluble sulfide, light, and bicarbonate. A small number of simple organic compounds, such as certain fatty acids, markedly stimulate their growth. *Ectothiorhodospira* species have been isolated from marine sources and hypersaline lakes, such as estuaries, salt flats, salt lakes, and soda lakes, from many parts of the world (Grant et al., 1979; Imhoff and Trüper, 1976, 1977, 1981; Imhoff et al., 1978, 1979, 1981; Matheron and Baulaigue, 1972; Pelsh, 1936; Raymond and Sistrom, 1967; Tew, 1966; Tindall, 1980; Trüper, 1968, 1970; Ventura et al., 1988) (for review, see Imhoff, 1988a). More recently a new species, *Ectothiorhodospira marismortui* has been isolated from a hypersaline sulfur spring (Oren et al., 1989). Occasionally, certain *Ectothiorhodospira* species may be found in soil. Alkaline soda lakes show a natural abundance of *Ectothiorhodospira* species (Imhoff et al., 1978, 1979), which can be taken as proof of their successful adaptation to these environments. Because of their mass development in alkaline soda lakes, the extremely halophilic species may cause red or green coloration of these habitats. *E. abdelmalekii, E. halochloris,* and in particular *E. halophila* are among the most halophilic phototrophic bacteria (see Imhoff, 1988a). Isolates of *E. halophila* from soda lakes in the Wadi Natrun (Egypt), which have salt optima of 25% total salts and also can grow in saturated salt solutions, are the most halophilic eubacteria known to date.

Isolation

Selective Enrichment

For the extremely halophilic species, the dependence on and the tolerance to high salinity and alkalinity are strongly selective conditions for their enrichment. Marine strains of *Ectothiorhodospira* have been selectively enriched under photoautotrophic conditions in Pfennig's medium (Pfennig, 1965; Pfennig and Trüper,

1981) with sulfide as an electron donor, and in saline and alkaline media (3% NaCl and pH 8.5 to 9.0), even in the presence of high numbers of *Chromatium* cells in the natural sample (Trüper and Imhoff, 1981). Many *Ectothiorhodospira* strains have been isolated from various locations with a medium based on the mineral composition of the soda lakes of the Wadi Natrun (Imhoff and Trüper, 1977; Imhoff et al., 1979; Jannasch, 1957) and modifications thereof. Depending on the species composition of the sample and the salt concentration of the media (from 3 to 25%), various *Ectothiorhodospira* species will develop in enrichment cultures. Investigations of the vitamin requirements of a number of *Ectothiorhodospira* isolates have demonstrated that vitamins are not essential, although vitamin B_{12} stimulates growth in some strains.

Isolation Procedures

For enrichment, environmental samples are inoculated into suitable media in 20-ml screw-cap test tubes or 50-ml bottles, which are completely filled with medium. For isolation, agar dilution series are prepared either with enrichment cultures or with promising natural samples by direct inoculation from the environment. Selectivity is not necessary with media used for direct isolation without prior enrichment procedures.

Preparation of Agar Dilution Series

In a modification of the method of Pfennig (1965; see also Trüper, 1970), purified agar is dissolved (1.8%) and distributed in amounts of 3 ml into cotton-plugged test tubes. The agar is sterilized by autoclaving. The liquid agar is kept at 50°C in a water bath until use. A suitable medium is placed in the same water bath, and 6 ml of the prewarmed medium is added to each test tube. Medium and agar are mixed thoroughly by turning the tubes upside down and back and kept at 50°C. Six to eight tubes are sufficient for each dilution series. The first tube is inoculated with a natural sample or enrichment culture and mixed carefully; approximately 0.5 to 1.0 ml is transferred to a second tube, mixed carefully, and the procedure continued up to the last tube. The tubes are immediately placed into a cold water bath. After the agar has hardened, they are sealed with a paraffin mixture (3 parts paraffin oil and 1 part paraffin) and kept in the dark for several hours before incubating them in light (500–2,000 lux). After cells have grown to visible colonies, the paraffin layer is removed by melting, and well-separated colonies are picked with a Pasteur pipette (the tip drawn out to a thin capillary) and transferred to a second dilution series. In general, three to four such dilution series are necessary to obtain pure cultures. When pure cultures have been obtained, single colonies are inoculated into liquid medium.

Cultivation on Agar Plates

A convenient method for growing phototrophic sulfur bacteria on agar plates has been described by Irgens (1983). Medium without added sulfide is used with the GasPak system (Becton Dickinson and Co., Cockeysville, MD). As a source of sulfide, a test tube with 0.05 to 0.1 g of thioacetamide and 1 ml of 0.5 N HCl are placed in the anaerobic jar. Thioacetamide decomposes under acidic conditions to ammonia, hydrogen sulfide, and acetic acid. The H_2S gas is released over a period of at least one week. As indicators, methylene blue (for oxygen) and a strip with lead acetate (for H_2S) are included. This method is also a convenient method for performing viable counts of purple sulfur bacteria. It has been successfully used for the isolation of species of the genera *Amoebobacter, Chromatium, Lamprocystis, Thiocapsa, Thiocystis,* and *Ectothiorhodospira* (Irgens, 1983).

Media for *Ectothiorhodospira* Species

Enrichment and subsequent isolation of *E. mobilis* and *E. shaposhnikovii* have been achieved by using Pfennig's medium with 3% NaCl at alkaline pH 8.0 to 8.5 (Trüper, 1970). This medium, however, is not suitable for the extremely halophilic species *E. halochloris, E. halophila,* and *E. abdelmalekii.* Raymond and Sistrom (1967) described a medium for the cultivation of *E. halophila* (for recipe, see Trüper and Imhoff, 1981). Apparently, *E. marismortui* also does not grow on these media, and therefore a modified medium was used for isolation and cultivation of this new species (Oren et al., 1989).

A medium based on the mineral salts composition of the soda lakes of the Wadi Natrun has been used for isolation of many *Ectothiorhodospira* strains from this and other environments (Imhoff and Trüper, 1977, 1981; Imhoff et al., 1978, 1981). This medium is well suited for isolation and cultivation of most of the *Ectothiorhodospira* species. It is buffered by bicarbonate (200 mM, pH 9.0) and adjusted to the desired salinity by changing the concentration of NaCl. In our experience, Raymond and Sistrom's strain also grows better in the mineral salt-based medium described here as compared with the one described by Raymond and Sistrom (1967). The mineral composition of this

medium (Imhoff and Trüper, 1977) and its preparation method have been modified several times. Although trace element solutions and sulfide solutions were sterilized separately, the filtration procedures used formerly yielded less reproducible growth, presumably because of some interaction of medium constituents with the filters. The reproducibility of growth was much better with the preparation method described by Imhoff (1988b):

Medium for Extremely Halophilic *Ectothiorhodospira* Species

The basal medium has the following composition (amounts per liter for a medium with 15% salinity):

Trace element solution SLA (see below)	1 ml
KH_2PO_4	0.8 g
Na acetate	2.0 g
$Na_2S_2O_3 \cdot 5H_2O$	1.0 g
NaCl	130.0 g
1 M Na carbonate, pH 9.0	200 ml

Trace element solution SLA (Imhoff and Trüper, 1977):

$FeCl_2 \cdot 4H_2O$	1,800 mg
$CoCl_2 \cdot 6H_2O$	250 mg
$NiCl_2 \cdot 6H_2O$	10 mg
$CuCl_2 \cdot 2H_2O$	10 mg
$MnCl_2 \cdot 4H_2O$	70 mg
$ZnCl_2$	100 mg
H_3BO_3	500 mg
$Na_2MoO_4 \cdot 2H_2O$	30 mg
$Na_2SeO_3 \cdot 5H_2O$	10 mg

The salts are dissolved separately in a total of 900 ml of double-distilled water; the pH is adjusted with 1 N HCl to about 2–3, and the volume is brought to 1 liter.

The components are dissolved in 600 ml of distilled water and the carbonate buffer is added. The volume is then adjusted to 980 ml and the solution is autoclaved. The salinity is adjusted to the desired value by variation of the NaCl content (assuming a contribution of 2% by the other medium constituents). The remaining salts (see below) are sterilized separately and, after they have cooled down, are added under gentle stirring. The final pH is 9.0.

2% $MgCl_2 \cdot 7H_2O$ (5 ml/liter)
1% $CaCl_2 \cdot 2H_2O$ (5 ml/liter)
5% $Na_2S \cdot 9H_2O$ (5–10 ml/liter)
20% NH_4Cl (4 ml/liter)

The medium is then immediately placed in sterilized culture vessels, which are almost completely filled with only a small air bubble left. The vessels are preincubated at the incubation temperature (33 to 40°C) to achieve volume expansion and then inoculated with 10% of a fresh preculture.

The addition of $Na_2S_2O_3$ is not necessary for the two green-colored *Ectothiorhodospira* species, as these can not use thiosulfate. In the red-colored species, it is suitable as an additional electron donor, and makes feeding with sulfide unnecessary. Acetate is a suitable carbon source for all species and may also be used as an additional electron donor.

In standard media for *E. halochloris* and *E. abdelmalekii* 10% of the total salinity is added as Na_2SO_4, and the NaCl is reduced by the equivalent amount (in g per liter). If *E. mobilis* is grown photoheterotrophically, reduced sulfur compounds are omitted and sodium ascorbate (0.1%) is added to achieve anoxic conditions. Under these conditions, sulfate is used as sole sulfur source.

Medium for *Ectothiorhodospira marismortui* (Oren et al., 1989)

For the preparation of 1 liter of medium, in a volume of 900 ml are dissolved:

NaCl	100 g
Na_2SO_4	0.5 g
Yeast extract (Bacto)	0.1 g

The following components were sterilized separately and added as sterile solutions to the medium to final concentrations of:

KH_2PO_4	0.33 g
NH_4Cl	0.33 g
KCl	0.33 g
$MgCl_2 \cdot 6H_2O$	0.33 g
$CaCl_2 \cdot 2H_2O$	0.33 g
Na acetate·3 H_2O	0.5 g
Na_2CO_3	1.5 g
Trace element solution (Pfennig and Lippert, 1966)	10 ml

The pH is adjusted with 1 M HCl to a final value of 6.5–6.8. Immediately before use of the medium, $Na_2S_2O_4$ was added to a final concentration of 0.08 g/liter from a freshly prepared filter-sterilized solution. Sulfide may be used as an electron donor and is added to a final concentration of 1 mM.

Cultivation

In general, cultivation of *Ectothiorhodospira* is possible in any size of bottle and in glass fermenters as long as the illumination is sufficient and the temperature is controlled. Cultures are incubated at 1,000 to 20,000 lux (approximately 100 to 2,000 foot candles) and at temperatures between 33 to 40°C. The pH optima found with different strains and species (and also in different media) are between 7.4 and 9.1. Salt optima of the different species are shown in Table 1. For routine cultivation with the medium for extremely halophilic *Ectothiorhodospira* species, we use salinities of 15% for *E. abdelmalekii, E. halochloris,* and some strains of *E. halophila* (including the type strain), 25% for the most halophilic strains of *E. halophila,* 5% for *E. vacuolata* and some strains of *E. mobilis,* and 2% for *E. shaposhnikovii.*

Table 1. Some characteristic properties of the *Ectothiorhodospira* species.

Species	Cell shape	Cell diameter (μm)	Flagellation	Color of culture	Major carotenoid	Major bchl	Major quinone	Gas vacuoles	Optimal salinity range	GC content (mol%)
Ectothiorhodospira										
mobilis	Rod—spiral	0.7–1.0	Polar	Red	sp	*a*	Q-7,MK-7	−	3–10%	62.0–69.9
shaposhnikovii	Rod—spiral	0.8–0.9	Polar	Red	sp	*a*	Q-7,MK-7	−	1–3%	61.2–62.8
vacuolata	Rod	1.5	Polar	Red	sp	*a*	Q-7,MK-7	+	1–6%	61.4–63.6
marismortui	Rod	0.9–1.3	Polar	Red	(sp)	*a*	ND	−	3–8%	65
halophila	Spiral	0.8–0.9	Bipolar	Red	sp	*a*	Q-8,MK-8	−	12–30%	64.3–69.7
halochloris	Spiral	0.5–0.6	Bipolar	Green	rhg,rh	*b*	Q-8,MK-8	−	14–20%	50.5–52.9
abdelmalekii	Spiral	0.9–1.2	Bipolar	Green	*	*b*	Q-8,MK-8	−	12–20%	63.3–63.8

Abbreviations. Carotenoids: rh = rhodopin; rhg = rhodopin glucoside and derivatives; sp = spirilloxanthin; (sp) = most probably spirilloxanthin; * = most probably similar to *E. halochloris*. bchl = bacteriochlorophyll; Q = ubiquinone; MK = menaquinone; ND = no data available.

Based on Imhoff (1984a), Imhoff and Trüper (1981), Imhoff et al. (1981), Oren et al. (1989), Schmidt and Trüper (1971), and Trüper and Imhoff (1981).

The less halophilic isolates may be grown on Pfennig's medium for purple sulfur bacteria (Pfennig, 1965) adjusted to the desired pH and salinity.

Preservation of Cultures

Well-grown cultures in screw-cap bottles may be kept at 4°C in a refrigerator or at room temperature. Screw-cap bottles with strains of *E. mobilis* and *E. halophila* that have been kept on a laboratory desk for several years contained numerous viable cells that grew well after transfer into fresh medium. Maintenance transfer of cultures should be every 2 to 6 months. In particular, cultures of *E. halochloris* and *E. abdelmalekii* lose viability much faster than do cultures of the other species. *Ectothiorhodospira* strains have also been stored in closed ampules kept in liquid nitrogen with good viability after more than 20 years.

Identification

Morphological and physiological properties are both very important for the identification of phototrophic bacteria. The Ectothiorhodospiraceae are distinguished from the Chromatiaceae by the intermediate deposition of elemental sulfur outside the cells. Their dependence on saline and alkaline growth conditions and the presence of intracytoplasmic membranes as lamellar stacks are characteristic.

Cells are rod- to spiral-shaped and are motile by means of mono- or bipolar tufts of flagella (Fig. 1, Table 1). They form red- or green-colored colonies. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series, with spirilloxanthin as the predominant component in the red-colored species (Schmidt and Trüper, 1971). Two green-colored species, *E. halochloris* and *E. abdelmalekii,* contain bacteriochlorophyll *b* esterified with Δ-2,10-phytadienol, not with phytol as is the bacteriochlorophyll *a* of the other *Ectothiorhodospira* species (Steiner et al., 1981; R. Steiner, personal communication). The carotenoid content is low in *E. halochloris* and *E. abdelmalekii.* The carotenoid composition of both of these species is apparently quite similar. Mainly methoxyrhodopin glucoside (major), rhodopin glucoside, and rhodopin have been found in *E. halochloris* (K. Schmidt, personal communication). Absorption spectra of living cells or chromatophore suspensions allow the identification of the bacteriochlorophyll present and provide some information on the types of carotenoids present (Fig. 2).

c

Fig. 1. Comparison of *Ectothiorhodospira* species. (*a*) *E. mobilis* DSM 237; (*b*) *E. halophila* BN 9621; (*c*) *E. halochloris* ATCC 35916. Note large and small sulfur globules in (*a*) and (*c*). Bar = 10 μm.

Ectothiorhodospira species have a characteristic composition of polar lipids (Asselineau and Trüper, 1982; Imhoff et al., 1982), fatty acids, and quinones (Imhoff, 1984a, 1984b), which distinguishes this group from Chromatiaceae and purple nonsulfur bacteria (Rhodospirillaceae).

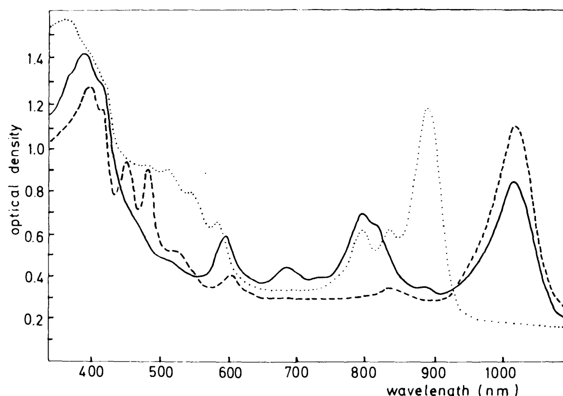

Fig. 2. Absorption spectra of chromatophore suspensions of: *Ectothiorhodospira halochloris* (———), *Ectothiorhodospira halophila* (.........), and, as reference, the bacteriochlorophyll *b*-containing *Rhodopseudomonas sulfoviridis* (---------).

DNA hybridization studies demonstrated the close similarity of *E. mobilis* and *E. shaposhnikovii* (Ivanova et al., 1985; Turova et al., 1982), although analysis of 16S rRNA clearly revealed a larger distance between these two species (Stackebrandt et al., 1984). The currently known species are well characterized by their content of pigments, salinity requirement, GC content of the DNA, major quinones, pigments, and cell sizes (Table 1).

Verification of enriched and isolated *Ectothiorhodospira* species is best obtained by comparison with the type strains deposited in and available from culture collections such as the American Type Culture Collection (ATCC, Rockville, Maryland) and the Deutsche Sammlung von Mikroorganismen (DSM, Göttingen, FRG). The type strains are: *E. mobilis* (DSM 237), *E. shaposhnikovii* (DSM 243), *E. vacuolata* (ATCC 43036, DSM 2111), *E. halophila* (DSM 244), *E. halochloris* (ATCC 35916), *E. abdelmalekii* (ATCC 35917), and *E. marismortui* (DSM 4180).

Physiological Properties

All *Ectothiorhodospira* species grow well under anaerobic conditions in the light, with reduced sulfur compounds as photosynthetic electron donors and in the presence of organic carbon sources and inorganic carbonate. *Ectothiorhodospira mobilis* and *E. shaposhnikovii* also grow microaerobically in the dark if sulfide is present. During phototrophic growth with sulfide as an electron donor, sulfide is first oxidized to elemental sulfur which is then oxidized to sulfate, as has been shown for *E. mobilis* (see Trüper, 1978). Under alkaline growth conditions that are favorable for *Ectothiorhodospira* species, polysulfides are stable intermediates in sulfide oxidation. As a result, polysulfides (probably formed by the chemical reaction between elemental sulfur and sulfide) and elemental sulfur are the first measurable oxidation products, and the medium becomes yellow-translucent at this stage. After sulfide depletion, elemental sulfur droplets are rapidly formed and the medium becomes cloudy to opaque. During further growth, cultures of red-colored species become pinkish and finally red if elemental sulfur disappears. These color changes are best observed with the red-colored species under photoautotrophic growth conditions. Our knowledge about the enzymes involved in the oxidation of reduced sulfur compounds by *Ectothiorhodospira* species has recently been summarized by Trüper and Fischer (1982).

Under autotrophic growth conditions, the fixation of carbon dioxide via the ribulose-bisphosphate pathway is apparently the major route of carbon assimilation in *E. shaposhnikovii* (Firsov et al., 1974). High activities of ribulose-bisphosphate carboxylase have been found in *E. shaposhnikovii* (Firsov et al., 1974), *E. mobilis* (Sahl and Trüper, 1977), and *E. halophila* (Tabita and McFadden, 1972). Under photoheterotrophic growth conditions, considerable proportions of cellular carbon are derived from carbon dioxide, which is assimilated by pathways not involving ribulose-bisphosphate pathway. The assimilation of several organic carbon sources (such as acetate and propionate) depends on the presence of carbon dioxide and proceeds via several carboxylation reactions (Firsov and Ivanovsky, 1974, 1975). Phosphoenolpyruvate carboxylase, ferredoxin-dependent pyruvate synthase, and α-ketoglutarate synthase were found in *E. shaposhnikovii* (Firsov et al., 1974); phosphoenolpyruvate carboxylase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase were found in *E. mobilis* (Sahl and Trüper, 1977). All enzymes of the glycolytic pathway and the tricarboxylic acid cycle, with the exception of α-ketoglutarate dehydrogenase, are present in *E. shaposhnikovii* (Krasilnikova, 1975). Cells grown on acetate had increased activities of isocitrate lyase, indicative of the function of the glyoxylic acid pathway. Poly-β-hydroxybutyric acid is the principal reserve material formed from acetate and butyrate in the absence of carbon dioxide. In the presence of carbon dioxide, carbohydrates are preferentially formed from acetate and butyrate as well as from other carbon sources (Novikova, 1971).

One of the most prominent properties of *Ectothiorhodospira* species is their ability to adapt to the most extreme salt concentrations tolerated by eubacteria. They not only tolerate these high concentrations, but optimally thrive. The structural and physiological basis of this adaptation is currently under investigation. To adapt to these high and sometimes varying concentrations of salts, *Ectothiorhodospira* species accumulate high concentrations of organic solutes that balance the outside osmotic pressure. In *Ectothiorhodospira halochloris,* glycine betaine has been found to be the main osmotically active cytoplasmic component (Galinski and Trüper, 1982), but by ^{13}C-NMR techniques, ectoine, a new cyclic amino acid, and trehalose were found in *E. halochloris* (Galinski et al., 1985) and in other species of *Ectothiorhodospira* (Imhoff and Galinski, unpublished observations; see also Imhoff, 1988a).

Applications

Like other phototrophic sulfur bacteria, *Ectothiorhodospira* species (in particular *E. mobilis* and *E. shaposhnikovii*) are suited for the removal of toxic sulfide from waste waters. Their growth requirements call for their application under alkaline and saline conditions. Further studies are necessary to show whether the isolation of ectoine from *Ectothiorhodospira* deserves applicability. At present, *Ectothiorhodospira* and products thereof are not used in commercial and technical processes.

CHAPTER 172

The Genus *Oceanospirillum*

BRUNO POT, MONIQUE GILLIS, and JOZEF DE LEY

Although *Oceanospirillum* (Hylemon et al., 1973) is a genus that has been only recently described, some of its members have a very long history as former species of the genus *Spirillum* (Ehrenberg, 1832).

Members of *Oceanospirillum* consist of rigid, helical, Gram-negative cells that have a clockwise helix. The cells have a diameter of 0.4 to 1.4 μm; the length of the helix is 1.2 to 75 μm. Cells are motile by bipolar tufts of flagella. In all species examined so far by electron microscopy, a polar membrane underlies the cytoplasmic membrane at the cell poles. Intracellular poly-β-hydroxybutyrate (PHB) is formed. The strains of most species form thin-walled coccoid bodies, which predominate in old cultures. They are chemoorganotrophic with a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate respiration does not occur and nitrate is not reduced to nitrite or beyond this stage. The optimum temperature for growth is 25° to 32°C. Cells are oxidase-positive, indole-negative, and casein, starch, hippurate, and esculin are not hydrolyzed. Carbohydrates are neither fermented nor oxidized and amino acids or organic acids serve as carbon sources. Seawater is required for growth. Growth factors are usually not required. The organism is isolated from coastal seawater, from decaying seaweed, and from putrid infusions of marine mussels. The GC content of the DNA ranges from 45 to 50 mol%, as determined by the thermal denaturation method. The type species is *Oceanospirillum linum* (Hylemon et al., 1973) and the type strain is *O. linum* ATCC 11336.

During the last 15 years, the classification of both freshwater and marine spirilla has changed considerably. In the original description (Hylemon et al., 1973), *Oceanospirillum* comprised five species: *O. linum, O. minutulum, O. beijerinckii, O. maris,* and *O. japonicum* (Table 1). Four other species, *O. hiroshimense, O. pelagicum, O. pusillum,* and *O. multiglobuliferum* (Table 1) were created later by Terasaki (1973, 1979). These nine species are described by Krieg (1984) in *Bergey's Manual of Systematic Bacteriology.*

Bowditch et al. (1984) and DeLong et al. (1984) reported a close immunological relationship among *O. linum, O. beijerinckii, Marinomonas vaga, M. communis* (Van Landschoot and De Ley, 1983), and two unnamed groups (groups H-1 and I-1) of marine bacteria. Although these relationships were not confirmed by other methods, Bowditch et al. (1984) concluded that *M. communis* and *M. vaga* should be assigned to the genus *Oceanospirillum* as *O. vagum* and *O. commune,* and they created the species *O. jannaschii* and *O. kriegii* for the two unnamed groups H-1 and I-1 respectively (Table 1). An unfortunate consequence of this extension of the genus *Oceanospirillum* was the loss of most of the readily determinable phenotypic features of the genus definition and the extension of the upper GC values for the genus from 51 to 57 mol% (Bowditch et al., 1984). Using DNA:rRNA hybridizations, Pot et al. (1989) showed that *O. vagum, O. commune, O. jannaschii,* and *O. kriegii* were erroneously included in the genus *Oceanospirillum.* Moreover, it was shown that *O. minutulum* and *O. pusillum* were likewise generically misnamed and ought to be removed from the genus *Oceanospirillum.* Using DNA-DNA hybridizations and protein gel electrophoresis, it was further shown that *O. hiroshimense* was very closely related to, and should be considered a subspecies of, *O. maris,* and that *O. pelagicum* is a subspecies of *O. beijerinckii.* Table 2 lists the differential characteristics for the five species of the emended genus *Oceanospirillum* (Pot et al., 1989).

As representatives of the genus *Oceanospirillum* and *Aquaspirillum* have a long common history as members of the genus *Spirillum,* many methods mentioned in the present chapter are described in more detail in Chapters 130 and 131.

Table 1. List of strains previously included in the genus *Oceanospirillum*.

Species name as in Krieg, 1984 and Bowditch et al., 1985[a]	Type strain		Source, place, and year of isolation	Reference
	Strain no. as received[b]	LMG no.[c]		
O. beijerinckii	NCMB 52	LMG 5405	Coastal water, United States, 1957	Williams and Rittenberg, 1957; Hylemon et al., 1973
[O.] commune	ATCC 27118	LMG 2864	Coastal surface water, Oahu, Hawaii, 1972	Baumann et al., 1972; Van Landschoot and De Ley, 1983; Bowditch et al., 1984
O. [hiroshimense]	IFO 13616	LMG 7371	Marine shellfish, 1963	Terasaki, 1973, 1979
[O.] jannaschii	ATCC 27135	LMG 6239	Coastal surface water, Oahu, Hawaii, 1972	Baumann et al., 1972; Bowditch et al., 1984
O. japonicum	ATCC 19191	LMG 5215	Marine shellfish, 1959	Watanabe, 1959; Hylemon et al., 1973
[O.] kriegii	ATCC 27133	LMG 6238	Coastal surface water, Oahu, Hawaii, 1972	Baumann et al., 1972; Bowditch et al., 1984
O. linum	ATCC 11336	LMG 5214	Coastal water, United States, 1957	Williams and Rittenberg, 1957; Hylemon et al., 1973
O. maris subsp. *maris*	ATCC 27509	LMG 5213	Seawater, 1973	Hylemon et al., 1973
O. maris subsp. *williamsae*	ATCC 29547	LMG 5210	From mixed culture, 1978	Linn and Krieg, 1978
[O.] minutulum	ATCC 19193	LMG 5334	Marine shellfish, 1959	Watanabe, 1959; Hylemon et al., 1973
O. multiglobuliferum	IFO 13614	LMG 5306	Marine shellfish, 1960	Terasaki, 1973, 1979
O. [pelagicum]	IFO 13612	LMG 5307	Marine shellfish, 1966	Terasaki, 1973, 1979
[O.] pusillum	IFO 13613	LMG 5308	Marine shellfish, 1961	Terasaki, 1973, 1979
[O.] vagum	ATCC 27119	LMG 2845	Coastal surface water, Oahu, Hawaii, 1972	Baumann et al., 1972; Van Landschoot and De Ley, 1983; Bowditch et al., 1984

Habitats

In a search for spirochaetes in Baltimore market oysters, Dimitroff (1926a, 1926b) found and isolated a spirillum *("Spirillum virginianum")* from the mud adhering to the outside of an oyster shell. It has been proven since that marine and freshwater shellfish are a source of spirilla. Although Watanabe (1959) isolated marine spirilla from the viscera of marine shellfish and Terasaki (1963, 1970) observed spirilla in the alimentary tracts of marine shellfish, it is more likely that the adherent mud is the source of the spirilla (Terasaki, 1963, 1970). Williams and Rittenberg (1957) isolated many strains from seawater samples taken from the intertidal zone and Jannasch (1963a, 1963b) isolated a marine spirillum from decaying seaweed. Whether *Oceanospirillum* occurs in the open sea is unknown. There is only one report, by Oppenheimer and Jannasch (1962), in which direct microscopic counts of bacteria present in clear and turbid seawaters near Port Aransas, Tex., revealed that 0.1 to 2.5% of the total bacterial population consisted of spirilla, compared to 0.9 to 4.8% vibrios and 90.0 to 99.5% cocci. The same study demonstrated that the turbid water along the shore of Redfish Bay contained 2.9×10^7 bacteria per ml, compared to 9×10^5 per ml outside the Gulf surf where the water was clear. This possible effect of nutrient concentration was further investigated by Jannasch (1963a, 1963b) with a marine spirillum isolated from decaying seaweed, using a chemostat with extremely low concentrations of asparagine as a nitrogen-limiting nutrient. With a medium composed of 3% commercial sea salt, phosphate buffer, lactate as carbon source, and asparagine as the limiting source of nitrogen, Jannasch maintained a steady state population of about

Table 2. Differential features of the species in the redefined genus *Oceanospirillum*.[a]

Feature	*O. linum*	*O. maris*	*O. beijerinckii*	*O. multiglobuliferum*	*O. japonicum*
Length of helix (μm)	4.0–30.0	2.5–40.0	2.0–15.5	2.0–10.0	5.0–75.0
Cell diameter (μm)	0.4–0.6	0.6–1.1	0.6–1.2	0.5–0.9	0.8–1.4
Coccoid bodies predominant					
After 3–4 weeks	+	+	+	+	−
After 24–48 h	−	−	−	+	−
Maximum salt tolerance not higher than 4% NaCl	−	−	−	+	−
Optimum temperature 25°C rather than 30–32°C	−	d[b]	−	−	−
Phosphatase	+	d[b]	+	+	W
Catalase	+ or W	d[b]	+ or W	+	W or −
Auxotrophic growth requirement	+[c]	d[d]	−	−	−
GC content (mol%)	48–50	45–47	47–49	46	45

Symbols: +, present in all strains; −, lacking in all strains; d, differs among strains; W, weak reaction.
[a]The phenotypic data are from Krieg (1984).
[b]*O. maris* strains can have an optimum temperature of 25°C; catalase can be present, weak or lacking, or weak; phosphatase may be present or lacking. For detailed information see Hylemon et al., 1973; Terasaki, 1972 and 1979.
[c]*O. linum* grows poorly or not at all in defined media with single carbon sources and ammonium ions as the nitrogen source; however, abundant growth occurs in a defined medium containing succinate plus malate as carbon sources and methionine as the nitrogen source.
[d]*O. maris* subsp. *williamsae* ATCC 29547 fails to grow in vitamin-free defined media and requires a growth factor that has not yet been identified.

4×10^5 cells per ml at 0.28 mg of asparagine-N per liter. Experiments with unsupplemented natural seawater (even extremely polluted water from Naples Harbor) and high dilution rates (to obtain higher growth rates) indicated that the spirillum was unable to multiply faster than one generation per 24 h and was therefore washed out of the chemostat. Addition of lactate and asparagine at the concentrations established in Jannasch's previous experiments stimulated growth. Jannasch therefore suggested that the growth of the spirillum might be restricted to environments of higher nutrient concentrations than found in ordinary seawater, such as in zones surrounding decaying particulate plant matter. In support of this, he found that all enrichments from seawater were unsuccessful unless pieces of decaying seaweed were added.

Isolation

For the isolation of marine spirilla, enrichment is necessary, since these bacteria are relatively slow-growing and are never the predominant organism in natural samples. The chance of isolating spirilla is increased by sampling water in environments with higher nutrient concentrations (Jannasch, 1963a, 1963b).

Isolation by Dilution

Harold and Stanier enriched for marine spirilla in 1955 by placing pieces of thalli of marine algae in flasks almost completely filled with seawater and by incubating these infusions for several days at 25°C. Williams and Rittenberg (1957), however, found it extremely difficult to use this method to enrich the seawater samples they collected from the intertidal zone along the coast of Long Island Sound. Sufficient enrichment was finally accomplished by mixing the seawater samples with an equal volume of doublestrength Giesberger's medium (Giesberger, 1936) containing per liter:

NH_4Cl	1 g
K_2HPO_4	0.5 g
$MgSO_4 \cdot 7H_2O$	0.5 g

and by adding 1% of calcium lactate to the mixture. Calcium malate, an excellent substrate for the enrichment of freshwater forms, was not successful for the marine spirilla, although these organisms all utilized malate when grown in pure culture. After incubation, spirilla appeared and a portion of the initial culture was sterilized and mixed with an equal volume of sterile Giesberger's medium lacking ammonium chloride. This sterile mixture was then inoculated from the unsterilized portion of the initial culture. After one to three subcultures in the transfer medium, spirilla predominated. Isolation was finally accomplished by diluting the enriched culture 1:100 to 1:100,000 times (depending on the relative abundance of contaminating forms) with sterile seawater in large dilution bottles. These were shaken vigorously and allowed to stand at room temperature for 20 min to allow spirilla to migrate to the surface of the dilution mixture, where they accumulated just beneath the surface scum that generally forms in

marine cultures. A loopful of this surface water was then streaked onto nutrient agar prepared with seawater and containing 0.3% yeast autolysate. Plates were incubated at 30°C and after 24 h examined for distinctive granular, umbonate, or pulvinate colonies with ground-glass appearance. After another 24 h, wet mounts were prepared from typical colonies to confirm the presence of spirilla. Samples of spirilla yielding colonies could then be restreaked serially until all colonies developing on a plate showed cells with a uniform spirillar morphology.

The effectiveness of the limitation of the available nutrients for the isolation of marine (and freshwater) spirilla (in particular, by reuse of a partially spent medium without the addition of supplementary nitrogen source) was also demonstrated by Jannasch (1967), who found that *Oceanospirillum maris* grew faster than a *Pseudomonas* species in a continuous culture with diluted media containing lactate as the limiting nutrient. The spirilla were outgrown, however, in more concentrated media. Williams and Rittenberg (1957) were convinced that the dilution method resulted in reduced growth of the undesired types rather than stimulating the development of the spirilla.

Isolation from Putrid Infusions

Terasaki (1963, 1970, 1972) and Watanabe (1959) obtained excellent results using undiluted enrichment media. The method used by Terasaki (1970) is comparable to the one he used before (Terasaki, 1961a, 1961b) for the isolation of freshwater spirilla (see Chapter 131).

A handful of marine mussels *(Tapes philippinarum)* were washed with distilled water and smashed with a hammer. The mussels were boiled for several minutes and after cooling they were placed in a petri dish with a teaspoon of mud. The dish is filled with sterilized seawater until the mussels sink completely in the solution. This infusion is incubated at 27–28°C and examined for the development of spirilla after 1, 2, 4, and 7 days. Isolation is accomplished by streaking dilutions on suitable agar media.

Maintenance of Marine Spirilla

The cultivation of isolates has been accomplished in media containing natural or synthetic seawater. Williams and Rittenberg (1957) found that growth in synthetic seawater media, when compared with media prepared with natural seawater, 1) required larger inocula, 2) initiated growth more slowly; and 3) after repeated transfers finally resulted in failure to grow.

Terasaki (1972) maintained cultures on seawater nutrient agar stabs at room temperature with monthly transfers.

Hylemon et al. (1973) maintained strains of *Oceanospirillum* in semisolid peptone-succinate-salt medium (PSS), containing per liter of synthetic seawater:

Peptone	10 g
Succinic acid	1 g
$(NH_4)_2SO_4$	1 g
$MgSO_4 \cdot 7H_2O$	1 g
$FeCl_3 \cdot 6H_2O$	0.002 g
$MnSO_4 \cdot H_2O$	0.002 g
Agar	1.5 g

Adjust to pH 6.8. The synthetic seawater contained per liter:

NaCl	27.5 g
$MgCl_2$	5.0 g
$MgSO_4 \cdot 7H_2O$	2.0 g
$CaCl_2$	0.5 g
KCl	1.0 g
$FeSO_4$	0.01 g

Using this synthetic seawater, Hylemon et al. (1973) could not detect any loss of viability. In our laboratory we have used the same medium with only 0.5% peptone (marine MPSS).

Long-term Preservation

Long-term preservation can be accomplished by suspending a dense concentration of cells in seawater nutrient broth containing 10% (v/v) dimethyl sulfoxide, with subsequent freezing in liquid nitrogen (Krieg, 1984).

Freeze-drying can be performed with cells grown on the appropriate medium, as described for the aquaspirilla. (see Chapter 131).

Identification and Taxonomy

The taxonomy of the genus has been investigated on several occasions (McElroy and Krieg, 1972; Terasaki, 1972, 1973; Hylemon et al., 1973; Carney et al., 1975; Krieg and Hylemon, 1976) and all investigators found the genus to be quite heterogeneous and difficult to classify in relation to other Gram-negative bacteria. Krieg (1976) has pointed out that, at least on the basis of phenotypic characters, a continuum of species may interconnect spirilla with various other genera of Gram-negative, oxidative bacteria. The genera that were recognized were useful, but may prove to be inadequate for expressing taxonomic relationships. Krieg has suggested that DNA-DNA or DNA-rRNA homology studies might be useful in clarifying these relationships.

Due to the scarcity of strains, the degree of variation within the species and genus has not been defined. Hylemon et al. (1973) mentioned

Table 3. List of phenotypic features of all the species of the genus *Oceanospirillum*.

Feature	*O. linum*	*O. maris* ssp. *maris*	*O. maris* ssp. *hiroshimense*	*O. maris* ssp. *williamsae*	*O. beijerinckii* ssp. *beijerinckii*	*O. beijerinckii* ssp. *pelagicum*	*O. multiglobuliferum*	*O. japonicum*

GC content (mol%)	48–50	46	47	45	47	49	46	45

Symbols: +, present in all strains; −, lacking in all strains; blank space, not determined; C, clockwise or right-handed helix (indicated by the pattern //// when focusing on the bottom of the cells); BT, bipolar tufts; W, weak reaction; d, differs among strains; PHB, poly-β-hydroxybutyrate.

[a] *O. linum* grows poorly or not at all in defined media with single carbon sources and ammonium ions as the nitrogen source: however, abundant growth occurs in a defined medium containing succinate plus malate as carbon sources and methionine as the nitrogen source.

[b] *O. maris* subsp. *williamsae* fails to grow in vitamin-free media and requires a growth factor that has not yet been identified.

From Linn and Krieg, 1973; Hylemon et al., 1973; Krieg, 1984; Pot et al., 1989; and Terasaki, 1972, 1979.

that the descriptions they provided for members of the genera *Aquaspirillum* and *Oceanospirillum* were in many cases based upon only a single strain. A number of new species have since been described, mostly based on a limited number of strains. Although Krieg (1984) recognized nine species in the genus *Oceanospirillum,* he pointed out again that no DNA-DNA hybridization studies were done to substantiate this subdivision.

Woese et al. (1982, 1985) measured the deeper relationships of the genus using the oligonucleotide cataloging method and provided information on the intrageneric relationships of five *Oceanospirillum* strains (*O. beijerinckii* ATCC 12754, *O. japonicum* ATCC 19191, *O. linum* ATCC 11336, *O. maris* ATCC 27649 and *[O.] minutulum* ATCC 19193; brackets enclose a generically or specifically misnamed taxon name). These studies indicated that these strains should be classified in the gamma group of the Proteobacteria (Stackebrandt et al., 1988).

Pot et al. (1989) included all named *Oceanospirillum* species in a polyphasic study in which DNA-rRNA hybridizations played an important role. They found that *O. beijerinckii, O. hiroshimense, O. japonicum, O. linum, O. pelagicum, O. maris,* and *O. multiglobuliferum* constitute one separate rRNA branch in the rRNA superfamily II (gamma group of the *Proteobacteria*) and concluded that *Oceanospirillum* consequently should be restricted to members of this rRNA branch. Therefore, the six other species are generically misnamed and ought to be removed from the genus *Oceanospirillum. [O.] vagum* and *[O.] commune* should be relegated to their previous generic positions as *Marinomonas vaga* and *M. communis,* respectively (Van Landschoot and De Ley, 1983); *[O.] jannaschii, [O.] kriegii,* and *[O.] minutulum* constitute three separate rRNA branches in rRNA superfamily II that are not related more closely to *Oceanospirillum* than to any other rRNA branch of this rRNA superfamily (see Chapter 100); *[O.] pusillum* belongs to rRNA superfamily IV, where it constitutes a separate rRNA branch, closest to and equidistantly removed from *Azospirillum, Rhodospirillum rubrum,* and some misnamed *Aquaspirillum* species.

Using DNA-DNA hybridizations and comparative protein gel electrophoresis, some species were found to be too closely related to be kept as separate species (Pot et al., 1989), but the differences in morphological and nutritional characteristics warranted the description of a number of subspecies (Table 3).

With a DNA binding of at least 84%, *Oceanospirillum [hiroshimense]* and *O. maris* should be included in one species, *O. maris.* From Table 3 it can be concluded that, due to the presence of phosphatase activity, a weak or negative catalase reaction and an optimum temperature for growth of 25°C rather than 30° to 32°C, it is appropriate to create a new subspecies, *O. maris* subsp. *hiroshimense,* in addition to the two existing subspecies *(O. maris* subsp. *maris* and *O. maris* subsp. *williamsae).* For other differentiating characteristics, see Pot et al. (1989) and Krieg (1984).

With a DNA binding of 77%, *O. [pelagicum]* should be included in *O. beijerinckii.* Table 3 shows that the difference in temperature range for growth and the range of NaCl for growth in peptone water justifies the description of the subspecies *O. beijerinckii* subsp. *pelagicum.* For other differentiating characteristics, see Pot et al. (1989) and Krieg (1984).

The inclusion of *O. japonicum* in the genus *Oceanospirillum* can be considered to be provisional because of its large $T_{m(e)}$ difference (8.2°C) with the homologous $T_{m(e)}$ value of the type strain for the genus *Oceanospirillum.* It has been described before that a $T_{m(e)}$ difference of 6°C or more between homologous and heterologous DNA-rRNA hybrids, usually represents differences on the generic level (see also Chapter 100).Phenotypically, *O. japonicum* is quite different from the other species of the genus (Table 3), but as long as there are no other strains of this species available, it is not appropriate to create a new genus for this single species.

CHAPTER 173

Serpens flexibilis: An Unusually Flexible Bacterium

ROBERT B. HESPELL

Habitats

Many eutrophic aquatic environments as typified by ponds or sewage lagoons harbor a wide variety of aerobic bacteria in the upper water layers. Thin, flexible bacteria such as spirilla, spirochetes, and *Serpens flexibilis* constitute a small fraction of the total microorganisms in these environments. The use of enrichment procedures to isolate these flexible bacteria usually is not successful because they are rapidly overgrown by the other bacteria, even when low-nutrient-containing media are used. Presumably, these flexible bacteria can compete in their natural environments because of factors such as high cell-surface to cell-volume ratios that allow for maximizing transport of nutrients, possession of chemotaxis mechanisms, and unusual motility properties that allow for movement through viscous solutions (Greenberg and Canale-Parola, 1977).

Isolation

Selective isolation

S. flexibilis can be selectively isolated by using procedures originally developed for isolation of thin spirilla and spirochetes (Canale-Parola et al., 1966). A small amount of pond water or mud slurry is placed in the center of a sterile cellulose filter disc (0.3 to 0.45 μm pore diameter) which has been placed on the surface of a petri dish containing isolation medium made with 1.0% agar. The disc is removed after aerobic incubation of the plate at 30°C for 6 to 12 h. After subsequent incubation of the plate for 2 to 4 days, a subsurface, whitish veil of growth develops. The organism can then be isolated by picking from the outer edge of the veil and streaking onto a second plate. Restreaking several times may be necessary to obtain pure, cloned cultures. An isolation medium that has been routinely used (Hespell, 1977, 1984) includes: yeast extract, 0.2 g; peptone, 0.1 g; 10 ml hay extract; and 90 ml distilled water. The pH of the medium is adjusted to pH 7.0 with KOH prior to autoclaving. The hay extract is prepared by boiling 1.0 g of dried wheat or barley straw in 100 ml of distilled water for 15 min., cooling the mixture to room temperature, and decanting the fluid which is then clarified by centrifugation (8,000 × g, 10 min).

Cultivation

Optimal growth yields (10^9 to 10^{10} cells/ml) and growth rates (20 to 30 min doubling times) of *S. flexibilis* can be obtained in a nutrient-rich medium such as LYPP medium (Hespell, 1977): 60% sodium lactate syrup, 1.0 ml; yeast extract, 0.3 g; peptone, 0.2 g; 0.2 M potassium phosphate buffer (pH 7.4), 10 ml; and 90 ml distilled water. Typical cultures consist of 250 ml of medium in 1-liter Erlenmeyer flasks shaken at 150 to 250 rpm at 30°C. The organism also can be grown on chemically defined media such as LCH, but the growth yields and growth rates are considerably lower. LCH medium consists of: 60% sodium lactate syrup, 1.0 ml; 0.4 g ammonium chloride; trace minerals (Hespell and Canale-Parola, 1970), 1.0 ml; 0.2 M potassium phosphate buffer (pH 7.4), 20 ml; and 78 ml of distilled water. Replacement of the ammonium chloride with an equivalent amount of peptone or Trypticase markedly stimulates growth. *S. flexibilis* will not grow on media having an initial pH of 5.8 or less, and optimal growth occurs when the initial pH is 6.8 to 7.2. During growth the pH of the medium rises to 9 to 11, and increased cell yields can be obtained by periodically lowering the pH by additions of weak HCl. Highest growth yields are obtained at 28° to 33°C, but no growth occurs at 10° or at 45°C.

Preservation of Cultures

Long-term storage of *S. flexibilis* can be accomplished by routine lyophilization of cultures. Alternatively, cultures can be stored in liquid ni-

trogen or ultracold (−75 to −85°C) freezers (Hespell and Canale-Parola, 1970).

Identification

S. flexibilis forms a subsurface veil of growth similar to that commonly observed with spirochetes. Microscopic examination of agar pieces removed from the leading edge of the veil show extremely flexible rods measuring about 0.3 by 10 μm long. Often several cells are seen together and appear as "a pit of microbial snakes." The cells display furious lashing motions and often tend to twist in and out of knot formations (Fig. 1a). In liquid media, the movement is less dramatic. The long, slender cells usually move in straight lines displaying an overall flexing of the cell with the trailing cell tip having a vibrating motion (Fig. 1b). No tumbling type of movement is observed. In stationary phase cultures, clumps of entwined cells are common, and often partially lysed cells, spherical cell bodies, are present (Fig. 1c). Electron microscopy shows that cells typically possess a cluster of 4 to 10 flagella that are present at the tips of both cell ends; in addition, the presence of several lateral flagella randomly distributed along the cell body is not uncommon. (Fig. 1d). The flagella are quite long (15 to 30 μm), have a constant waveform with a 0.3 μm amplitude, and possess the hook end and disk structure commonly observed with other bacteria.

In addition to its unusual motility characteristics, another key feature of *S. flexibilis* is the rather limited range of substrates that support its growth. Essentially, only lactate is catabolized and supports good growth. Limited growth can be obtained with α-ketoglutarate, acetate, or pyruvate. In the presence of peptone, the addition of glucose and a few other disaccharides results in about a doubling of cell yields over that observed in the absence of added substrates (2.0 to 6.0 × 10^7 cells/ml).

Colonies can be formed under aerobic conditions on media containing 2% agar. These are usually 3 to 4 mm in diameter, off-white to cream colored, and round with filamentous edges. The cells from colonies tend to be thicker (0.5 to 1.0 μm) and shorter (4 to 6 μm). Cell pellets from liquid cultures often are light pink to reddish in color, probably due to the presence of the cytochrome proteins; the pigments cannot be extracted with chloroform, methanol, or other solvents used to remove carotenoids. Whether taken from liquid cultures or colonies, cells are always Gram negative. Electron microscopy of thin sections of *S. flexibilis* shows that the cells have a classical double-track, Gram-negative cell structure (Hespell, 1977, 1984).

The phylogenetic status of *S. flexibilis* has been examined with the 16S rRNA oligonucleotide-cataloging technique. The results indicated that *S. flexibilis* has an S_{AB} of 0.9 with *Pseudomonas pseudoalcaligenes* (Woese et al., 1982). Woese et al. (1982) concluded that *S. flexibilis* was a close relative to *P. pseudoalcaligenes* and that it might be a variant pseudomonad that developed a defect in septum formation because *S. flexibilis* forms long cells with multiple cytoplasmic invaginations (Hespell, 1977, 1984). This 16S RNA phylogenetic placement of *S. flexibilis* has been confirmed by analysis of aromatic amino acid biosynthesis enzymes of *S. flexibilis* (Ahmad and Jensen, 1987). These studies indicate this organism belongs with subgroup Ia pseudomonads. While *S. flexibilis* shares a number of common features with *P. pseudoalcaligenes*, there are a number of distinct differences. Glucose and many other sugars do not support the growth of either organism, and both organisms can grow with lactate, acetate, or pyruvate as energy sources. However, *S. flexibilis* does not grow with succinate, citrate, ethanol, fructose, or glycerol. The GC content of the DNA of *S. flexibilis* is 66 mol% (Hespell, 1977) and that of *P. pseudoalcaligenes* strains is 62 to 64 mol% (Palleroni, 1984). *S. flexibilis* differs from many *Pseudomonas* species in having multiple flagella and in lacking poly-B-hydroxybutyrate formation. At present, it would seem reasonable to consider *S. flexibilis* to be related to the pseudomonads. Because of its distinct features, this organism should probably be classified in its own genus (*Serpens*) and species (*flexibilis*) within the family Pseudomonadaceae. Although *S. flexibilis* strains have been isolated from several geographical locations (Hespell, 1977), detailed studies have not been done to determine whether enough differences exist to justify multiple species of *Serpens*.

Physiological Properties

S. flexibilis is a strictly aerobic bacterium and cannot grow anaerobically even in the presence of electron acceptors such as nitrate or nitrite. The organism displays an endogenous respiratory quotient (CO_2 released O_2 consumed) of 0.7 to 0.8, and this value increases to 1.56 in the presence of sodium lactate. Approximately 60% of the lactate catabolized is converted to carbon dioxide and about 30% is incorporated into cell material (Hespell, 1977). Growth on lactate-containing media results in production

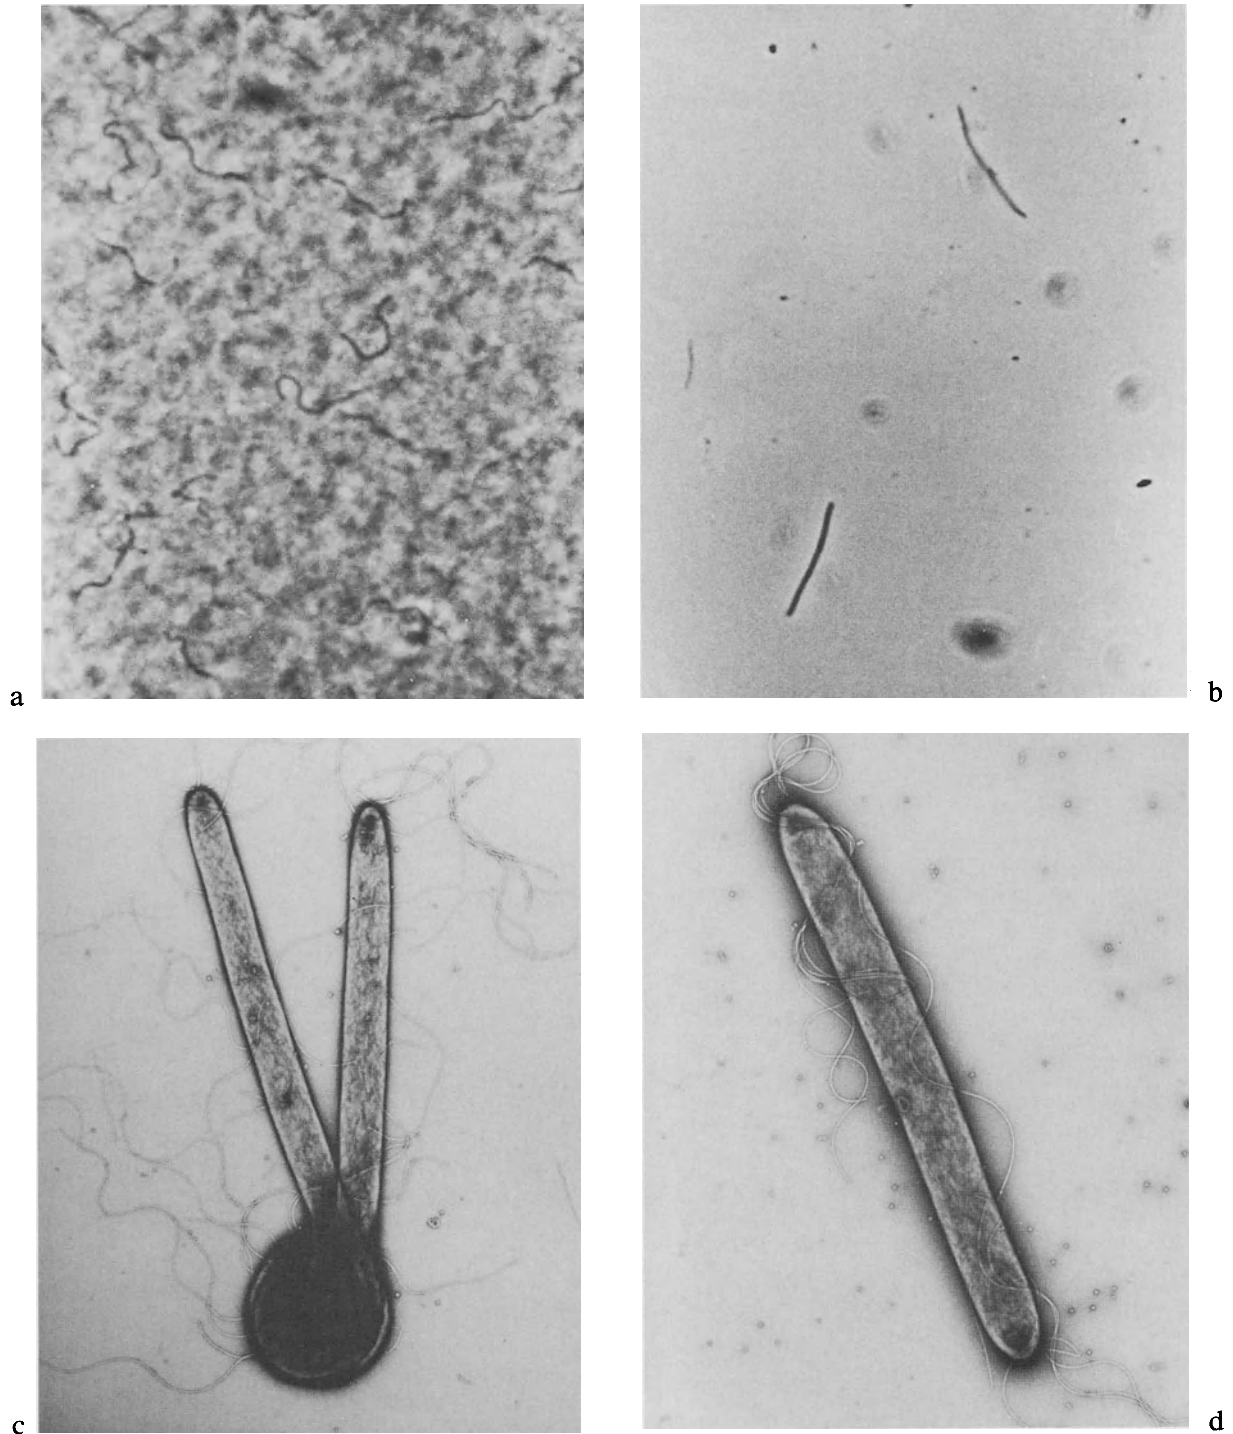

Fig. 1. Phase contrast micrographs (Fig. 1a and b) and transmission electron micrographs (Fig. 1c and d) of *S. flexibilis* strain PFR-1. Cells from subsurface growth in agar media show rapid coiling movements (1a), whereas in liquid media (1b), cells display straight-line movement of flexing rods. Cells are quite flexible and are able to coil up (1c). They are motile by means of lateral flagella (1c) and polar tufts of flagella (1d). Cells are about 0.3 μm in diameter and 10 μm in length.

of trace amounts of formate and acetate. Cell extracts contain high levels of lactic acid dehydrogenase and enzyme activities associated with the tricarboxylic acid cycle. However, only trace levels of enzymes of the Embden-Meyerhof and hexose monophosphate pathways are

present. Analysis of the peptidoglycan layer indicates that diaminopimelic acid is the main cross-linking compound, and the other constituents include alanine, glutamate, muramic acid, and glucosamine (Hespell, 1977). The peptidoglycan appears to be typical of that found in most Gram-negative bacteria.

CHAPTER 174

The Genus *Psychrobacter*

ELLIOT JUNI

In early studies, all saprophytic, nonpigmented Gram-negative rods were classified together in the genus *Achromobacter* (Bergey et al., 1923; Ingram and Shewan, 1960). Although the original *Achromobacter liquefaciens* type strain (no longer available) was motile, the genus was said to include both motile and nonmotile organisms. Brisou and Prévot (1954) suggested that the nonmotile achromobacters be separated from the motile species and grouped in the genus *Acinetobacter*. When the oxidase test, an assay for the presence of cytochrome *c* (Baumann et al., 1968a), first became widely used (Buttiaux and Gagnon, 1959), it was recognized that the genus *Acinetobacter* included both oxidase-positive and oxidase-negative members. Further studies resulted in classification of only the oxidase-negative organisms as strains of *Acinetobacter* (Lessel, 1971) because of similarities in their phenotypic properties (Baumann et al., 1968b), genetic interaction of all strains with a competent strain (Juni, 1972), and also from the results of DNA-DNA homology studies (Johnson et al., 1970).

Until recently, the large group of nonmotile, oxidase-positive, nonpigmented, chiefly psychrotrophic, Gram-negative rods or coccobacilli isolated from the skin of fish and chickens and also from a variety of processed foods were recognized and frequently referred to as "*Moraxella*-like" organisms (Shaw and Shewan, 1968), but remained unclassified. The morphological and physiological characteristics of these organisms were not sufficiently unique to permit the definition of a new genus based solely on the available phenotypic properties. Studies of a number of these organisms revealed that many of them were naturally competent for genetic transformation (Juni and Heym, 1980). This finding made it possible to devise a transformation assay in which only DNA from related strains could transform an auxotroph of a competent strain for ability to grow on a defined medium on which the auxotroph could not grow (Juni and Heym, 1980). It soon became clear that the large number of genetically interacting strains examined constituted a distinct genospecies and these were then grouped together as members of the genus *Psychrobacter* (Juni and Heym, 1986). The name *Psychrobacter* was chosen because most members of this group are psychrotrophic, i.e., they grow best at low temperatures.

Relationship to *Moraxella* and *Acinetobacter*

Psychrobacters are typically cocci or coccobacilli and resemble strains of *Moraxella* and *Acinetobacter* microscopically. These three genera have been shown to be fairly closely related. Since strains of each genus have been shown to be competent for genetic transformation, it has been possible to demonstrate weak, but distinct, genetic interactions between strains of these genera (Bøvre, 1967; Juni, 1972; Bøvre and Hagen, 1981). Because of qualitative similarity in fatty acid compositions, it was "suggested that the generic similarity among *Acinetobacter* species, *Moraxella* species and *Moraxella*-like species is fairly close" (Nishimura et al., 1979). In a study of similarities of ribosomal RNA cistrons of the family Neisseriaceae, it was shown that strains known to be psychrobacters cluster with the *Moraxella* group (Rossau et al., 1986). Because of a variety of findings regarding their relatively close relationship, it has been suggested that the genera *Acinetobacter, Moraxella,* and *Psychrobacter* be grouped together in a new, and as yet unnamed, family (Rossau et al., 1986). Although these genera are presently classified as members of the Neisseriaceae, it is clear that there is no longer any reason for such association. The original proposal that the moraxellae be included in the family Neisseriaceae was based primarily on similarities in phenotypic properties (Henriksen, 1952) and also because of the relatively strong genetic interactions between *Neisseria catarrhalis* and some moraxellae (Henriksen and Bøvre, 1968). The

organism orginally called *Neisseria catarrhalis* is currently designated *Moraxella (Branhamella) catarrhalis* (see Chapter 177) the subgenus *Branhamella* being used for the coccal species of the moraxellae (Bøvre, 1979).

Habitats

Psychrobacters have been found to occur normally on the skins and gills of fish (Scholes and Shewan, 1964) and on the skins of poultry (Barnes and Impey, 1968; Lahellec et al., 1975). Since many of these organisms apppear to be radiation resistant, in contrast to the more common food-spoilage bacteria, they have been found surviving in foods following irradiation for preservation purposes (Firstenberg-Eden et al., 1980; Ito et al., 1976; Laycock and Regier, 1970; Welch and Maxcy, 1975). Psychrobacters have been isolated from the open sea and have also been found as air contaminants on complex media plates (Juni and Heym, 1986). It has also been demonstrated that approximately 30% of the strains that were isolated from a variety of human sources and assigned to group EO-2 by the Center for Disease Control (Clark et al., 1984) were actually psychrobacters (Hudson et al., 1987; Moss et al., 1988).

Isolation

At the present time there is no selective medium for isolation of psychrobacters. Numerous psychrobacters have been isolated by immersing fish heads in saline solution, stirring for a short period of time, and streaking loopfuls of the wash solution on heart infusion agar (Difco) plates. After incubation at room temperature for 2 days, portions of nonpigmented colonies were placed on the surface of a dry oxidase test paper. Oxidase test paper consists of an 8-cm disk of Whatman no. 1 qualitative filter paper, which had previously been soaked thoroughly in a 1% solution of *N,N,N',N'*-tetramethyl-*P*-phenylendiamine dihydrochloride, placed in a 9-cm petri dish and dried at 35°C. The appearance of a deep purple color in a few seconds signifies a positive oxidase reaction. Wet mount suspensions of oxidase-positive colonies were examined for the presence of nonmotile rods or coccobacilli, and those meeting this criterion were then Gram-stained. All Gram-negative, oxidase-positive, nonpigmented rods or coccobacilli were then subject to the transformation assay for psychrobacters (Juni and Heym, 1980). More than half of these, presumptive psychrobacters, gave positive results in the transformation assay (E. Juni, unpublished observations).

Media

Psychrobacters usually grow well, from 5 to 30°C, on standard complex media such as heart infusion agar (Difco), tryptone-yeast extract agar (LB agar), and trypticase soy agar (BBL), exhibiting lower growth rates at the extremes of the temperature range. These organisms may be found growing slowly as contaminants on plates stored in the refrigerator. For many of them, 20–25°C is an optimal temperature. A complex medium containing vitamin-free casein hydrolysate (medium M9A) has been found useful for performing the *Psychrobacter* transformation assay (Juni and Heym, 1980) but the simpler defined medium (medium P96), described below, is equally effective.

Most psychrobacters can grow on a mineral-agar plate containing either (or both) sodium lactate and (or) monosodium glutamate as the carbon source(s) and ammonium salts as the nitrogen source. Strain ATCC 43116, the *Psychrobacter* type strain, has been demonstrated to have a generation time of approximately 100 min on such media when grown at 25°C (E. Juni, unpublished observations). Although not absolutely required, the addition of certain amino acids and Tween 80 to the lactate plus glutamate mineral medium serves to shorten the lag period for growth of liquid cultures in this medium. Double-strength medium P96 contains the following components dissolved in distilled water to a final volume of 1 liter:

Medium P96	
Na_2HPO_4	11.2 g
KH_2PO_4	4.0 g
NH_4Cl	2.0 g
$MgSO_4 \cdot 7H_2O$	0.4 g
$CaCl_2$ (1.0% solution)	1.0 ml
$FeSO_4 \cdot 7H_2O$ (freshly prepared 0.1%	0.5 ml
solution)	0.5 ml
Sodium DL-lactate (60% solution)	13.0 ml
Monosodium L-glutamate	10.0 g
Tween 80	8.0 ml
L-Methionine	0.4 g
L-Isoleucine	0.4 g
L-Leucine	0.4 g
L-Valine	0.4 g

This medium, which has a pH of 7.2, is sterilized by membrane filtration and may be stored in the refrigerator for longer than one year. Semisolid medium P96 plates are prepared by pouring 200 ml of double-strength medium P96 (warmed to room temperature, or higher) into 200 ml of freshly melted 3.0% agar (previously

sterilized by autoclaving), mixing thoroughly, followed by addition of 2.0 ml of sterile 2.0% ferric ammonium citrate and a final thorough mixing. After cooling to a suitable temperature (estimated by touching the bottle), approximately 20 plates are poured. Failure to include ferric ammonium citrate results in inability of single cells to give rise to colonies but confluent growth does take place in such media.

Carbon and Nitrogen Sources for *Psychrobacter*

Strain ATCC 43116 can grow in medium P96 lacking sodium lactate, monosodium glutamate, Tween 80, and all amino acids when supplied with any of the following carbon sources: sodium DL-lactate, sodium pyruvate, L-glutamate, L-serine, L-proline, L-alanine, sodium succinate, sodium n-butyrate, sodium caproate, sodium oleate, and Tween 80. Of these carbon sources, the combination of sodium lactate and monosodium glutamate was found to result in the best rate of growth (E. Juni, unpublished observations). In studies of possible carbon sources for 22 isolates of psychrobacters (Shaw and Latty, 1988), it was reported that 25% or more of these strains can utilize propionate, n-butyrate, isobutyrate, n-valerate, caproate, caprylate, pelargonate, caprate, fumarate, glutarate, suberate, azelate, D-malate, L-malate, DL-β-hydroxybutyrate, benzoate, phenylacetate, L-alanine, L-aspartate, L-glutamate, γ-aminobutyrate, δ-aminovalerate, histidine, proline, tyrosine, phenylalanine, α-ketoglutarate, ethanol, n-propanol, n-butanol, ethanolamine, and putrescine.

Ammonium salts can serve as the nitrogen source in a defined medium. Glutamate can also fuction as a nitrogen source but is not as effective as ammonium chloride (E. Juni, unpublished observations).

Identification

Phenotypic Properties

Pure culture isolates are tentatively identified as psychrobacters if they are fairly plump (0.9 to 1.3 μm in diameter), nonmotile, Gram-negative, aerobic, oxidase-positive, catalase-positive rods or coccobacilli, and form nonpigmented, smooth, opaque colonies on complex semisolid media. Fig. 1 illustrates the typical microscopic appearances of the two most common morphological types encountered. Diplo forms are common. Rod-shaped cells are frequently swollen, and the Gram stain often tends to be retained. Most psychrobacters grow well at room temperature and fail to grow at 35°C. They grow slowly at refrigerator temperatures (5–10°C). Growth takes place in media containing 6% NaCl, with some strains able to grow in the presence of twice this salt concentration. Most strains are sensitive to penicillin.

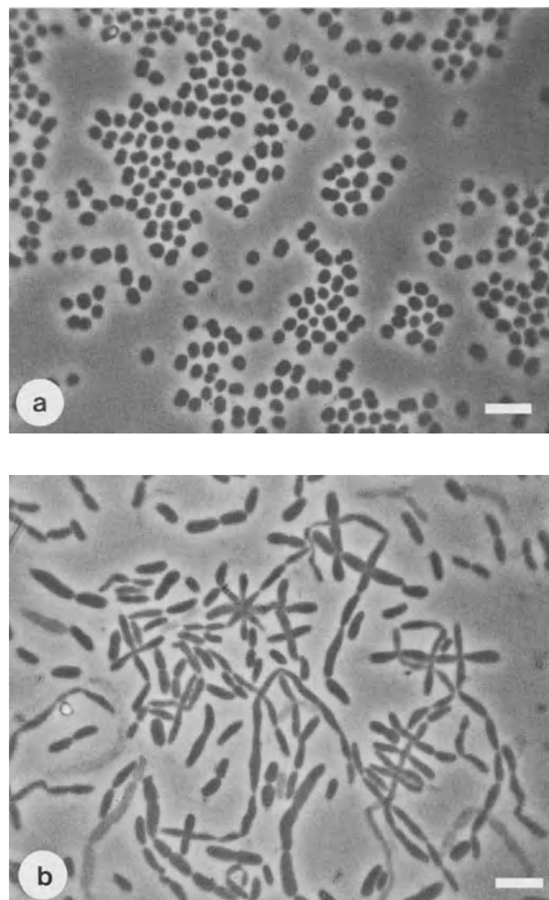

Fig. 1. Typical microscopic morphology of *Psychrobacter* grown overnight at room temperature on heart infusion agar. (a) strain ATCC 15174; (b) strain A103. Bar = 5 μm.

Unlike the oxidase-positive moraxellae, whose species fail to oxidize sugars, most psychrobacters form acid aerobically from sugars such as glucose, mannose, galactose, arabinose, xylose, and rhamnose, and thus resemble the strains of *Acinetobacter* that are capable of forming acid from sugars aerobically. Psychrobacters fail to form acid from fructose, maltose, or sucrose. Nitrate is reduced. Starch, gelatin, and serum are not hydrolyzed, and indole and H_2S are not produced. Urease activity is present. Phenylalanine and tryptophan are deaminated. Tween 80 is hydrolyzed. Phenethyl alcohol is formed from L-phenylalanine and ethanol (Chen and Levin, 1974). In this connection, it was noted that during growth (pre-

sumably on heart infusion agar plates) of certain human-derived psychrobacters, previously designated as EO-2 strains, the cultures "had an odor which resembled the odor of a phenethyl alcohol blood agar plate" (Hudson et al., 1987).

Identification by Transformation

A transformation assay has been devised for definitive identification of suspected strains of *Psychrobacter* (Juni and Heym, 1980). In this procedure crude DNA, prepared by lysing small quantities of cells in a saline-citrate solution containing a low concentration of sodium dodecyl sulfate, is mixed with a hypoxanthine and thiamine-requiring mutant *Psychrobacter* strain (ATCC 43117) and the mixture permitted to grow overnight. If the DNA was derived from an authentic strain of *Psychrobacter,* some of the mutant cells will be transformed to prototrophy and will be capable of giving rise to colonies when the overnight mixture is streaked on a medium upon which the mutant strain itself is unable to grow. The appearance of transformant colonies on a medium M9A plate (Juni and Heym, 1980), or on a medium P96 plate, described above, confirms unequivocally that the isolate is a *Psychrobacter.*

Chemical Characterization

Several investigators have analyzed the fatty acid composition of *Psychrobacter* strains (Thorne et al., 1973; Nishimura et al., 1979; Moss et al., 1988). Oleic acid ($C_{18:1}$) constitutes more than 50% of the total fatty acids with moderate amounts of $C_{16:0}$, $C_{16:1}$, $C_{17:1}$, and $C_{18:2}$ being detected. Based upon the proportions of the latter fatty acids in a group of six psychrobacters, it was concluded that these could be separated into two groups each containing three strains (Nishimura et al., 1979).

Psychrobacters have been demonstrated to contain waxes (Gallagher, 1971; Bryn et al., 1977; Russell and Volkman, 1980), which may be constituent parts of their cell membranes, since waxes have been found to be associated with these structures. Analysis of isoprenoid quinones of *Psychrobacter* has shown that the major ubiquinone contains eight isoprene units (Q_8) (Moss et al., 1988). The GC content of *Psychrobacter* DNA is 44–46 mol%.

Genetics

Since many psychrobacters are naturally competent for genetic transformation, the possibility for genetic studies of single strains, or for genetic interaction between different strains, is clearly evident. To date, the most extensive genetic study making use of transformation has concerned the establishment of *Psychrobacter* as a unique genospecies (Juni and Heym, 1986). In a preliminary report, transformation of a *Psychrobacter* strain (ATCC 15174) to grow at 30°C when incubated with DNA preparations from mutant strains able to grow at 30°C was described (Tai and Jackson, 1969a). Using DNA from radiation-resistant psychrobacters to transform two auxotrophs of a radiation-sensitive competent strain to prototrophy, it was demonstrated that prototrophic transformants remained radiations sensitive (Ito and Iizuka, 1983). Since the genetic loci determining radiation resistance are most probably unlinked to the nutritional loci that were transformed, the results obtained by Ito and Iizuka are to be expected.

Physiology

All psychrobacters are aerobic and their oxidase-positive characteristic indicates that they produce cytochrome *c* (Baumann et al., 1968a). Oxidase-negative *Psychrobacter* mutants have been reported (Tai and Jackson, 1969b; Juni and Heym, 1980). Although most psychrobacters have temperature optima from 20 to 25°C, mutants able to grow at higher temperatures have been reported (Tai and Jackson, 1969b), and some strains, such as ATCC 17955 (misnamed *Moraxella phenylpyruvica* in the ATCC catalog), are able to grow at 35°C. The physiological basis for these differences in optimal growth temperature is not known.

One strain of *Psychrobacter* (ATCC 15174), isolated from pork sausage, and originally designated *Micrococcus cryophilus* (McLean et al., 1951), has been studied in some detail because it was considered that the relatively large size of this bacterium made it particularly suitable for cytological studies. Enzymatic assays of cell-free extracts of strain ATCC 15174 have revealed the presence of all the enzymes of the tricarboxylic acid cycle (Tai and Jackson, 1969b). Studies have been reported of wax ester synthesis (Lloyd and Russell, 1983) and phospholipid synthesis (McGibbon and Russell, 1985) by strain ATCC 15174.

Cell membranes of *Psychrobacter* appear to resemble those of other Gram-negative bacteria (Thorne et al., 1973). The cell surface layer of one particular strain (199A) has been studied in considerable detail. An array made up of a single protein has been shown to be attached to and to cover the outer membrane (Thorne, 1977). When excreted into the medium, this

protein has phospholipase activity but such activity is lacking when the protein is arranged in the layered array (Thorne et al., 1976). The protein outer layer appears to be linked to the outer membrane by a salt bridge involving calcium or magnesium ions. It has been suggested that this additional surface layer, which is similar to surface layers in other Gram-negative bacteria, may serve to protect cells from hostile environments (Thorne, 1977).

Now that it is possible to identify *Psychrobacter* strains with certainty, it may be expected that in the near future the combined efforts of different laboratories concerned with various aspects of *Psychrobacter* physiology will serve to increase our understanding of this group of bacteria.

Taxonomic Considerations

Thornley (1967) studied the taxonomy of *Acinetobacter,* using the definition of this genus originally proposed by Brisou and Prévot (1954). On the basis of morphological properties and biochemical tests, she divided a large collection of strains into five phenones, most of which were grouped at 82.5% similarity. Some strains in Thornley's phenones 2, 3, and 4 were subsequently shown to be psychrobacters (Juni and Heym, 1980). Most of the oxidase-positive strains had been grouped into phenones 3 and 4. The results of this study serve to emphasize the difficulties in classifying the Gram-negative coccobacilli only on the basis of their phenotypic properties.

Since all known strains of *Psychrobacter* interact genetically, they are clearly members of a genospecies (Ravin, 1963). Because of their isolation from a variety of natural sources, it might be expected that different strains may have evolved independently and may be somewhat genetically heterogeneous. It has been shown, for example, that the streptomycin-resistance marker in some strains can transform certain competent psychrobacters poorly, or occasionally fail to transform a particular competent strain, in contrast to the efficient transformation observed when the DNA used was derived from a streptomycin-resistant mutant of the competent strain being transformed (Juni and Heym, 1980). Certain auxotrophic mutants of competent strains also display a similar range of transformation efficiencies when tested with DNA samples from a large number of psychrobacters (Juni and Heym, 1980). In spite of such findings, the apparent conserved nature of certain genetic markers has made it possible to demonstrate the relatedness of all *Psychrobacter* strains, since DNA from each of them is capable of transforming a conserved marker in a particular competent strain. Even with conserved markers, however, the efficiency of their transformation has been found to depend upon the strain from which the transforming DNA was derived (Juni and Heym, 1980).

It remains to be demonstrated whether the psychrobacters can be grouped into clearly defined species. Strains of the related genus *Acinetobacter* have been divided into more than 13 species based upon the results of DNA-DNA hybridization studies (Bouvet and Grimont, 1986). Unlike *Psychrobacter* and *Acinetobacter,* the moraxellae, which normally live in fairly constant environments associated with animal tissues, have been shown to occur in clearly defined species with all members of a given species being very nearly genetically identical (Bøvre and Hagen, 1981). At the present time all psychrobacters are considered to be members of a single genospecies, *Psychrobacter immobilis.* Further studies are required to explore the possibilities of more detailed speciation of *Psychrobacter.*

CHAPTER 175

The Genus *Leucothrix*

THOMAS D. BROCK

Leucothrix, a large-diameter, morphologically distinct, marine gliding bacterium, has been known in natural material since the time of Oersted in 1844, but its modern history began with the remarkable study Harold and Stanier published in 1955. In the introduction to their paper, Harold and Stanier state: "*Leucothrix* may be characterized succinctly as a chemoheterotrophic counterpart of the colorless sulfur-oxidizing organism *Thiothrix.* It has been observed on a few occasions . . . in the century since its original description, but the existing accounts of its morphology and development, based entirely on the examination of crude cultures, are either incomplete or inaccurate. Thanks to the ease with which it can be grown in pure culture, we have been able to determine its complete cycle of development, which includes a unique and hitherto undescribed process of gonidial aggregation to form many-celled rosettes."

Leucothrix is fascinating not only because of its morphological distinctiveness, but also because of its large size and the ease with which it can be recognized in natural material. The organism seems to be entirely marine and is widespread as an epiphyte of marine algae (Fig. 1) (Brock, 1966). It also causes an extensive infestation of benthic crustacea and fish eggs (Johnson et al., 1971), and has become a problem in the field of aquaculture, especially in the artificial cultivation of lobsters. *Leucothrix* appears to be related to the cyanobacteria (Pringsheim, 1957; Raj, 1977), as determined by morphological similarities. However, no detailed studies of molecular relationships between *Leucothrix* and any cyanobacteria have been carried out, although the DNA base composition of *Leucothrix mucor* isolates, 47–49 mol% GC (Brock and Mandel, 1966), is similar to that of a number of filamentous cyanobacteria (Edelman et al., 1967), which cluster in the range 42–51 mol% GC. This similarity is made even more striking when it is compared with the wide variation in DNA base compositions of the unicellular cyanobacteria (Edelman et al., 1967; Stanier et al., 1971) and with the wide variation found in the narrow-diameter gliding bacteria (Edelman et al., 1967).

Characteristics of *Leucothrix*

A simplified life cycle of *Leucothrix mucor* is given in Fig. 2. *Leucothrix* filaments are usually 2–3 μm in diameter and may reach lengths of 0.1–0.5 cm. The filaments have clearly visible cross-walls, and cell division is not restricted to either end but occurs throughout the length of the filament, as shown by autoradiography with tritiated thymidine (Brock, 1967). The free filaments never glide (thus distinguishing them from many other filamentous gliding bacteria, such as *Beggiatoa* and *Vitreoscilla*), although they occasionally wave back and forth in a jerky fashion. Under environmental conditions unfavorable to rapid growth, such as low temperature or low nutrient concentration, individual cells of the filaments become round and form ovoid structures called "gonidia," which are released individually, often from the tips of the filaments (Fig. 3). The gonidia are able to glide in a jerky manner when they come into contact with a solid surface. They settle down on solid surfaces, synthesize a holdfast, and form new filaments through growth and successive cell divisions. In nature, the gonidia are presumably elements of dispersal and enable the organism to spread to other areas. "Gonidia," first used by Winogradsky (1888) for *Thiothrix,* is an unfortunate term because it implies some sort of unique structure. Actually, the gonidium of *Leucothrix* and *Thiothrix* is functionally and structurally equivalent to the hormogonium of the cyanobacteria, which is a motile structure of dispersal formed by the rounding up of a vegetative cell or group of cells in a filament.

Both Winogradsky (1888) for *Thiothrix* and Harold and Stanier (1955) for *Leucothrix* con-

---

This paper is taken directly from the 1st edition of *The Prokaryotes.*

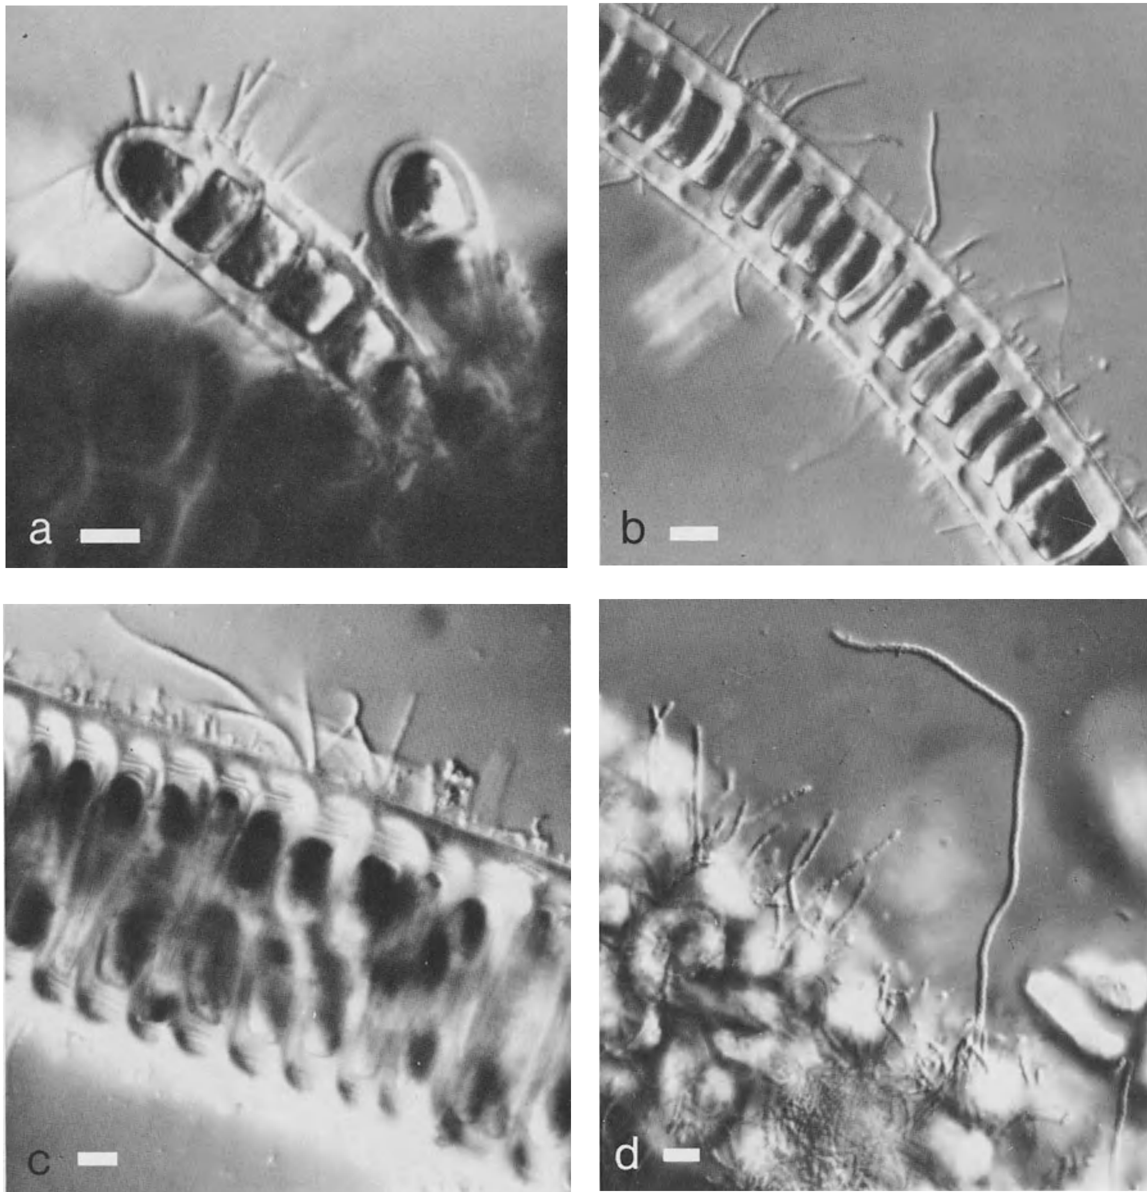

Fig. 1. Filaments of *Leucothrix mucor* attached to fronds of the seaweed *Bangia fuscopurpurea* of various ages. (a) Very young, (b) young, (c) mature, (d) old. Nomarski interference contrast photomicrograph. Bars = 10 μm. (From Bland and Brock, 1973.)

cluded that an apical-basal differentiation of filaments existed and that gonidia were formed primarily at the tips of filaments. Actually, such an apical-basal differentiation does not exist, and filaments do not taper. Careful examination of even long filaments has never revealed narrower cell diameters at the ends than in the middle. Also, although gonidia may form primarily at the filament tips, this is by no means always the case. I have frequently seen whole filaments convert to a series of gonidia, with every cell in the filament rounding up.

Gonidia do not have a holdfast when first formed, but make it only in response to the proper environmental conditions. If there are high concentrations of gonidia, individual cells may aggregate, probably because of reciprocal attraction (chemotaxis?). They then synthesize a holdfast and the gonidia become adherent to each other by the holdfast and form a small rosette. A new filament grows out from each gonidium, eventually resulting in a large and striking structure (Fig. 4). Rosette formation is found in both *Leucothrix* and *Thiothrix* and is

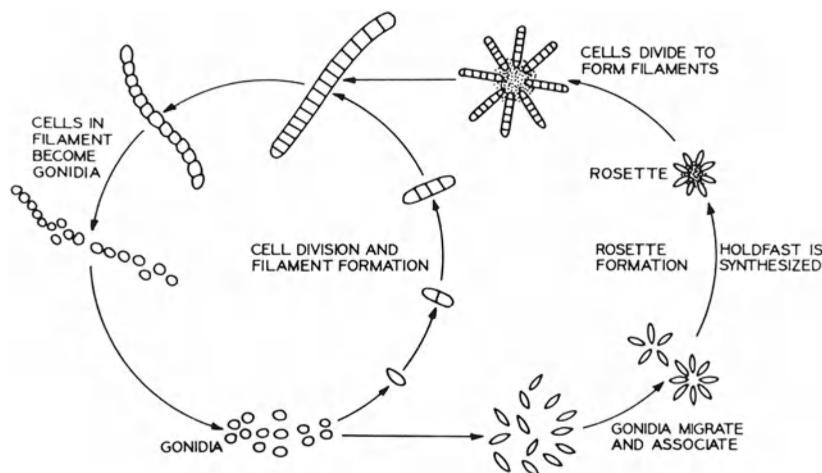

Fig. 2. Life cycle of *Leucothrix mucor.*

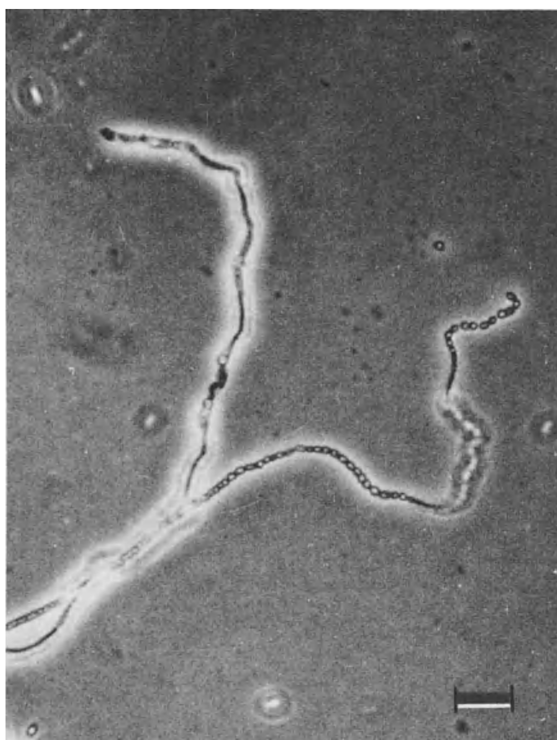

Fig. 3. Release of gonidia from filaments of *Leucothrix mucor.* Phase-contrast photomicrograph. Bar = 10 μm.

an important means of distinguishing these organisms from many other filamentous bacteria.

Another interesting characteristic of *Leucothrix* is the ability of filaments to grow in such a way that knots are formed (Fig. 5) (Brock, 1964). Knots occur mainly when the organism is growing in rich liquid culture media, where filamentous growth is rapid. Knot formation is frequent enough in *Leucothrix* cultures to be used as a taxonomic characteristic. Since individual filaments do not flex or glide, a preformed filament cannot form a knot. Actually, knots seem to be formed as part of the growth process, probably because growth occurs faster on one side of the filament than on the other, causing the filament to form a loop through which the tip of the filament can pass. Once the knot is formed it cannot be untied; rather, the cells in the region of the knot eventually fuse and form a bulb that is later released from the rest of the filament. As a result, the long filament is separated into two shorter filaments. Knots are also seen occasionally in *Thiothrix* filaments in sulfur springs, where large accumulations of these organisms appear, and in *Leucothrix* populations in nature (T. D. Brock, unpublished observations). All of the structural features of the *Leucothrix* life cycle can be observed not only in culture but also in natural material, especially when Nomarski optics are used to examine the surfaces of algal fronds (J. A. Bland, personal communication).

An electron microscopic study of *Leucothrix* was carried out by Brock and Conti (1969), and some of the structural features of the organism are seen in Fig. 6.

Taxonomy of *Leucothrix*

The question of the physiological or taxonomic relationship between *Leucothrix* and *Thiothrix* has not been resolved. A *Thiothrix* filament or rosette that has lost its sulfur granules cannot be distinguished from *Leucothrix.* Harold and Stanier (1955) placed pure cultures of *Leucothrix* in sulfide-containing sea water and examined them at intervals for the presence of intracellular sulfur granules. No evidence of sulfur accumulation was obtained; this was also my experience with one pure culture. However, Kjell Eimhjellen of the Technical University in

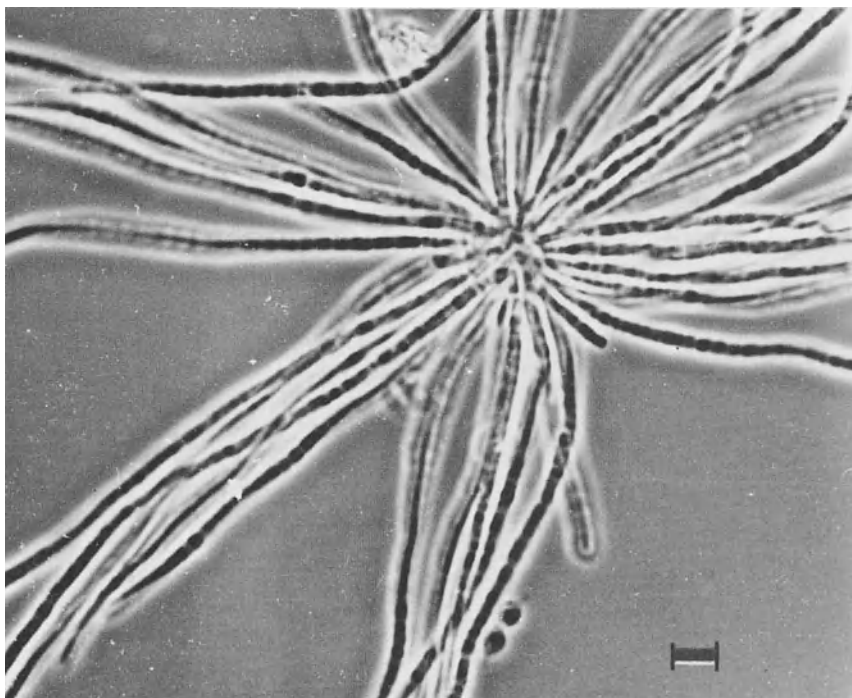

Fig. 4. Rosette composed of several *Leucothrix* filaments. Phase-contrast photomicrograph. Bar = 10 μm.

Trondheim, while working in C. B. van Niel's laboratory at Pacific Grove, California, was successful in attempts to show oxidation of hydrogen sulfide by *Leucothrix*. In his words (personal communication, 26 March 1970):

Leucothrix mucor (the strains I isolated all corresponded very well to the description of Harold and Stanier) pregrown on the usual media, can be made to oxidize sulphide when exposed to an atmosphere of hydrogen sulphide and oxygen, very much in the manner of *Sphaerotilus* observed by Skerman. Based on comparison of the pictures published by Skerman, *Leucothrix,* however, seemed to have a greater ability to oxidize sulphide. The filaments of *Leucothrix* often had a very heavy accumulation of internal S-globules, making the filaments resemble the very best rosettes of *Thiothrix* you can find in nature. After extensive washing of such cells to remove chemically produced sulphur, resuspension in low-sulphate media and incubation by gentle shaking, the internal S-globules disappeared and copious amounts of sulphate could be isolated from the supernatant. The sulphide oxidation was never followed manometrically, but I did a great many measurements of the ability of *L. mucor* to oxidize thiosulphate. Every time the oxidation would proceed quantitatively to tetrathionate and in a fair number of experiments the oxidation went further to a complete oxidation to sulphate. I could never clear up the reasons for this inconsistency. In separate experiments, the presence or absence of carbon dioxide seemed to make no difference on the total oxygen uptake, indicating no use of thiosulphate as electron donor for CO_2 fixation. . . . My conclusion is that the strain of *L. mucor* I used had the enzymatic capability to oxidize sulphide, sulfur and thiosulphate, all compounds being oxidized to sulphate, but no evidence for any energy link has been found.

It seems likely from a comparison of the results of Eimhjellen with those of Harold and Stanier (1955) that strain differences exist and that some strains of *Leucothrix* are able to deposit elemental sulfur. Further work on this problem would be of considerable interest.

Only a single species of *Leucothrix* is currently recognized, *Leucothrix mucor* (Brock, 1974). Pringsheim (1957) described *L. cohaerens* as a second species, based on cell diameter and filament length, but there is considerable variation in these properties even in a single pure culture, and since Pringsheim's isolates are no longer available, it seems preferable to maintain only a single species. Kelly and Brock (1969b) showed by physiological and molecular techniques that a wide variety of *Leucothrix* isolates, obtained from coastal areas around the world, were very similar. Of 35 strains characterized, all had a pH optimum of 7.6 and a salinity optimum of 30 parts per thousand. (The GC content of the DNA varied only over the narrow range of 48–51 mol% GC. Temperature optima of all strains were in the range 25–30°C, with a maximum of 33°C. Most strains showed a minimum temperature for growth of 0–2°C, although one strain, isolated from a tropical area, had a minimum temperature for growth of 13°C and hence was more stenothermal.

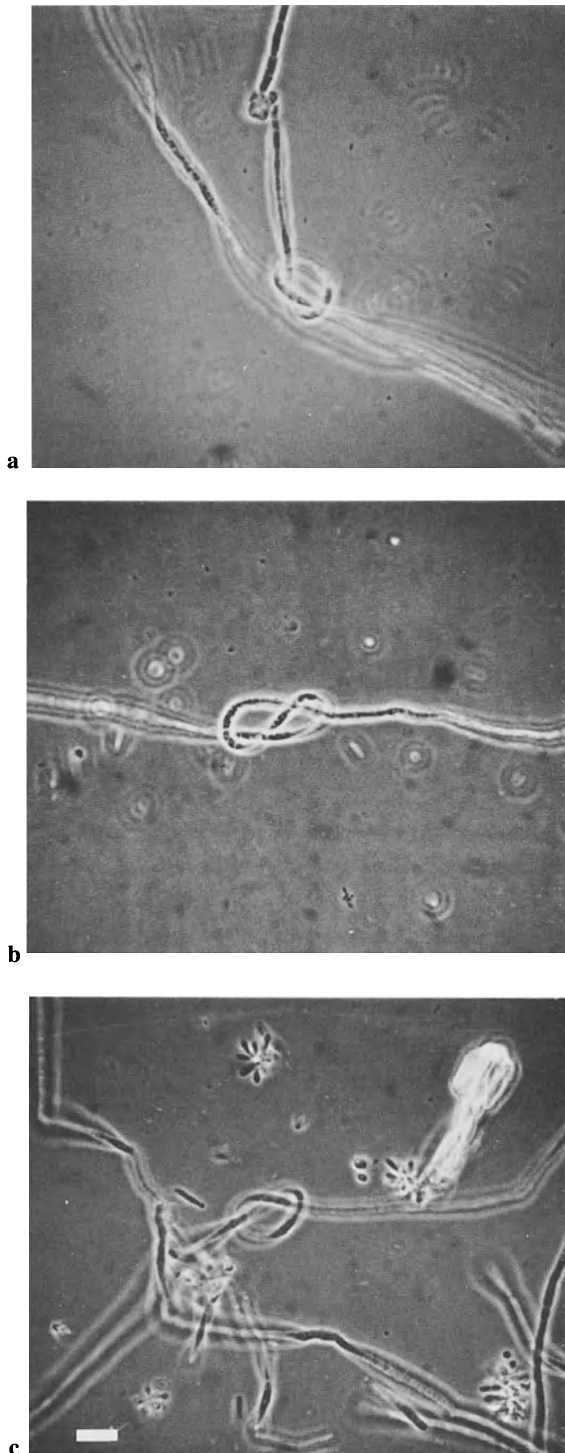

Fig. 5. Knots formed by filaments of *Leucothrix mucor*. Phase-contrast photomicrograph. Bar = 5 μm. (From Brock, 1964.)

Growth factor requirements were determined for all 35 strains. Most had no growth factor requirements and were able to grow heterotrophically on a simple glutamate culture medium, but 2 strains required thiamine, 1 strain (the warm water isolate) required vitamin B_{12}, and 3 strains showed a partial aspartate requirement. All the strains possessed the array of morphological characteristics typical of the species: filaments, gonidia, rosettes, knots, and bulbs.

Brock described a neotype strain of *Leucothrix mucor* and listed its characteristics as follows:

Morphology. Filaments are of variable length, often much greater than 100 μm, with a diameter of 2–3 μm. Sulfur granules are not formed. True knots are usually formed by pure cultures when growing in organically rich media. Filaments are colorless, unbranched, and nonmotile (although occasionally waving back and forth) and lack a sheath, although cells in regions of a filament may become emptied of their contents and give the appearance of a sheath. Filaments often grow intertwined or in dense tangles. Swollen cells often form at random along filaments. Larger structures (bulbs) usually form in knotty cultures, probably as a result of fusion of cells in the region of the knots. Filaments are attached to solid substrates by means of an inconspicuous holdfast that can be seen by staining with primulin and viewing with blue light in a fluorescent microscope; the holdfast fluoresces red. Individual filament cells round up and form ovoid to spherical gonidia that acquire a jerky gliding motility when released. Gonidia frequently aggregate in cultures, probably chemotactically, to form rosettes.

Nutrition. Most strains do not require growth factors. They grow on glutamate as sole source of carbon, nitrogen, and energy. They also use sugars, organic acids, and other amino acids as carbon and energy sources and NH_4^+ as nitrogen source. *Leucothrix* requires Na^+ for growth (optimum 1.5% NaCl, minimum 0.3%, maximum 7%).

Relation to temperature. Optimum 25–28°C; maximum 32–35°C. *Leucothrix* grows at 0°C to form visible colonies within 1–2 weeks.

Relation to O_2. Obligately aerobic.

Habitats

As noted in the Introduction, *Leucothrix* appears to be strictly a marine organism. It is widespread as an epiphyte on marine algae and also occurs as an infestation of benthic crustacea (Johnson et al., 1971). On seaweeds, it appears most commonly in temperate waters

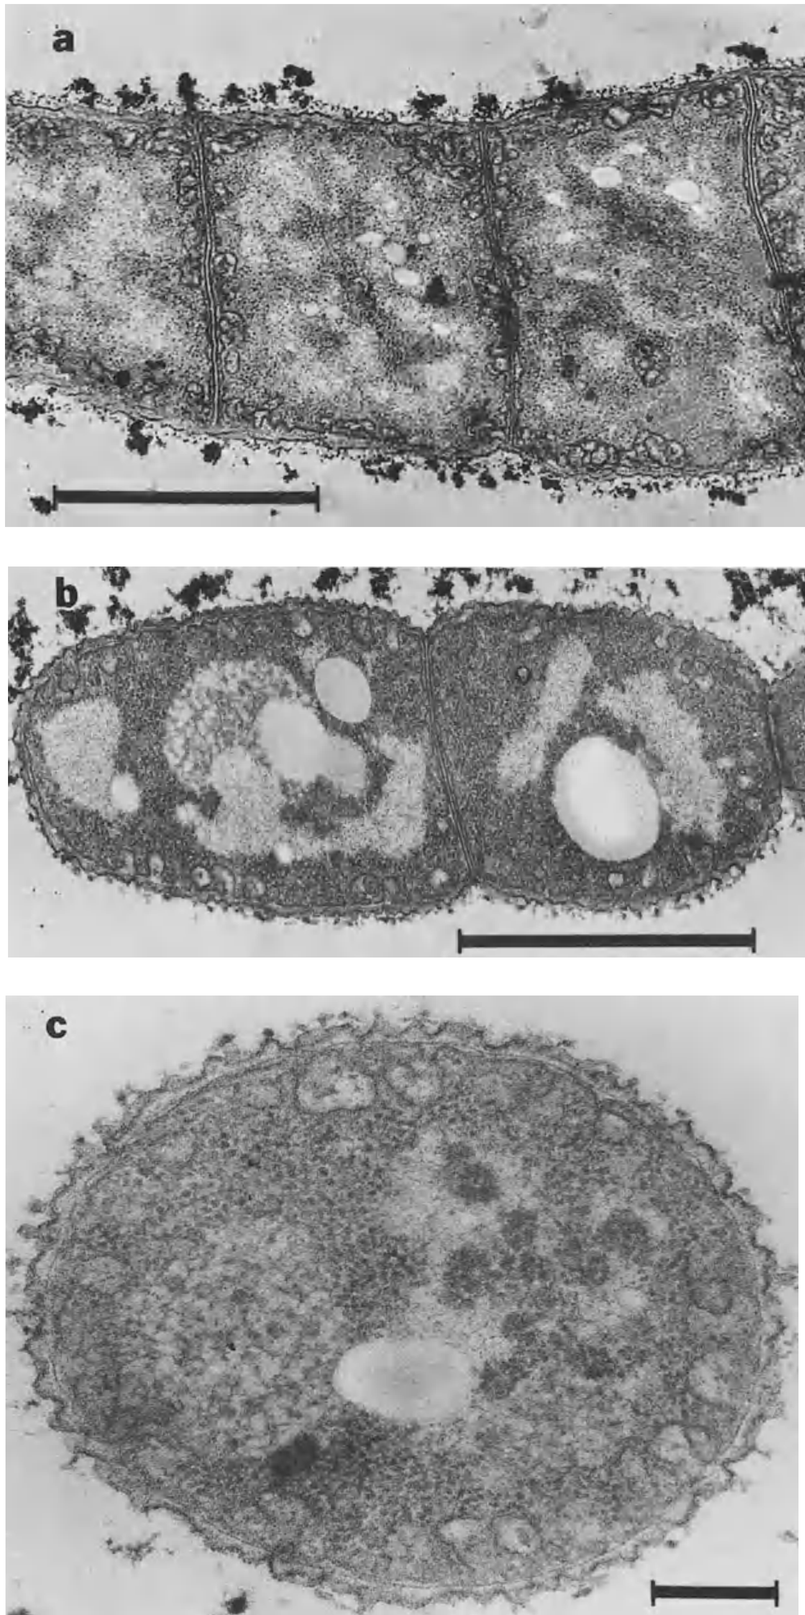

Fig. 6. Electron micrographs of thin sections of *Leucothrix mucor*. (a) Portion of a multicellular filament. (b) Filament in early stage of gonidial formation, showing rounding up of the cells. Note that there is no change in the ultrastructure of the wall. (c) A single gonidium. The gonidia retain all of the envelope structures observed in filaments. (Continued on next page.)

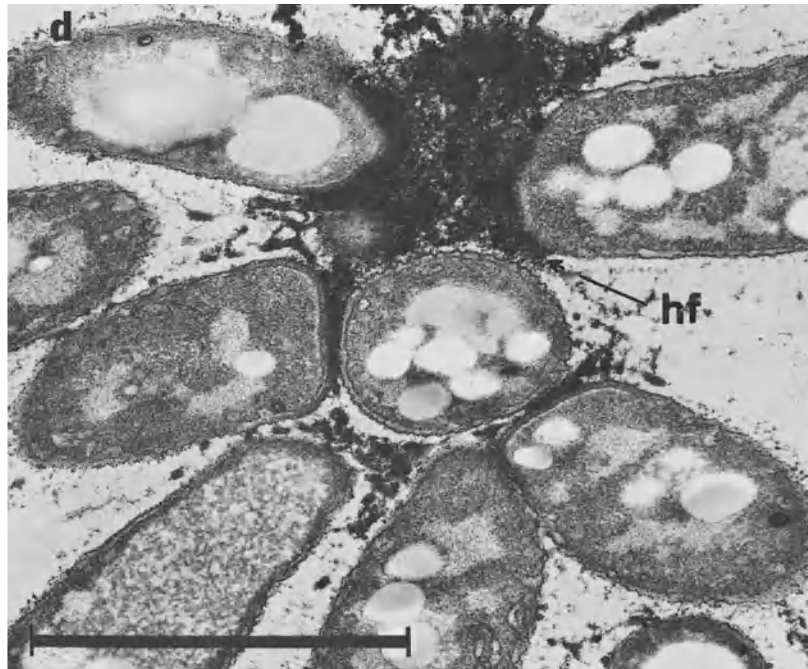

Fig. 6 (continued). (d) Thin section through a rosette. The holdfast material (hf) is an electron-dense material surrounding the cells. (a, b, d) Bars = 1.0 μm; (c) bar = 0.2 μm. (From Brock and Conti, 1969.)

(Kelly and Brock, 1969a), where densities are often quite high. In a detailed study at Friday Harbor, Washington, Bland and Brock (1973) made quantitative microscopic determinations of *Leucothrix* densities on a number of seaweeds. The organism was found on a variety of red, green, and brown algae, but was much more abundant on intertidal than on subtidal algae. The red alga *Bangia fuscopurpurea,* a filamentous species living in the high intertidal region, was unusually heavily colonized, with *Leucothrix* populations 10–30 times larger than those on other algal species in the same locations. Because of its high intertidal location, *B. fuscopurpurea* is exposed to air for fairly long periods during each tidal cycle. *B. fuscopurpurea* mats, dried during low tide, showed greater *Leucothrix* populations on the underside of the mats than on the top, presumably because the underside of the mats retained moisture longer. Examination of *B. fuscopurpurea* filaments of various ages showed that there was a continuous increase in the *Leucothrix* density with algal age, a finding that suggested growth on the alga itself. Using axenic two-membered cultures in an autotrophic medium with several red algae (including *B. fuscopurpurea*) and *L. mucor,* Brock (1966) showed that *Leucothrix* could grow on nutrients produced or liberated from the alga. Bland and Brock (1973) used artificial substrates and a variety of ecological studies to demonstrate that in nature *Leucothrix* obtained most of its nutrients from the alga and not from the sea water. Details of these ecological experiments and a review of other literature on the ecology of *Leucothrix* should be sought in the original paper (Bland and Brock, 1973).

Brock (1966) thought that *Leucothrix* was more abundant on seaweeds in temperate than in tropical waters (see also Kelly and Brock, 1969c), but Johnson et al. (1971) found *Leucothrix* to be abundant on tropical algae in the Pacific. Brock (1966) also concluded that *Leucothrix* was more abundant on algae in habitats of high aeration, such as open, exposed coasts and areas with heavy tidal currents. Since *Leucothrix* is an obligate aerobe, the preference for highly aerated habitats is not surprising. The finding that *Leucothrix* prefers algae in the intertidal rather than the subtidal zone is in keeping with this hypothesis, although there are, of course, factors other than aeration that differ in these two kinds of habitats. A survey of marine habitats showed that *Leucothrix* was worldwide in distribution (Kelly and Brock, 1969b), including the southern hemisphere (Brock, unpublished observations in New Zealand).

An authentic freshwater strain of *Leucothrix* has never been isolated, although *Thiothrix* occurs in both fresh and marine waters. Microscopic surveys of freshwater algae, even freshwater red algae, have never shown any indication of the presence of *Leucothrix* (Brock, unpublished observations), although Eikelboom (1975) found a number of *Leucothrix*-like organisms in activated sludge (see also van Veen, 1973; Sladka and Ottova, 1973). However, because there are various other filamen-

tous septate bacteria, positive confirmation of freshwater *Leucothrix* will require isolation in pure culture and demonstration of the various stages of the life cycle, especially gonidia and rosettes.

Isolation

Harold and Stanier (1955) first isolated *Leucothrix* from crude enrichment cultures of rotting seaweeds, but such cultures are generally grossly contaminated and purification of *Leucothrix* is often difficult. A more effective way of isolation (true for many other gliding filamentous bacteria as well) is to avoid enrichments completely and carry out a direct, single-colony isolation from natural material. This operation is made especially easy with *Leucothrix* when it is growing on relatively clean seaweeds, because on such samples, motile unicellular contaminants (the organisms presenting the greatest difficulty in isolation) are relatively small in number.

Any marine-type seawater base can be used in the formation of a culture medium; natural sea water (filter-sterilized) itself can be used, but pH control and avoidance of metal precipitation are easier in a Provasoli-type culture medium (Provasoli, 1963). The following salts formulation (Brock, 1966) proved quite effective:

NaCl	11.75 g
$MgCl_2 \cdot 6H_2O$	5.35 g
Na_2SO_4	2.0 g
$CaCl_2 \cdot 2H_2O$	0.75 g
KCl	0.35 g
Tris(hydroxymethyl) aminomethane	0.5 g
Na_2HPO_4	0.05 g
Deionized water	1 liter
Adjust to pH 7.6.	

The low phosphate concentration of this salts base is critical, as media of normal phosphate levels are inhibitory. Most strains have no vitamin requirements and use glutamate as the sole source of carbon, nitrogen, and energy, so that this salts medium with 0.1% monosodium glutamate (MSG) and 2% agar (to inhibit swarming organisms) will permit the isolation of *Leucothrix* from most materials. Other useful media include 0.1% MSG plus a vitamin mixture, 0.1% MSG plus 0.01% yeast extract, and 0.1% tryptone plus 0.1% yeast extract. In the initial isolation step, it is best to keep the organic concentration of the medium low to avoid problems with overgrowth by unicellular bacteria.

For isolation, single algal filaments are streaked directly (or after washing in sterile salts) onto agar plates, which are incubated at 20–25°C overnight. Within 12–18 h after streaking, the plates are examined under 125× magnification (10× eyepiece with a long working distance, phase-contrast objective is best) for the presence of characteristic *L. mucor* colonies, which have a coiled rope or thumbprint morphology. These colonies are picked by touching them with a sterile insect pin and transferring them to fresh agar plates of the same composition. It is important that colonies be identified early after inoculation, before the plates are overgrown. Although a dissecting microscope can also be used to locate *Leucothrix* colonies (Harold and Stanier, 1955), I have found that a 10× microscope objective (12.5× eyepiece) is better for locating colonies when they are very small (before they are overgrown). By using these procedures, it has been possible not only to isolate *Leucothrix* from seaweed from a wide variety of habitats, but also, with very clean material, to obtain growth of *Leucothrix* colonies directly from filaments still attached to seaweed fronds. In this way, the precise habitat from which the isolate was obtained is known; such information is of considerable value in studies on the molecular evolution of *Leucothrix* (Kelly and Brock, 1969b).

During transfer of colonies to liquid culture, it has often been observed that only very slight growth, if any, occurred after several days when an inoculum was transferred from agar to 100-ml liquid cultures; but when the inoculum was placed in a small volume of medium, such as 1–2 ml, heavy growth occurred overnight. Such small cultures could be easily used as the inoculum for large flasks and permitted the buildup of large-volume cultures. In liquid medium, growth is best when the flasks are shaken gently, such as on a wrist-action shaker or slowly on a rotary shaker. With the latter kind of shaker, growth rate is increased if the flasks contain small internal baffles, made by pushing in the sides of the flasks during heating with an oxygen flame.

For growing high-density cultures, a medium containing 1% MSG, 0.2% sodium lactate, and 0.01% yeast extract has proved quite suitable, the yeast extract providing growth factors needed by some strains. The sodium lactate was found to substantially increase the yield of most cultures.

Identification

Leucothrix is identified simply on the basis of morphological examination with the light microscope. The filaments are of large diameter

(greater than 2 μm; average, 2–3 μm), and each filament is composed of short cylindrical or ovoid cells, with cross-walls clearly visible. The filaments are colorless, unbranched, and of variable length, often very long. The filaments do not taper, but there may be variation in diameter along the length of the filaments. The filaments do not glide, although they may wave sporadically from side to side. Rosette formation is a key diagnostic characteristic. Without observation of the presence of rosettes, it is not possible to easily identify an isolate as *Leucothrix.* Conversion of cells in filaments into gonidia may result in the formation of chains of spherical cells, or gonidia may form only at the ends. The gonidia exhibit gliding motility, although the rate of motility is generally so slow that gliding itself is not a good diagnostic characteristic. To study gonidia formation, gliding, and aggregation, slide cultures are preferable; chambers that permit examination with 10–25× objectives should be used. Growth in such chambers is better if a considerable air space is left along one side, since *Leucothrix* is an obligate aerobe.

Filaments in culture often form true knots, and the presence of knots in a culture may be considered indicative of *Leucothrix* even without the formation of rosettes. However, the density of knots is never high, and a number of microscopic fields must be searched to ascertain if knots are present. Knot formation is most frequent when growth occurs to a high cell density in a relatively rich culture medium.

All strains that have been isolated are marine and require NaCl for growth; but, since freshwater strains could theoretically exist, NaCl requirement should not be considered a diagnostic characteristic. The GC content of the more than 30 strains examined ranged from 46 to 51 mol%, a relatively narrow range. Only one species is recognized (Brock, 1974), *Leucothrix mucor.*

CHAPTER 176

The Genus *Lysobacter*

HANS REICHENBACH

The species classified in the genus *Lysobacter* are Gram-negative rods that move by gliding. The cells are slender and cylindrical, with rounded ends (Figs. 1 and 2). They typically measure 0.4–0.6 × 2–5 μm, but in the population there are also always long to very long (up to 70 μm) cells and filaments. The cell shape and the occurrence of long cells are both very characteristic for the genus. *Lysobacter* cells resemble the vegetative cells of certain myxobacteria, specifically of the genera *Polyangium* and *Sorangium,* with which the lysobacters were confused for many years. They also share with the myxobacteria a high GC content of their DNA of 65 to 70 mol%. Due to the gliding movements of the cells, the colonies of *Lysobacter* are spreading or swarming on solid media and may become very large and extremely thin (Figs. 3 and 4). Sometimes the organisms produce copious amounts of slime, and the colonies then become thick and deliquescent, but colonies with a wrinkled and dry surface also occur. *Lysobacter* colonies may be white or cream-colored but often they are greenish-yellow, purplish-red, or brown, although their color is often rather pale. Some strains produce an unpleasant odor reminiscent of certain pseudomonads or of pyridine. In agitated liquid cultures, the lysobacters grow as homogeneous cell suspensions, but, as with all gliding bacteria, the suspended cells are unable to translocate. The *Lysobacter* species live in soil, decaying organic matter, and fresh water, sometimes in large populations. Many strains are of considerable ecological and biotechnological interest as producers of exoenzymes and of antibiotics.

The genus *Lysobacter* was defined by Christensen and Cook (1978) who also described the presently recognized species and created a new family, Lysobacteraceae, and a new order, Lysobacterales. The organisms thus classified had already been known, however, for a long time under various names, such as *Cytophaga, Sorangium,* and *Myxobacter* (the latter an obsolete myxobacterial genus), which were usually presented with some doubts of the investigators concerning the classification of their strains. The first lysobacter in the scientific literature may have been *Flexibacter albuminosus* (Soriano, 1945, 1947), which had the cell size and shape of a lysobacter and formed thick dirty-white colonies and a diffusible dark pigment. But the description is not accurate enough and the strains are no longer available so that the question cannot be decided. The first unequivocal *Lysobacter* strain was a chitinolytic strain first tentatively identified as *Cytophaga johnsonae* (Veldkamp, 1955). It is deposited at the National Collection of Industrial Bacteria (NCIB no. 8501) and was originally listed as a *Polyangium* species. The strain has a GC content of 71 mol% (T_m) and was noted as an unusual case of a cytophaga with a high GC content (Mitchell et al., 1969). Other early strains that later turned out to be lysobacters are: 1) "myxobacter" or *"Sorangium"* strain 495, which was studied because it attacks nematodes (Katznelson et al., 1964) and various bacteria (Gillespie and Cook, 1965) and contains very interesting proteases (for details, see "Practical Aspects," this chapter); the strain also produces two peptide antibiotics, the myxosidins (Clapin and Whitaker, 1976, 1978); 2) "Myxobacter" AL-1, which became of interest because it digested cells and cell walls of *Arthrobacter crystallopoietes* (Ensign and Wolfe, 1965) and which was later found to excrete two unusual proteases; 3) *"Sorangium"* 3C, producer of the wide-spectrum phenazine antibiotic myxin (Peterson et al., 1966); 4) *"Cytophaga"* L1, (NCIB 9497) for which a patent was filed for a number of unusual enzymes of practical interest, e.g., keratinase, laminarinase, and chitinase (Brit. Pat. 1,048,887, 23 November 1966), and 5) *"Cytophaga johnsonae"* (ATCC 21123), originally isolated because of its lytic enzymes at Kyowa Hakko in Japan (Jap. Pat. 06624, 1969), and from which the new quinoline antibiotic G1499-2 was obtained (Evans et al., 1978). In addition a number of lysobacters, usually labeled "myxobacters," were isolated because

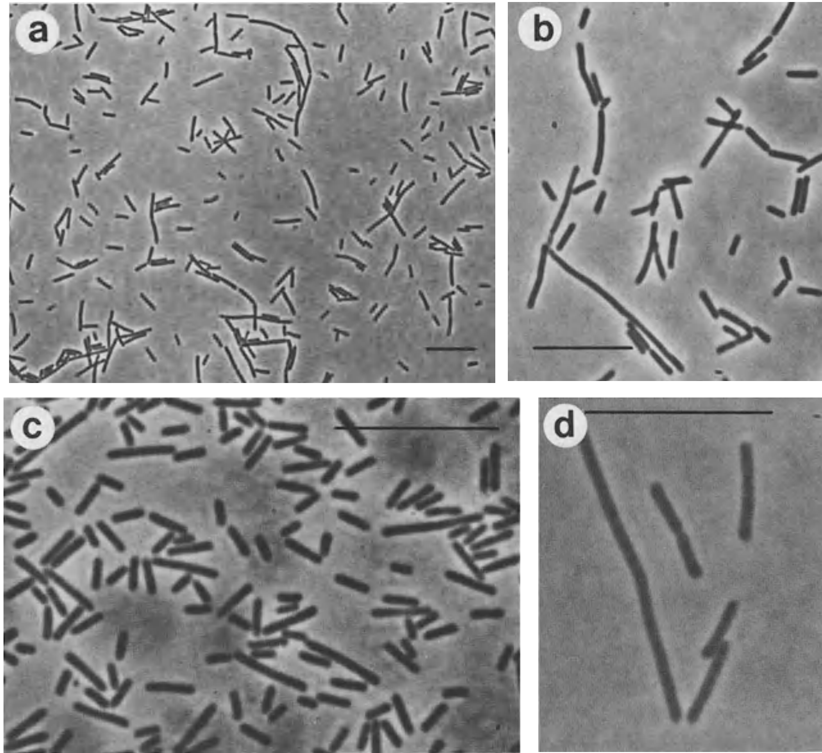

Fig. 1. Phase contrast photomicrographs of *Lysobacter*. (a), (b), and (d) *L. antibioticus* strain UASM L17 (= ATCC 29480) grown on CY agar (0.3% Casitone, 0.1% yeast extract) for 3 days at 20°C. Typical is a fairly regular cylindrical cell shape and a substantial variation in cell length. (c) *L. enzymogenes* type strain UASM 495 (= ATCC 29487), grown on VY/2 (yeast) agar for 13 days at 30°C. (a) Bar = 20 μm. (b), (c), and (d) Bars = 10 μm.

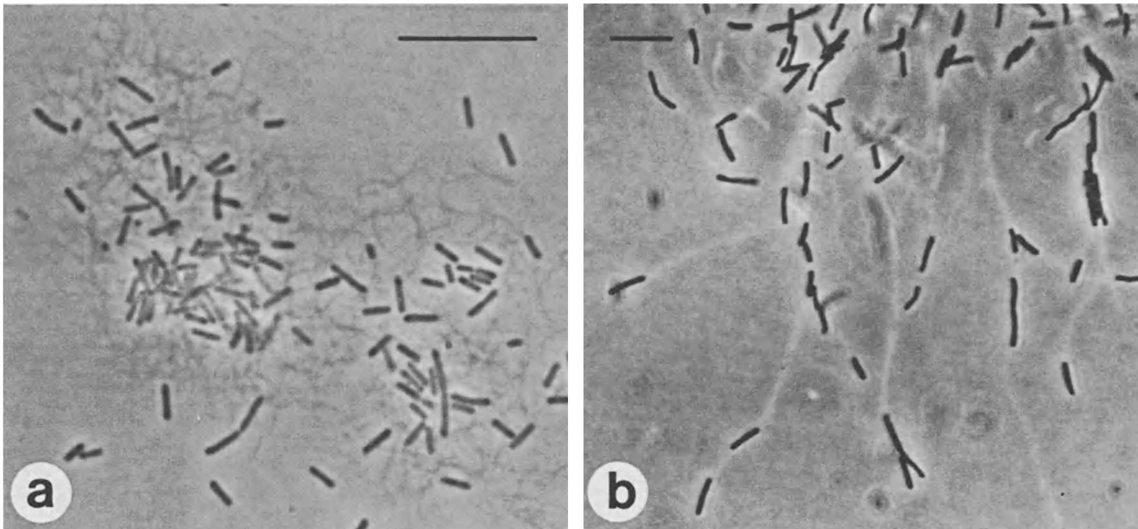

Fig. 2. Phase contrast photomicrographs of slime structures produced by *Lysobacter*. (a) *L. antibioticus* strain UASM L17 grown on CYG2 agar (CY agar plus 0.3% glucose) for 3 days at 20°C. For photography, the cells were transferred to a thin film of water agar. A network of slime threads is clearly visible. Bar = 10 μm. (b) The cyanobacteriolytic lysobacter of Shilo (1970). Edge of a colony on Shilo's (2% Casitone) agar in a chamber culture. Slime trails have been laid by the cells during their gliding movements. Bar = 10 μm.

they attacked cyanobacteria and green algae and multiplied spectacularly during algal blooms. Thus, "myxobacter" FP-1 specialized on cyanobacteria (Shilo, 1967, 1970); *"Cytophaga"* N-5, later renamed "myxobacter" 44, lysed cyanobacteria and green algae (Stewart and Brown, 1969); "myxobacters" 45 and 46, which with "myxobacter" 44, *"Sorangium"* 3C, and "myxobacter" AL-1, have an uncommonly high GC content of around 70 mol% (Stewart and Brown, 1971); and the cyanobacterium-lysing bacteria with a high GC content isolated from

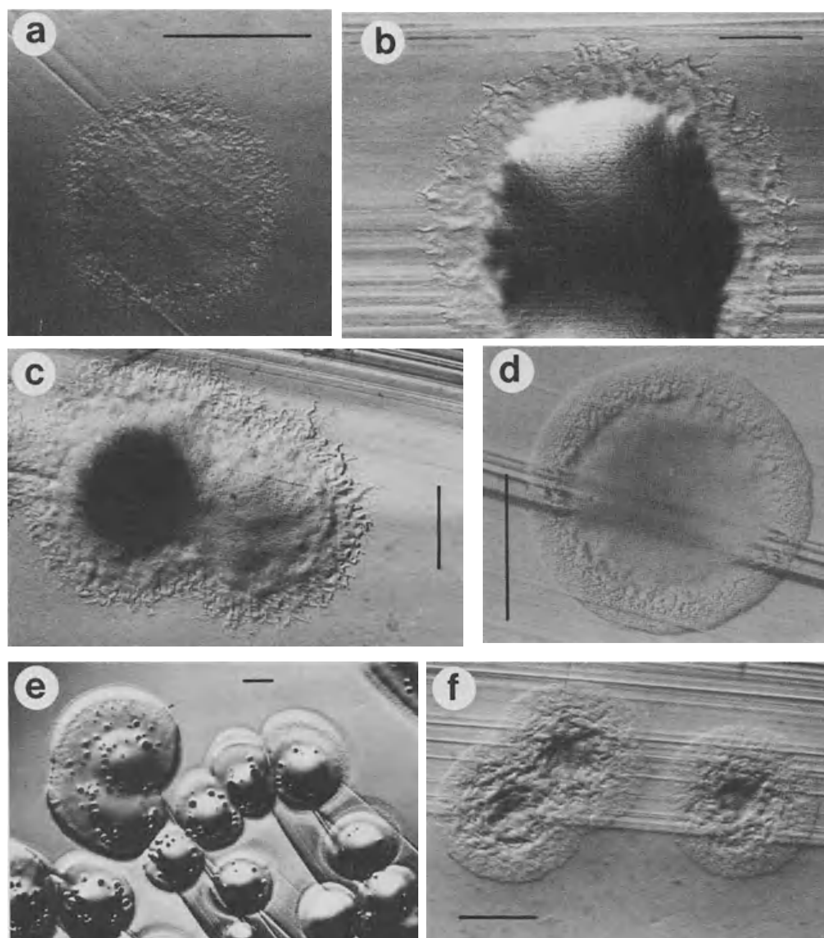

Fig. 3. The *Lysobacter* colony. Bars = 1 mm. (a), (b), and (c) *L. antibioticus* strain UASM L17 grown on different media for 7 days at 20°C: (a), on CA2 agar (0.075% KNO_3, 1% glucose); (b), on MYX agar (0.5% Na glutamate, 0.1% yeast extract, 0.2% glucose); and (c), on CY agar. (d) and (e) the chitinoclastic strain (NCIB 8501) of Veldkamp (1955): (d) grown on CA2 agar; (e) grown on CY agar; both 7 days old (20°C). (f) *L. enzymogenes* strain UASM 495 grown on CA2 agar for 7 days at 20°C. In all cases, the colonies are spreading, but they still are rather small after 1 week. On diluted CA2 agar containing nitrate as the sole nitrogen source, the swarm colonies of all three strains remain rather delicate. In (e), small crystals can be seen within the colonies, as is often the case with lysobacters.

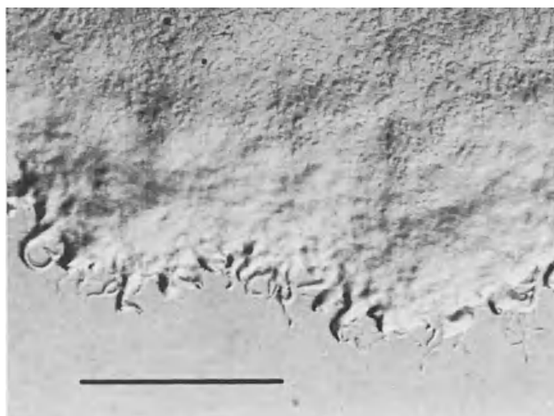

Fig. 4. *Lysobacter antibioticus* strain UASM L17. Edge of a swarm colony showing the typical flamelike protrusions. CY agar, 7 days at 20°C. Bar = 1 mm.

British waters, e.g., strains CP-1, -2, -3, and -4 (Daft and Stewart, 1971; Daft et al., 1975).

The phylogenetic position of the genus *Lysobacter* remained obscure until recently. To the early investigators, gliding motility suggested some relationship with other, existing groups of unicellular gliding prokaryotes, specifically the myxobacteria and the cytophagas (Reichenbach, 1981). This is reflected by the names given to the strains isolated at that time. But as was already correctly anticipated in the taxonomic description of the new organisms, these bacteria form a group of their own (Christensen and Cook, 1978). Later, 16S RNA studies demonstrated that *Lysobacter* is relatively closely related with the xanthomonads and belongs to the gamma-3 branch of the purple bacteria (Woese et al., 1985) known today as the class Proteobacteria (Stackebrandt et al., 1988).

Habitats

The lysobacters live in soil and fresh water and appear to be wide spread and in many places are rather abundant. They have been isolated from soils in the Netherlands (Veldkamp, 1955), Canada (Christensen and Cook, 1978; Katznelson et al., 1964; Peterson et al., 1966), the United States (Ensign and Wolfe, 1965), and

Scotland (Daft et al., 1975). In Scotland, they have been found in agricultural soils and sand dunes where the pH was neutral to slightly alkaline (pH 8.8) and not below pH 6. Population densities of up to 500 plaque-forming-units (PFU) per cm^3 were observed. This may seem very low, but the isolation method was designed only to detect organisms that lyse cyanobacteria (forming plaques in the cyanobacterial lawns), which may not be the case with all lysobacters. Also, the counts would be much reduced if most of the lysobacters are attached to particles. In soil, the lysobacters probably subsist by degrading various biomacromolecules and microorganisms other than cyanobacteria. In fact, lysobacters are known to decompose nematodes and different kinds of bacteria, as already mentioned. So, while their ecological niche is not really identified, the enzymatic equipment and lytic capabilities of the lysobacters suggest that they preferentially live in places rich in (recalcitrant) organic matter and microbial life.

Much more is known about the freshwater habitats of the lysobacters because there strains exist that can lyse living and healthy cyanobacteria and for this reason aroused much interest (see reviews by Stewart and Daft, 1976, 1977). The bacteria were found in fish ponds in Israel (Shilo, 1967; Shilo, 1970), in sewage plants in the United States (Stewart and Brown, 1969, 1971) and Scotland (Daft et al., 1975), and in lakes, reservoirs, and rivers in Great Britain (Daft et al., 1973, 1975). This, of course, does not mean that those lytic strains are the only lysobacters living in fresh water, as lysobacters were also isolated from that source by other techniques, and the ability of these strains to lyse cyanobacteria was never specifically demonstrated (in Canada: Christensen and Cook, 1978; in Germany: H. Reichenbach and coworkers, unpublished observations).

In contrast to cyanobacterial viruses, the lytic lysobacters have a wide activity spectrum with respect to the cyanobacterial species attacked. Thus, strain FP-1 lysed 9 out of 11 species of unicellular and filamentous cyanobacteria whereas the green alga *Chlorella pyrenoidosa* and the chrysophyte *Prymnesium parvum* were completely resistant (Shilo, 1970). All Gram-negative bacteria tested were also lysed, but Gram-positive bacteria were not. Strain CP-15 disintegrated 21 out of 23 strains of cyanobacteria (Daft et al., 1973), and strains CP-1 to -4 among themselves lysed 29 out of 42 cyanobacteria from nine different genera (Daft and Stewart, 1971). In the latter case, there were slight differences among the four strains with respect to the spectra of cyanobacteria attacked, and also different strains of the same cyanobacterial species could vary in their sensitivity to lysis. All 16 British *Lysobacter* strains used in these studies were serologically related and may have belonged to one species (Stewart and Daft, 1976).

The population densities of lysobacters observed in British waters are usually low (Daft et al., 1975), but since lysobacters attach themselves to plankton and other particles, the counts may not reflect the true numbers. In lakes in summer and at the water surface, between 0 and 400 PFU/ml were found, and the numbers decreased rapidly with depth (to 1 m). But 94% of all samples contained lytic bacteria. At the height of cyanobacterial water blooms, 0.001 to 0.05% of all cultivatable bacteria were lytic, and in general the population densities of cyanobacteria and lytic bacteria correlated well, with a slight shift in the time of the maxima. Large differences in the cell numbers could occur in simultaneous samples taken from different sites in the same lake. This apparently was simply due to wind drift which caused the plankton to accumulate at certain places. In samples with particularly high densities of cyanobacteria, the numbers of lysobacters could drop substantially. As the lysobacters are strict aerobes, their decline in number under such conditions was explained by oxygen depletion during the night, but perhaps the bacteria only seem to disappear because there was now an increased opportunity for attachment. In February, after 3 months of low phytoplankton density (and low temperature), the count of lytic bacteria fell to zero at the water surface, but some lysobacters still survived in the depth at the sediment-water interface. From there and from soils around the lakes, the repopulation of the water bodies may take place in spring. Another source for lytic bacteria was found in sewage works where in summer the counts in the final effluents were around 700 PFU/ml, and in the effluents from filter beds even as high as 1,300 PFU/ml. Also, in sewage plants, the numbers dropped during winter, in February to about 1% of the summer counts (Daft et al., 1975). Dense populations of lytic bacteria were found in the sand filters of a waterworks at a reservoir with blooming cyanobacteria. Up to 2,500 PFU/ml were found in the effluent, and 59,000 PFU/ml on the filter sand. The maximum in the open reservoir was 92 PFU/ml (Daft et al., 1973). No lysobacters were detected in water from underground springs (Daft et al., 1975).

While the lysobacters are able to lyse bloom-forming cyanobacteria, their low population densities make it questionable whether they really play a role in the control of natural water

blooms. In field trials, at least 10^5 cells/ml were required to induce rapid lysis in cyanobacterial populations. In small bays at the edge of a reservoir, which were separated artifically from the main body and inoculated to a density of 10^6 bacteria/ml, there was clear evidence for lysis within 24 h at 13°C, and within 60 h, the *Microcystis* population was completely destroyed. In the lysing cell suspension the number of lytic bacteria rapidly declined, which again was explained by a lack of oxygen (Daft et al., 1973; 1975). In summary, it appears that cyanobacteria and lysobacters have similar growth requirements and simply coexist rather than prey upon one another. As the lysobacters can grow perfectly well as saprophytes, they may utilize material, including biomacromolecules, excreted by the cyanobacteria. In fact, they appear to interfere in a subtle way with the photosynthesis of the cyanobacteria and their excretion of dissolved organic carbon, reducing the rate of the former and stimulating the rate of the latter, and are able to rapidly assimilate excreted material, particularly certain amino acids, and to grow exclusively on it with a generation time of about 10 hrs (20°C). In a similar way they also exploit bloom-forming green algae like *Scenedesmus quadricauda,* which they cannot lyse at all (Fallowfield and Daft, 1988). Under conditions unfavorable for the cyanobacteria, the lysobacters also may lyse some of them, but they probably have little to do with the cyclic break down of water blooms in nature.

Isolation

Two properties of the lysobacters may be used for their enrichment: their efficient hydrolytic exoenzymes and their gliding motility. As both attributes are also found with other organisms, the enrichment techniques are not entirely specific.

Christensen and Cook (1978) recommend enriching soil samples with chitin, ground mushrooms, or *Arthrobacter* cells, and then leaving them for at least one month. After this period, the soil is suspended in water and appropriate dilutions are spread on yeast agar.

Yeast Agar

Bakers' yeast	0.5 %
Agar	1.5%

Adjust to pH 7.2 and autoclave.

After incubation, colonies arise that are surrounded by lysis zones, and their number increases substantially during the enrichment phase. Two types are usually observed: 1) pink-colored *(Lysobacter antibioticus)* and 2) cream-colored *(L. enzymogenes).* Rarely, also, an off-white gummy colony may appear *(L. gummosus).* On subcultivation, most of the cream colonies produce two colony variants: 1) dirty-white mucoid, and 2) yellowish nonmucoid. When water samples from lakes and rivers are used, yellow-brown colonies are obtained *(L. brunescens).*

As all lysobacters appear to degrade chitin (Christensen, 1989), one also could try to isolate them on chitin agar as described by Veldkamp (1955). He used 1% of finely powdered chitin suspended in a medium containing 0.1% K_2HPO_4, 0.1% $MgSO_4$, and 2% agar. He purified the chitin from shrimp shells by a very cumbersome procedure, so a simpler method is given here as well as two chitin media, which are used in our laboratory with excellent results in enriching for cytophagas and myxobacteria.

Preparation of the Chitin Stock Suspension (Modified from Hsu and Lockwood, 1975)

Finely divided commercial chitin (e.g., from Fluka or Sigma) is suspended in concentrated (32%) HCl. For 40 g of chitin, approximately 400 ml of HCl is required, but sometimes more HCl (600–800 ml) has to be used. Within about 30 min, a relatively thin, blackish collodial solution is obtained. The hydrochloric acid solution should never stand for more than 1 h at room temperature to avoid degradation of the chitin. The solution is poured into 2 liters of ice-cold water, upon which the chitin precipitates immediately as a pure white, fluffy material. It is collected on a separating funnel under suction and extensively washed. During these manipulations the material should never become dry, because drying makes it very difficult to resuspend. The washed precipitate is dialyzed against tap water for 12 to 24 h until the pH of the water remains above at least 4.5. Then enough distilled water is added to the chitin suspension to give a slurry which is sufficiently thin to be pipetted. The pH is adjusted to 7.2 with KOH. The exact volume is determined, and the approximate chitin content of the suspension calculated from the amount employed in the beginning. The material is distributed in convenient aliquots in bottles, autoclaved, and stored at 6°C. If the precipitated chitin appears too coarse, which may happen if the starting material was not well ground, it can be further homogenized with a blender.

Chitin agars are prepared best as overlay media, which saves chitin and gives clearer results, because the layer to be hydrolyzed is thinner and the material remains at the top of the plate, so that the bacteria have an easier access to it.

CT6 Agar

Top layer:

$MgSO_4 \cdot 7H_2O$	0.1%
K_2HPO_4	0.02%
Agar	1.5%

Adjust the pH to 7.5. After autoclaving, enough of the sterile chitin suspension is added to give a good turbidity, which should be achieved with about 0.5% chitin and not more than 30% (by volume) of the suspension. The medium is poured as a thin layer on top of the following base agar:

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

Adjust the pH to 7.2 and autoclave.

CT7 Agar

The top layer is as above; the base agar, however, is water (WAT) agar, which is as follows:

WAT agar:

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Adjust the pH to 7.2 and autoclave.

In CT7 agar, chitin is the only nitrogen, carbon, and energy source besides agar, and thus the medium is more selective. But not all chitin degraders grow on it. On CT6 agar, on the other hand, chitin degradation is sometimes suppressed by the peptone, and organisms that are not chitinovorous also grow on it.

Lysobacters decompose many bacteria, living and dead, and therefore may be isolated on such substrates. Strain AL-1 was obtained from lysis zones in lawns of *Arthrobacter crystallopoietes* (Ensign and Wolfe, 1965). Aqueous soil extracts were streaked on plates of medium A and incubated at 30°C.

Medium A

A basal agar with 0.5% peptone and 1% agar was overlaid with the same medium containing 10^9 cells/ml of *Arthrobacter.*

The bacteria from the plaques that developed in the lawn were purified by plating diluted suspensions on medium B.

Medium B

Agar, 1.5%, containing 10^9 cells/ml of washed *Arthrobacter.*

Presumably the *Arthrobacter* cells were living in the isolation medium and dead in the purification medium. Strain AL-1 was also maintained on medium B (at 30°C, with weekly transfers).

Similar isolation techniques may be devised with other bacteria and in fact have been used repeatedly to obtain lysobacters that lyse cyanobacteria. Stewart and Brown (1969) and Shilo (1970) isolated their organisms from water collected from a waste stabilization pond and a fish pond with a water bloom, respectively. Both groups used the soft-agar overlay technique developed for the isolation of cyanophages, and living *Nostoc muscorum* or *Plectonema boryanum* as the indicator organisms. Shilo (1970) first enriched the lytic agent by inoculating the sample into a *Plectonema* culture. While viral plaques appear after just 2–3 days, the bacterial plaques need 5–7 days to develop, and in addition are slightly sunken into the agar. Further, the bacteria also produce lysis zones in layers of autoclaved cyanobacteria. Shilo (1970) separated her strain from the cyanobacteria by transfer to a mineral salts liquid medium with 0.2% Casitone and incubation in the dark. The overlay technique may also be used for counting the lytic bacteria. Stewart and Brown (1969) determined for strain N-5 (myxobacter 44) a ratio of 1.3 for the number of viable cells to plaque-forming units.

A slightly different method was applied by Daft and Stewart (1971) and Daft et al. (1973). The cyanobacteria were grown on a suitable mineral salts medium with 0.6% agar. On the lawns produced after 7 days at 22–25°C, 1-ml water samples from the top-most layer of lakes or other surface waters, preferentially such with a cyanobacterial water bloom, were spread and the lysobacters isolated from the lysis zones that arose in the lawns. As indicator organisms, *Nostoc ellipsosporum, Anabaena catenula, A. flos-aquae,* or *Phormidium foveolarum* were used, and *N. ellipsosporum* (strain 1453/19 Cambridge University) proved particularly sensitive to lysis. The CP strains could be maintained without loss of lytic activity on CP agar.

CP Agar

K_2HPO_4	17 mg
$MgCl_2 \cdot 6H_2O$	49 mg
$CaCl_2 \cdot 6H_2O$	15 mg
NaCl	60 mg
$FeCl_3$	0.3 mg
EDTA	7.4 mg
Standard trace element solution*	
Casitone (Difco)	2 g
Agar	6 g
Distilled water	1 liter

The mineral part is that of ASM medium (Daft and Stewart, 1971) for the cultivation of algae (and probably dispensable for the lysobacters).

*See, for example, Drews (1974), p. 6.

Lysobacter colonies may be recognized by their spreading growth due to gliding motility, and colony morphology can thus be used as a lead to isolate the organisms. Thus, on plates

designed for the isolation of myxobacteria and consisting of water agar (WAT agar) with streaks of living *Escherichia coli* that are inoculated with soil, we occasionally also observe swarming lysobacters.

The purification of *Lysobacter* strains is easy and is done either by plating of diluted cell suspensions or by making transfers from the advancing edge of swarm colonies. As swarming is much reduced or completely suppressed on rich media, the latter possibility exists only when the bacterium is grown on a lean medium like yeast agar or CY agar (see below). To avoid confluence of the arising colonies, plating is done best on a rich medium such as standard nutrient agar (Difco).

Cultivation

The lysobacters are robust, adaptable organisms, and their cultivation is no problem. They actually grow on any bacteriological standard medium. Christensen and Cook (1978) recommend the three following media:

PC Agar (Plate Count Agar, Difco)

Yeast extract	0.25%
Tryptone	0.5%
Glucose	0.1%
Agar	1.5%

CC Agar (Cook's *Cytophaga* Agar; Christensen and Cook, 1972)

Tryptone	0.2%
Agar	1.0%

SA Agar (Skim-Milk Acetate Agar; Christensen and Cook, 1972)

Skim milk powder	0.5%
Yeast extract	0.05%
Sodium acetate	0.02%
Agar	1.5%

The pH for all of these media is adjusted to about 7.0 and the medium is sterilized by autoclaving. On PC agar, the colonies remain small and compact like those of nongliding bacteria, whereas on CC and SA agar, spreading swarms are obtained. Another good medium for lysobacters, including stock cultures, is the Yeast Agar mentioned above. On this medium the organisms form thin, spreading swarms, and because no or much less ammonia is produced than on the peptone media, the cultures tend to remain viable for longer time.

SA medium may also be used as a broth for liquid cultures, but a nonturbid medium is more convenient, e.g., 1% yeast extract medium (Ensign and Wolfe, 1966). We often use PEP medium.

PEP Medium

Peptone from casein, tryptically digested	1%
$MgSO_4 \cdot 7H_2O$	0.1%
Adjust the pH to 7.2 and autoclave.	

Other peptones can be used as well, e.g., Casitone (Difco), which is a pancreatic digest of casein, and casamino acids have also been employed successfully (Gillespie and Cook, 1965). *L. brunescens* appears not to grow well or to lyse early in pure peptone media. It could, however, be cultivated with a generation time of 4 h at 20–22°C in tryptone-starch medium.

Tryptone-Starch Medium (von Tigerstrom and Stelmaschuk, 1987b)

Tryptone	0.8%
Yeast extract	0.2%
Starch	0.3%
$MgCl_2$	0.02%

A fully defined medium for *L. enzymogenes* strain AL-1 was developed by Ensign and is mentioned in Tan et al. (1974):

Defined Liquid Medium (for Strain AL-1)

Aspartic acid	0.2%
$K_2HPO_4 \cdot 3H_2O$	0.34% (0.03 M)
$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.01%
Tap water	1%
Glucose	0.5%
Adjust to pH 7.0 and autoclave.	

Although lysobacters tolerate relatively high pH values and can grow above pH 10 (Christensen and Cook, 1978), their optimum is between pH 7 and 9. While all appear to grow at 30°C, their temperature optimum is sometimes lower, and cultivation at 25°C or even 22°C may give better results. The organisms are strict aerobes, and liquid cultures have to be shaken.

The generation times are typically around 2.5 h (2.3 h for *L. enzymogenes* strain 495 in 0.8% yeast extract broth at 22°C: von Tigerstrom and Stelmaschuk, 1989; and 2.6 h for strain myxobacter 44 in a mineral salts medium with 0.2% starch and 0.25% peptone, 30°C: Stewart and Brown, 1971. Much longer generation times of 10.7 and 12.6 h are reported for growth under quasi-natural conditions in nutrient-poor culture filtrates from cyanobacteria and green algae, respectively (strain CP-1, 20°C: Fallowfield and Daft, 1988). A maximum cell yield of 2.5 g/l (dry weight) was obtained with strain 495 in condensed fish solubles with 2% glucose (Wah-On et al., 1980).

Large-scale fermentations with lysobacters have been performed for the production of the antibiotic myxin, and of an enzyme complex capable of lysing living yeast cells. While apparently nothing has been published about the industrial process developed by Hoffmann-La Roche (Nutley, NJ) for the manufacture of myxin with strain *"Sorangium"* 3C, some data on 10-liter fermentations are given in a Canadian patent (Can. Pat. 784,213; 30 April 1968). The fermentation was performed in the following medium: Tryptone, 0.1%; glucose, 0.1%; K_2HPO_4, 0.1%; $MgSO_4$, 0.02%; $CaCl_2$, 0.01%; and $FeCl_3$, 0.001%; at pH 7.5 and 25°C. The aeration rate was 0.1 liter air per liter medium and min; the stirring rate, 300 rpm; the harvest time, 20 h with a 2% (v/v) inoculum, and 12 h with a 10% inoculum.

Production of yeast-lytic enzymes by *"Cytophaga"* NCIB 9497 was studied at up to a 900–1 liter scale (Asenjo et al., 1981). The medium consisted of 1% yeast extract and 1% glucose and permitted a maximum growth rate (μ_{max}) of 0.36 h^{-1}. The inoculum size was 3.8%, the initial pH 7.2, and the temperature 26°C. The aeration rate was set at 0.2 liter air per liter medium and min, and the impeller tip speed between 1.21 and 1.57 $m \cdot sec^{-1}$ (around 100 rpm). It appeared that a relatively low level of dissolved oxygen around 20–30% was favorable, particularly in the beginning. Polypropylene glycol 2000 was added as an antifoam agent and was well tolerated at 2 ml/1 but not higher. Still, after 24 h, the broth began to foam heavily. Harvest was at 30 h with a good yield of active enzyme, part of which was set free only by cell lysis at the end of the fermentation. Early cell lysis may be a serious problem. Obviously it is essential to start with young, vigorous seed cultures, e.g., from freeze-dried material.

Preservation

Stock cultures may be kept on yeast agar at room temperature (21°C) and should be transferred every 1 to 2 weeks. With stock cultures on peptone media, production of toxic levels of ammonia can be a problem. Storage of cultures in the cold is not recommended. In one reported case, all cells were dead after 3 weeks at 5°C (Asenjo et al., 1981). It seems understandable that the lytic enzymes produced by lysobacters also destabilize resting cultures.

Lysobacters survive freezing very well, either at −80°C or in liquid nitrogen. Cells from young plate cultures are suspended in PEP medium, or young shake cultures in the same medium are taken, and 1-ml samples are frozen without further precautions. The preserved cultures are reactivated by immersing them in tap water for a quick thawing and transferring the content as soon as it is liquefied. The longest storage period we have tested so far was 13 years at −80°C, which was reliably tolerated by all strains.

Lysobacters also can be lyophilized in skim milk by the standard procedure. It is reported that reactivated freeze-dried cultures may show a slightly different colony morphology and reduced bacteriolytic and proteolytic activity (Christensen, 1989). We dry the organisms with good results at room temperature, which may be less harmful to them. A few drops of a cell suspension in sterile skim milk are applied to a plug of lyophilized skim milk in an ampule. The wetted plug is then dried in vacuo, the ampule filled with nitrogen gas, and sealed.

Characterization

Morphologically, the various lysobacter species resemble one another closely (Christensen and Cook, 1978; Christensen, 1989). The cells are slender cylinders with rounded ends, and, at least in young healthy cultures, are rather regular in shape (Figs. 1 and 2). They typically measure 0.3–0.6 × 2–6 μm, but much longer threads, up to 70 μm, are usually also present. Those filaments obviously are incompletely divided cells and cell chains. A mixed population of short and long cells is very characteristic for the lysobacters and distinguishes them at once from any myxobacterium. To avert confusion, it should be mentioned that the morphological description given by Veldkamp (1955) of his chitinolytic strain does not fit the present NCIB 8501 strain, which indeed is a typical lysobacter. Instead, Veldkamp has given the morphology and cyclic-shape change of *Flexibacter filiformis,* which also is strongly chitinolytic.

Electron micrographs of thin sections show a typical Gram-negative cell wall, large mesosome-like structures in the center or at the poles, and granules interpreted as poly-β-hydroxybutyrate and polyphosphate. On the surface there may be ruthenium-red-positive material, presumably slime (Shilo, 1970; Stewart and Brown, 1971; Stewart and Daft, 1977); in other cases no such material was seen ("myxobacter" AL-1: Pate and Ordal, 1967). True rhapidosomes, i.e., the contracted tails of a defective phage (Reichenbach, 1967), were found in cell lysates of *"Sorangium"* 495 (Pate et al., 1967).

In contact with an interface, the lysobacters may move by gliding. The movements usually are rather slow but observable under the mi-

croscope. An average speed of 1 μm per min (30°C) has been reported (Veldkamp, 1955). When suspended in liquid the cells are nonmotile.

On lean media like CC, SA, and yeast agar, most lysobacters produce thin, filmlike swarms with little flamelike extensions at the edge (Figs. 3 and 4). Only *L. gummosus* appears not to spread on any medium, and its gummy colonies always show an entire edge. In general, the spreading of lysobacter swarms is not too fast, and it may take 2–3 weeks before they cover the entire plate. The swarm sheet itself may be somewhat slimy, but otherwise it is rather unstructured and smooth. This distinguishes the lysobacter swarms from myxobacterial swarms, which almost always are morphologically differentiated with radial veins, concentric ridges, and oscillating waves or ripples, and which in addition may etch themselves deeply into the agar surface (degenerate strains may produce homogeneous, slimy swarms). On rich media like PC agar, the colonies tend to remain compact, small, with a smooth convex surface and an entire edge. Those colonies often are highly mucoid. Enough slime may be produced to drop from the colony into the lid of the inverted dish (Ensign and Wolfe, 1965). As briefly mentioned, *L. enzymogenes* produces two different colonies, one dirty-white and mucoid, the other yellowish and nonmucoid. While both colony types are always obtained when starting from white colonies, the yellow ones yield only the yellow type. Physiologically and biochemically, the two organisms are identical (Christensen and Cook, 1978). Often, small, colorless crystals are seen within the colonies (Fig. 3e). In the case of *L. gummosus,* the colonies are of a rubbery consistency.

The color of colonies of *Lysobacter* may be off-white; cream; pale to deep yellow, sometimes with a greenish hue; pinkish; salmon; or orange-brown, depending on the species and on the medium. The chemical nature of those pigments is not known. The published absorption spectra of crude extracts show maxima or shoulders at 455, 482, and 516 nm (*n*-hexane) for salmon-colored strain FP-1; 448, 466, and 470 nm (ethanol) for three yellow "myxobacters" (Stewart and Brown, 1971); and 424, 442, and 464 nm (in methanol) for the yellow strains CP-1 and CP-15 (Daft and Stewart, 1971; Daft et al., 1973). While those spectra suggest a polyene chromophore, perhaps a carotenoid, they may be spectra of a mixture of pigments and thus cannot be reliably interpreted. Many strains produce a water-soluble, dark-brown, probably melanoid pigment, which is particularly prominent in old cultures and on media containing amino acids or peptones. Color reactions of phenolic compounds indicate the presence of a mono- and diphenol oxidase (Stewart and Brown, 1971). Deep-red crystals of myxin may appear within the colonies of *L. antibioticus.* Also, many cultures give off an unpleasant *Pseudomonas*- or pyridine-like odor.

In agitated liquid media, the lysobacters grow as homogeneous cell suspensions. When gently rotated, those cultures appear silky. Depending on the medium, liquid cultures may become somewhat viscous, and those of *L. gummosus* virtually solid.

Relatively little has been published about the composition of the lysobacter cell. A typical Gram-negative peptidoglycan was demonstrated in *L. enzymogenes* strain AL-1, with *meso*-diaminopimelic acid and D-alanine crossbridges (Harcke et al., 1975). The inner and outer membrane could be separated starting from osmotically shocked cells. The outer membrane had a density of 1.30 $g \cdot cm^{-3}$ (CsCl), the inner one of 1.23 $g \cdot cm^{-3}$ (Hartmann et al., 1977). Ubiquinone Q-8 is the only respiratory quinone of *L. antibioticus* and *L. enzymogenes* (M. D. Collins, personal communication). This allows one to quickly distinguish lysobacters from myxobacteria as well as from organisms of the *Cytophaga* group (including high GC strains of *Taxeobacter*) which all contain menaquinones exclusively. The ribosomes of "myxobacter" 495 *(L. enzymogenes)* were difficult to isolate because tightly bound nucleases and proteases were attached to them and could not be removed by the usual methods (Sendecki et al., 1971). Otherwise, lysobacter ribosomes have the typical prokaryotic composition. The rRNA has the same base ratio as that of *E. coli* (GC/AU = 1.20). The presence of poly-β-hydroxybutyrate in the lytic "myxobacters" was substantiated by its conversion into crotonic acid (Stewart and Brown, 1971). The compound accumulates in the course of cultivation, with a maximum on the third day. Capnoids, a new type of sulfonolipids found in bacteria of the *Cytophaga* group (Godchaux and Leadbetter, 1983), and multicopy single-stranded DNA common in myxobacteria (Dhundale et al., 1985), are both absent in lysobacters. The lysobacter DNA has a high GC content of 65–71 mol% (Christensen and Cook, 1978; Daft and Stewart, 1971; Mitchell et al., 1969; Shilo, 1970; Stewart and Brown, 1971).

A number of metabolic enzymes have been studied in *L. enzymogenes* strain AL-1 (Guntermann et al., 1975; Hartmann et al., 1977). In the cytoplasm there is an α- and a β-glucosidase, a β-galactosidase, and an isocitrate dehydrogenase; on the cytoplasmic membrane, a

succinate dehydrogenase; and bound to the outer membrane, an alkaline phosphatase and a *N*-acetyl glucosaminidase. The activities of those enzymes change during the cell cycle. Two distinct patterns were noted, one for the five hydrolases, the other for the two dehydrogenases. In the case of the α-glucosidase, the activity increase was shown to be due to de novo enzyme synthesis. While β-glucosidase and β-galactosidase are constitutive, α-glucosidase is inducible by maltose. In a study on the phylogenetic implications of the isozyme pattern of 3-deoxy-D-arabino-heptulosonate 7-phosphate synthase (important for the synthesis of aromatic amino acids) in superfamily B (to which *Lysobacter* belongs according to 16S rRNA data), *L. enzymogenes* was found to possess only one enzyme variant, the one that is sensitive to feedback inhibition by tryptophan and, unique for *Lysobacter,* ultrasensitive to chorismate (Ahmad et al., 1986). This pattern is shared only by group V pseudomonads, which fits its classification based on 16S rRNA studies. In addition, the lysobacters produce a host of exoenzymes. As some of those are of a more general interest and have found applications, they will be discussed under "Practical Aspects," this chapter.

For a large number of strains, comparative physiological and biochemical tests were performed and used for the differentiation of species (Christensen, 1989; Christensen and Cook, 1978). The strains studied for their ability to destroy cyanobacteria were not characterized in the same scheme as those able to destroy other bacteria, so that the following generalizations may not always apply to them.

The lysobacters are aerobic organisms, although many strains appear to grow best at a reduced oxygen level (10% O_2). In the oxidation-fermentation (OF) test with glucose, practically all strains show oxidative growth but many also show fermentative growth. Growth of the lytic freshwater organisms stops immediately when the culture is flooded with N_2 gas; no growth is obtained in paraffin-sealed tubes, and the generation time increases to 9 h (30°C) when the oxygen tension is reduced to 20% of the normal atmospheric pressure (Daft et al., 1975; Stewart and Brown, 1971). Catalase and oxidase are positive, but the catalase reaction is very sensitive to the culture conditions and sometimes is very weak or even absent (H. Reichenbach, unpublished observations).

The pH range is 4.5 to over 10, the optimum between 7 and 9. There is almost always a remarkable tolerance to alkaline conditions. Even the freshwater strains usually grow well at pH 9 (Stewart and Brown, 1971; Daft et al., 1975). The ability to grow at an acid pH varies with the different strains; many do not grow below pH 6. During growth on peptones, the pH may rise substantially due to ammonia production.

The temperature optimum is usually around 30°C, even for the freshwater organisms, but it varies substantially from isolate to isolate. It may be as low as 25°C or as high as 40°C. A few strains can grow at 2°C and at 50°C, but the limits often are 4 and 40°C.

The salt tolerance is usually limited to 1% NaCl or less, and no strain was found to grow in the presence of 3% NaCl.

The lysobacters are chemoorganotrophs. For many strains, NO_3^-, NH_4^+, glutamate, or asparagine serve as the sole nitrogen source whereas urea appears to be utilized only by a few strains. Some organisms, however, are more fastidious. Several of the strains that lyse cyanobacteria do not grow on inorganic nitrogen (Daft et al., 1973; Shilo, 1970), while others do (Stewart and Brown, 1971). All lysobacters grow on peptone as the only organic substrate, but the type and concentration of the peptone may be critical. Casitone (Difco) seems to be suitable in all cases, but strain FP-1 has a low optimum of 0.2% for Casitone and does not grow at 0.5%. The same strain also does not accept yeast extract, tryptone, or casamino acids, and does not grow on nutrient broth or nutrient agar (Shilo, 1970). In general, peptides appear to be the preferred carbon and energy source, and monosaccharides may only be used slowly (von Tigerstrom and Stelmaschuk, 1987b).

Glucose is probably utilized by all strains. Growth may take place on a wide spectrum of carbohydrates, e.g., in one case on: glycerol, mannitol, arabinose (weak), glucose, galactose, fructose (weak), mannose, lactose, sucrose, raffinose, and rhamnose (Veldkamp, 1955). Acid is produced from glucose and from several other sugars in a varying pattern that may be useful for the differentiation of species. Many strains grow on citrate as the sole carbon source.

All strains are strongly proteolytic as can be seen, e.g., by cultivation on skim milk agar. They liquefy gelatin, peptonize milk, and produce α-, β-, or γ-type hemolysis on sheep blood agar, including strain AL-1, which originally was reported to be negative for hemolysis (Ensign and Wolfe, 1965). Almost all lysobacters hydrolyze chitin. Veldkamp (1955) observed *N*-acetylglucosamine, glucosamine, acetic acid, and NH_4^+ as products. Several of the isolates that decompose cyanobacteria did not attack chitin (the failure was perhaps due to the method used; Stewart and Brown, 1969; Daft et al., 1975), while others do (Stewart and Brown, 1971). Crystalline cellulose (filter paper) is not

decomposed, but many strains degrade carboxymethyl cellulose, and at least some strains can even grow on it as the only organic substrate (Stewart and Brown, 1971). While agar is not liquefied or softened, gelase fields (uncolored areas) may appear upon flooding with iodine solution (Shilo, 1970). Starch, pectate, and alginate may or may not be decomposed. Many strains produce lipases that cleave Tweens.

Ammonia is produced from proteins and peptones. Nitrate is only rarely reduced to nitrite. Some strains generate H_2S. The indole, methyl red, and Voges-Proskauer tests are always negative, and the phosphatase test is always positive.

Sodium dodecyl sulfate usually diminishes growth at 0.01% and completely inhibits it at 0.1%. All lysobacters appear to be sensitive to polymyxin B, although the result may vary somewhat with the way the test is done (Christensen and Cook, 1978; Shilo, 1970; Stewart and Brown, 1971). This is a valuable distinguishing characteristic in so far as most *Cytophaga*-like bacteria are resistant to polymyxin B (Mitchell et al., 1969). All strains of *L. brunescens* as well as the freshwater lysobacters (Shilo, 1970; Stewart and Brown, 1971) also are rather sensitive to actinomycin D (around 2 μg/ml), which is in contrast to most Gram-negative bacteria but in accordance with the behavior of most other gliding bacteria (Dworkin, 1969). All *L. brunescens* strains are inhibited by chloramphenicol, penicillin G, and usually also streptomycin, but most other lysobacters are not. Strain FP-1 was also resistant to erythromycin and tetracycline, but inhibited by kanamycin and neomycin (Shilo, 1970). The strains of Stewart and Brown (1971) and of Daft et al. (1975) were sensitive to all these and several more antibiotics.

As already mentioned, the lysobacters are able to kill and disintegrate many living and healthy microorganisms, such as both Gram-positive and Gram-negative bacteria, including actinomycetes and cyanobacteria; filamentous fungi; algae; and even nematodes. Gram-negative strains are usually less readily killed and lysed than Gram-positive ones. The first signs of lysis may be observed within minutes after the culture broth has been added to a suspension of sensitive bacteria (Gillespie and Cook, 1965). The technique by which the lysobacters destroy cyanobacteria is particularly well documented (Daft and Stewart, 1971, 1973; Daft et al., 1973, 1975; Shilo, 1970; Stewart and Brown, 1970). They use two different mechanisms: 1) One strain, strain N-5 (myxobacter 44) attacks the cyanobacteria with free exoenzymes (Stewart and Brown, 1969, 1970, 1971). The first assault seems to be on the cell wall with lysozyme-like enzymes, but later the whole cell with the exception of the membranes is digested. Heterocysts and akinetes are more resistant but finally also destroyed. Only their walls remain. 2) All other strains need to be in contact with the cyanobacteria before they can lyse them (Daft and Stewart, 1973; Shilo, 1970). Since neither culture supernatants nor cell extracts are sufficient to disintegrate cyanobacteria on solid or in liquid media, enzymes bound to the surface of the lysobacter cell are probably involved. It appears that the lysobacters move actively toward their prey, perhaps attracted by the oxygen produced by photosynthesizing cells. They attach themselves with one cell pole often close to the cross-septa of the filaments, and then become fixed perpendicularly on the surface of the target cells. No special organelle for attachment is recognizable. The need for contact explains why lysis does not take place in shaken cultures. In unshaken liquid cultures, the lysobacters are found fixed to the cyanobacteria within 20 min after mixing. A single lysobacter cell may lyse a *Nostoc* cell within 20 min. It then moves on and attacks another cell in the filament. There is no specific order in which the cells along a filament are assaulted. When a lysobacter culture of a sufficiently high cell density is added to a cyanobacterial population, lysis may be complete within 1 to 3 h. The time required depends, of course, on environmental factors, notably oxygen and temperature. Thus, in a well-aerated culture at 26°C, *Nostoc ellipsosporum* is completely destroyed within 60 min. On ultrathin sections in the electron microscope, it can be seen that the first structure to disappear is the peptidoglycan layer. The cell contents are then gradually broken down, and only the cell membranes, lipid droplets adhering to them and, if present, the gas vacuoles remain. The latter rise to the surface where they can be collected. The membranes often coil up, looking in cross-sections like scrolls. Protoplasts may be released from the filaments. If there is an outer sheath, it also may disintegrate. In the case of *Oscillatoria redekei,* amorphous material disappears from the sheath and a fibrous layer is left. Heterocysts initially resist lysis but eventually also disintegrate, either under the impact of the bacterial enzymes or by autolytic processes started after the cells are released from the filaments. In infected cyanobacterial cultures, the chlorophyll *a* content and the nitrogenase activity go down concomitantly with lysis, so that either parameters can be used to measure its progress (Daft et al., 1973).

Tan et al. (1974) have devised a method to establish synchronized cultures of myxobacter AL-1: Cells of different sizes, equivalent to different stages of the growth cycle, were separated by centrifugation in a sucrose density gradient. As already mentioned, in this way, changes of enzyme activities during growth could be determined.

Taxonomy and Identification

The first step in the identification procedure is to make sure that an isolate belongs to the genus *Lysobacter.* An organism qualifies as a lysobacter if it is a chemoorganotrophic, aerobic, unicellular, gliding, Gram-negative bacterium with a GC content of 65 to 71 mol%. Those characteristics are, however, shared by the myxobacteria and by certain organisms of the *Cytophaga* group (such as *Taxeobacter*). Some myxobacteria have a very similar cell shape (for instance, *Polyangium, Sorangium,* and *Chondromyces*) but the populations never show the variation in cell length typical for lysobacters. The morphology and structure of myxobacterial swarms is usually completely different, myxobacteria produce fruiting bodies and myxospores, and they contain menaquinones instead of ubiquinones as respiratory quinones. The organisms of the *Cytophaga* group, as far as they are gliding, may form very similar soft, slimy swarm colonies, but their cells usually look much different, they often contain flexirubin-type pigments and always menaquinones. The colonies of most *Cytophaga-* like bacteria are more-or-less yellow to orange, often brightly colored, particularly on peptone agar, and turn red if covered with 20% KOH (flexirubin reaction), which is never observed with lysobacter strains. Unfortunately, *Taxeobacter,* the only genus that in its GC content comes close to *Lysobacter,* is red. It has a similar cell shape to *Lysobacter,* but its cells are much stouter and tend to arrange themselves side-by-side in a palisade like fashion. Also, *Taxeobacter* lacks the unpleasant smell of *Lysobacter.*

Presently, four *Lysobacter* species are recognized. Their differential characteristics are listed in Table 1. The separation of the species rests entirely on physiological and biochemical data and is based on phenotypic analysis of a large number of strains (Christensen and Cook, 1978). However, the relatively wide GC range of the strains of two species (65–70 mol% in *L. enzymogenes* and 66–69 mol% in *L. antibioticus*) and the substantial differences in the temperature maxima of strains of *L. brunescens* (37–50°C) suggest that more than one taxon may be hidden among the strains presently allocated to one species. First attempts to subdivide one of the species have been made (*L. enzymogenes* subsp. *enzymogenes* and subsp. *cookii;* Christensen and Cook, 1978), but before that can reasonably be done, the methods of molecular taxonomy, notably DNA-DNA hybridization, need to be used. It seems doubtful whether the occurrence of myxin can be used as a characteristic of the species *L. antibioticus,* because production of an antibiotic usually is strain- and not species-specific.

As there is a free exchange of organisms between soil and fresh water, the habitats given in Table 1 for the various species should not be taken as absolute. In fact, the "freshwater" lysobacters attacking cyanobacteria have also been found in soil (Daft et al., 1975), and we have isolated myxin-producing lysobacters from freshwater (H. Reichenbach, unpublished observations).

Two more species not shown in Table 1 also have been proposed *L. lactamgenus* (Ono et al., 1984) was studied because of its new cephem antibiotics, the cephabacins. While several characteristics of the strain are in accordance with a lysobacter, it differs substantially in its extremely high GC content (76 mol%, T_m) and in its inability to produce acid from any sugar. *L. albus* (Nozaki et al., 1987) synthesizes the novel antibiotic lactivicin. The description of this isolate is very preliminary and lacks essential data, e.g., on gliding motility and GC content. Acceptance of the new species will require that the strains be made freely accessible to others in the field.

Practical Aspects

The spectacular lytic capabilities of the lysobacters suggest that they may play an important role in the control of microbial populations in nature, although their population densities appear never to become high enough to cause a breakdown of a cyanobacterial water bloom (Daft et al., 1975). Still, it may be possible to eliminate blooming organisms in a limited area, or pathogenic or otherwise undesirable bacteria in sewage plants, like the filamentous organisms responsible for the bulking of sludge, by introducing lysobacter strains with strong, lytic enzymes. The potential is probably limited by the requirement for cell-to-cell contact as a prerequisite for lysis, which would restrict any application to nonagitated environments, such as trickling filters or dense, floating mats of the target organisms.

Table 1. Characteristics distinguishing the four species of *Lysobacter*.

Character	*L. enzymogenes*[a]	*L. antibioticus*	*L. brunescens*	*L. gummosus*
Colony morphology	Sheetlike, soft slimy	Sheetlike, soft slimy	Thin, filmlike	Compact, gummy
Colony color	Cream to greenish-yellow	Pink to greenish-yellow	Yellow to brown	Yellowish-gray
Viscosity of broth cultures	+	+	−	+++
Urea as sole N-source	V	−	−	+
Citrate as sole C-source	+	+	+	−
Acid from cellobiose	+	+	−	+
Acid from sucrose	+	+	−	+
Acid from lactose	+	V	−	+
Hydrolysis of carboxymethyl cellulose	+	+	−	+
Hydrolysis of pectate	+	−	+	+
Hydrolysis of starch	V	−	+	−
Hemolysis (sheep blood)	α, β, or γ	β or α	γ or −	α
Sensitive to chloramphenicol	V	−	+	−
Sensitive to actinomycin D	V	−	+	V
GC content, Tm (mol%)	65–70	66–69	67	66
Habitat	Soil	Soil	Fresh water	Soil
ATCC no. of type strain	29487[b]	29479[c]	29482	29489

Symbols: +, present; −, absent; V, variable.
[a]Type species of the genus *Lysobacter*.
[b]Formerly "myxobacter" or *"Sorangium"* 495.
[c]Formerly *"Sorangium"* 3C.
Adapted from Christensen (1989) and Christensen and Cook (1978).

The ability of lysobacters to synthesize new secondary metabolites is of particular importance. The following antibiotics have been isolated from lysobacters (and *Lysobacter*-like organisms): the phenazine-*N*-oxide, myxin (Peterson et al., 1966; Weigele and Leimgruber, 1967); two cyclic decapeptides, myxosidin A and B (Clapin and Whitaker, 1976, 1978; Monahan and Whitaker, 1976); the quinoline compound, G 1499-2 (Evans et al., 1978); new cephem antibiotics, the cephabacins (Harada et al., 1984; Ono et al., 1984); the acyltetramic acids, catacandin A and B (Meyers et al., 1985); a dicyclic dipeptide with lactam-like properties, lactivicin (Harada et al., 1986, 1988; Nozaki et al., 1987, 1989); and a dibasic macrocyclic peptide lactone, lysobactin (Bonner et al., 1988; O'Sullivan et al., 1988; Tymiak et al., 1989).

Of those antibiotics, myxin has been produced industrially by Hoffmann-La Roche in Nutley for some time. It was applied in the form of a copper chelate called cuprimyxin and sold under the trade name Unitrop®. In contrast to free myxin, the chelate is very stable and practically insoluble. In contact with animal tissue, myxin is gradually released, so that the complex guarantees a sustained activity. Cuprimyxin was applied topically, mainly against skin infections including dermatophytes, and its use was restricted to veterinary medicine. The antibiotic is produced by strains of *L. antibioticus*, which was originally named *"Sorangium"* 3C (in the chemical literature, it is often further mislabelled as *"Sporangium"*). Myxin acts on DNA. There exists a voluminous literature on the various aspects of myxin, which can, however, not be reviewed here (see, e.g., on the chemistry: Sigg and Toth, 1967; Weigele and Leimgruber, 1967; Weigele et al., 1971; on the mechanism of action: Behki and Lesley, 1972; Lesley and Behki, 1967; on the biological activity and application: Grunberg et al., 1967; Maestrone and Brandt, 1980; Maestrone and Mitrovic, 1974; Maestrone et al., 1972; McDonald et al., 1980; Snyder and Imhoff, 1975).

The main reason why the lysobacters initially were noticed was their rich stock of exoenzymes. Several of those enzymes have a potential for an application in research or industry. One of the *Lysobacter* proteases has been studied in great detail for theoretical reasons and is one of the best-understood enzymes. Again, the literature on this topic is by far too extensive to be reviewed here comprehensively (see below).

Strain NCIB 8501 (if the present strain is really identical with the one first described, see above) was the first lysobacter to be studied for its exoenzymes, a chitinase complex (Veldkamp, 1955). The products of the enzymatic activity are *N*-acetylglucosamine, acetate, and ammonia, but not glucose. While chitin decomposition is a common feature of the lysobacters, it appears that so far no other study has been performed on the subject. An extracellular enzyme with both β-1,4-glucanase and chitosanase activity was purified from *L. enzymogenes* strain AL-1 (Hedges and Wolfe, 1974). It does not attack chitin. Enzymes of this type are probably responsible for the often-observed hydrolysis of carboxymethyl cellulose. They could also be useful for the study of the structure of fungal cell walls. Strain "Cytophaga" L1 (= NCIB 9497) was patented for its impressive combination of fast-working hydrolytic exoenzymes (Brit. Pat. 1,048,887, 23 November 1966). The enzyme complex includes chitinase, laminarinase, lipase, elastase, keratinase, and other proteolytic activity and may be useful for the decomposition of fungal mycelia from fermentations. Using the same strain, a process was later worked out for the degradation of living yeast cells (Andrews and Asenjo, 1984; Asenjo, 1980; Asenjo and Dunnill, 1981; Asenjo et al., 1981; Hunter and Asenjo, 1987a, 1987b). The yeast lytic enzymes are produced constitutively and consist of β-(1–6)-glucanase, mannanase, and high protease activities. The breakdown of the yeast cells is connected mainly with the protease and the glucanase activities, which have to act in sequence because a specific protease must remove the mannoprotein layer in the outer cell wall before the glucanase can become active. As the glucanase is repressed if more than 0.8 g of glucose is present per liter of medium, a 20-fold-higher enzyme yield is obtained in continuous cultures with optimal dilution rates compared with batch cultures. The lysobacter glucanase appears not to adsorb to the yeast glucan, attacks the fibrillar and the amorphous glucan fractions equally well, and shows no inhibition by its hydrolysis products. If crude enzyme preparations are applied in higher concentrations, the rate of lysis may decline. This may be due to competitive inhibition by carbohydrates present in the enzyme solution. The lysobacter enzyme mixture solubilizes the yeast cells almost completely and thus appears particularly useful for the production of yeast extract and of animal feed. A two-step model has been proposed to describe the kinetics of the process of lysis. Also, the separation of the enzyme complex from the culture broth and its application in an immobilized form has been studied. It appears, however, that the free enzyme is more promising for technical purposes.

Two alkaline phosphatases were demonstrated in *L. enzymogenes* strain 495 (von Tigerstrom, 1983; 1984; von Tigerstrom and Stelmaschuk, 1986, 1987a). The appearance of both activities is repressed by inorganic phosphate. One of those enzymes is excreted into the medium, has a molecular weight of about 25 kDa, and does not contain a metal ion, which is rather unusual for a bacterial phosphatase. As the enzyme is easy to recover and purify, it might be a useful tool in nucleic acid research. The other enzyme appears to be bound to the outer membrane, has a molecular weight of about 69 kDa, and seems to be composed of at least two subunits. It is a metal enzyme probably containing Zn^{2+}, hydrolyzes a wide variety of 5′-,3′-, and 2′-ribose and -deoxyribose nucleotides, as well as sugar phosphates, and shows a remarkably high specific activity. A corresponding cell-bound phosphatase was also found in the three other *Lysobacter* species, and all four enzymes are immunologically related among themselves but completely different from cell-associated phosphatases from other gliding bacteria. The extracellular and the cell-bound phosphatase also differ in their amino acid composition.

The same strain produces two extracellular endonucleases (von Tigerstrom, 1980, 1981). One is a nonspecific nuclease (22–28 kDa) preferentially cleaving double-stranded DNA and, with reduced efficiency, single-stranded DNA and RNA, but not poly(A) and poly(C). It produces large oligonucleotides with 5′-phosphate groups. The synthesis of this enzyme is inhibited by RNA in the medium. The second enzyme is an RNAse (46–47 kDa) that also cleaves poly(A) and poly(C) but not double-and single-stranded DNA. It appears to have no base specificity. The enzyme is unusual in that it generates short oligonucleotides with 5′-phosphate ends (instead of the more common 3′-phosphate groups). The production of the RNAse is inhibited by phosphate in the medium. During its purification, a contaminating enzyme was discovered that degraded the dialysis bags. The extracellular enzymes of strain 495 are obtained with good yields in tryptone (0.4%) broth at 25°C (von Tigerstrom, 1983). While the production of nuclease, RNAse, and phosphatase is inhibited by Mg^{2+} and by Mn^{2+} above 0.1 and 0.01 mM, respectively, that of protease is stimulated by Mg^{2+} and neutral to Mn^{2+}. The ions appear to interact specifically with the synthesis of the enzymes and not with their release from the cells.

Other hydrolases excreted by lysobacters are: endoamylases found in all four species (von Tigerstrom and Stelmaschuk, 1987b), which seems surprising because the characterization of the lysobacter species excludes starch hydrolysis in almost all strains of three species (see Table 1); the paradox may be a result of the test conditions. The enzyme of *L. brunescens,* the most potent organism, has a molecular weight of 47–49 kDa and also decomposes amylopectin, amylose, and glycogen, but not dextran. The enzyme probably has no commercial interest because of its enzymatic properties and low yield. Further, all species produce two extracellular lipolytic esterases (von Tigerstrom and Stelmaschuk, 1989). One is excreted into the medium and is inducible by olive oil. As it is synthesized only after exponential growth, it appears to be under catabolite repression. The other enzyme is associated with the outer membrane and is constitutive. The two esterases differ in their substrate specificity. Both are very active on Tween 20, but only the free enzyme is able to attack olive oil. In addition, there is a third, cytoplasmic esterase which, in contrast to the extracellular enzymes, is very active on tributyrin. Finally, there is a periplasmic β-lactamase.

The most fascinating *Lysobacter* enzymes are their proteases. Two proteases were isolated from the culture supernatant of *L. enzymogenes* strain (*"Sorangium"* or "myxobacter") 495; one of them α-lytic protease, became a very important enzyme for scientific reasons. The strain was originally noted for its ability to rapidly lyse a wide spectrum of bacteria (Gillespie and Cook, 1965) and nematodes (Katznelson et al., 1964). Soon it was realized that the lytic activity was due to at least two different proteases, α- and β-lytic proteases (Whitaker, 1965), and procedures were worked out to produce and purify those enzymes (Whitaker et al., 1965a; Whitaker, 1967a). Later it was found that there are at least two more proteases in the culture broth.

A major research effort has been made to characterize the α-lytic protease. This enzyme is an alkaline serine protease (for a summary of the early work see: Whitaker, 1970) that aroused great interest because it was the first bacterial serine protease with the same amino acid sequence in its active center, Gly-Asp-Ser-Gly-Gly, as the mammalian pancreatic serine proteases (Olson et al., 1970; Whitaker et al., 1966; Whitaker and Roy, 1967), and not Thr-Ser-Met as in most other bacterial serine proteases. This suggested a common ancestor for both enzymes and invited studies on the evolution of protein structure and function. The similarity to porcine pancreatic elastase is particularly notable, a similarity which also extends to substrate specificity and kinetic properties (Kaplan and Whitaker, 1969; Kaplan et al., 1970). While the homology in the amino acid sequence is only high in certain critical regions (overall homology 18%), long sections appear conserved in the three-dimensional structure as revealed by high-resolution X-ray analyses and molecular models (55% topological equivalence). There is an even higher correspondence with *Streptomyces griseus* proteases A and B, with 35% and 36% sequence homology and 80% topological equivalence (e.g., Brayer et al., 1979; Fujinaga et al., 1985; McLachlan and Shotton, 1971). The α-lytic protease (EC 3.4.21.12; 19.8 kDa) consists of 198 amino acids and contains three disulfide bridges. It cleaves polypeptides at the carbonyl side of short neutral aliphatic amino acids, preferentially alanine (Kaplan and Whitaker, 1969). It also attacks bacterial peptidoglycans, mainly at the cross-linkages (Tsai et al., 1965). Like other serine proteases, α-lytic protease has several subsites (in this case, six) for substrate binding, with different amino acid specificities (Bauer et al., 1981). This explains why the enzyme prefers long substrate molecules over short ones. While the pH optimum for catalytic activity is reached at pH 8, substrate binding is independent of pH between pH 5 and 10.5 (Kaplan and Whitaker, 1969; Paterson and Whitaker, 1969). The enzyme shows a high stability unparalleled in any other protease (Kaplan et al., 1970), which appears to arise from a high structural rigidity (Fujinaga et al., 1985). As with other serine proteases, a strong H-isotope effect is observed: the catalytic rate drops to one-third in $^{2}H_2O$ (Hunkapiller et al., 1973). The discovery that α-lytic protease contains but one histidine (His) residue (Jurášek and Whitaker, 1967) proved particularly momentous for the elucidation of the catalytic mechanism of serine proteases, for the other enzymes all contain more than one His. This finding at once excluded a requirement of several His residues for the catalytic process, as was postulated before. The histidine in α-lytic protease is homologous with the His-57 in α-chymotrypsin and is part of the catalytic triad, Asp-102/His-57/Ser-195 (the adopted numbering is that of α-chymotrypsin). By the use of a His auxotrophic mutant, ^{13}C and ^{15}N could substantially be enriched in His-57 (Westler et al., 1982), which allowed refined NMR studies of the dissociation behavior and hydrogen bonding in the active center (Bachovkin, 1986; Bachovkin et al., 1981; Hunkapiller et al., 1973). Another approach was the use of peptide-boronic acid inhibitors forming rather stable enzyme-substrate complexes, which can be analyzed as models of

the otherwise-not-accessible transition state (Bone et al., 1987; 1989). Those studies provided deep insights into the mechanism of catalysis and substrate specificity. The gene of α-lytic protease (the progene) has also been cloned in *Escherichia coli* (Epstein and Wensink, 1988; Silen et al., 1988). At the amino end of the protease domain, the gene has an open reading frame that extends 198 (or 199: the two articles do not completely agree in the details) amino acid codons upstream and represents a very large prepro sequence. The latter consists of a typical bacterial pre (or signal) peptide of 24 (or 33) amino acids ending with a Ala-Leu-Ala-Ala cleavage site, followed by a pro region of 174 (or 166) amino acids, i.e., more than twice the size of other known bacterial propeptides. The high sequence homology observed between α-lytic protease and proteases A and B of *Streptomyces griseus* continues for 49 amino acids into the pro region (21% and 38% homology, respectively), and then falls suddenly to a low value of 7% and 3%. This suggests that the *Lysobacter* pro region is a composite of two parts, perhaps of different origin and with different functions. In fact the amino acid sequence around the cleavage site of the signal peptide shows a unique homology to a trypsin inhibitor of maize, and it was speculated that this part of the peptide may block the protease activity, while the conservative part may serve an identical function as the (much shorter) propeptides of proteinases A and B, namely, arranging the correct folding of the protease domain (Epstein and Wensink, 1988). The *Lysobacter* ribosomal binding site (AGGAG) is homologous to known *E. coli* binding sites. When the *Lysobacter* gene is fused with an inducible *E. coli* promoter and signal sequence (e.g., pho A), α-lytic protease is expressed in *E. coli* and (probably unspecifically) exported into the medium (Silen and Agard, 1989; Silen et al., 1989). Deletion of the pro region results in inactive enzyme, which is immunologically and electrophoretically indistinguishable from α-lytic protease, but presumably improperly folded. Site-specific mutation of the Ser-195 in the catalytic pocket leads to the production of a double-sized inactive protease molecule, which suggests that the removal of the propeptide is an autocatalytic process. Surprisingly, the activation (not the production) of α-lytic protease proved temperature sensitive and did not take place above 30°C. If the pro region and the protease domain were cloned separately with independently inducible *E. coli* promoters, active enzyme was obtained when both were induced concomitantly, in spite of the fact that in this case, the two peptide were not covalently connected. Obviously, the propeptide functions as a chaperonin-like, though specific, folding template. It appears that α-lytic protease is produced exclusively by strain 495.

Much less is known about the β-lytic protease, a second protease from strain 495. The enzyme is a nonserine protease and resembles mammalian carboxypeptidase and particularly the bacterial neutral proteases (Oza, 1973). Its specificity is quite distinct from that of the pancreatopeptidases. It cleaves very selectively at the carbonyl side of neutral amino acids. Thus, only the B chain of (denatured) insulin is cleaved, and that between glycine-23 and phenylalanine-24 and, much more slowly, between valine-18 and cysteine-19 (Whitaker et al., 1965b). A free α-amino group or a free terminal carboxyl next to the cleavage site is not accepted, but an amido group on the carboxyl already eliminates the blocking effect of the latter. The β-enzyme is more active than the α-enzyme on bacterial peptidoglycan rapidly hydrolyzing the muramic-acid alanine bond (Tsai et al., 1965). The β-lytic protease (19 kDa) appears to be composed of 177 amino acids and to contain two disulfide bridges and one atom of zinc (Jurášek and Whitaker, 1967). The zinc can be removed and restored again with reconstitution of enzyme activity (Whitaker, 1967b). While the apoenzyme is no longer proteolytic (Oza, 1973), the cell-wall-lytic activity was still observed (Whitaker and Roy, 1967). But conceivably the protease was simply restored by a contamination of the peptidoglycan with zinc. The pH optimum of β-lytic protease is 6.5 (Oza, 1973). The proteases of strain 495 can be produced with good yields (4–4.5 g of α- and 2 g of β-enzyme from 100 liters) on casamino acid/glucose media (Whitaker, 1967a). Also, production on media with condensed fish solubles, a by-product of the salmon canneries, seems feasible (Wah-On et al., 1980).

Finally, the proteases of *L. enzymogenes* strain ("myxobacter") AL-1 (ATCC 27796) should briefly be mentioned. The organism was isolated because it lysed cells and cell walls of *Arthrobacter crystallopoietes,* and enzymes with that property were of much interest at that time for studies on the cell wall structure of bacteria (Ensign and Wolfe, 1965, 1966). In fact, one of the AL-1 enzymes was soon successfully applied for that purpose (for a review, see Ghuysen, 1968). The enzyme is particularly useful because it cleaves the bond between muramic acid and L-alanine, making it possible to isolate the pure polysaccharide backbones of peptidoglycan. The enzyme could thus be used to demonstrate a shortening of the polysaccharide chain length during the rod-to-sphere conversion of *Arthrobacter* (Krulwich et al., 1967). At

first, only the enzyme just mentioned, AL-1 protease or, later, AL-1 protease I, was recognized and characterized (Ensign and Wolfe, 1966; Jackson and Wolfe, 1968; Jackson and Matsueda, 1970). The enzyme can be produced by fermentation in 1% yeast extract medium at 30°C for 36 h, and is recovered from the culture supernatant with a yield of 350 mg of pure enzyme from 100 liters. The AL-1 protease I (13.5 kDa) is an alkaline endopeptidase with a sharp pH optimum at 9.0. The molecule consists of 136 amino acids, with Ser, Asp, Gly, Thr, and Ala accounting for more than 50% of the residues. It contains one disulfide bridge, and does not contain a hexose molecule, as was previously suggested. The enzyme is spherical, compact, and very stable. Within minutes, it completely lyses whole cells of many Gram-positive and some Gram-negative bacteria, as well as purified peptidoglycan (Ensign and Wolfe, 1965). It cleaves about 30% of the bonds in casein and albumin, and 15% in gelatin. In the B chain of insulin only the bonds between Ala and Leu, Gly and Phe, and Val and Cys are attacked. Thus it appears that a hydrophobic residue is required at the cleavage site, but the exact specificity is not yet known. In peptidoglycan, besides the connection of the peptide side chain to the polysaccharide backbone, only the bonds between terminal D-Ala and the pentaglycine or L-Ala bridges, and bonds within the pentaglycine bridge are cleaved. The enzyme therefore became a useful tool for the elucidation of the structure of bacterial cell walls (e.g., Ghuysen, 1968; Jarvis and Strominger, 1967; Katz and Strominger, 1967; Tipper, 1969).

Also, the second protease from strain AL-1, AL-1 protease II (17 kDa), is a small, stable, alkaline endopeptidase, but it does not attack bacterial cell walls (Wingard et al., 1972). It is obtained from the culture supernatant with a yield of 10% of protease I. The enzyme is very unusual in two respects: it readily crystallizes from the column fractions, and it cleaves exclusively at the amino side of lysine. It does not remove terminal lysine residues. The enzyme consists of 157 amino acids, 50% of which are Asp, Ala, Thr, and Gly, and has a broad pH optimum between 8.5 and 9.0.

A third unusual protease from AL-1 is called endoproteinase Lys-C. This enzyme has a high although not absolute specificity for peptide and ester bonds at the carboxyl end of lysine (information leaflet Boehringer Mannheim, Biochemica-Dienst no. 42, April 1980), so that it can be used for sequencing proteins and for peptide mapping (Au et al., 1989; Boileau et al., 1982; Hofsteenge et al., 1983; Jekel et al., 1983; Jolles et al., 1983). The enzyme (30 kDa unreduced, 33 kDa reduced) is an alkaline serine protease, is very stable even in the presence of 0.1% sodium dodecylsulfate or 5 M urea, and is commercially available from Boehringer Mannheim (Mannheim, Germany).

The *Moraxella* and *Branhamella* Subgenera of the Genus *Moraxella*

GARY V. DOERN

Introduction

The *Moraxella* genus is comprised of two subgenera, *Moraxella* and *Branhamella* (Bøvre, 1984). Within the *Moraxella* subgenus are found six clearly delineated species: *M. (M.) lacunata,* the type species of this subgenus, *M. (M.) nonliquefaciens, M. (M.) atlantae, M. (M.) phenylpyruvica,* and *M. (M.) osloensis.* In addition, there is one species of uncertain taxonomic status, *M. urethralis* (species incertae sedis). The *Branhamella* subgenus consists of four species: *M. (B.) catarrhalis,* the type species of this subgenus, *M. (B.) caviae, M. (B.) ovis,* and *M. (B.) cuniculi.*

Characteristics common to both subgenera of *Moraxella* include Gram-negative staining reactivity, lack of pigmentation, a positive oxidase test using either the tetra- or dimethyl-*p*-phenylenediamine reagent, catalase reactivity, and lack of motility. In addition, organisms within this genus are uniformly asacharolytic and chemoorganotrophic. Optimum growth occurs under aerobic conditions at a temperature of 33–35°C. With the exception of *M. (B.) catarrhalis* and *M. (M.) nonliquefaciens,* most strains are inhibited by low concentrations of penicillin. The GC content of the DNA varies between 40.0 and 47.5 mol% for all species of the *Moraxella* genus.

The principal distinguishing feature between the *Moraxella* and *Branhamella* subgenera of the *Moraxella* genus is cellular morphology. Species within the *Moraxella* subgenus typically produce large rods that are often blunted and plump, frequently appearing almost coccid in shape. In contrast, *Moraxella (Branhamella)* species form small cocci, usually occurring in pairs with flattened adjacent sides. In this respect, they closely resemble *Neisseria* species. Characteristics useful in identifying the species of both the *Moraxella* and *Branhamella* subgenera of the *Moraxella* genus are presented in detail in the most recent edition of *Bergey's Manual of Systematic Bacteriology* (Bøvre, 1984).

The *Moraxella* Subgenus

With the exception of *M. (M.) bovis,* all species of the *Moraxella* subgenus are found in association with mucosal surfaces of humans. They are uncommonly recovered as causes of disease. However, when found as etiologic agents of infection, the most frequent disease associations are as follows: *M. (M.) lacunata,* conjunctivitis; *M. (M.) nonliquefaciens,* acute tracheobronchitis; *M. (M.) atlantae, M. (M.) phenylpyruvica,* and *M. (M.) osloensis,* opportunistic systemic pathogens in profoundly immunocompromised individuals; and *M. urethralis,* a possible cause of acute urethritis and cystitis in women. *Moraxella (M.) bovis* on the other hand, is an important veterinary pathogen and will, therefore, be discussed further.

Moraxella (Moraxella) bovis

Moraxella (M.) bovis is a common cause of infectious bovine keratoconjunctivitis (IBK) (Gil-Turnes and Ribeiro, 1985). This disease most frequently affects calves and is often seen in the setting of an epidemic. The causative agent probably resides on the ocular and nasal mucosa of asymptomatic immune cattle as part of the normal commensal bacterial flora (Pugh and MacDonald, 1986). One phenotypic characteristic that has been most strongly associated with disease-producing strains of *M. (M.) bovis* is the presence of fimbriae on the cell surface (Moore and Rutter, 1987). Fimbriae appear to be a primary virulence determinant. Nonfimbrinated strains are avirulent in experimental infections of the corneas of cattle and laboratory mice (Marrs et al., 1988). Furthermore, antibody reactive with fimbrial antigens administered passively or acquired following vaccination with purified fimbriae is protective (Ostle and Rosenbusch, 1985).

The fimbriae of *M. (M.) bovis* can be divided into seven serogroups based on patterns of enzyme-linked immunsassay (ELISA) reactivity, tandem two-dimensional crossed-immunoelec-

trophoresis, and slide agglutination (Moore and Rutter, 1987). Humoral immune protection is fimbrial antigen-specific. The fimbriae mediate attachment to cultured bovine corneal cells in vitro; the attachment is abrogated by specific homologous antiserum (Moore and Rutter, 1989). There is no evidence that strains of one particular fimbrial serogroup are more virulent than others.

Expression of fimbrial proteins has been extensively studies in one strain (Epp 63) of *M. (M.) bovis.* This strain can express either of two different fimbrial proteins, alpha and beta (Marrs et al., 1988). The phase variation noted between the expression of alpha and beta fimbrial proteins appears to be under control of an approximate 2-kb region of DNA within the fimbrial gene. The amino acid sequences of both the alpha and beta fimbrial proteins have been determined and are approximately 70% homologous (Ruehl et al., 1988). Interestingly, beta-fimbrinated strains of *M. (M.) bovis* were significantly more virulent than alpha-fimbrinated strains when inoculated into calves eyes (Ruehl et al., 1988). Initial studies support the notion that other strains of *M. (M.) bovis* also produce two types of fimbriae and that this might be a characteristic of all fimbrinated strains within the species (Ruehl et al., 1988).

A second characteristic associated with virulence of *M. (M.) bovis* is hemolytic activity when grown on blood-containing medium (Kagonyera et al., 1989). Hemolytic strains appear to be more infectious for calves and laboratory mice and also demonstrate greater cytotoxicity for bovine neutrophils. In addition, cattle that have experienced IBK typically are found to have high titers of antihemolysin antibody (Ostle and Rosenbusch, 1985).

The *Branhamella* Subgenus

Among the four recognized species of the *Branhamella* subgenus of *Moraxella, M. (B.) catarrhalis* is clearly the most important. The other three species, *M. (B.) caviae, M. (B.) ovis,* and *M. (B.) cuniculi,* have been found in association with guinea pigs, sheep, and rabbits, respectively, although their significance in health or disease is unknown. *M. (Branhamella) catarrhalis* is, on the other hand, a well-documented commensal and pathogen of humans and thus, will be further discussed.

Moraxella (Branhamella) catarrhalis

First known as *Micrococcus catarrhalis* in the early 1900s, this organism came to be referred to as *Neisseria catarrhalis* during the 1950s due largely to its morphologic resemblance to members of the *Neisseria* genus (i.e., it consists of Gram-negative, kidney bean-shaped diplococci) and because of its positive oxidase reactivity, another characteristic of *Neisseria* species. Catlin (1970) proposed that this organism be renamed *Branhamella catarrhalis* in honor of the noted microbiologist Sarah Branham. Separation of *B. catarrhalis* from the *Neisseria* genus was predicated on a demonstrated lack of chromosomal DNA homology between the two, genetic transformation experiments which indicated unrelatedness, and widely varying DNA base composition. The taxon *Branhamella catarrhalis* was quickly adopted during the 1970s and has become widely applied since then.

Subsequent to the work of Catlin, however, Bøvre and colleagues provided additional information demonstrating a clear genetic and physiologic relatedness between *Branhamella catarrhalis* and species of the *Moraxella* genus, in particular *M. nonliquefaciens* (Bøvre, 1979). Based on their studies, Bøvre advocated assignment of the *Branhamella* genus to one of two subsgenera of the *Moraxella* genus; the other subgenus was designated *Moraxella* and contained all species of the previously designated genus *Moraxella* (Bøvre, 1984). As noted above, this taxonomy has now been adopted.

M. (B.) catarrhalis exists as part of the commensal flora of the upper respiratory tract. It is also recognized as a cause of a variety of human infectious diseases (Doern, 1986). The most important of these, at least with respect to incidence and morbidity, are acute otitis media, sinusitis, and infections of the lower respiratory tract. Otitis media and sinusitis due to *M. (B.) catarrhalis* are primarily found to occur in infants and young children. By contrast, *M. (B.) catarrhalis* lung infections usually occur in adults, in particular the elderly with some predisposing condition. The most common predisposition is chronic obstructive pulmonary disease.

MORPHOLOGY. *M. (B.) catarrhalis* may be visualized directly in clinical material obtained from infected patients by use of the Gram stain or by cultivation on suitable growth media with resultant biochemical identification. The Gram-stain morphology of *M. (B.) catarrhalis* noted previously is characteristic, but does not serve to differentiate this organism from *Neisseria* species which may look identical.

ISOLATION. *M. (B.) catarrhalis* grows readily on standard nonenriched laboratory media such as brain heart infusion and tryptic soy digest. Sup-

plementation of media with blood (e.g., 5% sheep blood agar) or boiled blood plus vitamin/amino acid enrichments (e.g., chocolate agar) yields enhanced growth (Doern and Morse, 1980). *M. (B.) catarrhalis* grows in ambient air at a wide range of temperatures, (i.e., 20–42°C), but optimum growth is achieved in 5% CO_2 at 35–37°C. A defined medium has been described for propagation of *M. (B.) catarrhalis* in which sodium lactate, proline, aspartate, arginine, glycine, and methionine suffice as source of carbon, nitrogen, and growth cofactors (Juni et al., 1986).

A variety of selective media have been described for use in recovering *M. (B.) catarrhalis* from sources likely to be contaminated with other bacteria or with fungi (Corkill and Makin, 1982; Soto-Hernandez et al., 1988; Vaneechoutte et al., 1988a). A common feature of these media is the inclusion of vancomycin, trimethoprim, and an antifungal agent to inhibit growth of Gram-positive bacteria, Gram-negative bacteria, and fungi, respectively. *M. (B.) catarrhalis* is resistant to all three antibiotics. Enhanced recovery of *M. (B.) catarrhalis* has been described when a fourth inhibitory substance, i.e., acetazolamide, a synthetic sulfonamide, was added to selective media already containing vancomycin, trimethoprim, and amphotericin B (Vaneechoutte et al., 1988a).

IDENTIFICATION. *M. (B.) catarrhalis* is catalase- and oxidase-positive but fails to ferment glucose, maltose, sucrose, and lactose (Doern and Morse, 1980). Proline aminopeptidase and gamma glutamylaminopeptidase are lacking. All strains produce extracellular DNAse and reduce nitrates to nitrites and ammonia. In addition, butyric acid esterase is produced (Riley, 1987). This enzyme can be detected using colorimetric assays with tributyrin or idoxyl butyrate as substrates or fluorimetrically using 4-methylumbelliferyl-butyrate as a substrate (Dealler et al., 1989; Janda and Ruther, 1989; Vaneechoutte et al., 1988b).

Taking advantage of the DNAse reactivity of *M. (B.) catarrhalis*, a selective and differential medium has been devised for the recovery and presumptive identification of this organism (Soto-Hernandez et al., 1988). Vancomycin, trimethoprim, and amphotericin B are added to DNAse test agar. Colonies of Gram-negative diplococci which grow on this medium are tested for DNAse production by exposure to a drop of toluidine blue O solution. Development of a purple color in the area adjacent to colonies is taken as a positive reaction.

CELL ENVELOPE CHARACTERISTICS. *M. (B.) catarrhalis* has been found to possess eight outer membrane proteins when analyzed by sodium dodecyl-sulfate polyacrylamide gel electrophoresis (Bartos and Murphy, 1988). These proteins range in molecular weight from 21–98 kDa and are remarkably conserved since there is only minimum variation in the outer membrane protein profiles among different strains of this species.

The lipopolysaccharide (LPS) of *M. (B.) catarrhalis* is also extremely homogeneous (Murphy, 1989). Its polysaccharide moeity is comprised of a small and simple seven-residue oligosaccharide consisting of D-glucose (4 mol) and D-galactose, 2-amino-2-deoxy-D-glucose, and 3-deoxy-D-manno-octulosonic acid (1 mol each) (Johnson et al., 1976). This oligosaccharide appears to be common to all strains of *M. (B.) catarrhalis*, although minor epitope differences in the antigenic composition have been noted (Murphy, 1989). The specific LPS of *M. (B.) catarrhalis* has not been observed in any other bacteria.

Preliminary observations also indicate the presence of fimbriae on the surface of at least some strains of *M. (B.) catarrhalis* (Murphy, 1989). It is possible, but yet unproven, that these surface appendages participate in the attachment of fimbrionated strains to receptors on epithelial cells of mucosal surfaces of the respiratory tract in humans who are colonized.

OTHER PHENOTYPIC CHARACTERISTICS. Restriction endonuclease digestion of chromosomal DNA has proven to be a useful tool for determining strain relatedness among different isolates of *M. (B.) catarrhalis* (Patterson et al., 1989). Four of eight restriction endonucleases, Hae III, Hind III, Pst I, and Cla I, produce distinguishable digestion patterns. Digests obtained from Hae III are the most definitive.

Other phenotypic characteristics that have been investigated include susceptibility to normal human serum-mediated bacteriolysis, ability to agglutinate human group O erythrocytes and trypsin sensitivity (Soto-Hernandez et al., 1989). Although a variety of interesting relationships among these attributes have been described for apparently unrelated strains of *M. (B.) catarrhalis*, no correlation with virulence has been proven.

The large majority of clinically significant strains of *M. (B.) catarrhalis* produce β-lactamase (Jorgensen et al., 1989). The enzyme is produced constitutively, is encoded for by chromosomal genes, and is produced in very small amounts and remains tightly cell-associated (Farmer and Reading, 1986; Labia et al., 1986).

It probably confers resistance to penicillin and ampicillin on strains that produce it (Doern and Tubert, 1987). Based on isoelectric profiles, the β-lactamase of *M. (B.) catarrhalis* exists in numerous different forms (Labia et al., 1985; Stobberingh et al., 1986). Two of them, designated Ravasio and 1908, or BRO-1 and BRO-2, respectively, appear to be most common (Farmer and Reading, 1986; Nash et al., 1986). BRO-1-type β-lactamase-producing strains can be distinguished from strains that produce the BRO-2-type enzyme by a number of different characteristics. These include the specific pattern obtained when β-lactamase isoelectric profiles are determined, the substrate affinity profile of the two β-lactamases, the relative prevalence of these strains (i.e., BRO-1-type strains are much more common among clinical isolates) and the absolute amount of enzyme produced. BRO-1-type strains produce significantly more enzyme than do BRO-2-type strains. Finally, BRO-1-type strains not surprisingly appear to be more resistant to penicillin and ampicillin than are BRO-2-type strains (Nash et al., 1986).

Aside from the variable activity of penicillin and ampicillin, the pattern of antimicrobial susceptibility of strains of *M. (B.) catarrhalis* is strikingly homogeneous (Doern and Tubert, 1988). Vancomycin, trimethoprim, and clindamycin are uniformly inactive. Colistin or polymycin B and the isoxazoly penicillins (methicillin, nafcillin, and oxacillin) have variable activity. All other agents are highly active.

CHAPTER 178

The Genus *Legionella*

A. WILLIAM PASCULLE

Legionnaires' Disease and Legionellosis

Legionnaires' disease is the commonly accepted name for an acute purulent bacterial pneumonia caused by *Legionella pneumophila.* The name resulted from the investigation of an explosive outbreak of pneumonia (189 cases with 29 deaths) among the approximately 3,000 delegates to the annual convention of the Pennsylvania Division of the American Legion in July 1976. Although the exact source of the infection was never determined, epidemiologic investigations demonstrated a strong association between disease acquisition and the amount of time spent in or near the headquarters hotel (Fraser et al., 1977). Initial attempts at isolation of the causative agent were unsuccessful, but subsequent attempts resulted in the isolation of a novel bacterium, *L. pneumophila,* from lung tissue removed at the autopsies of several of the patients (McDade et al., 1977). The new bacterium was not related to any recognized at that time and was placed into a new family, the Legionellaceae (Brenner et al., 1979).

The recognition of *L. pneumophila* as an important new etiologic agent was quickly followed by the discovery of additional outbreaks of Legionnaires' disease and the realization that Legionnaires' disease was in no way a new infection. Epidemics have been documented to have occurred as early as 1957 (Osterholm et al., 1983). The earliest known isolation of *L. pneumophila* occurred in 1947 from a guinea pig, which had been inoculated with blood from a patient with an unknown febrile illness (Bozeman et al., 1968). It is now well recognized that Legionnaires' disease occurs world-wide and that members of the family Legionellaceae are ubiquitous in distribution.

Additional organisms were also quickly recognized as belonging to the genus *Legionella.* An organism isolated by Tatlock (1944) from the blood of a patient who was involved in an outbreak of febrile illness among soldiers at Fort Bragg, NC, was subsequently shown to be a member of the new family and named *L. micdadei* (Hebert et al., 1980). Interestingly, the febrile illness in the patient from whom Tatlock recovered this *Legionella* isolate was subsequently shown to be caused not by *L. micdadei* but by *Leptospira interogans* serotype autumnalis and the role of the *L. micdadei* isolate in the patient's original illness is unknown (Gocehnour et al., 1952; Tatlock, 1982). A third historical isolate, WIGA, also isolated by Bozeman et al., (1968), was subsequently shown to be a member of the new family and named *Legionella bozemanii* in her honor (Brenner et al., 1980). The decade following the discovery of these important bacteria was marked by a rapid identification of additional members of the genus. At the current time, there are 29 named species and two subspecies in the genus *Legionella* which together account for 47 serovars (Table 1). There are also a number of isolates representing additional species that have been partially characterized but remain to be named (Brenner, 1987).

Clinical and Epidemiologic Features

Most of what is known about *Legionella* infections is derived in large part from the study of infections caused by *L. pneumophila.* The data that are available from the study of other *Legionella* infections, however, indicate that they are substantially similar. Collectively, these infections are referred to as legionellosis. Legionella infections have occurred in both sporadic and epidemic distributions. A second form of the disease, called Pontiac fever, was first recognized among visitors to a health department building in Pontiac, MI. Pontiac fever is a self-limiting nonpneumonic disease consisting of fever and vague constitutional symptoms but does not include pneumonia (Glick et al., 1978).

Table 1. Phenotypic characteristics of *Legionella* species.

Species (serovar)	Oxidase	β-Lactamase	Motility	Hippurate hydrolysis	Gelatin liquefaction	Autofluorescence

The reasons why patients develop one or the other form of infection are not known, but clearly Legionnaires' disease and Pontiac fever represent opposite ends of a clinical spectrum. Different persons exposed simultaneously to the same environmental source of *Legionella* have developed either Pontiac fever or Legionnaires' disease (Girod et al., 1982). In addition, guinea pigs exposed to the air-conditioning system in the Pontiac Health Department building developed pneumonias rather than Pontiac fever (Kaufmann et al., 1981). Pontiac fever-like illness has also been caused by *L. feeleii* (Herwaldt et. al., 1984) and *L. micdadei* (Goldberg et al., 1989).

Legionellosis is an acute purulent pneumonia that appears to begin with the inhalation of bacteria-laden aerosols. Following an incubation period of 2–10 days, patients often develop a prodromal illness, which is often described as "flu-like" and consists of malaise, lethargy, myalgia, and headache. As the disease progresses, patients develop high fever, chills, and a nonproductive cough accompanied by shortness of breath and pleuritic chest pain. Slightly fewer than 50% of patients with Legionnaires' disease suffer nausea, vomiting, and a watery diarrhea. Neurologic symptoms are also not uncommon and include headache, mental confusion, and even seizures (Kirby et al., 1980; Edelstein and Meyer, 1984; Yu et al., 1982; Strampfer and Cunha, 1987). The radiographic features of legionellosis are not sufficiently specific to differentiate legionellosis from other in-

fections. Most frequently, patchy alveolar infiltrates, which may eventually progress to consolidation, can be demonstrated. Spread of the pneumonia to another lobe of the lung is not uncommonly seen and pleural effusions may also be present.

Legionellosis has occurred among all age groups (range 2–84 years), but occurs most predominantly among persons over the age of about 50 (England et al., 1981). Various studies have attempted to calculate the incidence of legionellosis in various populations. Such studies are difficult to compare because of differing study populations and criteria for infection (Reingold, 1988). The reported incidence has been as low as 1% among members of a prepaid health group and as high as 26% among patients hospitalized with community-acquired pneumonia (Foy et al., 1979; Marrie et al., 1981). In addition to age, a number of other important risk factors have also been identified. The incidence of disease is almost three times greater in males than in females and the risk of infection is also increased in smokers, those with underlying chronic diseases, and other forms of immunosuppression (Fraser et al., 1977; England et al., 1981; Kirby et al., 1980). Renal and heart transplant patients appear to have increased risk of legionellosis as well (Dowling et al., 1984; Fuller et al., 1985).

Person-to-person spread of legionellosis is not known to occur (Marrie et al., 1986). Humans also appear to be the only natural hosts. Although horses have been found to have antibodies against legionellae, attempts to produce legionellosis experimentally in horses produced only asymptomatic seroconversion (Cho et al., 1983; Cho et al., 1984.)

Pathology and Pathogenesis

Pathologic Features

It is suspected that legionellosis arises after inhalation of aerosols or droplet nuclei that contain the bacteria. Most of the pathologic changes present in the lung of humans occur only in the alveoli, suggesting that the infecting agent is inhaled. A pathologically similar disease has been produced in guinea pigs following exposure to aerosolized legionellae (Baskerville et al., 1981). It has also been suggested that legionellosis might arise from aspiration of organisms from the oropharynx (Johnson et al., 1985). This indeed is possible and legionellosis has been produced in experimental animals by instillation of bacteria directly into the trachea, a technique that mimics aspiration. In animals so infected, the pneumonia uncharacteristically is in the portions of the lung nearest the major bronchi rather than in the peripheral segments seen in animals (and humans) infected via inhalation of aerosols (Winn et al., 1982).

Histologically, legionella infection is confined to the alveoli and bronchioles whereas the larger bronchi are spared. The exudate contained within the alveoli is composed of both polymorphonuclear leukocytes and alveolar macrophages. Early in the disease, the infiltrate is composed mostly of polymorphonuclear cells, while later in the infection, alveolar macrophage tend to predominate. Smaller lesions tend to coalesce into larger ones as the disease progresses, but there is very little destruction of the lung architecture and frank abscess formation only occurs in the most severe cases. In very late infections, lysis of the cells in the center of the infected area often occurs. Fibrin and edema fluid may be present in the alveoli but there is little or no blood. (Blackmon et al., 1981; Winn and Myerowitz, 1981). Other changes that are sometimes present, such as hyaline membrane formation and interstitial edema, are more likely related to the supportive care of the patient than to the infection.

Extrapulmonary infections with legionellae have also been infrequently reported and can occur in the absence of clinical Legionnaires' disease. Legionellae have been identified from hemodialysis fistulae (Kalweit et al., 1982), pericarditis (Nelson, 1984; Mayock et al., 1983), wound and skin infections (Brabender et al., 1983; Ampel et al., 1985), and even a perirectal abscess (Arnow et al., 1983). Bacterial endocarditis has been documented on prosthetic heart valves (McCabe et al., 1984; Tomkins et al., 1988).

Early investigations of legionellosis were hampered because the stains commonly applied to lung tissue (Brown-Brenn, Fite-Faraco, etc.) failed to detect bacteria in lung tissue that was obviously compromised by a purulent process. The bacterium was first visualized by Chandler et al. (1977), who employed the Dieterle silver impregnation stain on human lung tissue. Use of this stain enabled the demonstration that the bacteria are highly associated with the inflammatory cells in infected tissues. Extracellular bacteria are present primarily in areas of the lung where lysis of the inflammatory exudate (leukocytoclasis) has occurred. Large numbers of apparently multiplying bacteria are found in the cytoplasm of alveolar macrophage.

Bacteremia may occur in many patients with *Legionella* infection. Up to one-third of patients with culture-proven legionellosis in one series (Rihs et al., 1985) had positive blood cultures.

The bacteremia most likely leads to the seeding of other organs remote from the lung and is probably responsible for the extrapulmonary infections already mentioned. Soluble antigens of legionellae are detectable in the urine of many infected patients. In a small number of patients, this antigen may actually be present during the prodromal phase of the illness (Sathapatayavongs et al., 1982) and may continue to be shed for several months after illness.

As previously mentioned, many patients with legionellosis also display one or more symptom referable to organ systems other than the lung, such as mental confusion, diarrhea, abnormalities of liver function, and hyponatremia. These observations suggest that *Legionella* may indirectly affect other organs, perhaps by secreting one or more toxins (Friedman, 1978). The short incubation period (36 h) and lack of symptoms referable to the respiratory system also suggest that the symptoms of Pontiac fever may also result largely from intoxication rather than infection.

Pathogenesis and Virulence

Legionellae are facultative intracellular bacteria with pathologic properties that are intimately related to their ability to disarm and multiply within professional phagocytes. In the lung of both humans and experimental animals, large numbers of apparently multiplying bacteria can be visualized in the cytoplasm of alveolar macrophages. Extracellular bacteria are mainly present only in those areas of the lung where lysis of the inflammatory cells has taken place (Winn and Myerowitz, 1981). Multiplication of the legionellae has been demonstrated in vitro in peripheral blood monocytes (Horwitz and Silverstein, 1980) and in these cells, the doubling time of the bacteria may be as short as 2 h.

Studies in guinea pigs suggest that the polymorphonuclear leukocyte (PMN) is important in host defense against the legionellae. Although the first cells to encounter legionellae in the lung are the resident alveolar macrophage, the first cells recruited into the lung following infection are PMNs, which are present by the end of the first day. The numbers of alveolar macrophages present do not increase for about 3 days following infection. When the cellular infiltrate from infected guinea pigs was fractionated by cell type, the numerous viable bacteria were found to be associated with the macrophage fraction. In contrast, few bacteria were recovered on culture of the PMN fraction, but light and electron microscopy demonstrated that large numbers of dead bacteria were present in the PMNs (Davis et al., 1983). Similarly, Fitzgeorge et al. (1988) have demonstrated that guinea pigs that are made neutropenic are more susceptible to infection with *L. pneumophila* and suffer higher mortality than normal guinea pigs.

In vitro studies of the PMN, in contrast, do not demonstrate a protective role for these cells. Phagocytosis of *L. pneumophila* in vitro by PMNs requires the presence of antibody and complement, but few of the infecting bacilli are killed. PMN cultures that are co-infected with *Legionella* and *Escherichia coli* kill the *E. coli* while the legionellae survive (Horwitz and Silverstein, 1981). The reason for the apparent dichotomy between the in vivo and in vitro observations is not clear.

In vitro observations of the interaction between macrophages and legionellae complement those made in vivo and are outlined schematically in Fig. 1. Phagocytosis of legionellae by macrophages is enhanced in the presence of antibody plus complement and attachment of the bacteria to these cells is mediated by complement receptors, which fix complement via the alternate pathway (Payne and Horwitz, 1987). Phagocytosis of *L. pneumophila* has been reported to occur by a novel process, termed "coiling phagocytosis," whereby a pseudopod coils around the bacterium during its internalization by the phagocyte (Horwitz, 1984). The significance of this unusual phagocytic process is not understood. It has been demonstrated that phagocytosis of *Legionella* can be inhibited by cytocholasin D, suggesting that the phagocytic process may be only slightly different from that employed by other microorganisms (Elliot and Winn, 1986). Rechnitzer and Blom (1989) have also reported that phagocytosis of the Knoxville 1 strain of *L. pneumophila* and of *L. micdadei* did not involve coiling phagocytosis and that only the Philadelphia 1 strain appeared to be taken up by this mechanism.

The intracellular behavior of the legionellae is most fascinating. The internalized bacteria are surrounded by a membrane-bound phagolysosome, which eventually becomes associated with smooth vesicles. Later, these phagosomes become surrounded by mitochondria, which later are replaced by what appear by microscopic observation to be mitochondria (Fig. 2) (Horwitz, 1983a). The normal fusion of lysosomal granules and the phagosome does not occur in *L. pneumophila*-infected monocytes. Acidification of the phagosome also does not occur (Horwitz, 1983b; Horwitz and Maxfield, 1984), permitting the bacteria to multiply within and ultimately cause the rupture of the infected phagocyte. Monocytes that have phag-

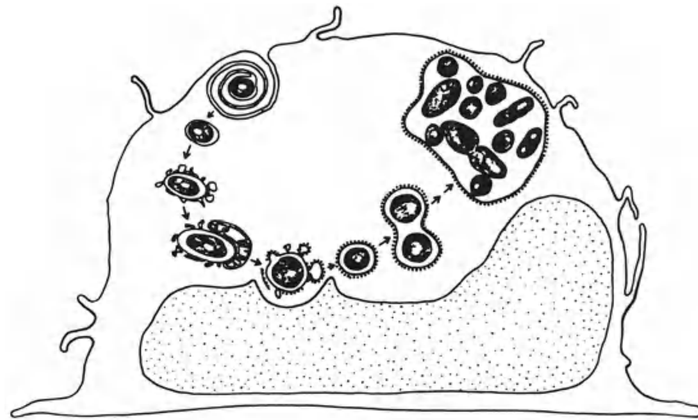

Fig. 1. Diagram of the sequence of cytoplasmic events involved in the intracellular multiplication of *L. pneumophila.* (a) Phagocytosis occurs by engulfment of the bacterium in a coiling pseudopod. (b) The internalized bacterium is surrounded in a membrane-bound vacuole, which is associated first with smooth vesicles within 15 min after ingestion. (c) Within 1 h after infection, the vesicles become surrounded by one or more mitochondria in addition. (d) At about 4 h after ingestion, the vesicles become surrounded by rough vesicles and ribosomes and by 8 h, the vesicle is studded entirely by ribosomes. (e) Multiplication of the bacteria occurs within these ribosome-studded vacuoles, eventually resulting in the rupture of the cell. (From Horwitz, 1983a.)

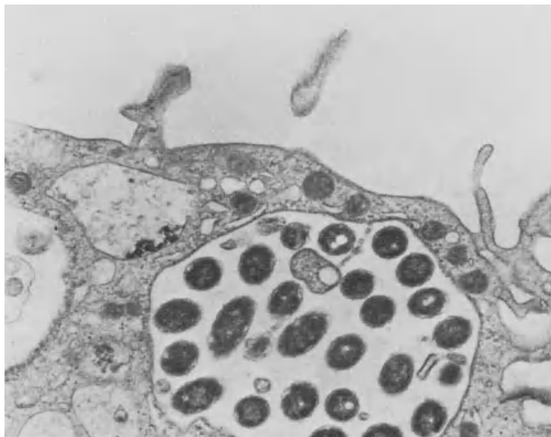

Fig. 2. *L. pneumophila* multiplying in a guinea pig alveolar macrophage. The bacteria are contained in a vacuole, which is studded with ribosomes.

ocytosed avirulent legionellae do not contain ribosome-studded phagosomes. In these cells, phagosome-lysosome fusion and phagosome acidification occur in normal fashion. While the legionellae are still not killed by these phagocytes, at the same time they neither replicate within nor kill the phagocyte (Horwitz, 1987).

Virulence Factors

While much is known about the intracellular behavior of the legionellae, the search for the virulence factors that underlie this behavior has to date been frustrating. The unique intracellular life cycle of these bacteria suggests that virulence must be multifactorial. Virulence must involve at least four attributes, as demonstrated in vitro. 1) Bacteria must be recognized and phagocytosed in order to gain entrance into the favored site for multiplication. This, as previously discussed, is known to be mediated by complement receptors on the bacterial cell (Payne and Horwitz, 1987). 2) Once within the bacterial cell, the organisms must inhibit phagosome-lysosome fusion, and also resist the oxidative killing mechanisms of the phagocyte. 3) Evasion of the oxidative killing mechanisms must be required because it has been shown that an avirulent mutant is not killed even in the presence of phagosome-lysosome fusion (Horwitz, 1987). 4) Having entered the cell and resisted or abrogated its defenses, a virulent bacterium must be capable of multiplication within the cell. How the legionellae effect such a life cycle continues to be the subject of much investigation.

Most of the legionellae, with the exception of *Legionella micdadei,* produce a 39-kDa metalloprotease that can be recovered from culture filtrates (Thompson Miller and Iglewski, 1981). The enzyme is cytotoxic for cultured chinese hamster ovary cells and causes the hydrolysis of canine erythrocytes (Keen and Hoffman, 1989). Conlan et al. (1986) reported that the instillation of this protease into the lungs of guinea pigs produced a pattern of cellular destruction which resembled that seen in Legionnaires' disease, but it was not demonstrated that such destruction in natural infections is caused by this enzyme. Blander and Horwitz (1989) demonstrated that animals immunized with the purified protease produced antibody against the molecule and displayed evidence of cell-mediated immunity to the protease. Such vaccinated animals were also resistant to aerosol challenge with virulent *L. pneumophila.* Later studies, however, showed that vaccinated animals were not immune to infection by a pro-

tease-deficient mutant, suggesting that while the enzyme may modulate the immune response, it is probably not a virulence factor.

A highly basic protein on the surface of *L. pneumophila* has been identified by Cianciotto et al. (1989). Mutants made deficient in the genetic sequence coding for this protein were found to be less capable of penetrating a macrophage-like cell line than was the isogenec parent strain. However, once internalized, the mutant strain appeared to be as capable of multiplication as the parent strain. These workers named this protein and the gene coding for it MIP (for macrophage infectivity promoter).

Saha et al. (1988) identified an acid phosphatase in *L. micdadei* that interferes with superoxide formation by stimulated human PMNs. The purified enzyme has been shown to hydrolyze phosphatidyl inositol 4,5-bisphosphate, an important intermediary molecule in the production of reactive oxygen intermediates by human PMNs. Since most legionellae contain such enzymes, they also may be an important virulence factor. At this time, however, the relationship of this property to virulence remains indeterminate since the enzyme can be isolated from highly passaged and hence avirulent organisms and a similar biochemical "lesion" has not been detected in PMNs infected with legionellae.

L. pneumophila, L. micdadei, and several other species produce novel cytotoxin, which might play some role in virulence. The molecules are small (300–3,400 kDa) peptides, which are heat and acid-resistant. The toxin from *L. pneumophila* has been shown to be cytotoxic for chinese hamster ovary cells (Friedman et al., 1980). The toxin also inhibits the respiratory burst and subsequent production of reactive oxygen intermediates by PMNs (Friedman et al., 1982), as does a similar product from *L. micdadei* (Hedlund, 1981). What role if any these molecules may play in virulence remains to be determined since these compounds have been isolated from laboratory strains of unconfirmed virulence.

Studies of immunity against legionellosis have also uncovered another potential virulence factor for the legionellae; the ability to scavenge iron from the cytoplasm of macrophages. Byrd and Horwitz (1989) discovered that gamma-interferon-activated human monocytes could limit the intracellular growth of *L. pneumophila* by decreasing the number of transferrin receptors present on the cell surface thereby limiting the availability of iron to the intracellular bacteria. Treatment of the immune cells with iron transferrin restored their ability to support growth of the legionellae. Likewise, an iron chelating agent, deferoxamine, prevented the multiplication of *L. pneumophila* in nonimmune cells. How legionellae are able to obtain needed iron from the intracellular milieu is not yet known. Siderophores have not been detected in *Legionella* to date (Reeves et al., 1983).

Therapy

The epidemiologic investigation of the Philadelphia outbreak of Legionnaires' disease suggested that erythromycin was an effective therapeutic agent and that β-lactam and aminoglycoside agents were not (Fraser at al., 1977). Subsequent studies in animals (Fraser, 1978) confirmed the efficacy of erythromycin against the legionellae. In addition, rifampin, the tetracyclines, and the combination of sulfamethoxazole with trimethoprim have been demonstrated to be efficacious in infected animals (Edelstein Calarco and Yasui, 1984; Pasculle, et al., 1985). The susceptibility of legionellae to antibiotics can be measured by in vitro susceptibility tests (Pasculle et al., 1981), but these tests do not predict which agents will be therapeutically efficacious because in vitro tests do not take into account whether or not these agents can penetrate cells. Most species of *Legionella* produce a broad spectrum β-lactamase and are not susceptible to penicillins and cephalosporins. A relatively new class of agents, the fluoroquinolones (such as ciprofloxacin) also appear to have both in vitro and in vivo activity against the legionellae and may also find clinical use (Saito et al., 1986).

On a weight basis, rifampin appears to be the agent most active against the legionellae. Rifampin, however, is never used alone for the treatment of legionellosis because it rapidly selects for resistant subpopulations of legionellae (Dowling et al., 1982). Most patients are treated with erythromycin alone or in combination with rifampin for 3 weeks. Tetracyclines and sulfamethoxazole/trimethoprim have also been reported to be therapeutically effective. The response of patients to therapy is variable. In some patients the clinical response to antimicrobial therapy may appear delayed and the patient may even seem to worsen after therapy begins. Legionellae may be detected by immunofluorescence or culture after up to 10 days of therapy, but this observation also does not correlate with the patient's ultimate response to therapy (Kirby et al., 1980).

Diagnosis

Culture

Culture remains the most sensitive test for the laboratory diagnosis of legionellosis (Edelstein

Meyer and Finegold, 1980; Zuravleff et al., 1983.; Edelstein, 1987; Pasculle et al., 1989). The sensitivity of culture methods varies not only with the type of specimen but also from laboratory to laboratory. Whether this phenomenon reflects variation in intra-laboratory proficiency or the varying quality of commercially prepared media is not known. Culture is most sensitive (about 90%) when applied to specimens such as those obtained by transtracheal aspirates or bronco-alveolar lavage, since these are not usually contaminated with oral bacteria. Culture of sputum specimens is much less sensitive and the sensitivity of culture in hospitalized patients may be somewhat lower, about 65–75%. The sensitivity will vary primarily because of variations in the prevalence of cefamandole-resistant bacteria (especially *Pseudomonas* and enterococci) in various hospitals.

The legionellae are not known to colonize humans (Bridge and Edelstein, 1983; Baumgardner et al., 1988.). Thus, the specificity of culture methods appears to be close to 100% and any patient from whom the organism is isolated should be presumed to have legionellosis. A variety of ancillary procedures are used to enhance cultural diagnosis of legionellosis. A discussion of these may be found elsewhere in this chapter.

Direct Antigen Detection

IMMUNOFLUORESCENCE. Direct fluorescent antibody staining (DFA) has been employed for the rapid detection of legionellae in both tissue and respiratory secretions (Broome et al., 1979). The major benefit of this technique is that it can be performed rapidly with results usually available within 2 h. The sensitivity of DFA in various laboratories has not been constant. Some laboratories have reported a sensitivity of 25–30% for DFA (Zuravleff et al., 1983; Buesching et al., 1983) while other have found the sensitivity of the test to be in the order of 70% (Edelstein, 1987; Pasculle et al., 1989). The reasons for the widely varying estimates of sensitivity are not fully understood but may include differing patient populations, methodological differences such as volume of specimen examined, or even laboratory proficiency. The above not withstanding, all laboratories find to a greater or lesser extent that culture is more sensitive than DFA.

Direct immunofluorescence has additional limitations as well. As the number of serovars has increased, the number of fluorescent conjugates required to detect all possible organisms has become unmanageable. At present, there are 47 serovars in the genus. Even more problematic is that conjugated antisera are not available commercially for most *Legionella* serotypes, making complete examination of specimens possible in only a few reference laboratories. On the other hand, since over 90% of all legionella infections are caused by *L. pneumophila* serogroups 1 through 6 and *L. micdadei* (Reingold et al., 1984), detection of the greatest majority of cases is possible using commercially available antiserum pools that contain antibodies for these organisms. Many American laboratories limit their immunofluorescent testing to these seven serovars and rely on culture (which should always be performed in parallel with DFA) to detect other serovars.

The specificity of DFA in most laboratories has been high (93–99%) (Edelstein, 1987; Pasculle et al., 1989). However, in areas of low disease prevalence, this level of specificity considerably lowers the predictive value of a positive test. A number of bacterial species are known to be stained by *Legionella* DFA conjugates. These include *Pseudomonas fluorescens, P. aeruginosa, P. putida,* and *Bacteroides species* (Tenover et al., 1986; Edelstein et al., 1980). There are also reported cross-reactions between *Legionella* and *Bordetella pertussis* (Benson et al., 1987; Ng et al., 1989).

Since legionellae are often present in water distribution systems, the buffers and other aqueous reagents used in the DFA procedure can become contaminated with these bacteria, producing false positive tests (Ristagno and Sarovolatz, 1985). This type of false positive reaction is easily prevented by membrane filteration of all the aqueous reagents used for the DFA test.

DFA staining is not usually applied to environmental specimens because of unsuitably low specificity. In some studies involving environmental specimens, fewer than 50% of samples that tested positive by DFA yielded *Legionella* upon culture (Fliermans et al., 1981.). Whether this is the result of cross-reactivity or of the presence of dead or dormant legionellae in these specimens is not actually known.

The first DFA reagents available were produced in rabbits and it is these polyclonal reagents that have been associated with most of the false positive reactions. Monoclonal antibody (MAb) reagents are now commercially available. One MAb recognizes all serotypes of *L. pneumophila* while additional reagents are also available for *L. micdadei* and *L. dumoffii.* These monoclonal reagents have been demonstrated to be of equivalent sensitivity to the polyclonal reagents and to have higher specificity (Edelstein et al., 1985; Cercenado et al., 1987.). In addition, the polyclonal reagents produce less

nonspecific florescence of the background material. The *L. pneumophila* MAb appears to be directed against a species-specific protein antigen, probably in the outer membrane. Because of this, the MAb does not react with organisms in formalin-fixed specimens (Edelstein et al., 1985). One false positive reaction caused by spores of *Bacillus cereus* spores in an environmental specimen has been reported (Flournoy et al., 1988).

Nucleic Acid Probes

A DNA probe which hybridizes with the rRNA of *Legionella* has been commercially produced. Initial studies using bacterial isolates indicated that the probe could detect all 22 *Legionella* species tested and did not react with other common and uncommon bacterial species (Edlestein, 1986; Wilkinson et al., 1986). A retrospective premarket study of the probe using frozen respiratory tract specimens demonstrated that the sensitivity of the DNA probe was about 75% compared to culture and the specificity was 99% (Edelstein et al., 1986). Two prospective studies of the commercial product have been performed. One (Doebbeling et al., 1988) found the sensitivity and specificity to be 50 and 99% respectively, while the other (Pasculle et al., 1989.) reported values of 71 and 99%. The probe appears to be equivalent to DFA testing, but not as sensitive as culture. The major advantage of such a reagent is the ability to detect all species and serogroups with a single reagent. The probe has two major disadvantages: its somewhat higher cost limits its use to high-volume laboratories; and the test probe employs an ^{125}I label and thus has a relatively short shelf life of 6 weeks.

Two other DNA probes have been prepared experimentally. Grimont et al. (1985) used radiolabeled chromosomal restriction endonuclease fragments to demonstrate in situ hybridization on nitrocellulose filters. Another group used cloned DNA, which codes for the major outer membrane protein of *Legionella* as a probe to detect the organism in lung tissue of mice (Engelberg et al., 1986).

Despite their differing compositions, all the above DNA probes appear to be about equal in sensitivity and are reported to detect between 10^4 and 10^5 colony-forming units/ml. Amplification of *Legionella* DNA in artificially seeded tap water has been accomplished using the polymerase chain reaction (Starnbach et al., 1989). It was reported that as few as 35 colony-forming units of *L. pneumophila* could be detected.

Urinary Antigen Detection

Legionella urinary antigen can be detected in the urine of patients with Legionnaires' disease by a number of immunologic methods. Enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA) appear to be more sensitive than latex agglutination. The sensitivity of the test has ranged from 70–100% (Sathapatayvayongs et al., 1982.; Aguero-Rosenfield and Edelstein, 1988) and the specificity appears to be in the 99–100% range as well. One study found that false positive ELISA tests could be eliminated by boiling the urine prior to testing (Sathapatayvayongs et al., 1982).

The RIA test has recently become commercially available. A retrospective evaluation of that reagent found it to be 100% sensitive and specific (Aguero-Rosenfield and Edelstein, 1988.). The major limitation of the tests for antigenuria is that the antibody employed to date detects the antigen of only *L. pneumophila* serogroup 1. Thus, in certain areas where other *Legionella* serotypes and/or species are more prevalent, the predictive value of a negative test will be unacceptably low. Also, the use of a radioisotope (^{125}I) in the RIA method will make the method undesirable for many laboratories. Finally, antigen may be present in the urine of some patients for several months after recovery, slightly diminishing the predictive value of a positive test.

Antigens of other *Legionella* serogroups also appear to be detectable in the urine (Kohler et al. 1987), suggesting that a polyvalent screening system might be possible. Alternatively, the production of a broadly reactive antibody that detects multiple serotypes and species has been demonstrated. Its sensitivity appears to be equivalent to the monovalent serogroup 1 reagent (Tang and Toma, 1986). If multivalent or panvalent antibody reagents become commercially available, the urinary antigen test may very likely become the method of choice for rapid screening for legionellosis.

Antibody Detection

Serological diagnosis is still often used despite a number of significant problems. Antibodies against the legionellae can be detected by a number of methods, including indirect immunofluorescence (IFA), ELISA, and microagglutination tests. The IFA test continues to be most often employed for the serological diagnosis of legionellosis. The sensitivity of the IFA test appears to be about 75% when paired sera are tested, while the specificity is above 99% in most series (Wilkinson et al., 1981). A number of factors reduce the diagnostic utility of serological testing. Most importantly, the antibody response following infection is variable. In patients with legionellosis documented by culture,

only about 25% of patients may have demonstrable antibody during the first 2 weeks following infection. Some patients do not appear to develop antibody for up to 6 weeks following infection documented by cultures and 15–20% of such patients fail to develop antibody at all (Kirby et al., 1980). Thus, for maximal diagnostic yield, paired sera, often collected 6 weeks apart, must be tested. Thus, serological testing can do little to establish the diagnosis of legionellosis in a critically ill patient within a clinically relevant time frame.

The varying prevalence of antibody (1–20%) among various populations and the probable lifelong persistence of antibody also make the interpretation of single antibody titers unreliable. Single IFA antibody titers of ≥256 appear to be associated with both recent and remote *Legionella* infection and cannot reliably establish a diagnosis of legionellosis in a critically ill patient. This is particularly true in areas where the antibody prevalence is known to be high. The most reliable diagnostic yields result from the demonstration of fourfold rises in antibody titer in paired sera with a titer of ≥128 in the convalescent serum (Wilkinson et al., 1981) These interpretive criteria are also often applied to the serological diagnosis of infections caused by other *Legionella* species and serotypes, but criteria for the interpretation of serologic titers for these organisms has not been conclusively established (Wilkinson et al., 1983). Finally, while antibody of the IgG, IgM, and IgA classes are produced in response to *Legionella* infection, they appear to be produced concomitantly in many patients and remain elevated. Thus, it is important to employ reagents that can detect both IgG and IgM. The detection of IgM alone does not always demonstrate recent infection (Wilkinson, 1987).

Serological testing also cannot determine the identity of the *Legionella* serovar causing disease in a particular patient. Patients with culturally proven legionellosis may produce antibody to another serovar or even to multiple serovars. The nature of the serological response seems to be influenced more by the patient than by the identity of the infecting organism (Wilkinson et al., 1983; Fallon and Johnston, 1987). Because of this, the interpretation of many published studies of the prevalence of legionellosis is subject to some skepticism (Reingold, 1988). In addition, serological cross-reactions have been reported in the sera of patients with *Bacteroides* infections and in patients with cystic fibrosis, presumably due to *Pseudomonas aeruginosa.* (Edelstein et al., 1980; Collins et al., 1984).

Isolation

L. pneumophila was initially isolated in guinea pigs and in embryonated eggs (McDade et al., 1977), as were some of the other early species in the genus. A number of artificial media have been developed that support growth of the legionellae. Artificial media are superior to inoculation of guinea pigs (Edelstein et al., 1982) because specimens with low numbers of organisms produce only subclinical infection of the animals. The legionellae require iron and cysteine in order to initiate growth on artificial media, and the first medium upon which *L. pneumophila* was cultivated consisted of Mueller-Hinton agar to which hemoglobin and the supplement IsoVitaleX were added (Feeley et al., 1978). Ferric pyrophosphate was found to be an acceptable substitute for hemoglobin, and L-cysteine was found to be the active component in IsoVitaleX. The addition of these compounds to a basal medium consisting of casein, beef extract, and starch produced F-G agar (Feeley et al., 1978) upon which many isolations of *L. pneumophila* were made. Feeley et al. (1979) subsequently developed a more sensitive semisynthetic charcoal-based medium, charcoal yeast extract agar. Good control of the pH of the medium was necessary since the legionellae initiated growth over a very narrow range of pH (6.85–6.95) and the addition of a zwitterionic buffer, ACES, to charcoal yeast extract agar by Feeley's group (Pasculle et al., 1980) resulted in buffered charcoal yeast extract agar (BCYE), which remains the medium of choice for the isolation of the legionellae. Edelstein (1982) added α-ketoglutarate to BCYE agar and demonstrated a marked increase in both the speed of growth and in the plating efficiency of the medium. It is this version, commonly referred to as BCYE-α, which is most widely used.

BCYE agar is very rich and in no way selective for legionellae. A number of modifications have been made to BCYE agar to produce selective and differential media for specialized use. Edelstein (1982) added cefamandole, polymyxin B, and the antifungal agent anisomycin to produce a semiselective medium that is often employed for clinical specimens such as sputum, which may contain other bacterial species. Wadowsky and Yee (1981) added glycine (to inhibit Gram-negative bacteria) vancomycin, and polymyxin B to produce a medium that they found highly useful for culturing environmental sites heavily contaminated with other bacteria. Vickers et al. (1981) found that the addition of bromcresol purple and bromthymol blue dye to these media enabled *L. micdadei* to be differentiated from other legionellae by the blue color

of their colonies on the agar. Selective media should not be used alone for clinical specimens since they are somewhat inhibitory for small numbers of legionellae (Roberts et al., 1987).

The pH of the medium is exceedingly critical and should be held between 6.85 and 6.95 (Feeley et al., 1979; Pasculle et al., 1980). Media should probably be poured in a darkened room to prevent the photochemical oxidation of yeast extract and the light-catalyzed autoxidation of cysteine. These oxidations produce inhibitory superoxide anion and peroxides (Hoffman et al., 1983). Adequate quality control of the media is necessary to ensure that the media are of good quality. Legionella isolates that have been subcultured several times on agar no longer constitute an adequate quality control challenge for these media and a virulent strain of bacteria maintained in homogenates of human or guinea pig lung should be used for this purpose (Feeley et al., 1979; Kealthly and Winn, 1984). All the media previously discussed are currently available from commercial vendors but the quality can be highly variable (Kealthly and Winn, 1984).

Additional techniques are often used to increase the yield of legionellae from clinical and environmental specimens. Treating specimens with an HCl-KCl buffer (pH 2.2) prior to inoculation on agar media kills many contaminating bacteria more rapidly than the legionellae in environmental specimens (Bopp et al., 1981; Roberts et al., 1987). This procedure also results in about a 10% greater yield of positive specimens when used with clinical samples (Buesching et al., 1983). Tissue specimens may harbor substances that are inhibitory for the legionellae. Dilution of such specimens at least 10—fold in bacteriological broth also may increase the yield of positive cultures from such specimens (Lattimer et al., 1980; Wilkinson, 1987). Other specimens that are dilute or otherwise contain small numbers of bacteria should be concentrated by centrifugation before inoculation onto media. Such specimens include pleural fluids, trans-tracheal aspirates, bronchoalveolar lavage fluids, and pericardial fluids.

Several methods have been employed to collect and process environmental specimens, which frequently contain small numbers of legionellae. Some method of concentration is often employed. These include centrifugation (Voss et al., 1984) and membrane filtration (Orrison et al., 1981). Both techniques appear to be of equal efficiency (Brindle et al., 1987).

Several liquid media have been developed for propagation of the legionellae for antigenic, metabolic, and other studies. Two chemically defined media contain complex mixtures of amino acids, vitamins, and trace elements (Pine et al., 1979; Warren and Miller, 1979). Ristroph et al., (1980) developed a novel semisynthetic broth medium, which consists of filter-sterilized yeast extract with cysteine and ferric pyrophosphate. Sterilized agar may be added to produce a semisynthetic agar and ACES buffer has also been added to this medium (Dowling et al., 1982) to produce more reliable growth. Wild type strains of *Legionella* do not appear to initiate growth well in liquid media. Growth of small inocula is variable and the lag phase may last over 24 h. Strains that have been transferred in broth culture several times appear to become somewhat adapted to growth in these media. Whether this poor growth of legionellae in liquid media is a characteristic of the genus or reflects remaining deficiencies in the available media is currently not known. Nevertheless liquid media are never relied on for the isolation of these bacteria from clinical or environmental sources.

Legionella has been isolated from blood by a variety of techniques including biphasic blood culture bottles (Edelstein et al., 1979), lysis centrifugation (Dorn and Barnes, 1979), and conventional radiometric methods (Rihs et al., 1985). However the diagnostic utility of routinely performing such blood cultures remains to be established.

Buffered Charcoal Yeast Extract Agar

N-(2-acetamido)-2-aminomethane sulfonic acid (ACES)	10 g
Yeast extract (Difco)	10 g
Charcoal (Norit SG)	2 g
Agar (Difco)	17 g
α-Ketoglutarate (monopotassium salt)	1 g
L-Cysteine $HCl \cdot H_2O$ (in 10 ml distilled water)	0.4 g
Ferric pyrophosphate (in 10 ml distilled water)	0.25 g
Distilled/deionized water	950 ml

Dissolve ACES completely in water, warming water if necessary. Add α-ketoglutarate and yeast extract. Adjust pH to 6.95 with 1 N KOH (40–45 ml) and then bring volume to 1 liter with water. Add charcoal, agar, and dissolve by boiling. Autoclave for 15 min at 121°C. Allow to cool to 50°C and add filter-sterilized cysteine and ferric pyrophosphate solutions, always adding the cysteine first. Check pH and adjust with 1 N KOH if necessary.

Swirl the flask or use a magnetic stirring bar while pouring plates to keep the charcoal particles suspended in the medium. Pour 25 ml per plate to resist drying out during prolonged incubation. It may be beneficial to pour media in a darkened room to prevent generation of peroxides.

Precautions: The ferric pyrophosphate must be kept dry (desiccator) and the solution must be freshly made just prior to use. If the powder changes from its green

color (yellow or brown), it is no longer usable. This solution must be made fresh each time it is required. Ferric pyrophosphate can be readily dissolved in water by heating it to 50°C.

Identification

Colonial Morphology

Colonies of legionellae appear on BCYE agar within 36–48 h of incubation. Recognition and preliminary identification of the bacteria are facilitated by the use of a dissecting microscope for the examination of the media. *Legionella* colonies display a characteristic appearance resembling "ground glass" when viewed under obliquely transmitted light. The colonies are gray, convex with an entire edge that usually displays a birefringent band, which is either greenish blue or pink depending on the species. As the colonies become several days older, the ground-glass appearance and the birefringent edge tend to disappear and the colonies appear more like those of other bacteria. When the colonies are illuminated with a Woods' lamp the colonies of most species will exhibit a dull yellow fluorescence (Table 1). The colonies of *L. bozemanii, L. gormanii, L. dumoffii,* and several other species display a very striking blue-white autofluorescence under similar conditions of illumination while colonies of *L. rubrilucens* and *L. erythra* produce a red fluorescence. (Feeley et al., 1978; Brenner et al., 1985).

Cellular Morphology and Biochemical Characteristics

The legionellae are fastidious bacteria that require iron and cysteine for primary isolation. Growth does not occur on common laboratory media such as blood or chocolate agar. Despite their apparent acid resistance (Bopp et al., 1981), the legionellae appear only to initiate growth on artificial media over a very narrow pH range of 6.8–7.0. The optimum temperature for human isolates appears to be 35°C, but isolates from warmer environments, such as hot water systems, may grow at higher temperatures. Growth of the legionellae on the agar media mentioned earlier, such as FG agar, appear to be stimulated by incubation in a 5–10% CO_2 atmosphere. In contrast, growth on yeast extract-based media (CYE and BCYE) appears not to be stimulated by incubation in an atmosphere enchriched with CO_2 (Feeley et al., 1978; Pasculle et al., 1980.). They do not grow appreciably under anaerobic conditions.

Legionella cells are small, Gram-negative rods, 1–2 μm in length and 0.5 μm wide. Filamentous forms up to 20 μm may also be present in some cultures, particularly after prolonged passage in artificial media (Pine et al., 1979). Their ultrastructural arrangement is typical for Gram-negative rods, with typical trilaminar inner and outer membranes. *L. micdadei* has a unique electron dense layer in the periplasmic space that is not seen in *L. pneumophila* (Gress and Myerowitz, 1980). Several species, except *L. micdadei,* appear to have an extracellular polysaccharide capsule or slime layer that can be vizualized by ruthenium red staining (Hebert et al., 1984), even though the bacteria appear unencapsulated by other means. Staining characteristics depend to some degree on the source of the bacteria. Typically, the legionellae in clinical specimens are not reliably stained by the Gram stain, although bacterial cells from artificial media stain somewhat better. The substitution of carbol fuchsin for the saffranin counterstain in the Gram technique makes the legionellae more readily visible. Staining of the legionellae can also be accomplished using crystal violet (de Freitas et al., 1979) and methylene blue (Pasculle et al., 1980). *L. micdadei* is unusual in that the cells are weakly acid fast when present in tissue but readily lose this property after a single passage on artificial media. The reason for this is unknown (Pasculle et al., 1980). The legionellae can also be readily stained by the Gieminez stain (McDade, 1978) and the Dieterle silver (Chandler et al., 1977) stains, but neither technique is specific for these bacteria.

The legionellae are chemoorganotropic and they do not possess a glucose transport system and do not appear to ferment any other carbohydrates as well. Early studies using several defined media suggested that methionine, arginine, threonine, serine, isoleucine, leucine, and valine are required by the legionellae, in addition to cysteine. Serine, glutamate, and perhaps threonine appear to serve as the primary carbon and energy sources for the legionellae and are catabolized via the Krebs cycle. Carbohydrate synthesis occurs through gluconeogenesis via the Embden-Meyerhof pathway (Pine et al., 1979; George et al., 1980; Keen and Hoffman, 1984; Tesh et al., 1983).

Members of the genus *Legionella* cannot be identified with any degree of certainty using traditional biochemical testing. The few phenotypic tests that can be used to separate these organisms into groups are given in Table 1. All species are motile via one to three polar or subpolar flagella and the flagella of all legionella species appear to be antigenically identical. Only *L. oakridgensis* appears to be nonmotile (Thomason et al., 1979; Orrison et al., 1983).

Tests for nitrate reductase and urease are negative for all species. Most strains are reported to be catalase positive when whole cells are tested for the ability to decompose hydrogen peroxide. Studies using cell-free extracts, however, have demonstrated the *L. pneumophila* and *L. gormanii* have only peroxidase activity whereas other *Legionella* species in actuality do possess catalase (Pine et al., 1984). Most species, except *L. feeleii* and *L. micdadei,* liquify gelatin. Most strains of *L. pneumophila* and some strains of *L. Feeleii* hydrolyze hippurate. Most strains produce a beta-lactamase that is active against cephalosporins and can readily be demonstrated using nitrocefin (Marre' et al., 1982.).

Cellular Lipids

The cell wall of the legionellae is somewhat unique among Gram-negative bacteria in that it contains large amounts of branched chain fatty acids and only minor amounts of hydroxy acids (Moss et al., 1977). When there were few species in the genus, the determination of the presence of these unusual fatty acids was a rapid means for the presumptive identification of these bacteria. With the subsequent recognition of multiple species in the genus, the determination of fatty acid profiles is useful primarily for the initial examination of an isolate. Both quantitative and qualitative measurements of fatty acid content are made by gas-liquid chromatography. Using such quantitative measurements, Lambert and Moss (1989) were able to divide the first 23 *Legionella* species into three major groups.

The legionellae also are unusual in that their isoprenoid quinones are ubiquinones with side chains containing greater than nine isoprenoid units (Karr et al., 1982; Lambert and Moss, 1989). Lambert and Moss (1989) were able to divide 23 *Legionella* species into four groups and differentiate *L. feeleii* from all the other legionellae by quantitative estimation of their ubiquinone content. The determination of fatty acid and ubiquinone profiles is generally too complex for routine laboratory use. These procedures are, however, very helpful in the preliminary characterization of isolates by reference laboratories.

Identification Techniques

The identification of *Legionella* isolates ranges from a simple task for common species to a very complicated task for new species. Traditionally, the first step is to demonstrate the requirement of an isolate for cysteine, which is characteristic of the genus *Legionella* (Brenner et al., 1988). In most laboratories, this is done by inoculating the isolate onto a BCYE agar plate from which the cysteine has been omitted (Wilkinson, 1988). Other cysteine-deficient media, such as sheep blood agar, may be used for this purpose, but occasional strains of other heterotrophic environmental bacteria may be encountered that will grow on BCYE and not on blood agar (Thacker et al., 1981). Isolates can also be preliminarily assigned to the genus by reacting them with a commercially available DNA probe, which appears to be highly specific for members of the genus (Wilkinson et al., 1986; Edelstein, 1986).

Other methods may eventually come into use to assign organisms to the genus *Legionella.* Most of the antibody in patients' sera appears to be specific for serogroup-dependent determinants in the lipopolysaccharide of the legionellae (Ciesielski et al., 1986.). There are, however, protein antigens associated with the cell surface that may be common to some or all species (Hindahl and Iglewski, 1986; Nolte and Conlin, 1986). The genetic locus for the major outer membrane protein of *Legionella* pneumophila appears to contain both genus- and species-specific regions. An experimental DNA probe for this locus has already been prepared (Engelberg et al., 1986). Butler et al. (1985) demonstrated extensive cross-reactions by immunoblotting between the major outer membrane proteins of 10 *Legionella* species. Similarly, Sampson et al. (1986) were able to demonstrate a common 58-kDa protein antigen in the outer membrane of the first nine *Legionella* species. The use of a genetic or immunological probe to detect one or more of these common antigenic determinants could also be used to assign isolates to the genus.

The identification of the various recognized species and serovars of *Legionella* is most readily achieved by serological methods. Fluorescein-conjugated antisera for direct immunofluorescence testing can be used for the rapid presumptive identification of isolates (Cherry et al., 1978; Wilkinson, 1987). Since *L. pneumophila* accounts for the greatest preponderance of clinical isolates (Reingold et al., 1984), most clinical isolates can indeed be identified using such commercially available antisera. Antibody conjugates are available commercially for *L. pneumophila* serogroups 1–6, *L. bozemanii, L. dumoffii, L. gormanii, L. micdadei,* and *L. longbeachae* serotypes 1 and 2. A monoclonal antibody conjugate that reacts with at least 10 serogroups of *L. pneumophila* is also available, as are similar conjugates for *L. micdadei* and *L. dumoffii* (Edelstein et al., 1985; Cercenado et al., 1987).

A simple slide agglutination test for the identification of the legionellae has also been developed. Extensive crossreaction among the legionellae requires that the polyclonal antisera used for this procedure and for immunofluorescence be subjected to reciprocal adsorption to remove cross-reacting antibodies. Thacker et al. (1985) were able to identify 22 *Legionella* species using slide agglutination reagents. The only organisms not identifiable were *L. bozemanii* and *L. parisiensis,* whose cross-reactions cannot be removed. Despite its rapidity and simplicity, slide agglutination reagents are not available commercially.

Identification of Strains

Epidemiologic studies are greatly enhanced by the recognition of common clones or strains among isolates. The earliest studies employed simple serotyping to recognize isolates that were different from each other. However, the preponderance of isolates belonging to *L. pneumophila* serogroups 1 and 6 limits the use of this technique to those situations involving other species and serotypes. Plasmid profiling has been used to characterize environmental and clinical isolates in several outbreaks. A large majority of isolates appear not to contain plasmids, but when present the identification of plasmid types has been useful (Mikesell et al., 1981; Brown et al., 1982). In addition to comparing plasmids by molecular weight, it is also possible to further characterize plasmids of similar size by analyzing the fragments produced after treatment of the plasmids with restriction endonucleases (Nolte et al., 1984.)

Panels of monoclonal antibody reagents have been developed for typing isolates of *L. pneumophila* serogroup 1. (Joly et al., 1983; McKinney et al., 1983; Watkins et al., 1985). A panel of standardized reagents has been developed that could separate *L. pneumophila* serogroup 1 into 10 major subgroups (Joly et al., 1986). A panel of two monoclonal antibodies for *L. pneumophila* serogroup 6 has also been developed, which could divide these isolates into two groups. In conjunction with other typing methods, monoclonal antibody typing of serogroup 6 isolates is also useful for epidemiologic purposes (McKinney et al., 1989).

Analysis of restriction endonuclease fragments of chromosomal DNA has also been employed to evaluate the relationships between isolates of *L. pneumophila, L. micdadei,* and *L. dumoffii.* The advantage of this technique is that it permits comparison of species and serotypes that do not contain plasmids and/or for which monoclonal antibodies are not available (Tompkins at al., 1987).

Multilocus enzyme electrophoresis (MEE) has also been applied to the study of the legionellae at both the strain and species level. In this analysis, as applied to *Legionella,* the electrophoretic mobility of a panel of 22 bacterial enzymes is measured. Differences in electrophoretic mobility of a particular enzyme result from small genetic changes in the structure of the enzyme, which do not affect enzyme function. Selander et al. (1985) could divide *L. pneumophila* into 62 distinct electrophoretic types and identified two groups of strains that were actually new species of *Legionella* (see below). Edelstein et al. (1986) compared MEE with monoclonal antibody testing and plasmid analysis of strains involved in a large outbreak and found that MEE was the most sensitive typing system in that it separated the strains into the largest number of types. Tompkins et al. (1987) found MEE and analysis of chromosomal restriction fragments of approximately equal sensitivity. McKinney et al. (1989) identified 11 MEE types among isolates of *L. pneumophila* serogroup 6, and in conjunction with two monoclonal antibodies were able to divide this group of organisms into 12 separate types. Two-thirds of the isolates fell into a single group.

Taxonomy

Isolates that cannot be identified by the above methods must be submitted to a reference laboratory for identification. Definitive identification requires the examination of cellular lipids, as described above, for preliminary characterization and also genetic analysis. The genus *Legionella* was initially defined by Brenner et al. (1979), who examined several isolates of the newly discovered Legionnaires' disease bacillus and concluded that they represented a new family, genus, and species. Since then, the genus has been redefined twice to take into account the ever-increasing number of species and subspecies. The creation of a single genus to hold this collection of species has been challenged by a small group of investigators.

Oligonucleotide cataloging of *Legionella* 16S rRNA has demonstrated that the legionellae are not closely related to other groups of organisms, but are closely related to each other at the ribosomal level. They are distantly related to the purple sulfur bacteria and their nonphotosynthetic relatives (Ludwig and Stackebrandt, 1983; Brenner, 1987). Other taxonomic studies have also demonstrated the uniqueness of the genus *Legionella.* Brenner (1987) reported that hybridization studies using the DNA which

specifies rRNA demonstrated that the legionellae were most closely related (approximately 60%) to common members of the *Enterobacteriaceae* and to *Pseudomonas,* all of which are also related at the ribosomal level to the purple photosynthetic bacteria.

The GC content of the DNA of species in the genus is 38 to 52 mol% (Brenner et al., 1985, 1988). The various *Legionella* species share up to 67% DNA relatedness at optimal hybridization temperature while strains within a given species have 70% or greater relatedness and <5% divergence in related sequences. It is upon this basis that the 29 species have been created within the genus (Brenner, 1987; Brenner et al., 1988; see also Table 1).

Garrity et al. (1982) recovered a number of isolates belonging to *L. pneumophila* serogroup 5, which were 15–42% related to the reference strain of *L. pneumophila* serogroup 5. They concluded that these isolates represented a species closely related to but separate from *L. pneumophila.* A taxonomic study of *L. pneumophila* isolates, using multilocus enzyme analysis, identified two clones among a collection of isolates with closely related, but not identical allotypes. Isolates belonging to these clones belonged to *L. pneumophila* serogroups 1, 4, and 5 (including the strains studied by Garrity) and an unnumbered serotype, Lansing 3. The analysis suggested that these two clones represented two species closely related but not identical to *L. pneumophila* (Selander et al., 1985). Upon further examination of their DNA, Brenner et al. 1988) also concluded that these two groups of clones form two distinct DNA hybridization groups. Organisms within each group are highly related (88–98%) to each other but were only distantly related (40–50% under stringent conditions) to *L. pneumophila,* with which most isolates share common antigens. Since these organisms can only be differentiated from each other in most cases by DNA hybridization studies rather than phenotypic testing, it was proposed that the species *L. pneumophila* be divided into three subspecies. The species formerly known as *L. pneumophila* was changed to *L. pneumophila* subsp. *pneumophila.* The second hybridization group was named *L. pneumophila* subsp. *fraseri,* and the third group, *L. pneumophila* subsp. *pascullei* (Brenner et al., 1988). While the creation of these subspecies is of taxonomic importance, the use of the subspecific epithets will be limited to those few laboratories that can identify *L. pneumophila* to this level.

The taxonomy of the legionellae has been challenged at the genus level by Garrity et al. (1980) and Brown et al. (1981), who examined *L. micdadei, L. bozemanii, L. dumoffii,* and *L. gormanii* by DNA hybridization. Their reported hybridization values were virtually identical to those reported by others (Brenner et al., 1980) and showed that these species are less than 25% related to *L. pneumophila.* These workers suggested that organisms that were less than 25% related to each other should be placed in separate genera and proposed the genus *Tatlockia* for *L. micdadei (T. micdadei),* and *Fluoribacter* for the autofluorescent species *L. bozemanii (F. bozemanae)* (sic), *L. dumoffii (F. dumoffii),* and *L. gormanii (F. gormanii).*

The controversy over the classification of the legionellae centers not on the degree of relatedness between the species tested, since both research groups have produced identical values, but lies in the interpretation of the data relative to what constitutes a genetic definition of a genus. Brenner (1987) has stated that there is no accepted definition of a species at the genetic level and that a genus should include organisms that are phenotypically related and show some degree of genetic relatedness. He suggests that the common ecological niche, metabolic pathways, pathologic features, antimicrobial susceptibility, and antigens shared by these organisms should also be taken into account along with their degree of genetic relatedness in the practical definition of a genus. It would appear that most agree with the proposal of Brenner et al (1979) because the generic designation *Legionella* is used almost exclusively in the scientific literature.

Habitat and Reservoirs

Natural Habitats

The legionellae are widely distributed in nature and seem to prefer moist environments. In addition to their isolation from cooling towers, water distribution systems, and various medical devices already mentioned, they have been isolated form a wide range of natural and artificial habitats, which include rivers, lakes, streams, and riparian soil (Fliermans et al., 1981). They have been isolated from water at temperatures ranging from 5–65°C and survive and multiply (in water) over a pH range of 5.5–9 (Fliermans et al., 1981; States et al., 1987b).

Reservoirs

One of the earliest recognized outbreaks of Legionnaires' disease occurred among patients in a psychiatric hospital in Washington, DC (Thacker et al., 1978) and nosocomial Legionnaires' disease outbreaks were recognized at

many institutions during the 1980s. It is through the investigation of such outbreaks that we have come to gain an appreciation of the ubiquitous distribution of the legionellae and their relationship to our natural and inanimate environment. The first association between *L. pneumophila* and water distribution systems occurred when the organism was isolated from the shower fixtures in the rooms of two renal transplant patients who had contracted Legionnaires' disease (Tobin et al., 1980). This observation was followed by many others, which also indicated that *Legionella* could be recovered from the potable water supply of large buildings and from equipment that came in contact with tap water (Shands et al., 1985; Edelstein et al., 1986; Helms et al., 1983). Legionellae have been found in numerous locations, such as showers (Tobin et al., 1980; Cordes et al., 1981) and faucets (Stout et al., 1985; Wadowsky et al., 1982), and ice machines (Stout et al., 1985). It is not surprising, then, that the legionellae are found in water-containing devices such as respiratory therapy equipment (Arnow et al., 1982; Gorman et al., 1980) and even a room humidifier (Zuravleff et al., 1983). They have also been found in both therapeutic and recreational whirlpool baths (Mangione et al., 1985; Brabender et al., 1983). The major source of legionellae that contaminate these devices appears to be the hotwater distribution system (FischerHoch et al., 1981; Wadowsky et al., 1982; Helms et al., 1983).

The source of the bacteria that ultimately colonize water distribution systems appears to be the municipal water distribution system, which may harbor the organism in small numbers (States et al., 1987). Reservoirs of warm water, such as hotwater tanks, then serve as efficient bacterial "amplifiers," allowing small numbers of the bacteria to multiply and subsequently colonize the water distribution system. Multiplication of the legionellae under such circumstances in water distribution systems appears to be enhanced by the presence of sediment and other microorganisms (Wadowsky and yee, 1985) and even by some components of the system such as faucet washers made from certain types of rubber (Colbourne et al., 1984). Legionellae have been detected in the home water systems of some, but not all, patients with community-acquired Legionnaires' disease (Stout et al., 1987).

Air conditioning cooling towers, which usually harbor a bacterial flora, also often contain legionellae (Dondero et al., 1980; Orrison et al., 1981; Girod et al., 1982). The source of legionellae that colonize cooling towers is also most likely the municipal water supply used to fill such systems. Again, because of their heat-exchanging function, cooling towers serve as amplifiers of legionellae. Bacteria-laden water vapor from cooling towers can travel long distances (Shands et al., 1985) and has even entered a building by traveling down an open chimney (Band et al., 1981).

While the epidemiologic associations between environmental contamination and Legionnaires' disease are strong, these organisms have also been isolated without any disease association (Bartlett et al., 1983). The reasons why Legionnaires' disease does not always occur in the presence of a contaminated water supply or cooling tower is not yet known. One very interesting hypothesis is that not all legionellae are of equal virulence. Plouffe et al. (1983) described the isolation of two different strains of *L. pneumophila* serogroup 1 from separate hospital buildings. Legionnaires' disease occurred in only one of the buildings and was caused by the strain associated with that building. Subsequent studies of the two strains in animals indeed suggested that one was more virulent than the other (Bolin et al., 1985).

Methods for the Control of Legionellae

A number of methods have been used for the control of legionellae in mechanical systems. Chlorination of building water systems has been shown to be very effective in eliminating the legionellae from potable water distribution systems (Fisher-Hoch et al., 1981; Shands et al., 1985; Helms et al., 1983). Most workers have employed initial shock chlorination of the water supply, followed by maintenance treatment with 1–5 ppm of free available chlorine. The major drawbacks of this method appear to be corrosion of the plumbing system and the potential for formation of toxic and/or carcinogenic trihalomethanes (Helms et al., 1988).

Elevation of the temperature of building hotwater systems to temperatures between 60 and 80°C has also been used to eliminate legionellae from plumbing systems both alone and in combination with chlorination (Fisher-Hoch et al. 1981; Best et al., 1983). This method is effective in reducing the numbers of legionellae in the plumbing system, but also increases the risk of scalding. Intermittent raising of the temperature followed by flushing of the hot water through all building fixtures is effective, but requires a highly coordinated staff to carry out. Treatment of a hospital water supply with ultraviolet radiation has also been used to elim-

inate legionellae (Farr et al., 1988). Ozone treatment also appeared to be effective in reducing the numbers of legionellae in a single study (Edelstein et al., 1982). No controlled comparisons of the various disinfection methods have been carried out. Each of the methods has been shown to be efficacious in the studies mentioned above and also under more controlled circumstances in a model plumbing system (Muraca et al., 1987).

Control of legionellae in cooling towers has been much more difficult, both because of their mechanical and biological complexity. In vitro studies have demonstrated that the legionellae are susceptible to a number of commonly used colling tower biocides (Grace et al., 1981; Skaliy et al., 1980). In use, however, biocides alone have failed to prevent multiplication of legionellae in cooling towers. Many factors are undoubtedly responsible for this, including inactivation of biocides by aeration and/or light, the presence of large amounts of biofilm, and the presence of other microorganisms that may protect the bacteria from inactivation (England et al., 1982; Kurtz et al., 1982). Chlorine has also been the most reliable decontaminating agent used to date, but its use is not simple because of corrosion problems (Fliermans et al., 1982; States et al., 1987b). Cooling tower maintenance programs are further complicated by the need to add antifouling and anticorrosion agents.

Relationships with Other Microorganisms

Symbiosis with Prokaryotes

A novel and probably important aspect of the ecology of the legionellae is their apparent symbiotic relationship with other members of their ecosystem. Early studies (Wadowsky et al., 1982) suggested that legionellae were found in greatest numbers at the botton of hotwater tanks and were often found in association with the sediment at the bottom of the tank. A strain of *Flavobacterium breve* present in one water system when cocultivated with *L. pneumophila* eliminated the need to supplement the medium with cysteine (Wadowsky and Yee, 1983). Other heterotrophic bacteria present in tap water are also capable of stimulating the growth of legionellae in cysteine-deficient media, but do not appear to stimulate the growth of these bacteria in water cultures (Wadowsky and Yee, 1985). Photosynthetic cyanobacteria (*Fischerella* sp.), which were recovered from an algal mat that also contained *L. pneumophila,* have also been shown to stimulate multiplication of *L. pneumohila* in mineral salts medium (Tison et al., 1980). The exact role of these organisms in the ecology of legionellae is not clear since these photosynthetic cyanobacteria require light and would not be expected to be present in mechanical systems such as water distribution systems.

Symbiosis with Eukaryotes

Studies of legionellae growth in tap water cultures demonstrated that a factor that was retained by 1-μm membrane filters supported the growth of *L. pneumophila. Hartmanella vermiformis* and two other species of hartmanellid amoebae were isolated from the filter retentates and shown to be capable of supporting the growth of *L. pneumophila* in tap water (Fig. 3). A number of other free-living eukaryotes were also shown to be capable of supporting the growth of the legionellae. Rowbotham et al. (1980) demonstrated that the free-living amoebae *Acanthamoeba* and *Naegleria* can become infected with legionellae. A similar growth-promoting ability has been demonstrated for the ciliate *Tetrahymena pyiriformis* (Fields et al., 1984). Clear proof of the role of these organisms in the multiplication or dissemination of legionellae to humans is still lacking, probably due in large part to the difficulty in reliably cultivating protozoa from water sources. One group (Barbaree et al., 1986) recovered ciliated protozoa from an air conditioning tower that was associated with an outbreak of legionnaires disease. *L. pneumophila* could infect and multiply within the ciliate in vitro. More reliable methods for determining the presence of various protozoal species in water systems are required.

Given that the intracellular milieu of the human monocyte is remarkably similar (see Figs. 2 and 3) to that of these one-celled organisms, many speculate that the legionellae have adapted to multiplication in human monocytes by co-evolving in the natural environment with simple protozoa. Indeed, one study has suggested that virulent *L. pneumophila* multiply more rapidly in ciliated protozoa than avirulent strains (Fields et al., 1986). Likewise, just as their intracellular location protects the legionellae from the action of many antimicrobial agents in humans, it is equally possible that residence within these protozoa provides the legionellae with nutritional support while at the same time protecting legionellae from environmental stress, including disinfecting agents added by humans to control the bacteria in mechanical systems.

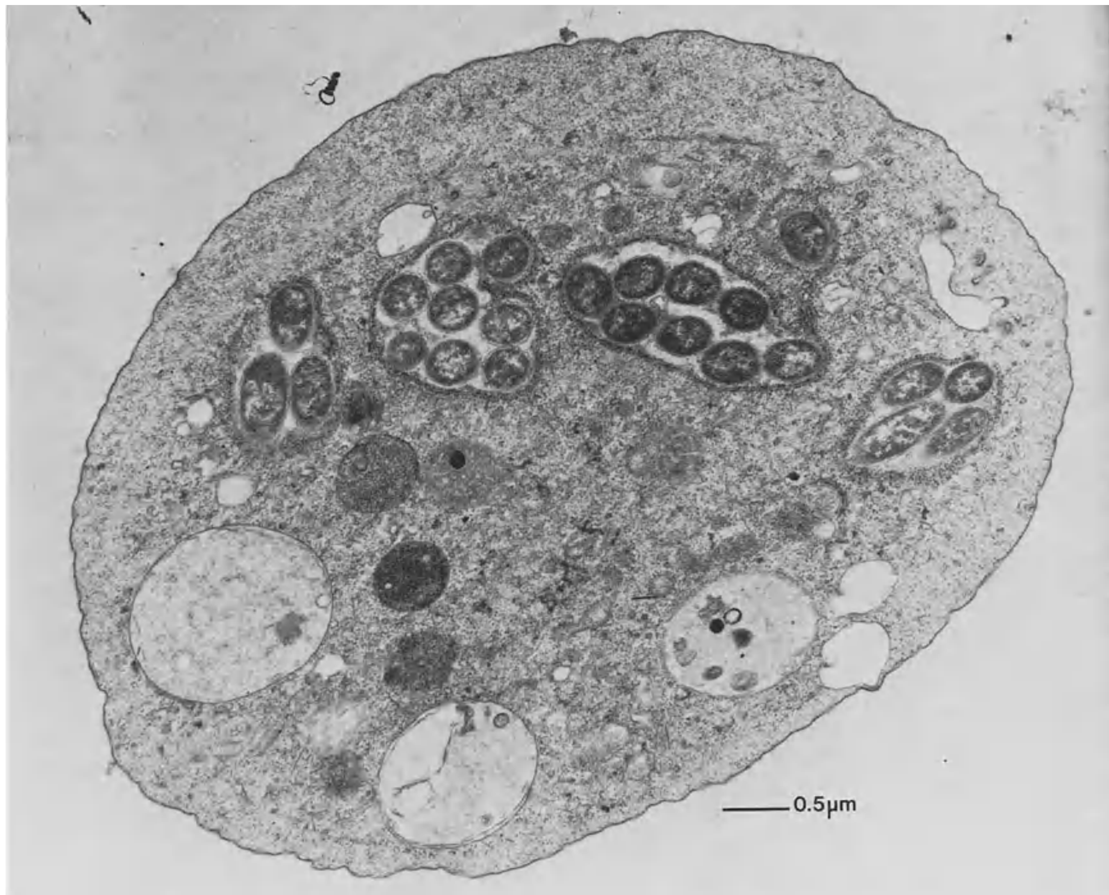

Fig. 3. Transmission electron micrograph of the free-living amoeba, *Hartmannella vermiformis,* infected with *Legionella pneumophila* serogroup 1. *Legionella* cells are multiplying within vesicles studded with ribosomes. CHAPTER 179

The Genus *Haemophilus*

SUSAN K. HOISETH

The genus *Haemophilus* is traditionally defined as being comprised of small, pleomorphic, Gram-negative rods (often coccobacilli) with growth requirements for one or more factors present in blood (NAD and/or hemin); hence the name *Haemophilus* (blood-loving). This is a diverse genus, comprised of both animal and human pathogens, as well as a number of species that are primarily commensals of the mucous membranes. The organisms are not free-living in nature.

The type species, *H. influenzae,* was described by Pfeiffer in 1892 and was erroneously thought to be the cause of influenza. The reason for this error probably lies in the fact that even though it is not the cause of influenza, *H. influenzae* can often be isolated in high numbers from the respiratory tract of individuals infected with influenza virus. *H. influenzae* is, however, a pathogen in its own right and is the leading cause of bacterial meningitis in the United States (Schlech et al., 1985). It also causes other invasive diseases (epiglottitis, arthritis, pneumonia, cellulitis, septicemia), primarily of children (see below).

The taxonomy of this genus has been subject to many changes and is still undergoing considerable revision. The genus *Haemophilus* was at one time included in the family Brucellaceae (Breed et al., 1957); it was included with "Genera of Uncertain Affiliation" in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Zinnemann and Biberstein, 1974) and was only recently included (along with *Actinobacillus* and *Pasteurella*) in the family Pasteurellaceae (Kilian and Biberstein, 1984). In contrast to the nonfermentative Brucellaceae, the haemophili are heterofermentative (with the possible exception of *H. ducreyi,* see below). All reduce nitrate to nitrite or beyond and are facultative anaerobes.

The haemophili are closely related to the actinobacilli and pasteurellae, and some investigators feel that based on DNA hybridization studies and rRNA sequences, *Actinobacillus actinomycetemcomitans* is more closely related to members of the genus *Haemophilus* than to other actinobacilli and should be placed in the genus *Haemophilus* (Potts et al., 1985; Chuba et al., 1988). Conversely, it has been suggested (and fairly well accepted) that *Haemophilus pleuropneumoniae* is more closely related to the actinobacilli than to other species of *Haemophilus* and should be placed in the genus *Actinobacillus* (Pohl et al., 1983). There are significant relationships between members of all three genera, and some species could be placed in one or more of these genera. Some of the taxonomic difficulties stem from the traditional definition of the genus *Haemophilus* based on requirements for NAD and/or hemin. *H. aphrophilus* has been reported to require hemin for primary isolation, but not usually for subsequent subculture (Kilian and Biberstein, 1984); it has the enzymes necessary to convert δ-aminolevulinic acid to protoporphyrin (White and Granick, 1963) and is therefore different from other hemin-requiring *Haemophilus* species. Since it also does not require NAD, the taxonomic position of *H. aphrophilus* has been questioned. *H. ducreyi* requires hemin, but based on a number of other criteria, may not be a valid *Haemophilus* species (Casin et al., 1985). Strains that were traditionally defined as *Haemophilus pleuropneumoniae* require NAD; there are however, strains associated with pleuropneumonia of pigs that resemble *H. pleuropneumoniae* but which do not require NAD. *H. avium* requires NAD, but may be more closely related to *Pasteurella multocida* (the type species of the genus *Pasteurella*) than to *H. influenzae,* and Mutters et al. (1985) have proposed transfer of *H. avium* to the genus *Pasteurella.*

Because the structure of the family Pasteurellaceae is undergoing considerable realignment, and the position of many species is still unsettled, I will for the purposes of this chapter discuss the traditionally defined *Haemophilus* species as they were listed in *Bergey's Manual of Systematic Bacteriology* (Kilian and Biberstein, 1984). I will note, where appropriate, the changes that have been proposed since 1984.

One of the most significant observations may be that of Niven and O'Reilly (1990), who suggest that inability to amidate the carbonyl group of nicotinic acid may be a characteristic of the entire family Pasteurellaceae; thus, all members of the Pasteurellaceae may require as a minimum, preformed nicotinamide (which is present in most complex media). Only certain species, however, are unable to add a phosphoribosyl group to nicotinamide, and therefore have a requirement for intact nicotinamide adenine dinucleotide (or nicotinamide mononucleotide or nicotinamide riboside, all of which are heat labile and/or otherwise lacking in most culture media). Although most members of the genus *Haemophilus* require NAD and/or hemin, these requirements may also appear in other members of the family Pasteurellaceae. A redefinition of the individual genera within the family is thus needed.

Bergey's Manual of Systematic Bacteriology (Kilian and Biberstein, 1984) included 16 species in the genus *Haemophilus* and listed three additional organisms as "species incertae sedis." Since the animal species rarely infect humans and vice versa, the individual *Haemophilus* species will be discussed in terms of their host origin.

Human Isolates

The human isolates include *H. influenzae, H. aegyptius, H. haemolyticus, H. ducreyi, H. parainfluenzae, H. parahaemolyticus, H. paraphrohaemolyticus, H. aphrophilus, H. paraphrophilus,* and *H. segnis* (Table 1). Of these, *H. influenzae, H. aegyptius,* and *H. haemolyticus* require both hemin and NAD; *H. ducreyi* only requires hemin (X factor), and *H. parainfluenzae, H. parahaemolyticus, H. paraphrohaemolyticus, H. paraphrophilus,* and *H. segnis* only require NAD (V factor). As mentioned earlier, *H. aphrophilus* sometimes requires hemin for primary isolation but not usually thereafter.

Animal Isolates

Haemophilus species isolated from animals include *H. parasuis* and *H. pleuropneumoniae* (from pigs), *H. paragallinarum* and *H. avium* (from poultry), *H. haemoglobinophilus* (from dogs), and *H. paracuniculus* (from rabbits). Of the three species listed as "incertae sedis," *"H. somnus"* is isolated from cases of bovine septicemia and meningoencephalitis (Kirkham et al., 1989); *"H. agni"* causes septicemia of lambs (Kirkham et al., 1989), and *"H. equigenitalis"* is the causative agent of contagious equine metritis (Taylor et al., 1978).

H. equigenitalis is not a "good" *Haemophilus* species; it does not require NAD or hemin (Sugimoto et al., 1983), does not reduce nitrate (Rossau et al., 1987), and does not ferment sugars (Taylor et al., 1978). Sugimoto et al. (1983) have proposed transfer of this organism to a new genus, *Taylorella,* as *Taylorella equigenitalis* comb. nov. This organism is not related to any of the Pasteurellaceae and the International Committee on Systematic Bacteriology (ICSB), Subcommittee on Pasteurellaceae has rejected it from the family (Frederiksen, 1987). The closest relatives of *T. equigenitalis* appear to be the family Alcaligenaceae and the newly proposed genus *Oligella* (Rossau et al., 1987); this organism will not be discussed further.

The remaining "species incertae sedis," *"H. somnus"* (isolated from cattle) and *"H. agni"* (isolated from lambs), are closely related and may represent host-specific subgroups of the same species (Kirkham et al., 1989). Both are related to a third group of organisms named *"Histophilus ovis." "H. ovis"* has been associ-

Table 1. The Genus *Haemophilus*.[a]

Host origin	NAD- and hemin-dependent species	NAD-dependent species	Hemin-dependent species	NAD- and hemin-independent species
Humans	*H. influenzae* *H. aegyptius* *H. haemolyticus*	*H. parainfluenzae* *H. parahaemolyticus* *H. paraphrohaemolyticus* *H. paraphrophilus* *H. segnis*	*H. ducreyi*	*H. aphrophilus*
Pigs		*H. parasuis* *H. pleuropneumoniae*		
Poultry		*H. paragallinarum* *H. avium*		
Dogs			*H. haemoglobinophilus*	
Rabbits		*H. paracuniculus*		

[a]Members of the genus according to Kilian and Biberstein, 1984.

ated with suppurative mastitis of sheep and epididymitis of rams (Walker et al., 1985). All three organisms are small, pleomorphic rods or coccobacilli and have fastidious growth requirements (optimal growth on chocolate or enriched blood agar with 5–10% CO_2); in this sense they resemble the haemophili. There is however, no specific growth response to NAD and/or hemin (Kilian and Biberstein, 1984). Based on DNA hybridization analyses, all three organisms appear highly related (Walker et al., 1985; Piechulla et al., 1986); they do not, however, appear to be significantly related to *H. influenzae* or *H. parainfluenzae*. Piechulla et al. (1986) found some binding to *H. haemoglobinophilus* DNA but did not recommend inclusion in the genus *Haemophilus* via *H. haemoglobinophilus*. There have been suggestions that the genus *Histophilus* be revived to accommodate these organisms (Piechulla et al., 1986) and the Subcommittee on Pasteurellaceae felt that such a genus could be accommodated in the family Pasteurellaceae (Frederiksen, 1987). These organisms will not be discussed further.

In addition to the above-named species, it has been reported that *Haemophilus*-like organisms can be isolated from the mucous membranes of the respiratory tract, mouth, or genitals of a wide variety of animals (Kilian and Frederiksen, 1981, and references therein). Most of these isolates have not been well characterized, although Nicklas (1989) has published a detailed description of NAD-dependent organisms isolated from rats.

Habitats/Pathogenesis

NAD- and Hemin-Dependent Human Isolates

H. HAEMOLYTICUS. *H. haemolyticus* is an occasional member of the normal pharyngeal flora (Kawakami et al., 1982; Kuklinska and Kilian, 1984); it rarely, if ever, causes disease (Albritton, 1982).

H. INFLUENZAE. The habitat for *H. influenzae* is mainly the upper respiratory tract (oro- and nasopharynx), where it is frequently present as part of the normal flora. The species contains both encapsulated and nonencapsulated forms (Pittman, 1931). As many as 50–80% of individuals may be colonized with nonencapsulated strains, whereas carriage rates for encapsulated strains are much lower (2–4% for type b strains and 1–2% for other capsule types; Turk, 1984). Disease, however, does occur in some individuals. The spectrum of disease caused by encapsulated and nonencapsulated strains is quite distinct. More than 95% of invasive *H. influenzae* disease (meningitis, epiglottitis, cellulitis, pneumonia, septicemia, septic arthritis) is caused by encapsulated type b strains; the majority of cases occur in children less than five years of age (peak age incidence six months to two years; Cochi et al., 1985). Antibody to the capsular polysaccharide is known to be protective (Peltola et al., 1977), and most adults have protective antibody levels. What is not known is why some infants succumb to disease whereas other infants (even though susceptible) become colonized but do not become ill (Moxon, 1986). The other *H. influenzae* capsule types (a, c–f) are only rarely isolated from cases of systemic disease. Nonencapsulated strains, while common members of the normal upper respiratory flora, are only rarely isolated from cases of systemic disease (and then patients are usually neonates, elderly, or have other underlying disease; see below). Nonencapsulated strains are, however, frequently isolated from localized diseases, especially otitis media (Turk, 1982); they also cause sinusitis and are implicated in exacerbations of chronic bronchitis (Turk, 1982).

Epidemiological studies suggest that there are approximately 12,000 cases of *H. influenzae* type b meningitis per year in the United States; an additional 7,500 cases of other invasive diseases due to type b strains also occur (Cochi et al., 1985). Because of the severity of the disease, and the fact that a significant number of survivors are left with neurologic deficits (Ferry et al., 1982), a great deal of work has been focused on the development of an *H. influenzae* type b vaccine. Antibody directed against the type b capsule is protective (Peltola et al., 1977), and vaccines aimed at eliciting anticapsular antibodies have recently been licensed. The first-generation vaccine, licensed in the USA in 1985, contained purified capsular polysaccharide and was recommended for use in children at 24 months of age or greater (Immunization Practices Advisory Committee, 1985). The problem with this vaccine is that the purified capsular polysaccharide is not a good immunogen in infants less than 24 months of age (the age group with the highest incidence of disease). Progress has been made in improving the immunogenicity of the vaccine by coupling the polysaccharide to protein carriers (Schneerson et al., 1980; Anderson et al., 1985; Weinberg and Granoff, 1988). A conjugate vaccine was originally approved for use in infants at 18 months of age (Immunization Practices Advisory Committee, 1988), and field trials are underway to determine the efficacy in younger age groups. Data from a large trial in Finland are encour-

aging (Eskola et al., 1987), and a conjugate vaccine was licensed in the USA in October of 1990 for use at two months of age.

Although viewed primarily as an inhabitant of the upper respiratory mucosa, *H. influenzae* is also capable of colonizing the genital mucosa. It is occasionally implicated in genital tract infections (Wallace et al., 1983; Quentin et al., 1989), and like other organisms capable of colonizing the vagina and cervix, it is occasionally associated with neonatal and obstetrical infections (Khuri-Bulos and McIntosh, 1975; Wallace et al., 1983; Friesen and Cho, 1986; Milne et al., 1988). Although only a small percentage (<1%, Khuri-Bulos and McIntosh, 1975; 0.3 to 0.5%, Albritton et al., 1982) of pregnant women were found to carry *H. influenzae* in their cervix or vagina, a number of studies have suggested that transmission to the infant during or prior to delivery can occur. In their study of eight cases of *H. influenzae* neonatal infection, Khuri-Bulos and McIntosh (1975) found evidence of genitourinary colonization with *H. influenzae* in all eight mothers. A number of more recent reports support this observation (Wallace et al., 1983; Campognone and Singer, 1986; Quentin et al., 1989). Although still moderately low (0.14 to 0.59 per 1,000 live births), the reported incidence of neonatal septicemia due to *H. influenzae* appears to be increasing (Wallace et al., 1983; Milne et al., 1988; Quentin et al., 1989). In contrast to *H. influenzae* meningitis in the pediatric patient (where most strains are encapsulated type b), many of the neonatal isolates are nonencapsulated (Wallace et al., 1983; Campognone and Singer, 1986; Friesen and Cho, 1986; Quentin et al., 1989). Vaccines directed against the type b capsular polysaccharide will not be effective in preventing disease due to nonencapsulated strains.

It is often stated that *H. influenzae* has no nonhuman hosts. This is not completely true, as *H. influenzae* (including encapsulated type b) has been isolated from the respiratory tract of naturally infected chimpanzees (Dochez et al., 1932). *H. influenzae* has also been reported to cause bacteremic pneumonia in monkeys (Good and May, 1971), and McClure (1980) reported a variety of naturally occurring *H. influenzae* infections in nonhuman primates. Dawkins (1982) reports a case of septic arthritis in a cynomolgus monkey. It is not known whether primates are colonized with *H. influenzae* in their native environment or whether they are accidentally infected via humans.

Infant monkeys have been used as an experimental model to study *H. influenzae* pathogenesis (Scheifele et al., 1980), although an infant rat model is more commonly used (Moxon et al., 1974; Smith et al., 1973). Rats are not naturally colonized with *H. influenzae,* but can be infected experimentally. The ability to infect rats decreases with the age of the rat, and unlike the human situation, resistance to infection in older rats is not due to anticapsular antibody (Smith et al., 1973). Infant rats are however, a good model in which to study the progression from nasopharyngeal colonization, to bacteremia, to meningitis.

H. AEGYPTIUS. *H. aegyptius* has traditionally been associated with acute conjunctivitis, particularly in warm climates (Pittman and Davis, 1950; Mazloum et al., 1982). The taxonomic status of this "species," however, is controversial (Pittman and Davis, 1950; Kilian et al., 1976; Martel et al., 1986; Casin et al., 1986; Mazloum et al., 1982). Koch (1883) first observed small bacilli in smears of exudates from the eyes of Egyptian children suffering from conjunctivitis. Weeks (1886) cultured what was assumed to be a similar organism from cases of conjunctivitis in New York. For many years, *Haemophilus*-like organisms, isolated from cases of conjunctivitis, were referred to as the Koch-Weeks bacillus; it was not clear how (or if) they differed from *H. influenzae;* some investigators attempted to make a distinction between *H. influenzae* and the Koch-Weeks bacillus, whereas others did not. Pittman and Davis (1950) proposed use of the name *H. aegyptius* for certain of the conjunctivitis-associated isolates. They suggested that *H. aegyptius* could be distinguished from nonencapsulated *H. influenzae* on the basis of its slightly more elongated cellular morphology, its inability to ferment xylose, the more fluffy, cometlike appearance of its colonies in semisolid agar, and its ability to agglutinate red blood cells. They also detected differences in serology between *H. aegyptius* and nonencapsulated *H. influenzae.* Their criteria have not, however, in subsequent studies allowed unambiguous distinction between *H. influenzae* and *H. aegyptius;* some isolates of *H. influenzae* also fail to ferment xylose (Brenner et al., 1988; Hollis et al., 1980). The hemagglutinating property is unstable, and can be lost on subculture (Kilian et al., 1976); furthermore, other *Haemophilus* isolates can exhibit hemagglutinating properties. Mazloum et al., (1982) proposed that *H. aegyptius* could be separated from *H. influenzae* on the basis of its inability to grow on tryptic soy agar with NAD and hemin, and by its susceptibility to troleandomycin. These tests have also not allowed unambiguous distinction between the two "species" (Carlone et al., 1985; Martel et al., 1986). Despite the confusion, the clinical picture sug-

gests that certain strains may be more likely than others to cause the highly contagious, epidemic form of conjunctivitis, especially in warm climates. Unfortunately, the characteristics that could be used to unambiguously identify such strains are not yet established. What is clear is that strains of *H. influenzae* that do *not* fit the classical description of *H. aegyptius* can also cause conjunctivitis (Pittman and Davis, 1950; Kilian et al., 1976); *H. parainfluenzae* is also occasionally isolated (Kilian et al., 1976).

The problems in distinguishing *H. aegyptius* from *H. influenzae* are not surprising in view of the high level of genetic relatedness between the two organisms. Pohl (1981), in his DNA relatedness study, reported 80% binding between *H. aegyptius* and *H. influenzae* DNA (three strains of *H. influenzae,* including the type strain, NCTC 8143, and two strains of *H. aegyptius,* including the type strain ATCC 11116, were included in his analysis). Albritton et al. (1984) reported 90% binding between the type strains of *H. aegyptius* and *H. influenzae.* Except for one strain of *H. aegyptius* (which bound *H. influenzae* DNA at levels of only 63–66%), Casin et al. (1986) also found high (80–90%) levels of binding between the type strains of *H. influenzae* and *H. aegyptius* and several other strains of each "species." Included in this study were three of the *H. aegyptius* isolates described by Pittman and Davis (1950). DNA binding levels of 70% or greater are generally taken as indicative of species identity (Brenner et al., 1982), suggesting that a distinction between *H. aegyptius* and *H. influenzae* may be unwarranted.

Interest in distinguishing these organisms, however, has recently been spurred by the finding that *"H. aegyptius"* is responsible for the newly described disease, Brazilian Purpuric Fever (BPF) (Brazilian Purpuric Fever Study Group, 1987a). This disease is characterized by a rapid onset of fever, often accompanied by vomiting and abdominal pain; in the absence of treatment there is a rapid progression to petechiae, purpura, vascular collapse, hypotensive shock, and death, usually within 48 hours of onset (Brazilian Purpuric Fever Study Group, 1987a, 1987b). Epidemiological investigations revealed an association with a preceding purulent conjunctivitis. An organism labelled *H. influenzae* biogroup aegyptius (to emphasize its relatedness to *H. influenzae*) was isolated from cases of conjunctivitis, and eventually (once proper blood culture techniques were initiated), from the blood of individuals during the purpuric stage (Brazilian Purpuric Fever Study Group, 1987a, 1987b). This is the first time *"H. aegyptius"* has been reported to cause anything more than conjunctivitis. Fortunately, cases have been limited to certain regions of Brazil, with two additional cases reported in Australia; the patients are young children, with a median age of 30 months (Harrison et al., 1989).

Extensive characterization (including plasmid profiles, outer membrane protein profiles, and multilocus enzyme typing) revealed that the BPF case isolates constituted a single clone of *H. aegyptius* (Brenner et al., 1988), and that there was a high degree of DNA homology between case isolates and reference strains of both *H. aegyptius* (including three of the Pittman and Davis isolates) and *H. influenzae* (averages of 88 and 85%, respectively). These results again confirmed the high level of genetic relatedness between isolates labeled *"H. aegyptius"* and *H. influenzae;* these investigators proposed use of the name *H. influenzae* biogroup aegyptius to emphasize this fact.

The occurrence of Brazilian Purpuric Fever raises a number of interesting questions concerning the evolutionary history of the organism involved. The factors responsible for the unique virulence potential of this organism are not known, although a number of potential factors have been examined (Carlone et al., 1989). The case clone differs from other *H. influenzae* biogroup aegyptius strains in several respects and may represent a "new" clone with unique pathogenic properties. Musser and Selander (1990) compared the relatedness of the case clone to other isolates of *H. influenzae* and *H. aegyptius* by the technique of multilocus enzyme typing (ET) and found that the closest relatives of the BPF clone are type c strains of *H. influenzae.* Although the case isolates do not appear to be encapsulated (Brenner et al., 1988), they do have some homology to an *H. influenzae* capsular gene probe (S. Hoiseth, unpublished observations; Carlone et al., 1989), and unlike other isolates of *"H. aegyptius"* (which produce a type 1 IgA protease), the BPF clone produces a type 2 IgA protease (as do type c *H. influenzae;* Carlone et al., 1989). Non-BPF isolates of *"H. aegyptius"* fell into two additional clusters on the *H. influenzae* ET dendrogram (Musser and Selander, 1990), again confirming the close relationship of *"H. aegyptius"* and *H. influenzae.* Clearly, additional work needs to be done to define the genetic relationships and pathogenic potential of the BPF isolates and established *Haemophilus* species.

NAD-Dependent Human Isolates

H. PARAINFLUENZAE, H. PARAHAEMOLYTICUS, H. PARAPHROHAEMOLYTICUS, H. SEGNIS, AND *H. PARAPHROPHILUS.* These organisms are part of

the normal flora of the oral cavity and pharynx. Unlike *H. influenzae,* which seems to be confined to the pharyngeal mucosa, *H. parainfluenzae* is frequently found in both the pharynx (Kuklinska and Kilian, 1984) and the oral cavity (mean counts in saliva of approximately 4 $\times 10^7$/ml, representing approximately 10% of the cultivable flora; Kilian and Schiott, 1975). It is also found in dental plaque (Kilian and Schiott, 1975; Liljemark et al., 1984). *H. segnis* and *H. paraphrophilus* are also found in the normal pharynx (Kuklinska and Kilian, 1984) and saliva (Kilian and Schiott, 1975) but much less frequently than *H. parainfluenzae. H. segnis* and *H. paraphrophilus* are more likely to be found in dental plaque than in saliva (Kilian and Schiott, 1975). Liljemark et al., (1984) found that a large percentage (98%) of individuals have *Haemophilus* species in their dental plaque; the total number of haemophili relative to other organisms, however, is low (in only 20% of the sites sampled did the proportion of *Haemophilus* exceed 5.9% of the total cultivable organisms; 50% of the sites had 1.5% or fewer *Haemophilus* organisms).

The oral haemophili are only rarely associated with disease. Like other members of the oral flora, they occasionally cause endocarditis; even more rarely, they are associated with brain abscesses, pneumonia, osteomyelitis, septicemia, and other miscellaneous infections (Albritton, 1982). *H. parainfluenzae* has been reported as a rare cause of meningitis (Albritton, 1982, cited 22 cases reported in the English literature between 1966 and 1980). *H. parainfluenzae* has also been implicated in genital tract infections (Sturm, 1986; Quentin et al., 1989) although it probably acts mainly as an opportunistic pathogen (e.g., many of the cases reported by Quentin et al. were associated with the use of an intrauterine device). The most recently described species, *H. segnis* (Kilian, 1976), has been isolated from several cases of appendicitis (Welch et al., 1986), from a pancreatic abscess in a 29-year-old alcoholic (Bullock and Devitt, 1981), and from a case of endocarditis (Bangsborg et al., 1988).

In his review of "Infections due to *Haemophilus* species other than *H. influenzae,*" Albritton (1982) emphasized (and rightly so) that many of the organisms reported may have been improperly speciated. This is especially true for the distinction between *H. parainfluenzae* and *H. paraphrophilus.* The tests to distinguish *H. parainfluenzae* from *H. paraphrophilus* are few (primarily lactose fermentation; see "Identification") and are often not done. The rationale for the distinction between *H. parainfluenzae, H. parahaemolyticus,* and *H. paraphrohaemolyticus* has been questioned (Kilian, 1976). *H. parahaemolyticus* is distinguished from *H. parainfluenzae* by its hemolytic activity (Pittman, 1953); this trait can, however, be lost on subculture (Kilian, 1976). *H. paraphrohaemolyticus* is distinguished from *H. parahaemolyticus* on the basis of its CO_2 dependence (Zinnemann et al., 1971), another trait that can be lost on subculture. Kilian (1976) has suggested that *H. parahaemolyticus* and *H. paraphrohaemolyticus* do not warrant species status, and he included them with *H. parainfluenzae. H. parahaemolyticus* and *H. paraphrohaemolyticus* were, however, included as separate species in *Bergey's Manual of Systematic Bacteriology* (Kilian and Biberstein, 1984), and the type strain of *H. parahaemolyticus* (NCTC 8479) does not appear to be related to strains of *H. parainfluenzae* when tested by DNA hybridization analysis (Pohl, 1981). In practice, the tests to distinguish these "species" are often not done. Of the 55 reports of *H. parainfluenzae* infection reviewed by Black et al. (1988), hemolysis testing was done for only 31. Many of the reports would also not have distinguished *H. parainfluenzae* from *H. paraphrophilus.* The distinction of *H. segnis* may also be problematic. This species was proposed by Kilian (1976) on the basis of its relatively high GC content and weak fermentation activity. It is difficult to distinguish from the other NAD-dependent haemophili, and as pointed out by Albritton (1982), will very likely be reported as *H. parainfluenzae* by most clinical laboratories.

In reviewing the literature on infections due to NAD-dependent *Haemophilus* species, one must keep in mind that there is often insufficient information to assign a species name (though one is generally reported). One must also keep in mind that the tests to distinguish these organisms are few, that some species distinctions may be unwarranted, and that additional taxonomic studies are needed.

Hemin-Dependent Human Isolates

H. DUCREYI. *H. ducreyi* is the causative agent of the sexually transmitted disease, chancroid (soft chancre). The disease is common in tropical or subtropical areas, but has been considered uncommon in developed countries such as the USA (Morse, 1989). The number of cases in the USA, however, has risen considerably over the past several years. There were an average of just under 1,000 cases per year throughout much of the 1960s, 1970s, and early 1980s; by 1987 there were over 5,000 cases reported per year (Morse, 1989).

H. ducreyi produces genital ulcers and localized adenitis, but has not been reported to cause

systemic infection; untreated ulcers can, however, become superinfected with other microorganisms, resulting in extensive tissue destruction (Morse, 1989). D'Costa et al. (1986) state that they have been unable to culture *H. ducreyi* from asymptomatic men; the possibility of asymptomatic carriage, however, remains controversial, especially in females (Morse, 1989). Although ulcers on the external genitalia are more common, females may occasionally have cervical lesions. These are often painless, and the woman may be unaware of the infection (D'Costa et al., 1986; Morse, 1989); this is probably important in transmission of the disease. In addition to the above situation, occasional women may be culture-positive for *H. ducreyi* but have no symptoms or cervical lesions (D'Costa et al., 1986); whether these are true asymptomatic carriers or whether they are still in the incubation period for disease is not yet established. Unlike the oral haemophili, *H. ducreyi* can rarely, if ever, be considered normal flora.

The history, biology, and epidemiology of chancroid has been hindered by difficulty in cultivating the organism (Deacon et al., 1954, 1956) and by the fact that many different organisms have at one time or another been labeled *"H. ducreyi."* Kilian and Theilade (1975) reported that several of the strains studied by Reymann (1947, 1949) had cell walls typical of Gram-positive bacteria when examined by electron microscopy. The strains studied by Deacon et al. (1954) were later found to be *Corynebacterium* (Deacon et al., 1956). Part of the problem stems from the fact that *H. ducreyi* is extremely fastidious, and the lesions are often contaminated with other organisms. Progress has been made, however, with the introduction of enriched, selective media. Hammond et al. (1978) used an Isovitalex-enriched chocolate agar containing 3 μg/ml vancomycin and were able to enhance the recovery of *H. ducreyi* by suppression of many of the contaminating organisms. Inclusion of fetal bovine serum may further enhance recovery (see "Isolation" for additional comments).

Although improvements have been made in the cultivation of *H. ducreyi,* there is still a great deal that is not known concerning the basic physiology and taxonomy of this species. *H. ducreyi* requires hemin for growth, and has a GC content (38%) within the range for the genus *Haemophilus* (37–44%); it differs from other haemophili, however, in a number of respects, and its position within the genus has been questioned (Casin et al., 1985; Albritton, 1989). Casin et al. (1985) found very little homology between DNA from *H. ducreyi* and DNA from other *Haemophilus* species (1–4%, S1 nuclease method, 60°C). Albritton (1989) found binding levels of 13% between the DNA of *H. influenzae* and *H. ducreyi* (hydroxyapatite method, 55°C), but found higher binding ratios (31%) for *H. ducreyi* and *Actinobacillus (Haemophilus) pleuropneumoniae* DNAs, and for *H. ducreyi* and *Pasteurella ureae* (27%), suggesting that *H. ducreyi* is at least moderately related to some members of the family Pasteurellaceae.

There also appear to be basic differences between *H. ducreyi* and the other haemophili in terms of carbohydrate metabolism, with *H. ducreyi* generally regarded as inert in sugar fermentation tests (Kilian, 1976; Kilian and Biberstein, 1984). Sng et al. (1982), however, reported positive reactions for glucose, fructose, and mannose, although the only reference strain tested, Institut Pasteur strain CIP 542, was negative. Sottnek et al. (1980) reported that occasional strains gave weakly positive results with glucose or maltose, but the reactions could not be consistently repeated. Hammond et al. (1978) apparently found negative sugar fermentation for 19 clinical isolates and 4 reference strains, and S. Spinola and S. Misra (personal communication) reported negative sugar reactions for five reference strains of *H. ducreyi* (CIP 542, Winnipeg strain 35,000, and CDC strains 82–029362, 84–018676, and 85–023233). These results suggest that *H. ducreyi* is either not fermentative, or at a very minimum, only weakly fermentative. Additional studies are needed to clarify these and other problems pertaining to the taxonomic status of *H. ducreyi.*

NAD- and Hemin-Independent Human Isolates

H. APHROPHILUS. *H. aphrophilus* is found primarily in the oral cavity and in dental plaque. Using a selective medium containing bacitracin, vancomycin, and sodium fluoride, Tempro and Slots (1986) detected *H. aphrophilus* in the saliva of 6 of 14 subjects; *H. aphrophilus* was detected in subgingival dental plaque of 11 of the 14 subjects. The proportion of *H. aphrophilus* relative to other organisms, however, was low. In healthy subjects, *H. aphrophilus* comprised only 0.13% of the cultivable plaque flora, and in periodontitis patients, the percentage was even lower. They concluded that *H. aphrophilus* is frequently found as part of the normal oral flora; it comprises only a small proportion of the total oral flora and apparently plays no role in periodontal lesions.

Like other members of the oral flora, *H. aphrophilus* occasionally causes endocarditis, brain abscesses, and other miscellaneous infections (Albritton, 1982; King and Tatum, 1962).

The taxonomic position of this species is also somewhat of a problem. *H. aprophilus* was originally included in the genus *Haemophilus* because it is a small, Gram-negative coccobacillus that reportedly required hemin (Khairat, 1940; Boyce et al., 1969). Both Khairat (1940) and Boyce et al. (1969) noted that the hemin requirement could be lost after repeated subculture, but felt it was required for primary isolation. Kraut et al. (1972), however, reported that *H. aphrophilus* could be recovered from the oral cavity by direct plating on trypticase soy agar with bacitracin but without added hemin. Tempro and Slots (1986) performed primary isolations on hemin-containing media, but found that none of 12 *H. aphrophilus* isolates required hemin when tested on subculture. White and Granick (1963) showed that one of Khairat's original strains (NCTC 5886) contains the enzymes necessary for hemin biosynthesis; analysis of additional *H. aphrophilus* isolates has shown that they give positive (but often weak) porphyrin tests (Kilian and Biberstein, 1984; see "Identification" for details of the porphyrin test). Thus, although it is possible that some *H. aphrophilus* isolates require hemin for primary isolation, *H. aphrophilus* does not appear to be a true hemin-dependent species. Since it also does not require NAD, the taxonomic position of this species has been questioned. *H. aphrophilus* is, however, closely related (both biochemically and at the DNA level) to the NAD-dependent species, *H. paraphrophilus* (Kilian, 1976; Potts and Berry, 1983; Potts et al., 1985; Tanner et al., 1982). Both species are also related to *Actinobacillus actinomycetemcomitans,* although *H. aphrophilus* and *H. paraphrophilus* are more closely related to each other (~70% DNA binding; Potts and Berry, 1983; Tanner et al., 1982) than to *A. actinomycetemcomitans* (~20 to 40% DNA binding; Potts and Berry, 1983; Tanner et al., 1982). Because of the significant relationships between *H. aphrophilus, H. paraphrophilus,* and *A. actinomycetemcomitans,* Potts et al. (1985) proposed transfer of *A. actinomycetemcomitans* to the genus *Haemophilus.* Assessment of the DNA relatedness between *H. aphrophilus, A. actinomycetemcomitans,* and the type species of the genera *Haemophilus* and *Actinobacillus* has, however, yielded conflicting results. Potts and Berry (1983) found that neither *H. aphrophilus* or *A. actinomycetemcomitans* showed significant binding to *H. influenzae* or *A. ligniersii* DNA (<10% binding, S1 nuclease method, 63°C). Pohl (1981), however, using the renaturation rate method, found *A. actinomycetemcomitans* to be 40% related to *A. ligniersii* and 30% related to *H. influenzae;* he found *H. aphrophilus* to be 30% related to *H. influenzae.* Albritton et al. (1984) found relative binding ratios of 29% for *H. aphrophilus* and *H. influenzae* DNAs (hydroxyapatite method, 60°C). Additional studies are needed to resolve the taxonomic status of *H. aphrophilus* and related organisms.

Additional Comments: Human Isolates

As can be seen from the above descriptions, the human haemophili primarily inhabit the oral and pharyngeal mucosa. *H. influenzae* and *H. parainfluenzae* may occasionally colonize the genital tract (Albritton et al., 1982; Sturm, 1986) and with appropriate selection, haemophili can even be recovered from feces. Using selective media, Palmer (1981) detected *H. influenzae* in 1.5% of the fecal specimens he examined; NAD-dependent haemophili *(H. parainfluenzae, H. segnis,* and *H. paraphrophilus)* were detected in 20% of the specimens. Using the *Campylobacter* filtration technique, Megraud et al. (1988) detected *H. influenzae* in 0.4% of fecal specimens and *H. parainfluenzae* in 1.9%; whether this reflects active colonization, or simply survival from the nasopharynx through the alimentary canal is not known.

NAD-Dependent Avian Isolates

H. PARAGALLINARUM AND *H.* AVIUM. *H. paragallinarum* causes infectious coryza of fowl. This acute respiratory disease causes economic loss to poultry growers through reduced weight gain and lowered egg production (Blackall, 1989). The organism responsible for infectious coryza was originally named *H. gallinarum* and was thought to require both hemin and NAD. Subsequent studies have not confirmed a requirement for hemin and all currently existing strains only require NAD (Blackall, 1989). The name *H. paragallinarum* was proposed by Biberstein and White (1969) for strains requiring NAD only. *H. gallinarum* is no longer a recognized species name (Skerman et al., 1980; Kilian and Biberstein, 1984).

The apparent hemin dependency of the original isolates was probably due to inadequacy of the methods used by early investigators for growth factor testing (Blackall and Yamamoto, 1989). *H. paragallinarum* is somewhat finicky in its growth characteristics, and many strains require chicken serum and/or CO_2 for growth (Blackall, 1989).

The species *H. avium* was proposed by Hinz and Kunjara (1977) to accommodate avian isolates that are catalase-positive and nonpathogenic (in contrast to *H. paragallinarum,* which is catalase-negative and pathogenic). *H. avium*

is considered to be a member of the normal respiratory flora of poultry (Blackall, 1989).

Mutters et al. (1985) have suggested that *H. avium* is more closely related to *Pasteurella* species than to other members of the genus *Haemophilus* and should be transferred to the genus *Pasteurella.* Based on DNA homology, Mutters et al. (1985) further divided the catalase-positive avian isolates into three species, *P. avium, P. volantium,* and *Pasteurella* species A. The number of isolates examined, however, was small. Blackall (1988), using the biochemical criteria proposed by Mutters et al. (1985), was able to assign only 25 of 39 strains of *"H. avium"* to one of the three proposed species, and suggested that additional studies are needed to resolve the taxonomic status of the biochemically heterogeneous, catalase-positive, avian haemophili.

NAD-Dependent Porcine Isolates

H. PARASUIS AND *H.* PLEUROPNEUMONIAE. *H. parasuis* is responsible for the disease syndrome of pigs referred to as Glässer's disease. This disease is characterized by polyserositis, arthritis, and/or meningitis (Nicolet, 1986). In addition to its role in Glässer's disease, *H. parasuis* may also cause pneumonia, probably as a secondary invader (Nicolet, 1986); it is frequently found in the normal upper respiratory flora of healthy pigs (Biberstein et al., 1977; Nicolet, 1986).

H. parasuis requires NAD but not hemin. Controversy exists, however, concerning organisms originally labeled *"H. suis."* Lewis and Shope (1931) observed hemophilic bacilli in the respiratory tract of pigs infected with swine influenza virus, and proposed the name *H. influenzae suis* (which was later shortened to *H. suis*). *H. suis* was originally thought to require both hemin and NAD. Existing *H. suis* strains, however (including two of Shope's original isolates), require NAD but not hemin (Kilian, 1976), and Biberstein and White (1969) proposed use of the name *H. parasuis* to indicate this fact. *"H. suis"* was not included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), although occasional hemin- and NAD-requiring strains can apparently be isolated from pigs (Biberstein et al., 1977; Biberstein and White, 1969). The relationship of these hemin- and NAD-dependent isolates to strains originally described as *H. suis* is not known, nor is much known about their pathogenic potential.

H. pleuropneumoniae is the etiological agent of porcine necrotizing pleuropneumonia. The history of this species has also been somewhat complicated. The disease was first described in the 1960s (Matthews and Pattison, 1961; Shope, 1964), and the NAD-dependent organisms isolated were called *H. parainfluenzae* or *H. parahaemolyticus* by some investigators, and *H. pleuropneumoniae* by Shope (1964). Kilian et al. (1978) demonstrated that the porcine isolates were significantly different from the NAD-dependent human isolates, and recommended adoption of Shope's proposal (Shope, 1964) that they be given specific status as *H. pleuropneumoniae.* In addition to being distinct from the human isolates, these strains also differed from *H. parasuis,* particularly in their more luxuriant growth characteristics (*H. parasuis* grows quite poorly, even on chocolate agar; Matthews and Pattison, 1961; see "Identification" for additional tests) and by differences in disease pathology.

No sooner had *H. pleuropneumoniae* been accepted as the etiologic agent of porcine pleuropneumonia, when the situation was once again complicated by the isolation of *Pasteurella haemolytica*-like organisms from cases of porcine pleuropneumonia. These NAD-independent isolates were otherwise biochemically very similar to *H. pleuropneumoniae,* and DNA hybridization analysis indicated that both groups were highly related (Pohl et al., 1983). Furthermore, both groups were found to be much more closely related to the type species of the genus *Actinobacillus* (56 to 75% binding) than to *H. influenzae* (6% binding), and Pohl et al. (1983) proposed that both the NAD-dependent and NAD-independent porcine pleuropneumonia isolates be renamed *Actinobacillus pleuropneumoniae.*

The majority of *Actinobacillus (Haemophilus) pleuropneumoniae* isolates appear to be encapsulated (Sebunya et al., 1982; Sebunya and Saunders, 1983; Jacques et al., 1988), and there is apparently some homology to an *H. influenzae* capsular gene probe (J. S. Kroll, unpublished observations, cited in Musser et al., 1988). Unlike the situation with many other encapsulated organisms, antibody to the *H. pleuropneumoniae* capsule does not appear to be fully protective (Inzana et al., 1988); hemolysins and/or other toxins may contribute to the organism's pathogenic potential.

In addition to the named species, other *Haemophilus*-like organisms can be isolated from pigs. These include the "minor group" strains (Kilian et al., 1978) and taxon C (Kilian, 1976). Minor group strains are similar to *H. pleuropneumoniae* in that they are urease positive, but are negative in several sugar fermentations for which *H. pleuropneumoniae* is positive (see Identification Section). Minor group strains are commonly isolated from porcine lungs at slaughter (Pijoan et al., 1983), but are thought

to be less virulent than *H. pleuropneumoniae* (Rosendal et al., 1985).

NAD-Dependent Isolates from Rabbits

H. PARACUNICULUS. NAD-dependent coccobacilli have been isolated from the gastrointestinal tract of rabbits with mucoid enteritis (Targowski and Targowski, 1979). The isolate examined had a GC content of 40%, was nitrate reductase positive, and differed from most other NAD-dependent isolates in being indole positive (though occasional *H. parainfluenzae* strains may also be indole positive; Bruun et al., 1984); the name, *H. paracuniculus* was proposed (Targowski and Targowski, 1979). The pathogenic potential of this organism and its relationship to other NAD-dependent haemophili have not been established, and the biochemical description of the species appears to have been based on the analysis of a single isolate (Kilian and Biberstein, 1984; Targowski and Targowski, 1979).

Hemin-Requiring Animal Isolates

H. HAEMOGLOBINOPHILUS. *H. haemoglobinophilus* forms part of the normal flora of the preputial sac of dogs. Its pathogenic potential is probably low. It has, however, been isolated from dogs with suppurative inflammation of the prepuce (Rivers, 1922), and reportedly from two human infections (otitis media in a 10-year-old agammaglobulinemic and from a case of osteomyelitis following a dog bite in a 12-year-old boy; Frazer and Rogers, 1972; Lavine et al., 1974). This organism was originally referred to as *H. haemoglobinophilus canis* and later as *H. canis; H. haemoglobinophilus* has priority and is the taxonomically correct name (Kilian, 1976).

Additional Comments: Habitats

As indicated in the introduction, *Haemophilus*-like organisms have been isolated from many additional animal species (Kilian and Frederiksen, 1981); these isolates have not, however, been well characterized. It is generally held that animal isolates do not colonize humans and vice versa, and for the most part, this is probably true. Occasional exceptions may, however, occur, and perhaps some of the heterogeneity found for the NAD-dependent human isolates will someday be explained as the occasional isolation of animal species from humans (e.g., *"H. parainfluenzae"* strain NCTC 4101, isolated from human tongue, has been shown by DNA hybridization to be highly related to *H. avium;* Mutters et al., 1985; Pohl, 1981).

Isolation

Haemophili are fastidious organisms and require enriched media for their isolation. The most commonly used is chocolate agar, which provides both hemin and NAD. Although unheated blood also contains both hemin and NAD, strains requiring NAD do not grow on ordinary sheep blood agar (the type of blood used in most blood agar media). This is because sheep blood contains enzymes that degrade NAD, and unless the enzymes are destroyed by heating, the NAD is rapidly inactivated (Holt, 1961). Other sources of blood (e.g., rabbit or horse) provide more NAD, but the amounts can vary, and these types of blood are more expensive and not as readily available. What is commonly used, therefore, is chocolate agar. Originally, chocolate agar was prepared by adding 5 to 10% defibrinated blood to sterilized blood agar base media and holding the mixture at 80°C for 15 to 20 min, until the medium turned a dark chocolate brown. This served to release NAD from the red cells, as well as to inactivate NAD-degrading enzymes. However, NAD itself is heat labile, and this procedure also destroys some of the NAD; individual lots of chocolate agar must be carefully checked for their ability to support the growth of NAD-requiring strains. More commonly used is a somewhat artificial "enriched" chocolate agar, prepared by adding "hemoglobin" and either supplement B (Difco) or Isovitalex (BBL) to the autoclaved base medium. Supplement B and Isovitalex are chemically defined supplements that contain NAD as well as other nutrients, and are added (at a final concentration of 1%) after the autoclaved base media has cooled to 50°C. The "hemoglobin" is not purified hemoglobin, but rather a dried preparation consisting of washed and hemolyzed blood cells (Spray, 1930; available from Difco). The "hemoglobin" preparation is dissolved in water at a concentration of 2% and autoclaved separately; it is cooled to 45 to 50°C, and one volume is added to one volume of double-strength base media. The base medium can be one of several (GC agar base, brain heart infusion (BHI), blood agar base, etc.); the final agar concentration is usually 1%. Commercially prepared chocolate agar is available from a number of vendors and is also useful for cultivation of pathogenic *Neisseria.*

Because of its transparent nature, supplemented brain heart infusion agar (sBHI) is useful for distinguishing encapsulated from nonencapsulated organisms. This medium is prepared by adding purified NAD and hemin to autoclaved BHI agar or by adding Fildes extract (a commercially available peptic digest of blood)

to BHI. The latter method is preferable, as the extra nutrients present in the Fildes extract generally result in slightly larger colonies, and plates made with Fildes extract can usually be stored for longer periods than plates made with NAD and hemin only. Plates should be stored in sealed plastic bags (to prevent loss of moisture) and can generally be kept for about a month. Occasional isolates may not grow on sBHI, and sBHI cannot be recommended for *H. ducreyi* (see below).

Methods for Preparation of Supplemented BHI (sBHI) Agar

This medium can be made in either of the following ways.

sBHI made with NAD and hemin:

1. Prepare Difco brain heart infusion agar according to the manufacturer's instructions; autoclave at 121°C for 15 min; cool to 45–50°C.
2. Add 10 ml of a 1 mg/ml hemin stock solution (see below) per liter of BHI (final concentration 10 μg/ml).
3. Add 5 ml of a 2 mg/ml NAD stock solution (see below) per liter of BHI (final concentration 10 μg/ml).

sBHI made with Fildes extract:

1. Prepare BHI agar as in step 1 above.
2. Add Fildes extract to a final concentration of 2%.
3. Fildes extract contains some NAD, but we recommend adding more (2 ml of a 2 mg/ml NAD stock solution per liter).

NAD stock solution:

1. Dissolve β-NAD powder in water (2 mg/ml).
2. Sterilize by filtration.
3. Aliquot and store at −20°C.

Hemin stock solution:

1. To a sterile bottle, add 100 mg hemin powder and 4 ml triethanolamine (Kodak).
2. Add 96 ml sterile water.
3. Heat at 70°C for 10 min; test sterility.
4. Store at 4°C in a dark bottle; use within one month (generation times will increase with increasing length of storage).

Alternatively, hemin can be prepared in 0.2 M KOH in 50% ethanol (Kilian, 1981).

Other methods that have been used in the preparation of transparent media are based on the method of Levinthal (1918). This method is similar in concept to that of chocolate agar (i.e., a blood-containing medium is heated), but the medium is made transparent by removal of particulate material. This is done by filtration through sterile filter paper or by centrifugation. Horse blood is added to autoclaved BHI broth at a concentration of 35%, the mixture is boiled with stirring (use of a magnetic stirrer is helpful) until a clotted brown suspension forms. This is then filtered through sterile filter paper or centrifuged, and the clear filtrate referred to as "Levinthal" stock. This can be stored frozen and added to autoclaved (and cooled) BHI agar at a 1 to 10 ratio. The original formulas did not add additional NAD; however, as with the original chocolate agars, the amounts can vary. We recommend addition of extra NAD to a final concentration of 10 μg/ml.

BHI supplemented with Fildes extract gives satisfactory results and is much simpler to prepare than Levinthal's medium. Although use of sBHI as a sole medium for recovery of haemophili from clinical specimens is not advisable, its use along with chocolate agar might solve many problems concerning capsule status and/or mixed populations. The iridescence of encapsulated strains can be detected very readily by examination of sBHI plates with a strong, obliquely transmitted light source. Capsule production by *H. influenzae* is genetically unstable (Hoiseth et al., 1985, 1986) and in vitro passage tends to select out nonencapsulated variants. The ATCC reference culture of type b *H. influenzae* (strain 9795), as received from the ATCC, consists predominantly of capsule-deficient variants (S. Hoiseth, unpublished observations). Unless sBHI is used, most investigators will be unaware of this problem.

Liquid media may be prepared as per sBHI agar but the agar is omitted; less NAD can be used for liquid media (3 μg/ml) than for agar plates (10 μg/ml).

Care should be taken to avoid excessive autoclaving; even a slight excess of time or temperature can affect doubling times and ability of the media to support growth from small inocula. Evans and Smith (1974) suggest that dithionite or sodium oleate may be useful for neutralizing potential inhibitors; they found that some strains of *H. parainfluenzae* failed to grow on proteose peptone agar with NAD unless sodium oleate was also added. Additionally, some strains may require more thiamine than is available in certain nutrient agars (Evans and Smith, 1972). These and other problems may occasionally affect the ability to determine hemin and NAD requirements on such media. Doern and Chapin (1984) compared four different base media (all from Scott Laboratories, Inc.) for their suitability in growth factor tests. They found that BHI agar (plus strips containing hemin and NAD) supported growth of 185 of 187 strains of *H. influenzae;* tryptic soy agar (plus strips) supported growth of 181 of the 187 strains. Nutrient agar (plus strips), however, failed to support growth of 80 of the 187 strains, and Mueller-Hinton (plus strips) failed for 51 strains.

Tebbutt (1983) compared proteose peptone, Columbia agar, nutrient broth, nutrient broth No. 2, BHI, and blood agar base No. 2, all from Oxoid, and found that with the exception of

proteose peptone, all (when supplemented with NAD and hemin at 10 mg/l each) supported growth of 93 to 99% of 438 strains of *H. influenzae.* Several of these media, however, failed to support the growth of a significant number of NAD-dependent strains (only 75% of NAD-dependent strains grew on BHI plus NAD, 68% grew on nutrient broth No. 2 plus NAD, and 49% grew on proteose peptone plus NAD). In contrast, both Columbia agar plus NAD and blood agar base No. 2 plus NAD supported growth of 93 to 95% of the V-dependent isolates. The above studies suggest that some NAD-dependent isolates may be more exacting in their growth requirements, and that base media from various manufacturers may not always give similar results. (See "Identification" for further discussion of hemin and NAD tests, and for problems with hemin contamination of the base media.)

Minimal Media

Several minimal media have been developed, primarily for genetic studies (see below). In addition to requirements for NAD and hemin, *H. influenzae* has been shown to have a number of other growth factor requirements. The defined medium of Michalka and Goodgal (1969) contains 15 different components and that of Herriott et al. (1970b) contains even more. Not all strains of *H. influenzae* will grow on such media (according to Klein and Luginbuhl, 1979, 11 of 43 clinical isolates failed to grow even on the medium of Herriott et al., 1970b). Klein and Luginbuhl (1979) developed a somewhat less complicated defined medium, but even so, it contained a minimum of 13 compounds. Although not required, Tween 80, polyvinylalcohol, and bovine serum albumin (BSA) were found to improve growth (probably by adsorption of toxic products) and were generally included in addition to the 13 basic ingredients. Requirements for glutamic acid, glutathione, inosine, and citrulline (or arginine and uracil in place of citrulline) were common among the strains examined (Klein and Luginbuhl, 1979); thiamine and pantothenate are also apparently required (Holt, 1961; Klein and Luginbuhl, 1979).

Selective Media

Isolation of haemophili from nonsterile body sites is enhanced by inclusion of bacitracin (and/or vancomycin) in the culture media. This is particularly important in studies attempting to determine the frequency of *Haemophilus* species in the normal flora of the oral, pharyngeal, and genital mucosa, for isolation of haemophili from patients with upper respiratory tract infections, and for isolation of *H. ducreyi* from genital lesions. In these settings, other microorganisms may be more numerous and overgrow the haemophili, or in some instances, produce products that are inhibitory to haemophili. Haemophili are generally resistant to bacitracin, and Hovig and Aandahl (1969) recommended use of 300 μg/ml bacitracin to inhibit many of the contaminating organisms; this method has been used extensively by Kilian and coworkers in their surveys of normal oral and pharyngeal haemophili (Kilian and Schiott, 1975; Kuklinska and Kilian, 1984). Chapin and Doern (1983) observed break-through growth of normal upper respiratory tract flora on chocolate agar containing only bacitracin, and they devised a selective medium containing bacitracin (300 μg/ml) plus 5 μg/ml vancomycin and 1 μg/ml clindamycin. Although they did not compare their formulation to that of chocolate agar with bacitracin alone, they did find significantly improved recovery of *H. influenzae* on their medium compared to chocolate agar without antibiotics or to chocolate agar containing only vancomycin. Tempro and Slots (1986) found that a number of strains of *H. aphrophilus* were inhibited by 300 μg/ml bacitracin, and they devised a medium containing 75 μg/ml bacitracin, 5 μg/ml vancomycin, and 50 μg/ml sodium fluoride. Although *H. aphrophilus* was inhibited by 300 μg/ml bacitracin, they found that reduction of the bacitracin concentration to 75 μg/ml also failed to inhibit many of the contaminants (especially streptococci) and that these organisms significantly inhibited recovery of *H. aphrophilus* from clinical specimens. Addition of vancomycin (5 μg/ml) inhibited the streptococci and greatly improved recovery of *H. aphrophilus.* The sodium fluoride was added to inhibit *Actinobacillus actinomycetemcomitans.* Since this medium was designed to be selective for *H. aphrophilus,* it was deliberately lacking in NAD and would not have supported the growth of other *Haemophilus* species. The usefulness of this selective combination (particularly the use of sodium fluoride) for isolation of other *Haemophilus* species is not known.

The above studies all suggest that unless selective media are used, haemophili may often be missed. This is important in the interpretation of studies in which selective media were not used. Furthermore, some early studies of normal flora did not include media that would be capable of supporting the growth of haemophili.

H. ducreyi has traditionally been difficult to isolate. Introduction of Isovitalex-enriched chocolate agar containing 5 μg/ml vancomycin

(Hammond et al., 1978) has greatly improved recovery of *H. ducreyi* from chancroidal lesions. Inclusion of 5 to 10% fetal bovine serum has been reported to further enhance recovery (Sottnek et al., 1980; Nsanze et al., 1984), and the use of two different media may also improve chances of recovery. For a review of the various formulations that have been tested, see Morse (1989).

Growth Environment

It is often stated that *H. influenzae* does not require CO_2, but that some strains may grow better with CO_2. The author's experience, however, has been that CO_2 does not affect the growth of most strains, but occasional strains may not grow at all unless incubated in a candle jar. This includes some encapsulated strains as well as certain nontypables. It is not always clear from the literature, however, whether "CO_2 requirements" reflect a requirement for CO_2 per se, or a requirement for the increased humidity that is present in a candle jar or CO_2 incubator. Three "CO_2-requiring" strains tested in our laboratory grew in a closed jar with moistened paper towels (without a candle) but did not grow on parallel plates placed on the incubator shelf. Kraut et al. (1972) also found that moisture could substitute for the "CO_2 requirement" of *H. aphrophilus.*

The species *H. aphrophilus, H. paraphrophilus,* and *H. paraphrohaemolyticus* all supposedly require CO_2. Indeed, the original species definitions were based on a CO_2 requirement (Khairat, 1940; Zinnemann et al., 1968, 1971), and the names are derived from "aphros," the term used in classical times to describe CO_2 bubbles escaping from fermenting wine (Khairat, 1940). CO_2 dependence can, however, be lost on subculture (Zinnemann et al., 1971; von Essen et al., 1987). As already mentioned, the validity of CO_2 requirements for species distinction has been questioned (Kilian, 1976), especially as pertains to the distinction between *H. parahaemolyticus* and *H. paraphrohaemolyticus.* What is clear, however, is that many of these strains do require a "CO_2 environment" for optimal growth (particularly on primary isolation). Again, it is not clear whether it is CO_2 per se or increased humidity. According to Kilian (1976), occasional strains of *H. parainfluenzae* also need CO_2 for optimal growth (including certain nonhemolytic, biotype I strains that do not fit the classical definition of *H. paraphrohaemolyticus*). *H. ducreyi* also grows better under increased humidity and 5% CO_2 (Albritton, 1989). Incubation in a moist environment containing 5–10% CO_2 is thus recommended for all specimens potentially containing haemophili; this is true for the animal species as well (especially *H. paracuniculus, H. parasuis,* and *H. paragallinarum*).

Optimal growth for most *Haemophilus* species occurs between 35–37°C. *H. ducreyi* prefers a slightly lower temperature (33°C was reported as optimal; Sturm and Zanen, 1984).

Growth Rates

Haemophili are fastidious organisms, but contrary to what is often stated, they are not necessarily slow growing. In rich media, free of inhibitory substances, *H. influenzae* can double with a generation time similar to that of *E. coli* (26 min; Rubin, 1986). Not all species are rapid growers, however, and for *H. ducreyi,* it may take 48 h or more for colonies to appear (Morse, 1989). Some conjunctival isolates may also be slow growing *("H. aegyptius"?),* and *H. parasuis* is reported to grow "feebly," even after 48 h on chocolate agar (Kilian and Biberstein, 1984). *H. segnis, H. pleuropneumoniae,* and *H. paragallinarum* may also be somewhat slower growing.

Identification

Identification of the various *Haemophilus* species has been based primarily on hemin and NAD requirements, host origin, and a few additional biochemical tests (Kilian, 1976, 1985; Kilian and Biberstein, 1984). Haemophili are small, pleomorphic, Gram-negative rods (sometimes with filamentous forms); all reduce nitrate.

Hemin-and NAD-Requiring Human Isolates

Human isolates requiring both hemin and NAD are *H. influenzae, H. haemolyticus,* and *H. aegyptius. H. haemolyticus* is identified by its hemolytic activity, whereas *H. influenzae* and *H. aegyptius* are nonhemolytic. The problems in distinguishing *H. influenzae* and *H. aegyptius* have already been discussed (see description of the individual species under "Habitats"). *H. influenzae* is further identified on the basis of capsular antigens, with most invasive isolates being serotype b. The serotype b capsule is composed of a linear, repeating unit of ribose-ribitol-phosphate (Crisel et al., 1975) and is considered to be a major virulence determinant (Turk, 1982; Zwahlen et al., 1989). The structures of the other capsule types (a, c-f) are listed in Table 2. Serotyping reagents for both traditional slide agglutinations, and for latex or coagglutination

tests are available from a number of commercial suppliers (Difco, Wellcome Diagnostics, Pharmacia) and have been evaluated by Himmelreich et al. (1985). Nonencapsulated strains are nonagglutinable with capsular typing sera, although some strains are autoagglutinable, and saline controls should always be performed. Other factors may also cause occasional false positive reactions, and as emphasized earlier, iridescence on sBHI agar is an extremely useful aid in distinguishing encapsulated and nonencapsulated strains. Note, however, that iridescence begins to fade after approximately 20 to 24 h incubation.

Kilian (1976) introduced a biotyping scheme for *H. influenzae* based on the production of indole, urease, and ornithine decarboxylase (see Table 3). Biotyping is not mandatory for routine identification of *H. influenzae,* but has been of some use in surveys of normal flora versus disease isolates. It has limited value as an epidemiological tool for studying transmission of type b strains, since most invasive isolates tend to be biotype I (Barenkamp et al., 1981; Kilian et al., 1979; Oberhofer and Back, 1979). Biotype IV may be more common among genital isolates (Albritton et al., 1982; Wallace et al., 1983), and *"H. aegyptius"* is biotype III (though not all nonencapsulated, biotype III strains are *"H. aegyptius"*).

NAD-Dependent Human Isolates

As already mentioned (see "Habitats"), identification of NAD-dependent species is often problematic, and in practice, often not even attempted. Many labs simply report NAD-dependent isolates as *H. parainfluenzae.* Although the original description of *H. paraphrophilus* was based on a CO_2 requirement, this alone is not a reliable criterion for species designation (see "Habitats" and "Isolation"). Lactose fermentation, however, has been reported to be useful for separating *H. parainfluenzae* (lactose negative) from *H. paraphrophilus* (lactose positive; Albritton, 1988; Kilian, 1976; Kilian and Biberstein, 1984). Additional sugars that may be useful for distinguishing the NAD-dependent isolates are listed in Table 4. The biotyping scheme described above for *H. influenzae* has also been applied to *H. parainfluenzae,* although the numerical designations for a given combination of plus and minus test results are not the same for *H. influenzae* and *H. parainfluenzae* (Table 3). The situation is further complicated by the fact that two different definitions have been given for biotype IV *H. parainfluenzae.* Oberhofer and Back (1979) designated strains that were negative for all three tests as biotype IV, whereas Bruun et al. (1984) designated strains that were positive for all three tests as biotype IV. Some investigators have used the

Oberhofer and Back (1979) designation (Sturm, 1986; Doern and Chapin, 1987) whereas others have used the Bruun et al. (1984) designation (Kilian, 1985). Fortunately, a large percentage of *H. parainfluenzae* isolates fall into biotypes I–III (Oberhofer and Back, 1979), so this is only occasionally a problem. It becomes important, however, when the results of the biotyping tests are used as an aid in distinguishing *H. parainfluenzae* from *H. segnis* and *H. paraphrophilus,* both of which are reported to be negative for all three tests (Kilian, 1976; Kilian and Biberstein, 1984; Kilian and Theilade, 1978). A strain that is positive for one or more of the biotyping tests is probably not *H. segnis* or *H. paraphrophilus,* but a strain that is negative for all three tests should be carefully evaluated if a definitive species identification is desired. It should, however, be kept in mind that the above statement is based on data from only a limited number of strains of *H. segnis* and *H. paraphrophilus.*

The problems in distinguishing *H. parahaemolyticus, H. paraphrohaemolyticus,* and *H. parainfluenzae* have already been discussed (see "Habitats"). *H. parahaemolyticus* was defined on the basis of NAD-dependence and hemolysis, while *H. paraphrohaemolyticus* was de-

fined as NAD-dependent, CO_2-requiring, and hemolytic. These traits can, however, be lost on subculture, and/or appear in other species. *H. parahaemolyticus* and *H. paraphrohaemolyticus* are otherwise biochemically similar to *H. parainfluenzae* (Kilian, 1976), although there may be an inverse correlation between hemolysin production and mannose fermentation (Kilian and Biberstein, 1984; Oberhofer and Back, 1979). The type strain of *H. parahaemolyticus* (NCTC 8479) does not, however, appear to be related to *H. parainfluenzae* when tested by DNA hybridization (Pohl, 1981). The type strain of *H. paraphrohaemolyticus* (NCTC 10670 = ATCC 29237) also appears to be unrelated to *H. parainfluenzae;* it does, however, appear to be closely related to *H. aphrophilus* and *H. paraphrophilus* (Pohl, 1981). It is thus not surprising that there is considerable confusion concerning the identification of the NAD-dependent haemophili. Other discrepancies concerning NAD-dependent strains include ATCC strain 7901, which was deposited as *H. parainfluenzae,* but which by DNA hybridization appears to be *H. paraphrophilus* (Pohl, 1981; Potts et al., 1986). Conversely, *H. paraphrophilus* strain NCTC 10558 (= ATCC 29242) was considered to be *H. parainfluenzae* by Kilian (1976); DNA hybridization studies with this strain, however, have yielded conflicting results (Tanner et al., 1982; Potts and Berry, 1983). The DNA hybridization studies of Roberts et al. (1986) also suggest considerable heterogeneity among strains labeled *H. parainfluenzae,* although in this study ATCC strain 7901 showed significant homology to a number of strains labeled *H. parainfluenzae.* Clearly, additional DNA hybridization studies are needed in order to clarify some of the above-mentioned problems, as well as to establish the appropriateness of the biochemical tests used for speciation of the NAD-dependent haemophili.

The DNA hybridization studies of Potts et al. (1986) appear to have justified Kilian's proposal (1976) for creation of the species *H. segnis.* This species was proposed on the basis of a high GC content, and weak fermentation capacity. *H. segnis* is reportedly negative for all three biotyping reactions (urease, indole, and ornithine decarboxylase), and gives weak acid reactions for glucose and sucrose, but is negative for lactose, ribose, and melibiose (Kilian and Theilade, 1978; see Table 4).

Hemin-Dependent Human Isolates

H. ducreyi is identified partially on the basis of its clinical circumstance (i.e., from genital lesions), combined with Gram stain, hemin dependence, and negative sugar reactions. Gram stain alone should not be used to make a definitive diagnosis, as other (sometimes Gram-variable) organisms can resemble *H. ducreyi.* The "school of fish" pattern (arrangement of organisms in long parallel chains) observed by early investigators is not always observed and is more commonly observed with plate-grown organisms than in direct smears (Morse, 1989). Hemin dependence cannot be demonstrated by the traditional disk or strip methods (see below) because *H. ducreyi* does not grow on the routine media used for these tests (Hammond et al., 1978; Oberhofer and Back, 1982). Hemin dependence has, however, been demonstrated using BBL strips on GC agar base supplemented with 0.1% glucose and 0.01% glutamine (Hammond et al., 1978), or on GC agar base supplemented with glucose, glutamine and cysteine (Sottnek et al., 1980). *H. ducreyi* requires much higher hemin concentrations than do other hemin-dependent haemophili (Hammond et al., 1978), and while the hemin strips from BBL contain sufficient hemin to initiate growth of *H. ducreyi* (Hammond et al., 1978; Sottnek et al., 1980), the Difco disks apparently do not (Difco Laboratories, personal communication). The recommended method for determining the hemin requirement is the porphyrin test (see below).

Hemin- and NAD-Independent Human Isolates

H. aphrophilus does not require NAD, and as indicated earlier, generally does not require hemin either (although it may on primary isolation); it is porphyrin positive. *H. aphrophilus* can be distinguished from other haemophili, since with the exception of *H. ducreyi* (and the animal species, *H. haemoglobinophilus*), all other haemophili require NAD, or both hemin and NAD. The major problem, therefore, lies in distinguishing *H. aphrophilus* from other small, Gram-negative coccobacilli, including *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis,* and *Eikenella corrodens,* all of which share a similar habitat with *H. aphrophilus,* and which like *H. aphrophilus,* may occasionally cause endocarditis or brain abscesses. Like *H. aphrophilus,* these organisms also grow best with increased CO_2. Tests useful for distinguishing these organisms are shown in Table 5.

NAD-Dependent Porcine Isolates

The porcine isolates *H. pleuropneumoniae* and *H. parasuis* are distinguished from each other primarily on the basis of the urease test and the

Table 5. Tests useful for distinguishing *Haemophilus aphrophilus* from other Gram-negative coccobacilli or small rods.

Species	Glucose fermentation	Indole	Catalase	Lactose fermentation	Sucrose fermentation	Nitrate reduction

Actinobacillus actinomycetemcomitans[c]	+ (119/120; but some take > 3 days)	− (0/120)	+ (119/120)	− (0/120)	− (0/120)	+ (120/120)

Symbols: +, >90% positive; −, <10% positive; numbers in parentheses indicate number of strains giving a positive test out of the total number of isolates tested.

[a]Based on Kilian, 1976. *H. aphrophilus* is resistant to 50 μg/ml sodium fluoride, whereas *A. actinomycetemcomitans* is reported to be sensitive (Tempro and Slots, 1986).

[b]Rubin et al., 1985.

[c]Weaver et al., 1985.

CAMP reaction, with *H. pleuropneumoniae* positive, and *H. parasuis* negative for both tests (Table 6). The CAMP reaction detects a hemolysin that acts synergistically with the *Staphylococcus aureus* β- toxin; *H. pleuropneumoniae* is the only *Haemophilus* species to give a positive CAMP reaction. Mannitol fermentation also serves to distinguish *H. pleuropneumoniae* from the other porcine isolates, as well as the human NAD-dependent species, all of which are negative for mannitol fermentation (See Tables 4 and 6). *H. parasuis* grows much more feebly than *H. pleuropneumoniae*, and this is also a useful distinction.

NAD-Dependent Avian Isolates

The avian isolates *H. paragallinarum* and *H. avium* are distinguished from each other primarily on the basis of the catalase test and galactose fermentation, with *H. avium* being positive for both tests and *H. paragallinarum* negative (Blackall, 1988; Blackall and Reid, 1982). As mentioned earlier, *"H. avium"* isolates are genetically and biochemically heterogeneous, and Mutters et al. (1985) have proposed that *H. avium* be split into three species in the genus *Pasteurella* (as *Pasteurella avium, Pasteurella volantium,* and *Pasteurella* species A). Not all isolates from chickens fit the criteria for these three species (Blackall, 1988), and additional studies are needed.

Of the 39 catalase-positive strains studied by Blackall (1988), all were found to produce acid from glucose, galactose, fructose, and mannose; 37 of 39 strains also fermented trehalose. Of the 19 catalase-positive strains studied by Mutters et al. (1985), all were found to ferment glucose, galactose, fructose, mannose, sucrose, and trehalose. In both studies, the variable profiles for arabinose, maltose, mannitol, sorbitol, and xylose indicated considerable heterogeneity among strains. The nearly universal fermentation of trehalose, however, helps distinguish *"H. avium"* from human isolates of *H. parainfluenzae* (Oberhofer and Back, 1979, found that none of 83 *H. parainfluenzae* strains fermented trehalose). Readers should consult Blackall (1988) and Mutters et al. (1985) for the biochemical profiles of individual *"H. avium"* isolates. Biochemical profiles for 39 strains of *H. paragallinarum* can be found in Blackall and Reid (1982). Most *H. paragallinarum* isolates require chicken serum and CO_2 for growth (Blackall and Reid, 1982).

The animal isolates are generally assumed to be relatively host-species adapted, and this is weighted quite heavily in most identification schemes. It is interesting to note, however, that one strain considered by Mutters et al. (1985) to be *Pasteurella (Haemophilus) avium,* was isolated from a calf; this calf isolate showed 88% homology to the type strain of *Pasteurella (Haemophilus) avium.* As already mentioned, an organism highly homologous to *H. avium* has also been isolated from a human tongue (e.g., NCTC 4101, originally considered *H. parainfluenzae,* shows 80% homology to *H. avium* DNA; Mut-

[d]Some urease-negative, CAMP-negative strains isolated by Pijoan et al. (1983) were positive for xylose and/or mannitol, suggesting that the situation might not be as straightforward as this table would indicate.

ters et al., 1985; Pohl, 1981). In addition to these *"H. avium"* isolates from nonavian hosts, organisms considered to be *H. pleuropneumoniae* have been isolated from a lamb and a steer (Biberstein et al., 1977).

Laboratory Tests for the Identification of *Haemophilus* Species

One of the most important tests for identifying *Haemophilus* species is the determination of the hemin and NAD requirements. While conceptually simple, this step can cause problems unless carefully performed. Originally, NAD requirements were demonstrated by satellite growth on blood agar plates containing a contaminant NAD-secreting organism, or on blood agar plates that had been deliberately cross-streaked with an NAD-secreting strain of *Staphylococcus aureus.* The presence of satellite colonies around such NAD-producing organisms, and absence of growth on sheep blood agar plates without a feeder culture, is suggestive evidence that one is dealing with an NAD-dependent *Haemophilus* species. This evidence should not, however, be taken as definitive proof, since other microorganisms can occasionally show satellite growth for reasons other than NAD-dependency. Determination of hemin and NAD requirements has long been performed by placing hemin and NAD-impregnated paper disks or strips on blood-free media. The problem with this method is that haemophili have nutritional requirements in addition to NAD and hemin (see "Isolation"), and the media used for testing must satisfy all the other requirements, but be free of NAD and hemin. Since NAD is destroyed by autoclaving, this is not a problem; hemin contamination of base media, however, is sometimes a problem, and individual lots should be carefully checked (i.e., should be incapable of supporting growth of known strains of *H. influenzae* unless both factors are added). Another problem concerning hemin testing may be carry-over of hemin from the original culture plate. Colonies should be picked carefully and resuspended in saline (to reduce carry-over) before swabbing to the plate for factor testing. Factor-containing disks or strips are available from a number of commercial suppliers (BBL, Difco, Remel); brain heart infusion, heart infusion, or tryptic soy agar are commonly used as base media (Doern and Chapin, 1984; Lund and Blazevic, 1977).

Because of the problems associated with the above method, more definitive proof of a hemin requirement can be obtained by the porphyrin test. This test, based on the observations of Biberstein et al. (1963), and modified by Kilian (1974), detects intermediates in the hemin biosynthetic pathway. When supplied with the hemin precursor, δ-aminolevulinic acid (ALA), hemin-independent species can convert ALA to porphyrin. Because they lack the enzymes of the hemin pathway, hemin-dependent species are unable to convert ALA to porphyrin. Porphyrin production by hemin-independent species can be readily detected by the orange-red fluorescence produced following exposure of ALA-exposed cultures to long-wave ultraviolet light (360 nm). A variety of formats have been used to detect porphyrin production from ALA, including a tube test (Kilian, 1974), disk tests, and incorporation of ALA into the agar growth medium (Zadik, 1982; Gadberry and Amos, 1986). The disk method is probably not as sensitive as the tube test; the tube test, however, requires a large inoculum and may require subculture from the primary isolation plate before inoculation. Porphyrin test agar is relatively new, and has not been extensively compared to the other methods; it may be more sensitive than the disk

method (Gadberry and Amos, 1986), but the number of isolates tested was small.

Porphyrin Tube Test (Based on Kilian, 1974)

1. Prepare 2 mM ALA (Sigma), 0.8 mM $MgSO_4$ in 0.1 M phosphate buffer, pH 6.9. Distribute in 0.5-ml quantities in small glass tubes (solution can be frozen at −20°).
2. Resuspend a *heavy* loopful of bacteria in the above solution (culture should be <24 h old and suspension should appear milky; Lund and Blazevic, 1977).
3. Incubate 4 h at 37°C.
4. Expose tube to 360-nm UV light; red fluorescence indicates porphyrin production (i.e., hemin not required for growth).

Other tests of importance for identifying *Haemophilus* species include sugar fermentations and the production of indole, urease, and ornithine decarboxylase. For determination of sugar reactions, Kilian (1976; 1985) recommended use of 1% sugar in phenol red broth base (Difco), supplemented with 10 μg/ml each NAD and hemin. This method generally requires incubation for 24 h or longer. Workers at the U.S. Centers for Disease Control prefer a rapid (4 h), nongrowth method, utilizing small volumes and heavy inocula (Hollis et al., 1980; Miller and Sottnek, 1987). A number of kits containing miniaturized, dehydrated reagents are available commercially, although these sometimes give discrepant sugar reactions. Doern and Chapin (1984) found that the RapID NH System (Innovative Diagnostics Systems, Inc.) correctly identified only 89.8% of 187 strains of *H. influenzae;* most of the incorrect identifications were due to false-negative glucose reactions. Oberhofer and Back (1979), using the BBL Minitek system, however, reported very consistent sugar reactions for a large number of strains (461 of 464 strains of *H. influenzae,* and 83 of 83 strains of *H. parainfluenzae* gave positive glucose reactions; none of 464 *H. influenzae* fermented sucrose, whereas 83 of 83 strains of *H. parainfluenzae* gave positive reactions with sucrose). Kawakami et al. (1981) compared the Minitek system to that of the conventional phenol red broth method and found extremely good agreement between the two methods.

Several of the commercially available kits also contain reagents for the detection of urease, tryptophanase (indole production), and ornithine decarboxylase. Traditional methods (Kilian, 1976, 1985) for determination of these reactions are presented below. All substrates are dispensed in 0.5-ml volumes.

Indole Test

1. Prepare 0.1% tryptophan in 0.05 M phosphate buffer, pH 6.8.
2. Inoculate heavily and incubate at 37°C for 4 h.
3. Add an equal volume of Kovac's reagent and shake; red color in the upper layer indicates the presence of indole.

Urease Test

1. Prepare a 20% solution of urea; filter sterilize.
2. Prepare 1:500 phenol red (0.2 g phenol red, 8 ml NaOH, 92 ml water).
3. Add 0.1g KH_2PO_4, 0.1g K_2HPO_4, 0.5g NaCl, and 0.5 ml of the phenol red solution to 100 ml water. Adjust to pH 7.0 and autoclave. After autoclaving, add 10.4 ml of the filter-sterilized urea.
4. Inoculate heavily and incubate at 37°C for 4 h. Red color indicates urease activity.

Ornithine Decarboxylase Test

Use Moeller's decarboxylase medium (Difco) and inoculate heavily. Incubate at 37°C for 4–24 h; purple color indicates decarboxylase activity.

Genetics

Although *H. influenzae* is one of the naturally transformable microorganisms (Kahn and Smith, 1984), it has not been as amenable to genetic analysis as some of the more robust organisms like *E. coli* and *Salmonella.* The complex nutritional requirements of the haemophili have made analysis of auxotrophic mutants difficult, and only a limited number of auxotrophic markers and antibiotic resistance genes have been mapped by transformation (Michalka and Goodgal, 1969; Stuy, 1985). Transducing phages have not been described, and there is but a single report of a conjugal system for the ordered transfer of chromosomal genes (Deich and Green, 1987). This system utilized an F′ from *E. coli* and transfer of *H. influenzae* chromosomal genes occurred only at very low frequency. Until recently (see below for a discussion of mapping by pulse-field electrophoresis), transformation has been the mainstay for genetic analysis in this genus, with work limited mainly to *H. influenzae* and *H. parainfluenzae.*

Transformation

During exponential growth, *H. influenzae* and *H. parainfluenzae* transform poorly, as only about one cell in ten thousand is competent for DNA uptake. Under conditions of slowed growth, however, competence can be induced in the entire population, and transformation of chromosomal markers can occur with frequencies of 1–5% (Herriot et al., 1970a; Kahn and

Smith, 1984). The protocols for induction of competence in *H. influenzae* and *H. parainfluenzae* are different. *H. parainfluenzae* undergoes a significant loss of viability in the protocol giving optimal transformability of *H. influenzae,* whereas *H. influenzae* undergoes severe loss of viability in the protocol giving optimal transformation of *H. parainfluenzae* (Barany and Kahn, 1985). The protocol for *H. influenzae* involves an incubation period in a nongrowth minimal medium (the MIV medium of Herriott et al., 1970a), whereas the protocol for *H. parainfluenzae* utilizes overnight incubation as a thin layer in a stationary petri dish (Gromkova and Goodgal, 1979). The latter method has, however, been used by Gromkova et al. (1989) for transformation of *H. influenzae,* but the transformation frequencies were significantly lower than those obtained by other investigators using the MIV protocol. The stationary method is easier to perform, so depending on the transformation frequency required, this method may be sufficient (e.g., to move a chromosomal streptomycin-resistance marker into a new strain, etc.). Growth of cells (with aeration) to a density of 1×10^9/ml, followed by a shift to more anaerobic conditions (e.g., by tipping the culture into the arm of a side-arm flask and holding without agitation for 90 min) has also been used with some success (Goodgal and Herriott, 1961) but this method is not as reliable as the MIV method of Herriott et al. (1970a).

Transformation of both *H. influenzae* and *H. parainfluenzae* involves binding of DNA (via specific uptake sequences—see below) to membranous blebs that appear on the surface of competent cells (Barany et al., 1983; Kahn et al., 1983). These membranous blebs have been termed "transformasomes." The mechanism by which DNA passes from the transformasomes into the cell also differs between *H. influenzae* and *H. parainfluenzae* (Barany and Kahn, 1985).

Unlike the artificial transformation of *E. coli* with plasmid DNA (which utilizes calcium chloride plus a temperature shock and which produces a leaky membrane), transformation of naturally transformable organisms like *Haemophilus* occurs via a genetically determined system for the active uptake and integration of exogenous DNA. DNA is bound by specific receptors that appear on the surface of competent cells, and for *H. influenzae* and *H. parainfluenzae,* these receptors recognize specific sequences that occur on *Haemophilus* DNA and which are generally absent or rare on foreign DNA; transformation of *Haemophilus* is thus relatively specific for uptake of *Haemophilus* DNA (Danner et al., 1982; Deich and Smith, 1980; Goodgal and Mitchell, 1984; Kahn and Smith, 1984; Scocca et al., 1974; Sisco and Smith, 1979).

During transformation of competent *H. influenzae,* DNA passes from the transformasome into the cell via a mechanism that results in degradation of one complete strand of DNA, as well as degradation of the entering strand from the 3′ end (Barany et al., 1983). The entering single strand searches for its homolog in the chromosome and is incorporated via *rec*-dependent homologous recombination. Although highly efficient for introduction of chromosomal markers, the degradative step makes this a poor method by which to introduce plasmid DNA into *H. influenzae.* Plasmid transformation of competent *H. influenzae* occurs only at very low frequency, and is thought to occur via accidental escape of intact double-stranded plasmid DNA from the transformasome (Pifer, 1986). The efficiency of plasmid transformation can be improved by adding glycerol to competent cells (Stuy and Walter, 1986) or by ligating linearized plasmid DNA to form concatamers (Pifer, 1986).

As indicated above, *H. influenzae* and *H. parainfluenzae* are considered to be naturally transformable microorganisms, and their mechanisms of transformation have been extensively studied. It was thus somewhat surprising to learn that a significant number of clinical isolates of *H. influenzae* appear to be nontransformable (Cope et al., 1989; Rowji et al., 1989). The evolutionary significance of this observation is not yet understood. Transformation of other *Haemophilus* species has not been well studied, but Leidy et al. (1956) and White et al. (1964) reported transformation of *H. parasuis* by *H. parasuis* DNA; the efficiency, however, was considerably lower than they observed for transformation of *H. influenzae* with *H. influenzae* DNA. White et al. (1964) also attempted to transform *H. pleuropneumoniae* but found it to be "virtually incompetent as a receptor in transformation studies." Additional studies, however, are needed. As expected (by virtue of its close relationship to *H. influenzae*), *"H. aegyptius"* is also naturally transformable (White et al. 1964).

Transposon Mutagenesis

A system for direct transposon mutagenesis of *Haemophilus* species has only recently been described (Kauc and Goodgal, 1989a). This system utilizes the 16.4-kb, tetracycline-resistance element, Tn*916,* derived originally from *Streptococcus.* Cloned *Haemophilus* genes can also

be mutagenized with transposons in *E. coli* and the insertion mutations returned to the *H. influenzae* chromosome by transformation (Grundy et al., 1987; Tomb et al., 1989). The kanamycin-resistance gene of Tn*5* is apparently not expressed well in *Haemophilus* and selection on even low concentrations of kanamycin leads to amplifications and other chromosomal rearrangements (Grundy et al., 1987; S. Hoiseth, unpublished observations). The kanamycin-resistance gene of Tn*903*, however, appears to function well in *H. influenzae* and mini-Tn*10 kan* (which contains the kanamycin-resistance gene from Tn*903*) has been used successfully (Tomb et al., 1989).

Haemophilus Cloning Vectors

The tetracycline-resistance gene (non-Tn*10*) of the *E. coli* cloning vector pBR322 does not express in *Haemophilus,* and the plasmid does not replicate in *Haemophilus.* Shuttle vectors capable of replicating in both *E. coli* and *Haemophilus* have therefore been developed for cloning *Haemophilus* DNA in *H. influenzae* (Danner and Pifer, 1982; McCarthy et al., 1982; Tomb et al., 1989). A number of *Haemophilus* genes have also been cloned in *E. coli* (see Lee et al., 1989, for a partial list); at least some of these genes appear to be expressed in *E. coli* using their own promoters (Holmans et al., 1985; Nelson et al., 1988).

Chromosome Mapping by Pulse-Field Gel Electrophoresis

The technique of pulse-field gel electrophoresis has been used to study the organization of the *H. influenzae* and *H. parainfluenzae* chromosomes, and ordered restriction maps of these species have recently been published (Kauc and Goodgal, 1989b; Kauc et al., 1989; Lee et al., 1989). By this technique, the size of the *H. influenzae* chromosome was estimated to be 1834 (Lee and Smith, 1988) to 1980 kb (Kauc et al., 1989) while that for *H. parainfluenzae* was estimated at 2340 kb (Kauc and Goodgal, 1989b). A number of cloned *Haemophilus* genes have been used as hybridization probes to localize known gene products to specific chromosomal restriction fragments (Lee et al., 1989). This technique should very rapidly increase our understanding of the genetics of *Haemophilus* species and should be useful for comparing the relationships between isolates.

CHAPTER 180

The Genus *Pasteurella*

REGGIE Y. C. LO and PATRICIA E. SHEWEN

The genus *Pasteurella* is the type genus of the family Pasteurellaceae which comprises the recognized genera *Actinobacillus, Haemophilus,* and *Pasteurella* (Mannheim, 1984). The organization of *Actinobacillus, Haemophilus,* and *Pasteurella* in a family has been established from phenotypic comparisons (Kilian and Frederiksen, 1981a, 1981b) as well as DNA-DNA hybridization analysis (Christian et al., 1981; Mannheim, 1981; Pohl, 1981) and 16S rRNA sequence analysis (Chuba et al., 1988). The members of the family Pasteurellaceae have had various taxonomic placements over the past 50 years. Some of these include Parvobacteriaceae in 1934 (Bergey, 1934) and Brucellaceae in 1957. The latter family included other genera such as *Yersinia, Francisella, Moraxella, Bordetella,* and *Brucella* in addition to *Actinobacillus, Haemophilus,* and *Pasteurella* (Breed et al., 1957). In the 1984 *Bergey's Manual of Systematic Bacteriology,* the family Pasteurellaceae is listed in Section 5 under "Facultatively Anaerobic Gram-Negative Rods" (Manheim, 1984). A detailed taxonomic analysis of the genus *Pasteurella* is described by Mutters et al. (1989). Using 16S RNA cataloging analysis, Woese et al. (1985) proposed that the family Pasteurellaceae be placed in the gamma subgroup of the purple bacteria together with the Enterobacteriaceae and the Vibrionaceae as the three families of Gram-negative facultative anaerobic bacteria (Woese, 1987).

The genus *Pasteurella* was established by Trevisan in 1887 and named after Louis Pasteur. The type species for the genus is *P. multocida,* which was previously named variously as *P. cholerae-gallinarum* and *P. gallicida.* Bacteria in the genus *Pasteurella* are commensal parasites on mucous membranes of vertebrates, particularly mammals and birds. Many species are potential pathogens, acting opportunistically when the host's defenses are compromised. The 1984 *Bergey's Manual of Systematic Bacteriology* recognized the following species: *P. multocida, P. pneumotropica, P. haemolytica, P. ureae, P. aerogenes,* and *P. gallinarum* (Carter, 1984).

The species *P. anatipestifer* has been placed under the name of *Moraxella anatipestifer* in the same edition of *Bergey's Manual* (Carter, 1984) even though there is considerable doubt about its proper placement. Due to the extensive use of its name, some of the properties of *P. anatipestifer* will also be described in this article. Although the species *P. ureae* has been proposed to be placed under the genus *Actinobacillus* (Bercovier et al., 1984; Escande et al., 1984), this reclassification is still under debate.

Using DNA-DNA hybridization studies under stringent reassociation conditions, a genus-like group *P. sensu stricto* was also established which includes a group of bacteria having a DNA binding level of 50% or higher with the rest of the genus of *Pasteurella* (Mutters and Mannheim, 1984; Mutters et al., 1985). The genetic relationship of the bacteria in this group remains to be clarified.

Biochemical Characteristics

The genus *Pasteurella* may be characterized as: small, Gram-negative cocci or rods of dimensions 0.3–1.0 by 1.0–2.0 μm, bipolar staining, nonmotile, facultatively anaerobic, catalase and oxidase positive, fermenting glucose and other carbohydrates and producing acid but no gas. Temperature range for growth is 22–44°C, with the optimum at 37°C. They are negative in the methyl-red, Voges-Proskauer, and gelatinase tests. The GC content of the DNA is between 40–45 mol%. Only *P. haemolytica* produces a zone of β-hemolysis on blood agar plates. Most strains of *P. haemolytica* and *P. multocida* also produce a neuraminidase.

Habitats

Members of this genus are commonly found as commensals on the mucous membranes of the upper respiratory and digestive tracts of healthy

mammals and birds. *P. multocida* has been recovered from many species including domesticated and wild, as well as healthy and diseased animals (Rimler and Rhoades, 1989b; Snipes et al., 1988a). Some of the major sources of *P. multocida* include cattle, buffalo, swine, goats, turkeys, chicken, ducks, geese, wild fowl, cats, and dogs. As an animal pathogen, *P. multocida* causes fowl cholera in chickens, turkeys, and other avian species (Rhoades and Rimler, 1989b); hemorrhagic septicemia of cattle and buffalo (Carter and de Alwis, 1989); and atrophic rhinitis of pigs (Chanter and Rutter, 1989). *P. multocida* is also the major cause of bacterial infections in humans resulting from animal bites (Arons et al., 1982).

P. haemolytica has been recovered frequently from cattle, sheep, and goats and occasionally from the upper respiratory tract of chickens and turkeys. It is the principal microorganism involved in pneumonic pasteurellosis in cattle in North America (Frank, 1989; Yates, 1982) and pneumonia and septicemia in sheep in the United Kingdom (Gilmour and Gilmour, 1989). It has also been reported to cause fatal pneumonia in bighorn sheep in the wild (Foreyt, 1989).

P. pneumotropica can be recovered from guinea pigs, hamsters, mice, rats, cats, and dogs (Kunstyr and Hartmann, 1983; Lesher et al., 1985). Most reported isolations of *P. pneumotropica* have been from laboratory animals where it is a potential respiratory pathogen (Kunstyr and Hartmann, 1983). Additionally, *P. pneumotropica* has also been shown to be one of the dominant microorganisms in the vagina of healthy adult rats (Carthero and Aldred, 1988; Ward et al., 1978; Yamada et al., 1986). In rare incidences, *P. pneumotropica* has been found to cause infections in humans (Gadberry et al., 1984; Sammarco and Leist, 1986).

The natural host of *P. ureae* appears to be humans, the bacterium being located mainly in the upper respiratory tract (Bigel et al., 1988). Reports of *P. ureae* isolation from rats or mice may be the result of misidentification (Mutters et al., 1984). In the compromised host, *P. ureae* may cause peritonitis (Nobel et al., 1987), septicemia and meningitis (Grewal et al., 1983; Marriott and Brady, 1983; Verhaegan et al., 1988; Yagupsky et al., 1985).

P. anatipestifer is an opportunistic pathogen in domestic ducks and turkeys as well as in waterfowl such as geese and swans in the wild (Donahue and Olson, 1969; Munday et al., 1981). It affects primarily the respiratory tract and the nervous system and results in pericarditis and perihepatitis as well as meningitis in a variety of avian species (Brogden, 1989). The bacterium may be transmitted among young avian species under favorable conditions and then be spread to other birds. The mode of transmission among waterfowl in the wild is not known, although the bacterium appears to be carried by healthy geese and swans in a subclinical form. Under conditions of environmental stress, overcrowding and predisposing viral or other bacterial infections (Mo and Burgess, 1987), *P. anatipestifer* can result in disease outbreaks in dense natural bird flocks. Juvenile birds appear to be more susceptible to infection than mature adults (Wobeser and Ward, 1974). Once an enzootic outbreak occurs, transmission to domestic duck and turkey populations may take place via contaminated drinking water. Mortality may reach 12% in turkey flocks. The route of infection is thought to be the respiratory tract or puncture wounds. Acute clinical signs include lacrimation, nasal discharge, and diarrhea, as well as mild coughing and sneezing in the early stages (Chaudbury and Mahanta, 1985). Later stages of infection result in leg weakness, tremors, loss of equilibrium, and eventually death (Heddleston, 1975). As mentioned above, the taxonomic placement of *P. anatipestifer* is uncertain. This bacterium has been placed in the genus *Pfeifferella* (Bergey, 1934), and recently *Moraxella* (Carter, 1984). However, based on DNA hybridization studies and biochemical characterization of fatty acids, it has been suggested that *P. anatipestifer* should be transferred to the family Cytophagaceae together with other members of *Flavobacterium* and *Cytophaga* (Piechulle et al., 1986).

P. gallinarum is usually recovered from the upper respiratory tract in chickens and turkeys. It is a weak pathogen and is often associated with secondary respiratory infections (Heddleston, 1975). *P. aerogenes* is found in the intestinal tracts of pigs and appears to be part of the normal flora and nonpathogenic (McAllister and Carter, 1974). Little is known about the characteristics of these two species of *Pasteurella* since they appear to be of minor importance in veterinary medicine.

Pathogenesis and Virulence

Most of these bacteria coexist peacefully with the animal hosts as obligate parasites. However, under conditions which compromise the host defenses, clinical infections are manifested. Such conditions include environmental stress as well as concurrent or prior infection by other bacterial or viral agents. As successful pathogens, bacteria of the *Pasteurella* genus possess and express a number of virulence factors that

contribute to the manifestations of disease. To date, most of the research on the pathogenesis and virulence factors of these bacteria has been focussed on *P. multocida* and *P. haemolytica* due to the significant economic loss resulting from diseases caused by these two microorganisms.

Virulence Factors of *Pasteurella multocida*

Based on specific antigens associated with the capsule, there are five serotypes of *P. multocida* (Rimler and Rhoades, 1989b). Recently, a sixth serotype has been proposed (Rhoades and Rimler, 1989a). In pigs, and sometimes goats, *P. multocida* serotypes A and D cause atrophic rhinitis and pneumonia. Atrophic rhinitis is a contagious disease with clinical symptoms of sneezing, nasal discharge, shortening and twisting of the snout, pneumonia, and reduced growth rates. Death does not necessarily occur. Pathogenic strains of serotypes A and D produce a similar toxin which is a major virulence factor in atrophic rhinitis. *P. multocida* strains of serotype A have also been shown to be the primary cause of fowl cholera in poultry. The common symptoms of fowl cholera include ruffled feathers, fever, anorexia, and diarrhea, leading to death. *P. multocida* also infects cattle and water buffaloes and causes a disease called haemorrhagic septicemia (Carter and de Alwis, 1989). Hemorrhagic septicemia is a fatal disease caused by serotype B (and occasionally serotype E) of *P. multocida,* resulting in respiratory stress, edematous swelling of the head-throat-brisket region, and hemorrhage in many organs and tissue.

P. multocida isolates recovered from atrophic rhinitis of pigs produce a protein toxin which has been shown to be a major virulence factor of the bacterium (Chanter and Rutter, 1989). Comparison of experimental infection of pigs with toxigenic and nontoxigenic *P. multocida* isolates further demonstrates the importance of this toxin in pathogenesis (Elling and Pederson, 1985; Rutter, 1985). Intranasal inoculation of cell-free culture supernatant from toxigenic *P. multocida* results in atrophy of the turbinate bones in rabbits and pigs (Dominick and Rimler, 1986; Rutter and Mackenzie, 1984).

The toxin is produced in stationary-phase cultures and appears to be released on cell lysis (Nakai et al., 1985). The purified toxin has a molecular weight varying from 112–160 kDa. The toxin contains 2–8% carbohydrate and can be inactivated by formaldehyde, heat, or proteolytic enzymes. Mild treatment with trypsin and partial denaturation with dithiotheritol dissociate the toxin into three fragments of molecular weights 23 kDa, 67 kDa, and 74 kDa (Nakai and Kume, 1987a). The fragments may reassociate to form an active protein (Nakai and Kume, 1987b). The primary histopathological features of turbinate atrophy produced by the purified toxin were progressive degeneration of osteoblasts, increase in osteoclasts, and osteoclastic bone resorption (Chanter et al., 1986; Dominick and Rimler, 1986). The mode of action of the toxin is currently unknown; no ultrastructural changes are apparent in embryonic bovine lung cells after treatment with the toxin in vitro. In addition, there are no detectable changes in the levels or synthesis of protein or DNA in the treated cells nor any alteration in the intracellular concentrations of ATP and cAMP (Chanter et al., 1986). The gene encoding the toxin has been cloned and expressed in *E. coli* (Chanter, 1989).

P. multocida capsular type A isolates from rabbits produce fimbriae which mediate adhesion to isolated pharangeal cells (Trigo and Pijuan, 1988). Porcine type A isolates adhere more readily than type D isolates to porcine epithelial cells. However, there is no evidence to demonstrate adhesion of toxigenic *P. multocida* isolates to turbinate mucosal cells, indicating that these adhesins may only be accessory factors.

Colonization of toxigenic *P. multocida* is greatly enhanced in combined infection with *Bordetella bronchiseptica* (Cowart et al., 1989). It appears that a protein factor produced by *B. bronchiseptica* acts to facilitate colonization of *P. multocida.* Similarily, toxigenic *P. multocida* also enhance colonization of *B. bronchiseptica,* suggesting a synergistic action of the two bacteria in pathogenesis.

The capsule of type A *P. multocida* is largely made of hyaluronic acid. An antiphagocytic protein of 50 kDa was recently purified from an avian isolate of serotype A3 (Truscott and Hirsh, 1988). Other virulence factors of *P. multocida* may include neuraminidase and a hyaluronidase, but there is no evidence for their role in pathogenicity (Drzeniek et al., 1972).

In addition, the outer-membrane proteins of *P. multocida* have also been suggested to be virulence factors (Truscott and Hirsh, 1988). Some of the outer-membrane proteins may be involved in an iron-scavaging role to promote growth in vivo (Snipes et al., 1988b).

Virulence Factors of *P. haemolytica*

There are 16 serotypes of *P. haemolytica* based on agglutination using specific typing sera (Biberstein et al. 1960; Frank and Wessman, 1978; Fodor et al., 1988; Fraser et al., 1982). Two bio-

types, A and T, are also established. Serotype A1 of *P. haemolytica* is the most common isolate from bovine pneumonic pasteurellosis, a fibrinous pneumonia of feedlot cattle (Wessman and Hilker, 1968). Other serotypes, serotype A2 in particular, have been shown to cause ovine pneumonic pasteurellosis (Gilmour and Gilmore, 1989). The bacterium produces a number of virulence factors which contribute to pathogenesis of the diseases (Adlam, 1989; Moiser et al., 1989). However, environmental and physical stress and concurrent or prior infection with respiratory viruses predispose the animals to the bacterial infection.

One of the major virulence factors produced by pathogenic isolates of *P. haemolytica* is a heat-labile toxin specific for ruminant leukocytes (Kaehler et al., 1980; Shewen and Wilkie, 1982). This toxin may contribute to pathogenesis either by imparing the primary defense of the lungs and subsequent immune response or by the induction of inflammation as a consequence of leukocyte lysis. The genetic determinant for the leukotoxin has been cloned and its nucleotide sequence determined (Chang et al., 1987; Lo et al., 1985, 1987). The data were used to predict that the size of the active toxin was 102 kDa (Lo et al., 1987). In addition to a structural gene which encodes the toxin, an activation protein was also identified, as well as two secretory proteins which participate in the secretion of the toxin out of the cell (Strathdee and Lo, 1989). The leukotoxin has been found to share extensive homology with the *E. coli* alpha-haemolysin as well as with many other haemolysins in pathogenic bacteria (Strathdee and Lo, 1987). The leukotoxin has been suggested to act by the formation of a transmembrane pore in the target cells which leads to cell swelling, loss of electrolytes, and eventually cell lysis by osmotic pressure (Clinkenbeard et al., 1989).

At least two types of fimbriae have been detected on *P. haemolytica* serotype one grown in vitro or recovered in lavage fluid from experimentally infected animals (Morck et al., 1987). Transmission electron microscopy revealed that fimbrial structures on *P. haemolytica* adhered to tracheal epithelium (Morck et al., 1988). Although role for fimbriae in pathogenesis of *P. haemolytica* pneumonia has not been demonstrated, fimbriae may be important in colonization of the upper respiratory tract in the early stages leading to pneumonic pasteurellosis (Morck et al., 1989). Recently, Potter et al. (1988) reported the purification of the larger rigid fimbriae from *P. haemolytica* A1, and these purified fimbriae does not seem to have hemagglutinating activity.

A polysaccharide capsule has been observed on *P. haemolytica* cells recovered from the trachea or the alveoli of infected animals (Adlam et al., 1984; Morck et al., 1987, 1988, 1989). The capsule may enhance attachment of the bacterium to alveolar and bronchiolar surfaces, inhibit the phagocytic and bactericidal activities of neutrophils, or impair complement-mediated serum killing of the bacteria (Brogden et al., 1989; Corstvet et al., 1982; Emau et al., 1986, 1987).

Although the lipopolysaccharide (LPS) of *P. haemolytica* was not lethal for bovine leukocytes in vitro, it does affect many biological activities of these cells (Confer and Simons, 1986), including altered migration of peripheral blood leukocytes as well as enhancement of phagocytosis of polymorphonuclear leukocytes (Confer and Simons, 1986). However, the actual contribution of LPS to the pathogenesis of lung lesions is not known.

Other potential virulence factors of *P. haemolytica* have been identified, including a glycoprotease and a neuraminidase (Otulakowski et al., 1983). These two proteins may act to cleave surface components off the target cells, rendering the cells more susceptible to attachment or lysis by the leukotoxin. In addition, many cell-surface serotype-specific antigens may also be important in adherence or colonization of the bacterium (Donachie et al., 1984; Durham et al., 1986; Gonzalez-Rayos et al., 1986).

Future Studies on the Genus *Pasteurella*

The advent of recent techniques in molecular biology will continue to allow further understanding of the bacteria in the genus *Pasteurella*. The use of nucleic acid analysis, both DNA-DNA hybridization and 16S rRNA comparison, has already changed the taxonomic organization of the genus, and its relationship to other genera within the same family. A number of bacteria will no doubt be reassigned to more appropriate placements. For example, it has been proposed that the biotype A species of *P. haemolytica* should more appropriately be included in the genus *Actinobacillus* (Pohl, 1981). Such a change from the traditional may be faced with resistance, although at least new isolates will be properly named and catagorized appropriately.

In addition to redefining the taxonomic placement of these bacteria, the use of molecular approaches enable a stepwise dissection of their

many virulence factors. As well, the genetic determinants of the encoded virulence factor(s) could be used for detail characterization of their function and activities during an infection. An understanding of the role(s) of the various virulence factors, singularly and in concert, is important in the design and development of efficacious vaccines to protect animals against infection by these pathogenic bacteria (Confer et al., 1988; Kobish and Pennings, 1989; Mosier et al., 1989; Rimler, 1987; Shewen and Wilkie, 1987; Sutherland et al., 1989).

CHAPTER 181

The Genus *Cardiobacterium*

SYDNEY M. HARVEY and JAMES R. GREENWOOD

The genus *Cardiobacterium* consists of one species, *Cardiobacterium hominis,* originally designated "group II D organisms" until further described and named by Slotnick and Dougherty (1964). This organism is a fastidious, facultatively anaerobic, nonmotile, pleomorphic Gram-negative rod with a fermentative type of metabolism.

The first known report of these organisms was by Tucker et al. (1962). This paper described four cases of endocarditis caused by a *Pasteurella*-like organism. These isolates and two subsequent isolates, also from cases of endocarditis, were designated as "group II D" by the Centers for Disease Control, Atlanta, GA, until the name C. *hominis* was proposed by Slotnick and Daugherty (1964). The current assumption is that infectious endocarditis is the only disease caused by *C. hominis* in humans. This assumption may be valid or it may be based on a lack of more complete knowledge of the biology of the organism. Although past isolation of *C. hominis* has been almost exclusively limited to blood cultures, there have been at least two isolations from cerebral spinal fluid (Slotnick, 1968; Francioli et al., 1983).

Slotnick (1964, 1968), in an attempt to extend our knowledge of the human occurrence of this organism, used fluorescent antibody smears and culture techniques to sample other sites. He and his colleagues isolated *C. hominis* from nose and throat specimens of 68 of 100 persons sampled, from cervical and vaginal cultures of 2 among 159 studied, and obtained positive fluorescent smears from stool specimens of 14 of 20 individuals. No positive stool cultures were obtained because of a lack of a selective medium and the overgrowth of *C. hominis* by the enteric bacilli. No isolations or positive smears were obtained from any urine specimens collected (no sample size was given for the urine specimens). These investigators concluded that *C. hominis* is part of the indigenous commensal respiratory flora and supported this conclusion with the following observations: 1) None of the individuals harboring the organism had any signs or symptoms of disease. 2) Injection of viable suspensions of representative strains into laboratory animals elicited no visible sign of disease. 3) In relation to the high proportion of individuals who harbor the organism, few clinical cases occur. With the exception of these studies, there is a paucity of information concerning the ecology and pathogenicity of these organisms. All recently published information is limited to descriptive case reports of isolation of *C. hominis* from bacterial endocarditis, with the exception of one case report of *C. hominis* meningitis (Francioli et al., 1983). There appear to be no published reports on pathogenicity or virulence mechanisms.

Even though *C. hominis* was originally called a *Pasteurella*-like organism (Tucker et al., 1962), it was soon discovered that it was antigenically unrelated to members of the genus *Pasteurella* as well as to the genera *Brucella, Bordetella, Moraxella, Hemophilus, Streptobacillus, Corynebacterium, Bacteroides, Neisseria, Escherichia, Aerobacter (Enterobacter)* and *Lactobacillus* (Slotnick et al., 1964). It was compared to both Gram-negative and Gram-positive organisms because of the Gram-variable characteristics noted by early investigators. Because of this anomalous Gram-stain reaction, the fine structure of *C. hominis* was studied by Reyn et al. (1971). These investigators found that the cell wall was of the Gram-negative type, but an unusual feature of all strains examined was a 20–40-nm thick polar cap. This material was strictly limited to the terminal portion of the cell, adhering to the outside of the cell wall. Profile sections of this cap indicated that it was formed by radial arrangements of tufts of material but subsequent studies employing freeze-etching and negative-staining techniques were unable to further elucidate the nature of this cap material. The other notable feature of the *C. hominis* cell wall was an unusually dense outer layer. This layer was composed of a repeating structure which consisted of units exhibiting tetragonal or rectangular packing. The periodicity of these arrays measured 5.5 nm; the

average diameter of the units was 3.4 nm and the space between them was 2 nm. Surface arrays are more typical of Gram-positive bacteria than of Gram-negative bacteria but are not unknown in the latter (Reyn et al., 1971).

Limited genetic studies have demonstrated that the GC content of the DNA for *C. hominis* is quite different from the other Gram-negative rod-shaped organisms which have similar physiological characteristics. *C. hominis* GC is 59–60%, *Haemophilus aphrophilus* is 42%, *Kingella* sp. is 47.3–54.8%, *Actinobacillus actinomycetemcomitans* is 42.7%, *Pasteurella* sp. is 40–45%, *Eikenella corrodens* is 56.2–58.2%, and *Capnocytophaga* sp. is 33–41% (Weaver, 1984).

Isolation

Except for the studies of Slotnick and colleagues, all published isolation attempts have been from normally sterile sites, predominantly blood. The one recorded isolation from cerebral spinal fluid does not give cultural information (Francioli et al., 1983). *C. hominis,* although a slow-growing organism, appears to be able to initiate growth on a variety of blood culture media under both anaerobic and aerobic conditions. Only two types of basal media were reported not to support primary blood culture isolation attempts—thioglycollate and Schaedler broths (Bruun et al., 1983; Midgley et al., 1970; Piot et al., 1978). Since it has been reported that *C. hominis* growth may not be noted until after 23 days of incubation, the failure to see growth in the above two media may be due to the fact that the cultures were discarded as negative after 14 days of incubation (Geraci et al., 1978). More typically, growth of the organism is seen after 5 to 8 days of incubation. For subculture from primary cultures, 5% sheep blood or chocolate agar are most frequently used although *C. hominis* will grow on media without blood (Midgley et al., 1970). Neither CO_2 or humidity is an absolute growth requirement for all strains, but both supplemental CO_2 and increased humidity enhance growth (Savage et al., 1977).

For isolation from nonsterile sites, no selective medium is presently available. Earlier studies on throat and nose specimens used typticase-soy agar slants or plates enriched with 5% human blood incubated at 37°C for 48–72 h (Slotnick et al., 1964). Slotnick's subsequent screen of vaginal and cervical swabs for *C. hominis* employed a slightly different method. Swabs were placed in tubes containing 2 ml of Trypticase Soy Broth (BBL) for transport to the laboratory where they were plated on a Casman's blood agar plate and a chocolate agar plate (BBL). Incubation was at 37°C for 4 days in a candle jar (Slotnick, 1968).

Identification

Differential characteristics of *C. hominis* which distinguish it from other similar Gram-negative organisms are given in Table 1. General biochemical characteristics of *C. hominis* are given in Table 2.

Microscopically, cells of *C. hominis* are pleomorphic Gram-negative rods which may show retention of crystal violet in the central portion or in the enlarged ends. Teardrop cells and filaments of varying lengths may occur. One study attributes this extreme pleomorphism and the irregular staining to growth on media without

Table 1. Biochemical differentiation of *Cardiobacterium hominis* and other fastidious Gram-negative rods.

CHAPTER 182

The Genus *Actinobacillus*

JAMES E. PHILLIPS

Organisms of the genus *Actinobacillus* were first described by Lignières and Spitz (1902) in actinomycotic lesions in cattle in Argentina. The authors referred to this organism as "l'actinobacille" based on its morphology and its association with the pathological lesion. In 1910, Brumpt proposed the name of *Actinobacillus lignieresii.*

This genus has also been used as a repository for "species for which no obvious home can be found" (Cowan, 1974). In *Bergey's Manual of Systematic Bacteriology* (Phillips, 1984) five species are listed as comprising the genus; *Actinobacillus lignieresii, A. equuli, A. suis, A. capsulatus,* and *A. actinomycetemcomitans.* Each of these species is discussed in detail in this chapter. Various other organisms have been described as actinobacilli, but here they have not been included in (nor excluded from) the genus. Ross et al. (1972) isolated actinobacilli from sows that were related to, but not identical with, the generally accepted species of the genus. Hacking and Sileo (1977) have recovered a hemolytic actinobacillus from waterfowl and have shown it to have close similarities with *A. lignieresii* and *Pasteurella ureae,* an organism already reported by Jones (1962) as closely resembling the actinobacilli and considered by Frederiksen (1973) to be an *Actinobacillus* of human origin.

The close relationship of organisms of the genus *Actinobacillus* and those of the *Pasteurella* group may give rise to difficulties in identification and has certainly presented taxonomic problems. Genetic studies of these two groups together with the genus *Haemophilus* by Mannheim et al. (1980) have given support to the inclusion of the three genera within a single family, the Pasteurellaceae. Mráz (1969), in a comparative study of *A. lignieresii* and *P. haemolytica,* has drawn attention to the close similarity between these two species (similarity index, 95% on 60 characters) and has proposed that *P. haemolytica* should be renamed *Actinobacillus haemolyticus.* Mráz et al. (1976) have also examined strains of another organism originally described by Kohlert (1968) under the name *Pasteurella salpingitidis* and have proposed that this be renamed *Actinobacillus salpingitidis.* The rearrangement of organisms within these three genera has also been supported by genetic studies by Pohl (1981), who noted a close relationship between members of the *Actinobacillus* group and *Haemophilus pleuropneumoniae.* Pohl et al. (1983) later concluded that an organism recovered from cases of necrotizing pleuropneumonia in pigs and designated *Pasteurella haemolytica*-like organism (Bertschinger and Seifert, 1978) is a biotype of *Haemophilus pleuropneumoniae* and that both should be transferred to the genus *Actinobacillus* under the name *Actinobacillus pleuropneumoniae.* This organism will be discussed in this chapter.

There are also some species that have previously been included in the genus but which should now be excluded: *A. actinoides* (Smith, 1918), a cause of pneumonia in calves, bears great similarities to *Streptobacillus moniliformis* and should probably be placed in the same genus. *A. mallei* has been removed to the genus *Pseudomonas.* The organism described by Baynes and Simmons (1960) from cases of ovine epididymitis, *A. seminis,* should not be included in the genus *Actinobacillus.*

Habitats

Members of the genus *Actinobacillus* are encountered most often as pathogens causing a variety of conditions in animals, especially domesticated stock. They also occur as commensal organisms in the alimentary, respiratory, and genital tracts of normal animals. They are to be regarded as opportunistic pathogens, there usually being some factor present that assists entry of the organism into susceptible tissues. The cases of disease caused by the actinobacilli are usually sporadic, but where the trigger factor is common to a group of animals, several individuals in that group may be affected.

Actinobacillus lignieresii

The classical disease in cattle caused by *Actinobacillus lignieresii* is wooden tongue, a chronic granulomatous lesion affecting the tongue and other soft tissues of the head and upper alimentary tract together with the associated lymph nodes (Bosworth, 1923; Davies and Torrance, 1930; Thompson, 1933; Till and Palmer, 1960). Lesions have also been reported in the lungs and liver (Davies and Torrance, 1930), in the pleura (Misdorp. 1963), and in the heart (Thornton, 1976). Subcutaneous lesions affecting the skin of various areas of the body have been recorded (Hebeler et al., 1961; Mawditt and Greenham, 1962).

In sheep, the lesions are more usually suppurative in character, often with involvement of the skin or lungs (pyobacillosis). The infecting organism was first described by Christiansen (1917) as *Bacterium purifaciens,* but the identity of this organism with *A. lignieresii* was established by Tunnicliff (1941) and Taylor (1944). The organism has been reported to cause epididymo-orchitis (Laws and Elder, 1969a) and mastitis (Laws and Elder, 1969b) in sheep.

Infection of animals other than cattle and sheep with *A. lignieresii* is not common, but lingual lesions have been reported in the dog by Fletcher et al. (1956) and by Kemenes and Markói (1959) and epidural abscess in a horse by Chladek and Ruth (1976). In ducks the organism has been recovered from cases of salpingitis (Bisgaard, 1975). The presence of *A. lignieresii* associated with disease in humans has also been reported (Dibb et al., 1981; Orda and Wiznitzer, 1980; Pathak and Ristic, 1962; Thompson and Willius, 1932).

A. lignieresii has been demonstrated as a commensal organism in the mouth of healthy cattle (Phillips, 1964), in normal bovine rumen (Phillips, 1961), and in the rumen of healthy sheep (Phillips, 1966). It is likely that such organisms constitute the source of infection, with entry occurring through minor wounds produced in the epithelial surfaces of the upper alimentary tract. The presence of agents that may cause mechanical damage of the epithelium has been found associated with multiple cases of actinobacillosis in herds of cattle (Campbell et al., 1975; Gerring, 1947; Hebeler et al., 1961; Nakazawa et al., 1977) and in sheep (Davis and Stiles, 1939; Hayston, 1948; Thomas, 1931).

A. lignieresii is worldwide in distribution, and clinical infections have been reported from all continents.

Actinobacillus equuli

Actinobacillus equuli is a pathogen of horses found in association with various clinical conditions, especially in young animals. The most usual syndrome in foals, occurring within the first few days of life, is an acute septicemic infection ("sleepy foal disease") that may become chronic ("joint ill") with lesions of purulent nephritis and purulent arthritis (Dimock et al., 1947). In adult horses it may be found associated with septicemia (Magnusson, 1919; Mráz et al., 1968; Zakopal and Nesvadba, 1968), purulent nephritis (Meyer, 1910), endocarditis (Innes et al., 1950; Svenkerud and Iversen, 1949; Vallée et al., 1974), meningitis (Weidlich, 1955), chronic alveolar emphysema (Larsen, 1974), and abortion (Webb et al., 1976).

The organism is also pathogenic for swine. Piglets are most often affected, but older animals may show lesions. The lesions that may be found include abortion (Werdin et al., 1976), arthritis (Pedersen, 1977), endocarditis (Ashford and Shirlaw, 1962; Jones and Simmons, 1971), meningoencephalitis (Terpstra and Akkermans, 1955), metritis (Edwards and Taylor, 1941), and septicemia (Magnusson, 1931; Windsor, 1973).

A. equuli has been recognized in horses as part of the normal bacterial flora of the intestinal tract (Cottew and Francis, 1954; Laudien, 1923) and has been isolated from both the tonsillar region (Dimock et al., 1947; Jarmai, 1929) and the tracheal mucus (Kim et al., 1976) of healthy horses. The occurrence of *A. equuli* in normal swine, however, has not been documented.

A. equuli has not been widely recognized as a pathogen in other animal species, but Moon et al. (1969) isolated it from monkeys, and du Plessis et al. (1967) and Osbaldiston and Walker (1972) described outbreaks of enteritis in calves in which *A. equuli* predominated in the intestinal flora. Vallée (1959) reported *A. equuli* causing disease in rabbits and Vallée et al. (1960) recorded its association with skin lesions in a dog.

The opportunistic character of *A. equuli* as a pathogen is recognized, especially in the case of young animals, where it is often the weak individual that is liable to succumb to infection.

Actinobacillus suis

The porcine actinobacillus, *Actinobacillus suis,* is found as a pathogen of all ages of swine; there is both an acute septicemic form (Mair et al., 1974; Zimmermann, 1964), sometimes with pneumonia (van Dorssen and Jaartsveld, 1962) or nephritis (Bouley, 1966), and a more chronic

form with arthritis (van Dorssen and Jaartsveld, 1962). It has also been recognized as a pathogen of horses (Veterinary Investigation Service, 1975). In a number of cases of disease in horses reported to be due to *A. equuli,* the infecting organism has undoubtedly been *A. suis* (Bell, 1973; Carter et al., 1971; Cottew and Francis, 1954), and it is likely that other unidentified actinobacilli from horses (Larsen, 1974) are also strains of this species. An organism identified as *A. suis* was isolated from conjunctivitis in a free-living Canada goose (Maddux et al., 1987), and previously reported, unnamed actinobacilli from ducks and swans (Hacking and Sileo, 1977; Onderka and Kierstead, 1979) have characteristics which indicate they also belong to this species.

The presence of *A. suis* in normal swine has not been reported, but the hemolytic actinobacilli recovered from irradiated swine by Wetmore et al. (1963) may have been commensal strains of *A. suis* that had assumed the pathogenic role in the stressed hosts. Cutlip et al. (1972) isolated actinobacilli from the tonsils of normal pigs in a herd in which a case of septic embolic actinobacillosis had occurred.

The presence of *A. suis* in normal horses has also been reported (Kim et al., 1976).

Actinobacillus capsulatus

For many years after its first isolation from lesions of arthritis in laboratory rabbits (Arseculeratne, 1961, 1962), *Actinobacillus capsulatus* was not recovered from any other animal species; however, Zarnke and Schlater (1988) have recently reported the isolation of *A. capsulatus* from a generalized infection in free-ranging snowshoe hares in Alaska. In rabbits the lesions of arthritis show characteristic granules consisting of a central mass of organisms with radiating club-like structures similar to those seen in lesions in cattle. The organism has not been recognized in the commensal state in the rabbit nor any other host species.

Actinobacillus actinomycetemcomitans

Actinobacillus actinomycetemcomitans was first described by Klinger (1912) in actinomycotic lesions in humans. Heinrich and Pulverer (1959) considered that it played a distinct part in the pathogenesis of actinomycosis. More recently it has been recognized as a commensal organism in the human oral cavity, where it was present in 36% of adults cultured (Slots et al., 1980). However, its role as a human pathogen has been firmly established in cases of juvenile periodontitis in which it is regarded as the major etiological agent (Zambon, 1985). It occurs also as the sole infecting organism in other lesions in humans, such as endocarditis and abscesses (Page and King, 1966; Blair et al., 1982), and it may give rise to chronic skin lesions in drug abusers arising from infection of injection sites (Fenichel et al., 1985).

A. actinomycetemcomitans may also be responsible for infections in animals. It is found associated with epididymitis in rams (DeLong et al., 1979; Bulgin and Anderson, 1983).

Actinobacillus (Haemophilus) pleuropneumoniae

Actinobacillus (Haemophilus) pleuropneumoniae is a primary bacterial respiratory pathogen of pigs, causing porcine contagious pleuropneumonia. It was named by Shope (1964) but some early authors classified it as *H. parahaemolyticus,* along with isolates from human beings (Nicolet, 1968). Kilian (1976a), however, was strongly of the opinion that the porcine strains constituted a species distinct from the human isolates.

The organism is often the only infective agent present in the lungs of affected pigs, although other secondary organisms may be present. In very young piglets the disease may be septicemic in form, often resulting in death, but in older pigs a subclinical form of the disease often results in high economic loss but no overt clinical disease.

A. pleuropneumoniae can be detected in the tonsillar crypts of clinically normal pigs (Brandreth and Smith, 1985) and also in the nasal cavity (Kume et al., 1984).

Isolation of *Actinobacillus*

Representatives of the genus *Actinobacillus* grow readily on the enriched media usually employed for the isolation of pathogens from animal tissues. In most fresh tissues they will usually be found as the sole or predominant organism. The following procedure can be used to isolate actinobacilli from lesions in the tongue and associated lymph nodes of cattle:

Isolation of *A. lignieresii*

To prepare Hartley's digest broth, the following ingredients are used:

Ox heart (minced)	3,000 g
Water	5 liters
Anhydrous sodium carbonate (0.8% solution)	5 liters
Pancreatin	50 g
Concentrated hydrochloric acid	80 ml

Mix the minced meat and water and heat to 80°C. Add the sodium carbonate and cool to 45°C. Add pancreatin and incubate at 45°C for 4 h, stirring frequently. When digestion is complete, add the hydrochloric acid and steam at 100°C for 30 min. Cool to room temperature and add 1 N caustic soda to bring the pH to 8.0. Boil for 25 min to precipitate phosphates and filter while hot. Allow to cool and adjust to pH 7.5. Sterilize by autoclaving at 121°C for 15 min.

Prepare horse blood agar by adding 1% agar (Oxiod no.1) to the digest broth, autoclave to sterilize, cool to 50°C and add 5% oxalated horse blood. Distribute into sterile petri plates.

Preparation of diseased tissue: Incise to the center of the lesion using aseptic technique and withdraw samples of the scanty volumes of pus with an inoculating loop or capillary pipette.

Inoculation of medium: Spread the inoculum so as to give well-isolated colonies at one side of the plate.

Incubation: Incubate at 37°C for 18–24 h. The addition of 5–10% carbon dioxide to the atmosphere usually improves the growth for primary isolation, but most strains will grow adequately without this addition.

The ability of most strains of actinobacilli to grow on MacConkey agar (Mrâz, 1975) suggests that it also might be of use for isolation, especially if cultures on this medium are set up in parallel with those on blood or serum agar. When working with *A. suis,* the use of sheep blood agar has the advantage that colonies of this species, being hemolytic, are more easily selected.

The isolation of actinobacilli from mixed populations (e.g., from the surface of the tongue and from the contents and the epithelial and mucosal surfaces of the alimentary tract) may prove difficult because of the overgrowth of the actinobacillus colonies by other more rapidly growing bacteria. In these situations selective media may be of advantage. Two selective media have been described, that of Till and Palmer (1960) for the isolation of *A. lignieresii* from the mouth of normal cattle and that of Phillips (1961, 1964) used to recover *A. lignieresii* from the rumen and mouth of normal cattle.

Selective Medium for *Actinobacillus lignieresii* (Till and Palmer, 1960)

Prepare Filde's peptic digest of blood according to the method of Cruickshank (1965) as follows:

Sodium chloride, 0.85% aqueous solution	150 ml
Hydrochloric acid	6 ml
Defibrinated sheep blood	50 ml
Pepsin	1 g
Sodium hydroxide, 20% aqueous solution	about 12 ml
Chloroform	0.5 ml

Mix the saline, acid, blood, and pepsin in a stoppered bottle and heat at 55°C for 2–24 h. Add sodium hydroxide until a sample of the mixture diluted with water gives a permanganate red color with cresol red indicator. Add pure hydrochloric acid drop by drop until a sample of the mixture shows almost no change of color with cresol red but a definite red tint with phenol red. It is important to avoid an acid excess. Add chloroform and shake the mixture vigorously.

The complete medium consists of:

Hartley's digest broth	900 ml
Agar	10 g
Filde's peptic digest*	100 ml
Oleandomycin phosphate*	20 mg
Neomycin sulfate*	1.5 mg

The medium is dispensed in petri plates.

Swabs taken from the surface of the bovine tongue are inoculated on to the medium and the inoculum is spread. Incubate the plates overnight at 37°C and then select colonies of the correct morphology for further examination.

*These components are added after the basic nutrient agar has been sterilized and cooled to 50°C.

Although Till and Palmer (1960) did not succeed in isolating *A. lignieresii* from the surface of the tongues of normal cattle, they showed that their medium would support the growth of known strains of *A. lignieresii* while providing a high degree of inhibition of contaminating organisms.

Selective Medium for *Actinobacillus lignieresii* (Phillips, 1961, 1964)

Phillips' selective medium incorporates an antifungal agent and is prepared as follows:

Prepare a stock solution of oleandomycin phosphate (5 mg/ml) in sterile distilled water, distribute it in 0.2 ml amounts, and store it frozen at −20°C. After thawing, prepare a working solution by adding 9.8 ml sterile distilled water. Prepare a stock suspension of nystatin (200 units/ml) in sterile distilled water, distribute in 1-ml amounts, and store frozen at −20°C. Both these stocks will store satisfactorily for at least 2 months. The final medium is prepared by adding the antibiotics to horse blood agar, to give final concentrations of oleandomycin (1 μg/ml) and nystatin (200 units/ml) as follows:

Hartley's digest agar	93 ml
Horse blood (oxalated)	5 ml
Oleandomycin phosphate working solution	1 ml
Nystatin stock suspension	1 ml

Melt the agar base and cool to 50°C. Add the blood and antibiotics and pour into sterile petri plates.

The ability to recover *A. actinomycetemcomitans* from environments with mixed bacterial populations has become increasingly important with the recognition of the association of this organism with human periodontal disease, especially as some of the normal oral organisms

may exert an inhibitory effect upon the actinobacilli (Yamamoto et al., 1981).

Selective Medium for *Actinobacillus actinomycetemcomitans* (Slots, 1982)

This medium is tryptic-soy-serum-bacitracin-vancomycin agar. Vancomycin suppresses the growth of streptococcal species, including *Streptococcus mitis* which has been shown (Yamamoto et al., 1981) to produce in vitro a substance inhibitory to *A. actinomycetemcomitans* and to other Gram-negative organisms found in the mouth.

The medium consists of:

Tryptic soy agar (Difco)	1 liter
Yeast extract (BBL)	1 g

Adjust pH to 7.2 and autoclave at 121°C for 15 min. Cool to 50°C and add the following (which have been sterilized by filtration) to give the respective final concentrations:

Horse serum	10%
Bacitracin	75 μg/ml
Vancomycin	5 μg/ml

Pour into sterile petri plates: Inoculated plates should be incubated either with 10% carbon dioxide in air, or under anaerobic conditions with 5% carbon dioxide added.

The isolation of *A. pleuropneumoniae* from infected tissues can be done using blood agar prepared from Hartley's digest broth. Although horse blood agar will support the growth of the organism, the use of bovine blood or sheep blood has the advantage that the colonies of freshly isolated strains of *A. pleuropneumoniae* will lyse the red cells of these two species, thus making selection of colonies easier especially when secondary bacteria such as *P. multocida* are present. Most strains of this organism require the V factor for growth and this is provided by using a "blood agar satellite plate," i.e., by inoculating a streak of a β-toxigenic staphylococcus strain across the plate after the tissue has been inoculated (Morgan and Phillips, 1978). This provides an additional identification character, the CAMP reaction (potentiation of the β-lysin of the staphylococcus) shown by all strains of *A. pleuropneumoniae* (Kilian, 1976b).

The presence of other organisms may make the isolation of *A. pleuropneumoniae* difficult, but selective media can be used to inhibit such organisms.

Selective Medium for *Actinobacillus pleuropneumoniae:* Modification of Sims' (1970) Medium (Morgan and Phillips, 1978)

Sims' medium consists of chocolate agar with bacitracin and cloxacillin added. The medium is prepared by cooling Hartley's digest agar to 80°C after autoclaving, adding 5% horse blood and heating in a steamer until it is a rich chocolate color. This is then cooled to 56°C and 10% yeast extract (Hers' method described by Marmion, 1967) added together with bacitracin and cloxacillin solutions to give final concentrations of 10 units/ml and 5μg/ml respectively. Yeast extract and antibiotic solutions are previously sterilized by filtration.

Best results are obtained by incubating inoculated plates in 10% carbon dioxide in air at 37°C for up to 48 h.

Heavy suspensions of actinobacilli may be prepared by growing the organisms on Hartley's digest agar in Roux flasks at 37°C for 24 h and washing off the growth into sterile saline or other suitable medium using sterile glass beads to dislodge the growth. An alternative method is to grow the organism in a flask of Hartley's digest broth in a shallow layer and incubate at 37°C for 24 h in a shaking bath (120 strokes/min).

Actinobacilli rapidly lose their viability when stored on solid media (e.g., blood agar) for more than 4 days. Cultures suspended in sterile rabbit serum or sterile 20% peptone solution and dried from the frozen state will remain viable in sealed ampules for many years. An alternative method of keeping stock cultures is as heavy suspensions in either rabbit serum or 20% peptone solution, stored at −70°C in a low-temperature cabinet.

Identification

All members of the genus *Actinobacillus* are markedly pleomorphic, having short bacillary or coccobacillary forms interspersed with coccal elements lying in close association with the rods and having the "Morse code" form described for *A. lignieresii* (Phillips, 1960). On media containing glucose or maltose, longer rods and almost filamentous forms may be seen, and often chains of short bacillary elements are present. In the case of *A. equuli* and *A. suis,* extracellular material staining faintly pink with Gram's stain is often seen. *A. capsulatus* and *A. pleuropneumoniae* both form capsules that can be demonstrated in wet india ink preparations.

Colonies of all species are sticky, especially on primary isolation, but those of *A. lignieresii* lose this characteristic on subculture. *A. suis* and *A. equuli* are very sticky (*A. suis* less so than *A. equuli*), and colonies are firmly adherent to the underlying medium. In broth cultures, the sticky nature of these two species is also apparent. The colonies of *A. actinomycetemcomitans* are not so sticky, but they characteristically adhere firmly to the underlying medium.

Table 1. Characteristics of the genus *Actinobacillus*.

Positive:	Reduction of nitrate to nitrite
	Production of β-galactosidase and urease
	Fermentation (acid only) of glucose, levulose, mannose, galactose, xylose, and maltose
Negative:	Production of indole
	Fermentation of inulin, inositol, dulcitol, adonitol, rhamnose, and sorbose

This adherence to the medium is also seen with the "waxy" colonies of *A. pleuropneumoniae,* but not with the soft, glistening colony form.

All members of the genus share the characteristics shown in Table 1. These characteristics would not exclude some members of the *Pasteurella* group, and, indeed, differentiation between the two genera may be difficult, so many isolates do not fall clearly into the recognized species of either genus. Close similarities of the two genera have been pointed out (Hacking and Sileo, 1977; Mráz, 1969, 1975; Smith, 1974).

The differential characteristics of the species of *Actinobacillus* are set out in Table 2. There is evidence, however, that a degree of overlapping between species occurs, especially between *A. equuli* and *A. suis.* The occurrence of strains isolated from horses having characters similar to those of *A. suis* has been reported (Kim et al., 1976); these differ from *A. equuli* mainly in their hydrolysis of esculin, fermentation of cellobiose and salicin, and nonfermentation of mannitol, and in being hemolytic on sheep blood agar. However, Mráz et al. (1968) drew attention to the existence of strains that, while being strongly hemolytic on blood agar, are similar in all other respects to *A. equuli,* and this possibility should be borne in mind in identification. The equine strains examined by Kim et al. (1976) have, on further investigation (Kim, 1976), shown one difference from those of porcine origin: unlike the porcine strains, they do not produce pigment. The pigment, creamy-yellow in color, can best be demonstrated by washing centrifuged broth cultures and observing the color of the deposit.

Gelatinase activity was considered by Phillips (1974) to be a characteristic feature of *A. equuli,* based upon the examination of a small number of strains from the National Collection of Type Cultures, using the gelatin agar method of Frazier (1926). Examination of a wider selection of strains (Kim, 1976) has shown that many are gelatinase negative, although positive strains are encountered from time to time (Frederiksen, 1973; Meyer, 1910; Vallée et al., 1974).

The determination of DNA base ratios does not give useful differentiation among species. Boháček and Mráz (1967) reported GC values lying within the range 40.0–42.6 mol% for *A. lignieresii* and *A. equuli,* while Mannheim et al. (1980) obtained values between 42.1 and 47.1 mol% for the strains of actinobacilli they investigated.

Most of the organisms included in this genus can be separated into a number of antigenic types or serotypes. In *A. lignieresii,* at least six such types have been described (Phillips, 1967), based upon heat-stable somatic antigens, and *A. equuli* presents at least 28 types (Kim, 1976). *A. actinomycetemcomitans* strains can be di-

Table 2. Differential characteristics of *Actinobacillus* species.

Characteristic	*A. lignieresii*	*A. equuli*	*A. suis*	*A. capsulatus*	*A. actinomycetemcomitans*	*A. pleuropneumoniae*

[a]Response is slow.
[b]Some strains are negative.

vided into three distinct serotypes based on their immunodiffusion and indirect immunofluorescence properties (Zambon et al., 1983), and there is evidence that the serotype might be related to the pathogenicity of the organism. In *A. pleuropneumoniae* the indirect haemagglutination test, together with immunodiffusion, makes possible the recognition of 12 serotypes (Nielsen, 1986).

Some minor antigenic cross relationships between members of the genus *Actinobacillus* and those of the *Pasteurella*, especially *P. haemolytica,* have been noted, but in general there are no strong antigenic cross-reactions between these two genera (Mráz, 1977; Ross et al., 1972).

Within the genus, however, antigenic cross relationships have been recognized. Such cross-reactions may occur between *A. equuli* and *A. suis* (Kim, 1976; Vallée et al., 1974), between *A. lignieresii* and *A. suis,* (Ross et al., 1972; Vallée et al., 1974) and between *A. lignieresii* and *A. equuli* (Wetmore et al., 1963).

MacInnes and Rosendal (1987), using polyacrylamide gel electrophoresis (PAGE) and immunoblotting to investigate the major antigens of *A. pleuropneumoniae,* were able to show similarities in the protein profiles of all the actinobacilli and also of *Pasteurella haemolytica.* This supports the earlier work suggesting that PAGE could be of value in differentiation (Ross et al., 1972; Vallée et al., 1974).

Gram-Negative Mesophilic Sulfate-Reducing Bacteria

FRIEDRICH WIDDEL and FRIEDHELM BAK

An overview of the sulfate-reduction process is given in Chapter 24. Most types of dissimilatory sulfate-reducing bacteria that have been isolated from nature and described so far are mesophilic, nonsporeforming anaerobes. They are members of the delta subdivision of the proteobacteria. The earliest known representative of this category is *Desulfovibrio* (Beijerinck, 1895). Further investigations have revealed a great morphological and nutritional diversity within this group. Various cell types have been described including cocci; oval or long straight rods; more or less curved rods or spirilla; cell packets; cells with gas vesicles; and gliding, multicellular filaments (Figs. 7–9). Electron donors used for sulfate reduction include H_2, alcohols, fatty acids, other monocarboxylic acids, dicarboxylic acids, some amino acids, a few sugars, phenyl-substituted acids, and some other aromatic compounds (Table 2). Even long-chain alkanes can be anaerobically oxidized by a particular type of sulfate-reducing bacterium (Aeckersberg et al., 1991). The utilization of polysaccharides or polypeptides, such as has been observed with the extremely thermophilic sulfate-reducing archaebacterium *Archaeoglobus* (Stetter, 1988; Stetter et al., 1987), has not been reported for mesophilic sulfate reducers.

All mesophilic, nonsporeforming, sulfate-reducing bacteria in which 16S rRNA has been sequenced form a phylogenetically distinct group of Gram-negative bacteria (Devereux et al., 1989, 1990; Fowler et al., 1986). The closest relatives are the phototrophic purple bacteria and their nonphototrophic relatives assigned to the alpha, beta, or gamma subdivision (Woese, 1987). The mesophilic, Gram-negative, sulfate reducers are thus grouped with the purple phototrophs and are termed the delta subdivision, even though no phototroph has been detected in this subdivision until now. However, the delta subdivision does contain chemotrophic nonsulfate-reducing bacteria; these are the obligately anaerobic *Pelobacter* species (Stackebrandt et al., 1989), sulfur-reducing bacteria of the genus *Desulfuromonas,* and the obligately aerobic *Bdellovibrio* and *Myxococcus* species (Fowler et al., 1986; Woese, 1987).

Habitats

Mesophilic nonsporeforming types appear to be the most wide-spread sulfate reducers in nature. The sulfur cycle in aquatic habitats depends on sulfate reduction as a primary process and is mainly governed by members of this subdivision of sulfate-reducing bacteria. The typical habitats of sulfate reducers are the subsurface parts of aquatic environments like sediments or bottom waters that have turned anoxic. The greatest variety of species has been isolated from marine sediments (Widdel, 1988) where sulfate, due to its high concentration in sea water (28 mM), is seldom a growth-limiting factor. Sulfate reducers are also found in rice paddies (Jacq and Dommergues, 1971; Takai and Kamura, 1966; Watanabe and Furusaka, 1980) and in anaerobic digestors of sewage plants (Badziong et al., 1978; Widdel, 1980). From anoxic sediments and sludge, these bacteria may spread into oil production plants (Cord-Ruwisch et al., 1986, 1987) and occasionally other industrial water systems such as paper production plants (Soimajärvi et al., 1978). Dissemination from anaerobic aquatic sediments may occur via oxic water in which sulfate reducers may survive for a while, probably in a metabolically inactive state (Cypionka et al., 1985). Significant activities and cell densities of sulfate-reducing bacteria have been observed even in the upper oxic zones of fresh water and marine sediments (Bak and Pfennig 1991a, 1991b; Jørgensen and Bak, 1991); growth of sulfate reducers at these sites may be explained by the presence of anoxic microniches (Jørgensen, 1977). Furthermore, sulfate reducers have been detected in the sheep rumen (Howard and Hungate, 1976) and in human intestines (Beerens and Romond, 1977; Moore et al., 1976).

Members of the genera *Desulfovibrio* and *Desulfobulbus* appear to be equally common in

fresh water and marine or other saline habitats (Bak and Pfennig, 1991b; Postgate, 1984a; Widdel, 1988), even though particular isolates are often adapted to a certain salt concentration. The growth of freshwater strains may be inhibited in salt media, whereas marine strains often require NaCl and Mg^{2+} ions. There are also salt-tolerant sulfate reducers such as *Desulfovibrio desulfuricans* and *Desulfococcus multivorans* that grow almost equally well in freshwater and saltwater medium. *Desulfobacter, Desulfobacterium, Desulfosarcina,* and *Desulfonema* may be regarded as primarily marine or brackish; most of their strains require media with $\geq$100 mM NaCl and $\geq$5 mM $MgCl_2$. Some *Desulfobacter* species have been isolated from freshwater sediments far away from the sea; however, growth was stimulated in saline media (Widdel and Pfennig, 1981; Widdel, 1987).

With H_2 as electron donor, *Desulfovibrio* species have a high maximum growth rate (μ_{max} = 0.23 h^{-1}) and a low half-saturation constant (K_s = 3.3 μM; for overview and literature, see Widdel, 1988). The μ_{max}/K_s value, which indicates the effectiveness of substrate utilization at limiting concentration, is higher than in the case of H_2-consuming methanogenic bacteria. Therefore, *Desulfovibrio* species and probably also the physiologically similar *Desulfomicrobium* species seem to be important H_2 scavengers in the anaerobic degradation of organic matter in sediments. High numbers of *Desulfovibrio* have been also found in a methane-producing whey fermenter without added sulfate (Zellner et al., 1987; Zellner and Winter, 1987). This suggests that even in the absence of sulfate, *Desulfovibrio* is involved in anaerobic degradation, namely by channeling lactate into methanogenesis. In aquatic sediments, lactate may be formed after rapid high-carbohydrate input. *Desulfobacter* is probably the main utilizer of acetate in brackish or marine sediments, as shown by growth kinetic data of this sulfate reducer in comparison to those of the important acetate-utilizing methanogenic bacteria (for overview, see Widdel, 1988). The role of other more versatile sulfate reducers, e.g., *Desulfobacterium* species, may be a simultaneous utilization of various electron donors produced during the primary breakdown of dead biomass in sediments.

Cultivation Techniques and Media

Sulfate-reducing bacteria grow under anoxic, reducing conditions. If inoculated into oxygen-containing (air-saturated) media, only fresh cultures of a few robust species may continue to grow. If the size of the inoculum is not too small, enough sulfide is transferred to scavenge oxygen. However, sulfide may also increase the toxicity of O_2, especially if the latter is present in excess (Cypionka et al., 1985). Removal of O_2, e.g., by sparging with N_2 prior to inoculation, eliminates the danger of cell damage by O_2 and always facilitates initiation of growth. Still, removal of O_2 merely by physical means is not sufficient for most slowly growing or fastidious strains, or in case of small inocula such as in dilution series. For these, addition of reductants is usually necessary. Reductants* that have often been used for the cultivation of sulfate-reducing bacteria are ascorbate (dehydroascorbate/ascorbate, $E^{0\prime}$ = +0.058 V); thioglycollate (dithioglycollate disulfide/thioglycollate, $E^{0\prime}$ = −0.14 V); sulfide (S^0/H_2S, $E^{0\prime}$ = −0.243 V; for 1 mM H_2S, E' = −0.198 V); and dithionite ($2SO_3^{2-}/S_2O_4^{2-}$, $E^{0\prime}$ = −0.29 [−0.46] V; for 1 mM, E' = −0.38 [−0.55] V). Dithionite is relatively toxic and can be added only at low concentrations (0.1–0.2 mM), usually in addition to other reductants; such low concentrations were clearly growth-promoting for many sulfate reducers (e.g., Bak and Widdel, 1986b; Widdel and Pfennig, 1981; Widdel et al., 1983). Sulfite, a rather strong reductant (SO_4^{2-}/SO_3^{2-}, $E^{0\prime}$ = −0.516 V), is part of the commercially available "iron-sulfite agar" (Postgate, 1984a), but has otherwise not been used for many media. One disadvantage of sulfite is a certain toxicity; in serial dilutions for viable counts, as little as 0.5 mM inhibited growth of certain sulfate reducers (F. Bak, unpublished observations). Also, below pH 7, sulfite tends to react with sulfide to yield thiosulfate, which by further reaction with sulfite yields polythionates and sulfur (Heunisch, 1976). Cysteine (cystine/cysteine, $E^{0\prime}$ = −0.325 V), which is frequently used for the cultivation of methanogens (Balch et al., 1979), may be also useful for sulfate reducers. As an indicator of reducing conditions, resazurine (resorufin/dihydroresofin, $E^{0\prime}$ = −0.03 to −0.04 V; Veldkamp, 1970) may be added at a final concentration of 1 mg/liter compatibility should be tested first.

All Gram-negative mesophilic sulfate reducers known so far grow in defined medium

*The redox potentials given refer to pH 7.0; values were taken or calculated from Dawson et al. (1986), Loach (1970), Thauer et al. (1977), and Weast (1989). Values for dithionite calculated from literature values given for alkaline solution (pH = 14) and for acidic solution (pH = 0) are not consistent. The latter yielded the values given in brackets; the dissociation constants of the corresponding acids (Greenwood and Earnshaw, 1984; Hollemann et al., 1985) were considered in these calculations.

without complex nutrients such as yeast extract or peptone. Complex nutrients, however, may be stimulatory for a number of species. Defined media are supplemented with growth factors only; many sulfate reducers require *p*-aminobenzoate, biotin, and/or some other vitamins.

It is recommended that media be prepared in big batches and then dispensed into smaller culture vessels. The expense of equipment for media preparation and cultivation largely depends on how strict the demand for anaerobic conditions is.

In case of robust, rapidly growing species, it may not be necessary to prepare media under anoxic conditions; it is sufficient to exclude air from the cultivation vessel during growth. A device for preparation of media in such simple way is shown in Fig. 1. After addition of reductants, the completed medium is distributed to tubes or bottles via a dispenser made of a piece of glass tubing and a small glass hood ("bell," e.g., a bottle with cut bottom) for protection against contamination from the air. Useful cultivation vessels are tubes (20 to 25 ml) or bottles (50 or 100 ml) with aluminum caps fitted with rubber disks. They are autoclaved with loosely attached caps or with a drop of water and tightly closed caps. Autoclaved tubes and bottles are completely filled with medium to exclude air. If incubated at elevated temperature, the tightness of the screw caps must be released somewhat (without loosening them) for about one hour because of liquid expansion. A small drop will be squeezed out between rubber seal and orifice. Then, the screw caps are tightened. Before being opened again for transfer, the aluminum caps are briefly heated in a flame to minimize the danger of contamination; therefore plastic caps are unsatisfactory.

For the cultivation of most sulfate-reducing bacteria, it is necessary to exclude air as far as possible, even during preparation of the me-

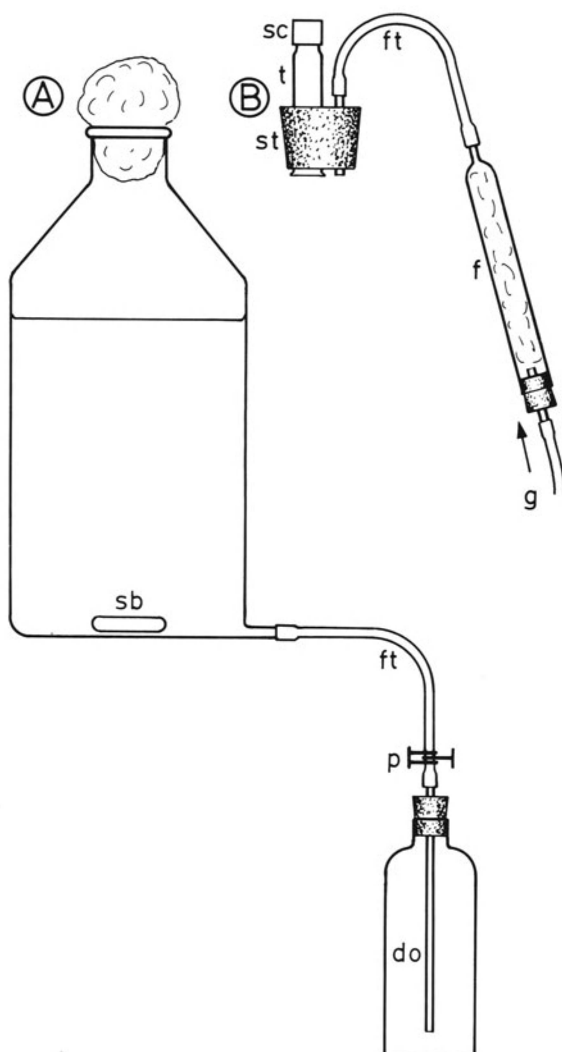

Fig. 1. Bottle for batch preparation of sterile medium and dispensing to culture tubes or bottles. Components that are not autoclaved with the medium are added afterwards from separately sterilized stock solutions. (A) For the preparation of media for some robust strains, exclusion of air during preparation may not be necessary so that a cotton stopper (or metal cap) is sufficient. Nevertheless, the completed medium should be dispensed into the culture vessels soon after addition of the reductants. (B) For more strict exclusion of air, the bottle is autoclaved with a stopper (st) containing a protruding flanged tube (t) with a screw cap (sc); the stopper is also connected to a cotton filter (f) for aseptic gassing. Before autoclaving, the screw cap is loosened and the dispenser is wrapped in aluminum foil. After autoclaving, the filter is connected to a gas supply (g) of N_2 or an N_2/CO_2 mixture which is flushed for some minutes through the head space to replace air while the screw cap is kept open. The gas pressure should be below 20 kPa (0.2 atm); this allows tightening of the screw cap after flushing or addition of stock solutions without blowing off the stopper. If insoluble iron compounds are formed (as in medium B of Postgate, 1984), the medium is gently stirred during dispensing to guarantee equal distribution of the precipitate. The end of the dispenser for open culture vessels (do) is always kept below the meniscus of the bottled medium to minimize contact with air. Other abbreviations: (ft) flexible tubing; (p) pinch clamp; (sb) stirring bar.

dium. The batch is therefore prepared under an anoxic gas phase. Some useful devices are shown in Fig. 1B and Fig. 2. The device in Fig. 2 is made from a pressure-proof Erlenmeyer flask. This is advantageous especially for media containing sulfide as a reductant. Since the flask is inverted when the media is dispensed, the surface area of the liquid gets smaller as its level decreases; this minimizes the loss of H_2S to the gas space towards the end of dispensing. Again, the medium may be dispensed into open tubes or bottles via a piece of glass tubing with a protective hood. During this procedure, the medium is in brief contact with air; however, if the exposure is minimized by keeping the tip of the dispenser below the miniscus (Fig. 2B), only

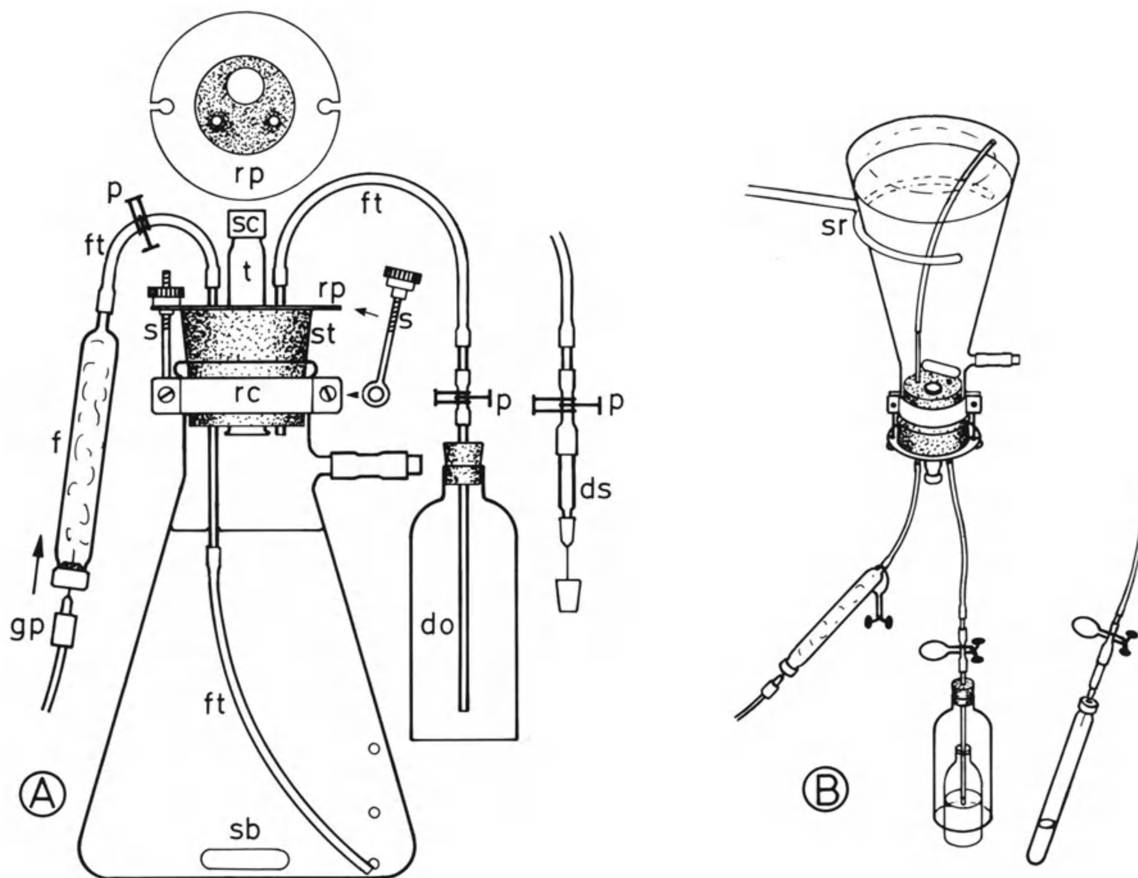

Fig. 2. Pressure-proof device for batch preparation of anoxic medium and dispensation into culture tubes or bottles. A suction pipe on the pressure-proof (vacuum-proof) flask is closed by means of a piece of rubber tubing with a glass rod. (A) Detailed view. A stopper (st) is provided with a cut and flanged tube (t) with screw cap (sc) and connected to a cotton filter (f) and dispenser (do, ds). The stopper is fixed by means of a ring clamp (rc) and a ring plate (rp) held together with long screws (s) and nuts. The ring clamp is made up of two half-circles that are fixed around the neck of the flask by means of short screws; the latter also hold the long screws. The upper part of the figure shows a view of the top of the stopper with the holes and the ring plate. Instead of the dispenser for open culture vessels (do), a different one for stoppered vessels (ds) may be used to allow injection. The latter is made of a cut narrow syringe barrel (or autoclavable needle adaptor) with a needle. For the flexible tubings (ft) outside the flask, rather gas-impermeable material (e.g., Viton, butyl) should be used. However, a short piece of tubing close to the dispenser should be made of silicon since this allows easy, rapid closing and opening with the pinch clamp (p). Since silicon is relatively gas-permeable, this piece is kept as short as possible. The medium with heat-stable components is autoclaved in the flask with loosened screw cap and pinched tubings. Dispensers are wrapped in aluminum foil before autoclaving. After autoclaving, the needle of a gassing probe (gp) is inserted in the stopper of the filter to gas the medium and the head space with an N_2/CO_2 mixture. At the same time, the flask may be cooled in a water bath. Stock solutions are added through the open tube (t) while the escaping anoxic gas prevents the entry of air. Between and after the additions, the screw cap is tightened. After anoxic gassing of the dispenser (ds) by brief opening of the pinch clamp, the needle may be closed with a sterile rubber stopper if not immediately used for injection. (B) The medium is dispensed either into open or stoppered culture vessels. In the latter case, an overpressure of 1 to 1.5 atm may be applied from the gas supply. For safety, use of a plexiglas shield is recommended. Other abbreviations: (sb) stirring bar; (sr) support ring.

traces of oxygen get into the medium, and they are soon scavenged by the reductant.

For very strict exclusion of air, the dispenser is made of a small syringe (or autoclavable needle adaptor) which allows injection into stoppered, anoxically gassed culture vessels (Fig. 2). Tubes or bottles with black rubber or butyl stoppers are used (Balch et al., 1979). Desorption of O_2 from stoppers and glass should be allowed. This may be achieved by pregassing the stoppered vessels with N_2, and waiting for one day. If available, an anoxic hood (with an N_2/H_2 mixture in the presence of a palladium catalyst) is preferred for desorption of O_2. After incubation in the hood for one day, a drop of water is placed in the culture vessels, and they are sealed inside the chamber with stoppers that are fixed with crimps or open-top screw caps. Tubes and bottles pregassed with N_2 or taken from the chamber are repeatedly evacuated and flushed with an N_2/CO_2 mixture. A device for evacuation and gassing is shown in Fig. 3. For the described medium with 30 mM $NaHCO_3$ and a pH of 7.0–7.4, the CO_2 content in the mixture should be 5–10%. For buffering at lower pH, the CO_2 content is increased, e.g., to 20% for a pH of around 6.8. At the end of the gassing procedure, tubes or bottles are brought to ambient pressure. Before dispensing the medium, the gas space of the dispenser with the needle is briefly flushed with the gas from the head space of the pressure-proof flask. The medium is injected by pressure (101 kPa, 1 atm) from the inverted flask into the anoxic tubes or bottles so as to fill approximately ⅓ to ½ of the volume. Anoxic gas bubbles inside the dispensor can be removed by inverting it during dispensing. The overpressure created in the culture vessels by addition of the medium is favorable for maintaining anoxic conditions. All further additions or withdrawals are carried out through the stoppers by means of syringes. Syringes are gassed immediately before use by repeated suction and release of sterile N_2. This is done by inserting the needle into another needle (of larger diameter) attached to a sterile gassing syringe, such as the one shown in Fig. 5. Stopper surfaces are sterilized with ethanol (that may be burned) before injection. Sterile stoppers should be covered with flamed aluminum foil or caps.

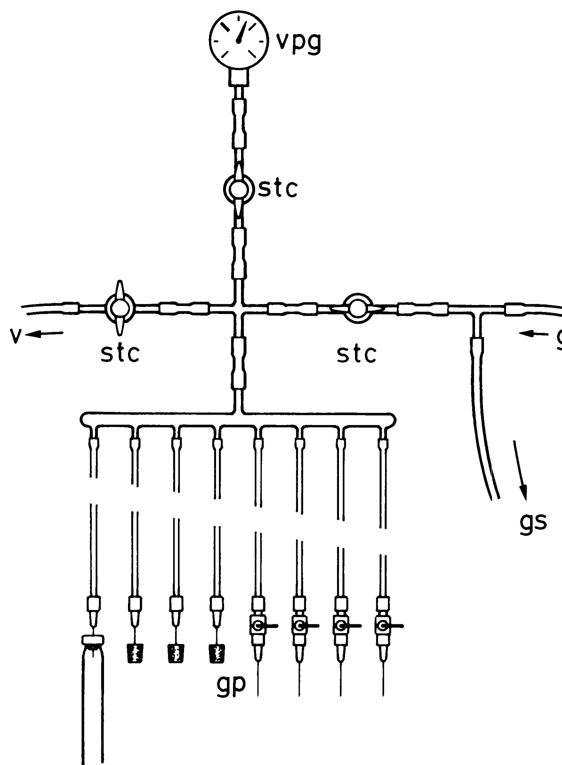

Fig. 3. Gassing manifold, modified from Balch et al. (1979). A glass tube with side arms and gassing probes (gp) can be alternately connected via stopcocks (stc) to a gas supply (g) or a vacuum line (v). A separate line branches off to a sterile gassing syringe (gs) as shown in Fig. 5. Gassing probes (gp) not inserted into culture vessels are closed with stoppers or stopcocks. Culture tubes (one shown on the left gassing probe) or bottles are gassed by alternate opening and closing of the vacuum line and gas supply. The process is controlled by means of the vacuum-pressure gauge (vpg). The applied overpressure may be 100 to 200 kPa (1 to 2 atm), depending on the thickness of the glass wall. In any case, for safety, the use of a plexiglas shield is recommended. Culture vessels to be filled as described in Fig. 2B are finally brought to ambient pressure by briefly opening a free gassing probe or the vacuum line. If cultures rich in sulfide have to be evacuated and gassed, the connection to the gauge via the stopcock is closed to avoid corrosion of metal parts by H_2S.

Culture Media

Many different types of media have been used for the cultivation of sulfate-reducing bacteria; however, no one medium is well suited for all species. In the following, two media frequently employed are described.

A lactate medium that can be prepared rather simply has been used successfully for decades for cultivation of the "classical" sulfate reducers *Desulfovibrio* and *Desulfotomaculum*. The medium has not been used so far for other sulfate reducers. Lactate (or pyruvate) serves as both the electron donor and carbon source. The medium is buffered with phosphate and contains iron. Further trace elements or vitamins are not added; they may be present in the yeast extract or as impurities in chemicals or water.

Lactate Medium for *Desulfovibrio*

Preparation of stock solutions:

1. $FeSO_4$ solution

Distilled water	10 ml
$FeSO_4 \cdot 7H_2O$	0.5 g

It is advantageous to autoclave the solution under a head space of N_2 in tubes with fixed stoppers to prevent oxidation. Also acidification, e.g., with 1 ml of 1 M H_2SO_4, counteracts oxidation.

2. Reductants solution

Distilled water	10 ml
Sodium thioglycollate*	0.1 g
Ascorbic acid	0.1 g

Autoclaving under N_2 as described for the $FeSO_4$ solution is recommended.

---

*Stocks of sodium thioglycollate should not be old since the compound easily undergoes oxidation even as a dry salt. Its reducing capacity may be checked by iodometric titration.

Preparation of media:

Of several reported versions of lactate medium, two are given here using the designations of Postgate (1984a, 1984b); suggestions by Lapage et al. (1971) are included. The simple device depicted in Fig. 1 may be used for preparing and dispensing these media.

	Medium B	Medium C
Distilled or tap water	1 liter	1 liter
Sodium lactate (50% solution)	7.0 g (5.5 ml)	12.0 g (9.5 ml)
Na_2SO_4	–	4.5 g
$CaSO_4$	1.0 g	–
$CaCl_2 \cdot 2H_2O$	–	0.06 g
Sodium citrate	–	0.3 g
NH_4Cl	1.0 g	1.0 g
KH_2PO_4	0.5 g	0.5 g
$MgSO_4 \cdot 7H_2O$	2.0 g	2.0 g
NaCl (only for marine strains)	(2.5 g)	(2.5 g)
Yeast extract	1.0 g	1.0 g

To avoid formation of precipitates, dry salts should not be mixed together before dissolution. They are added successively to the water during stirring. The pH is adjusted to approx. 7.2 and the solution is autoclaved. Further components are added from the sterile stock solutions after autoclaving:

$FeSO_4$ solution	10 ml	0.08 ml
Reductants solution	10 ml	10 ml

In several cases, the $FeSO_4$ and reductants solutions were added to the medium before autoclaving. However, it is better to autoclave the solutions separately. Since the additions are somewhat acidic, the pH may be controlled and readjusted using aseptic techniques. The completed medium is aseptically distributed into bottles or tubes as described. For storage of medium B or C in batches, the $FeSO_4$ and reductants are omitted; they are added only directly before use, after the medium has been boiled again. Alternatively, the complete medium with $FeSO_4$ and reductants may be stored as batch under N_2.

For plates, media B and C are prepared with 10 g agar per liter. Before autoclaving, the agar should be dissolved and distributed in the medium by stirring in a boiling water bath.

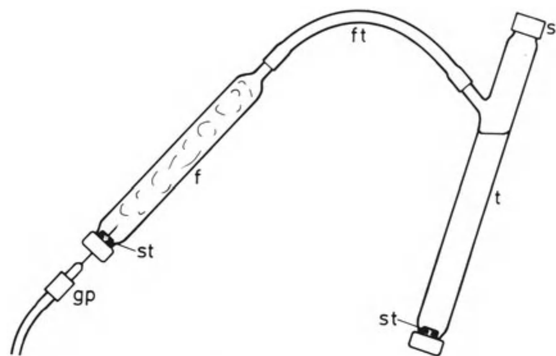

Fig. 4. Tube (t) with side arm and cotton filter (f) connected by flexible tubing (ft) for preparation or maintenance of a dithionite solution. Sterile distilled H_2O in the tube is deaerated by evacuation and repressurized with N_2 via the gassing probe (gp) inserted in the stopper (st). $Na_2S_2O_4$ weighed on a flamed, dry piece of aluminum foil is added while a slow stream of the anoxic gas prevents access of air. The tube is closed with the screw cap (sc). After dissolution by gentle shaking, samples are taken by means of pipettes via the upper opening under a stream of the anoxic gas. Alternatively, samples may be taken by means of N_2-flushed syringes via the bottom stopper (st) that is fixed with an open-top screw cap. For refrigeration of the dithionite solution, the gassing probe is disconnected.

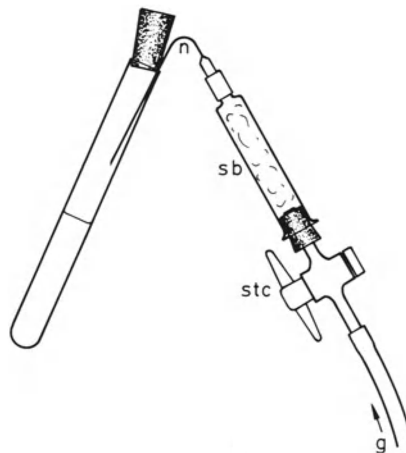

Fig. 5. Anoxic gassing of an agar tube with a gassing syringe according to the Hungate technique (Bryant et al., 1972). A syringe barrel (sb) filled with cotton and a bent needle (n) is connected to a gas supply (g) via a stopcock (stc). Before gassing, the needle is sterilized in a flame; the needle fixture should therefore be of metal. Tubes or bottles with liquid medium or stock solutions may be gassed in the same way.

Medium B turns black upon bacterial sulfide production (precipitation of FeS) and can thus be used for diagnostic purposes, e.g., for detection of sulfate reducers in counting series. Also for maintenance of stock cultures, the medium is useful since the abundant precip-

itate apparently provides a favorable microenvironment for the preservation of viable cells. Medium C is almost clear; it is suitable for mass culture of *Desulfovibrio*.

For cultivation of *Desulfovibrio* with H_2, media B and C are supplemented with about 0.2 to 0.4 g sodium acetate per liter; the H_2 gas phase should contain some CO_2. Acetate and CO_2 are the main carbon sources required for lithotrophic growth (Badziong et al., 1979; Brandis and Thauer, 1981). The added yeast extract usually contains only limited amounts of acetate. Acidification by CO_2 can be counteracted by addition of $NaHCO_3$ (see the next recipe).

A second major type of medium is a defined one that contains all the minerals, trace elements, and vitamins that may be required by sulfate-reducing bacteria. The medium has been developed for sulfate reducers of the newer genera (Widdel, 1980; Pfennig et al., 1981; Widdel et al., 1983; Widdel and Pfennig, 1984) but may be used for the classical *Desulfovibrio* species as well. The main buffer is HCO_3^-/CO_2, which may also serve for carboxylation reactions. Sulfide is added as a reductant. The phosphate concentration is low to allow addition of high Ca^{2+} concentrations if necessary (Widdel et al., 1983). Precipitates other than very small amounts of dark metal sulfides (mainly FeS) are not formed. Compounds that are volatilized, precipitated, or destroyed by heat are sterilized separately and added to the autoclaved, cold medium. The medium is first prepared as batch without organic electron donors and carbon sources and dispensed into tubes or bottles. Electron donors, carbon sources, and eventually other supplements are added to each culture vessel from sterile concentrated stock solutions as required for individual species and growth experiments.

Defined Multipurpose Medium

Preparation of basal stock solutions:

1. Nonchelated trace element mixture (Widdel et al., 1983)

Distilled water	987 ml
HCl (25% = 7.7 M)	12.5 ml (100 mM)
$FeSO_4 \cdot 7H_2O$*	2100 mg (7.5 mM)
H_3BO_3	30 mg (0.5 mM)
$MnCl_2 \cdot 4H_2O$	100 mg (0.5 mM)
$CoCl_2 \cdot 6H_2O$	190 mg (0.8 mM)
$NiCl_2 \cdot 6H_2O$	24 mg (0.1 mM)
$CuCl_2 \cdot 2H_2O$	2 mg (0.01 mM)
$ZnSO_4 \cdot 7H_2O$*	144 mg (0.5 mM)
$Na_2MoO_4 \cdot 2H_2O$	36 mg (0.15 mM)

The trace element mixture is autoclaved in bottles tightly closed with rubber-fitted screw caps or fixed stoppers; a head space of approx. ⅓ of the volume must be left (air for common use; N_2 for strictly anoxic procedures).

*Sulfates of ferrous iron and zinc are easier to handle than the corresponding chlorides, which, in air, undergo weathering or deliquesce, respectively; chlorides are only used if strictly sulfate-free media are required for special experiments.

2. Trace element mixture with EDTA (modified from Pfennig and Trüper, 1981)
The solution has the same composition as trace element mixture 1 except that HCl is replaced by 5.2 g (15.5 mM) sodium EDTA; the pH is adjusted to 6.0 with NaOH. The solution is autoclaved as described for solution 1.
3. Trace element mixture with NTA (Badziong et al., 1978)

Distilled water	800 ml
Nitrilotriacetic acid (NTA)	12.8 g (190 mM)

The pH is adjusted to 6.5 with dilute NaOH.

$FeSO_4 \cdot 7H_2O$	420 mg (1.5 mM)
H_3BO_3	10 mg (0.16 mM)
$MnCl_2 \cdot 4H_2O$	100 mg (0.5 mM)
$CoCl_2 \cdot 6H_2O$	170 mg (0.7 mM)
$CuCl_2 \cdot 2H_2O$	20 mg (0.12 mM)
$ZnSO_4 \cdot 7H_2O$	210 mg (0.73 mM)
$Na_2MoO_4 \cdot 2H_2O$	10 mg (0.04 mM)

Add distilled water to a final volume of 1000 ml. The solution is autoclaved as described for solution 1.
4. Selenite-tungstate solution

Distilled water	1 liter
NaOH	0.4 g (10 mM)
$Na_2SeO_3 \cdot 5H_2O$	6 mg (0.02 mM)
$Na_2WO_4 \cdot 2H_2O$	8 mg (0.02 mM)

The solution is autoclaved as described for solution 1. A slight turbidity and flocs may be formed by reaction of the alkaline solution with the glass surface, but the solution is still useful.
5. Bicarbonate solution (1.0 M)
84 g $NaHCO_3$ are dissolved in distilled water to a final volume of 1 liter. The solution is dispensed in the required portions (30 ml for 1 liter of medium) into bottles, leaving approx. ⅓ as head space. Gassing of the head space with CO_2 and saturation of the solution by repeated flushing and shaking is recommended. Bottles are tightly closed with rubber stoppers and autoclaved. Stoppers must be fixed before autoclaving with aluminum crimps or screw caps. Alternatively, bottles may be mounted between two parallel metal sheets that are held together by screws.
6. Vitamin mixture

Sodium phosphate buffer (10 mM; pH 7.1)	100 ml
4-Aminobenzoic acid	4 mg
D(+)-Biotin	1 mg
Nicotinic acid	10 mg
Calcium D(+)-pantothenate	5 mg
Pyridoxine dihydrochloride	15 mg

The solution is filter-sterilized (pore size, 0.2 μm). The solution is kept at 4°C in the dark, preferentially in bottles of brown glass. For strictly anoxic procedures, the solution may be kept under N_2 as described later for phenol solution (solution 17).
7. Thiamine solution
10 mg thiamine chloride dihydrochloride are dissolved in 100 ml of 25 mM sodium phosphate buffer, pH 3.4. The solution is filter-sterilized and stored as described for solution 5.

8. Vitamin B_{12} solution
   5 mg cyanocobalamine are dissolved in 100 ml distilled water. The solution is filter-sterilized and stored as described for solution 5.
9. Sulfide solution, 0.20 M
   Clear, colorless, large crystals of $Na_2S \cdot 9H_2O$ from a fresh and not deliquesced stock* are weighed and dissolved in dist. H_2O so as to yield a solution of 48 g/liter. Crystals from old stocks, which usually contain oxidation products on the surface, should be washed on a plastic sieve by briefly rinsing with distilled water. Crystals are dissolved in distilled water under N_2. The solution is dispensed in the required portions (7.5 ml for 1 liter of medium) into tubes that are stoppered under N_2; stoppers are fixed with screw caps or aluminum crimps. The tubes are autoclaved. Formed precipitates from etched glass do not affect usability (see solution 4).

*Sodium sulfide is autooxidizable and hygroscopic. The chemical should be refrigerated or, preferably, be kept under N_2.

10. Acid or carbonate solution
    1 M H_2SO_4, 2 M HCl (for sulfate-free media), or 1 M Na_2CO_3 solution are autoclaved as described for solution 1. Autoclaving in closed bottles is necessary, especially for the heat-volatile HCl solution.

Preparation of basal media:

	Freshwater medium	Brackish medium	Saltwater medium
Distilled water	1.0 liter	1.0 liter	1.0 liter
NaCl	1.0 g	7.0 g	20.0 g
$MgCl_2 \cdot 6H_2O$	0.4 g	1.2 g	3.0 g
$CaCl_2 \cdot 2H_2O$	0.1 g	0.1 g	0.15 g
Na_2SO_4*	4.0 g	4.0 g	4.0 g
NH_4Cl	0.25 g	0.25 g	0.25 g
KH_2PO_4	0.2 g	0.2 g	0.2 g
KCl	0.5 g	0.5 g	0.5 g

*If fermentative growth or syntrophic growth with methanogens is tested, sulfate is omitted.

To avoid formation of precipitates, dry salts should not be mixed before dissolution. They are added successively to the stirred water. The solution is autoclaved in one of the devices shown in Figs. 1B or 2. After autoclaving, redissolution of oxygen is prevented by cooling under N_2/CO_2. Then, the aforementioned stock solutions or aliquots therefrom are aseptically added (amounts per liter of medium):

Trace element mixture 1*	1.0 ml
Selenite-tungstate solution	1.0 ml
$NaHCO_3$ solution	30.0 ml
Vitamin mixture	1.0 ml
Thiamin solution	1.0 ml
Vitamin B_{12} solution	1.0 ml
Na_2S solution	7.5 ml

*Alternatively, 1 ml of trace element mixture 2 or 10 ml of trace element mixture 3 are added. Trace element mixture without chelator is tolerated by all sulfate-reducing bacteria and is therefore used for enrichment of new types and most pure cultures. The possibility of growth stimulation by one of the chelated trace element mixtures has to be tested for each species; chelators can also impede growth.

The pH is controlled in aliquots aseptically withdrawn by means of a sterile pipettes; aliquots are collected in small test tubes. To avoid loss of CO_2 from these samples and increase of the pH, the tip of the pipette is kept below the meniscus of the added sample. A pH value of 7.0 to 7.3 (or other pH desired) is obtained using sterile 1 M H_2SO_4 (for sulfate-free medium, with 2 M HCl) or Na_2CO_3 solution (see below). Ordinary pH probes may gradually deteriorate if exposed to sulfide. Therefore, sulfide-resistant probes with bridged reference electrodes (e.g., Ross™, Orion) are recommended. Electrode damage may be also avoided by adjusting the pH before the addition of Na_2S to the medium (i.e., after addition of vitamin B_{12}). Then, an additional, calculated amount of acid is added that exactly compensates the increase in pH caused by the following addition of the alkaline Na_2S. Per ml of Na_2S solution (0.2 M) to be added, approx. 0.13 ml of 1.0 M H_2SO_4 or 2 M HCl are added in advance. Thereafter, the sulfide solution is added, and the medium is dispensed into sterile bottles or tubes (Fig. 2) that are stored in the dark.

Organic substrates and further additions:
Depending on the type of sulfate reducer to be enriched or cultivated, aliquots from the following stock solutions are added to tubes or bottles with basal media.

11. Acetate solution, 2.0 M
    27.2 g $CH_3COONa \cdot 3H_2O$ are dissolved in distilled water to a final volume of 100 ml and autoclaved in a closed bottle as described for solution 1.
    Application: 5 to 10 ml per liter of medium.
12. Propionate solution, 2.0 M
    Unlike acetate, propionate (and also salts of most other acids) is prepared from the free acid, which is usually of higher purity than the commercially available sodium salt.
    Distilled water 20 ml
    Propionic acid 14.9 ml (14.8 g)
    NaOH (4.0 M) 48 ml
    The NaOH is added slowly with stirring. The pH is then adjusted between 8 and 9 by dropwise addition of further NaOH (preferentially more dilute). To remove propionic acid ester that is often present, the slightly alkaline solution is gently boiled until the ester smell has disappeared. Distilled water is added to a final volume of 100 ml. The solution is autoclaved in a closed bottle as described for solution 1.
    Application: 5 to 10 ml per liter of medium.
13. Butyrate or isobutyrate solution, 1.0 M
    Distilled water 40 ml
    Butyric or isobutyric acid 9.20 ml (8.81 g)
    NaOH (4.0 M) 24 ml
    Adjustment of pH between 8 and 9 and removal of ester is carried out as described for solution 11. Distilled water is added to a final volume of 100 ml. The solution is autoclaved as described for solution 1.
    Application: 5 to 15 ml per liter of medium.
14. Palmitate or stearate solution, 0.10 M
    Water 80 ml

Palmitic acid 2.54 g
NaOH (4.0 M) 2.50 ml

Stearate solution is prepared with 2.85 g of stearic acid. The suspension is heated in a closed bottle (with head space) in a boiling water bath. The bottle is vigorously shaken until the solution has become clear and all particles and droplets have disappeared. Distilled water is added to a final volume of 100 ml. The solution is autoclaved as described for solution 1. The solution solidifies when cooled and has to be remelted in a boiling water bath before use. Gradually formed precipitates from glass do not affect the usability (see solution 4).

Application: 8 to 15 ml per liter of medium.

15. Ethanol solution, 2.0 M

11.6 ml (9.21 g) ethanol are dissolved in water to a final volume of 100 ml and autoclaved in a tightly closed bottle as described for solution 1.

Application: 5 to 20 ml per liter of medium.

16. Lactate solution

The commercially available 50% (5.7 M) sodium lactate solution is autoclaved as described for solution 1. More dilute solutions, e.g., 2.0 M, may be also used.

Application: 2 to 7 ml (50%) per liter of medium.

17. Benzoate or nicotinate solution, 0.5 M

Distilled water 40 ml
Benzoic acid 6.11 g
NaOH (4.0 M) 24 ml

Nicotinate solution is prepared with 6.16 g of nicotinic acid. The NaOH is added under stirring. The poorly soluble acids dissolve gradually. Heating in a water bath and breaking up the clumps that form using a flat-ended glass rod facilitates dissolution. The pH is adjusted to 7 to 8 with further NaOH. Distilled water is added to a final volume of 100 ml. The solution is autoclaved as described for solution 1.

Application: 4 to 10 ml per liter of medium.

18. Phenol, catechol, or aniline solution, 0.25 M

2.4 g phenol, 2.75 g catechol, or 2.3 ml (2.3 g) aniline* are dissolved in distilled water in a final volume of 100 ml. Anoxic storage is important especially for catechol and aniline. Solutions are filter-sterilized (pore size, 0.2 μm) into autoclaved bottles with crimped rubber stoppers; the filter holder is connected with a needle to pierce through the stopper. The bottles are repeatedly evacuated and aseptically gassed with N_2 via a cotton-filled syringe according to Balch et al. (1979). The solutions are kept in the dark. Aliquots are withdrawn by means of syringes.

Application: 2 to 4 ml per liter of medium.

*Caution: aniline is highly toxic.

19. Indole solution, 0.025 M

0.29 g indole are added either to 100 ml distilled water or, in case of marine strains, to 100 ml of an aqueous solution containing 2 g NaCl and 0.3 g $MgCl_2 \cdot 6H_2O$. The suspension is heated in a closed bottle (with head space) in a boiling water bath. The hot bottle is vigorously shaken until droplets of indole have disappeared. The solution is autoclaved and kept in the dark. Indole recrystallizes after cooling. Before use, the indole is redissolved as described.

Application: 10 to 20 ml per liter of medium.

20. Sulfite solution, 1.0 M

An aqueous solution of 12.6 g Na_2SO_3 per 100 ml is filter-sterilized and stored under N_2 at 4°C as described for solution 17.

Application: 0.5 to 3 ml per liter of medium.

21. Thiosulfate solution, 1.0 M

An aqueous solutions of 24.8 g $Na_2S_2O_3 \cdot 5H_2O$ in 100 ml is filter-sterilized and stored at 4°C. For maintenance over many months, storage under N_2 is recommended.

Application: 5 to 15 ml per liter of medium.

22. Salt concentrate

NaCl 286.4 g
$MgCl_2 \cdot 6H_2O$ 44.7 g
$CaCl_2 \cdot 2H_2O$ 2.2 g

The salts are dissolved in water to a final volume of 1 liter and is autoclaved as described for solution 1. Applications are described in the section on "Special Procedures and Modifications."

23. Dithionite solution

Stocks of solid $Na_2S_2O_4$ are stored in dry, sterile glass bottles closed with screw caps. A tube with a side arm connected to a sterile cotton filter as shown in Fig. 4 is recommended for preparation of solutions. 10 ml of autoclaved distilled water is deaerated by evacuation and repressurization with N_2. 0.2 g of dry $Na_2S_2O_4$ are weighed on a sterile (flamed) piece of aluminium foil placed in a petri dish; the amount is poured into the deaerated water while a slow stream of N_2 is flushed through the tube to avoid entrance of air. Dithionite is dissolved by gentle shaking. The tube is wrapped against light. If dithionite samples have to be taken with syringes, a more dilute solution may be prepared to facilitate withdrawal. If refrigerated, the solution is stable for about 5 days.

Solid $Na_2S_2O_4$ is usually sterile, as can be demonstrated by adding aliquots into complex test media (e.g., AC medium, Difco). If doubts exist about sterility, a solution prepared under N_2 is sucked into an anoxic syringe and filter-sterilized into the storage tube shown in Fig. 4.

Applications are described in the section on "Special Procedures and Modifications."

24. Yeast extract or peptone solution

An aqueous solution of 10 g yeast extract or 10 g peptone in a final volume of 100 ml is autoclaved as described for solution 1, or, preferably, under anoxic conditions as described for solution 17.

Application: 5 to 10 ml per liter of medium.

25. Fermented peptone broth

2 g peptone, 0.2 ml trace element solution 1, 0.1 g KH_2PO_4, and 0.05 g $MgSO_4 \cdot 7H_2O$ are added to 100 ml water, adjusted to pH 7.0, and deaerated by shaking under N_2 in a stoppered bottle. As a source of fermentative bacteria, approximately 1 ml of anoxic dark mud from a ditch, pond, or sewage digestor is added. The enrichment is incubated at 30°C. The pH is measured from time to time and readjusted to 7.0. After 10 days, insoluble matter is removed by centrifugation (40,000× *g*). The supernatant is

filter-sterilized and stored under N_2 as described for solution 17.

Application: 25 to 50 ml per liter of medium.

Inoculation procedures:

For inoculation of completely filled bottles or tubes, a certain amount of medium is withdrawn by means of a sterile pipette. Required organic or inorganic substrates (see Table 2, later) are added from one of the stock solutions 10 to 20 or other solutions of choice not listed here. Furthermore, approximately 1 ml dithionite solution (solution 22) is added per liter of medium, which significantly favors initiation of growth of many sulfate reducers. The tip of the pipette is dipped into the medium to avoid direct contact of dithionite with air. Instead of the dithionite solution, an estimated amount of dry $Na_2S_2O_4$ may be added by means of a microspatula, e.g., a flattened platinum wire. Finally, the inoculum is added by means of a pipette so as to fill the bottle completely, and it is immediately sealed with the screw cap.

If strictly anoxic procedures are employed throughout, additions are made via the stoppers of the rubber-sealed bottles or tubes by means of N_2-flushed syringes.

Special Procedures and Modifications

CULTIVATION ON H_2. For cultivation with H_2 as the electron donor, a mixture of H_2/CO_2 (90/10 to 80/20, v/v) in a head space of 2/3 to 3/4 of the culture volume is provided. A slight overpressure of 50 kPa (0.5 atm) may be applied; higher overpressures (200 kPa) may be applied after growth has started. Nonautotrophic sulfate reducers require acetate (1–4 mM) as a carbon source in addition to CO_2 if growing with H_2. Vessels are incubated horizontally or shaken to facilitate dissolution of gas.

CULTIVATION ON LONG-CHAIN FATTY ACIDS IN SALTWATER MEDIA. Addition of melted sodium palmitate or sodium stearate to saltwater media yields compact clumps of insoluble magnesium and calcium alkanoates that are poorly utilized by bacteria. To avoid this, the melted palmitate or stearate stock solution is first added to freshwater medium. Thereafter, 22 or 67 ml of salt concentrate (solution 21) are added per liter which yields brackish or saltwater medium, respectively; the alkanoates will precipitate as loose flocs.

CULTIVATION ON LIQUID ALKANES. If sulfate-reducing bacteria are grown with liquid alkanes (e.g., hexadecane), tubes or bottles with medium and a head space (approximately 1/5 of the volume) are used. After inoculation, 5–10 ml of autoclaved or filter-sterilized deaerated alkane is added per liter while the head space is gassed with an N_2/CO_2 mixture. After sealing with stoppers, tubes or bottles are inverted and intensely shaken for some seconds to remove alkane droplets adhering to the stopper. Inverted bottles are incubated at a slightly inclined angle to avoid permanent contact of the water-insoluble, buoyant alkanes with the stopper. More detailed information about anoxic cultivation on alkanes is given in the original literature (Aeckersberg et al., 1991).

ARTIFICIAL SEDIMENT FOR GLIDING SPECIES. Filamentous sulfate reducers of the genus *Desulfonema* require an insoluble substratum for optimal gliding movement and growth. Precipitated aluminum phosphate and sloppy agar (0.2%, w/v) have both been used as substrata (Widdel 1983). The former is precipitated by adding per liter of medium, 5 ml from an autoclaved solution of 48 g $AlCl_3 \cdot 6H_2O$ per liter; the pH is readjusted with 1.6 ml from a solution of 106 g Na_2CO_3 per liter.

GROWTH-STIMULATING ADDITIONS. Complex nutrients such as yeast extract or peptone may stimulate growth of *Desulfovibrio* and some other species (Postgate, 1984a) or promote their development after transfer from old cultures. Several sulfate reducers degrading fatty acids or aromatic compounds are not stimulated by complex nutrients; for a few, yeast extract may be even inhibitory (see e.g., Aeckersberg et al., 1991; Bak and Widdel, 1986b).

For a number of sulfate reducers, fermented peptone (solution 24) is a better stimulant than yeast extract or fresh peptone.

Growth of *Desulfonema* species on acetate is stimulated by low concentrations of additional, defined electron donors and carbon sources. For instance, succinate at a final concentration of 0.5 mM and a mixture of straight- and branched-chain volatile fatty acids at final concentrations between 0.02 and 0.05 mM have been used (Widdel et al., 1983; Widdel, 1989).

MEDIA WITH MODIFIED MINERAL COMPOSITION. During isolation and cultivation of sulfate-reducing bacteria from lake sediment, best growth was observed in a low-salt version of the multipurpose freshwater medium given earlier (Bak and Pfennig, 1991b). The amounts per liter were: 0.25 g NaCl, 0.2 g $MgCl_2 \cdot 2H_2O$, 0.1 g $CaCl_2 \cdot 2H_2O$, 0.1 g NH_4Cl, 0.1 g KH_2PO_4, and 0.1 g KCl. Concentrations of the other compounds were unchanged.

Desulfonema magnum requires high concentrations of Ca^{2+} ions. Good growth was observed in saltwater medium with 5 g $MgCl_2 \cdot 6H_2O$ and 1.4 g $CaCl_2 \cdot 2H_2O$ per liter. Other additions were as described.

If a medium with the same concentrations of major salts as in natural seawater has to be pre-

pared, Na_2SO_4 in the given saltwater medium is replaced by 6.8 g $MgSO_4 \cdot 7H_2O$ per liter, and 26 g NaCl, 5.6 g $MgCl_2 \cdot 6H_2O$, 0.72 g KCl, and 1.4 g $CaCl_2 \cdot 2H_2O$ are added per liter instead of the indicated amounts. Concentrations of other minerals in this artificial seawater medium are as described.

Further media with somewhat different content of major salts, trace elements, and organic substrates have been described by Gibson et al. (1987) and Tanner (1989).

Enrichment, Isolation, and Maintenance

Selective Enrichment

Many species of the Gram-negative mesophilic sulfate reducers can be selectively enriched by adding a particular electron donor (Table 1). Other important selective factors may be the salt concentration and the incubation temperature.

Most new types of sulfate-reducing bacteria have been enriched in batch cultures. Such cultures enrich for bacteria with the highest maximum growth rate under the given conditions. However, such species are not necessarily the most important degraders of the respective substrate in the natural habitat. Types growing more slowly in batch enrichments may occur in higher numbers in the natural habitat, due to a better adaptation to the in situ conditions. Of the many factors that are decisive for adaptation to the habitat, two important ones are effective competition at limiting substrate concentration (high μ_{max}/K_s value) and an advantage as a result of mixed substrate utilization. Enrichment of sulfate reducers at low, limiting substrate concentrations may be attempted in chemostat cultures. So far, however, chemostat enrichments have only yielded known types of sulfate reducers. Still, an interesting result from chemostat cultures was that *Desulfobulbus propionicus* can be selectively enriched not only with propionate and sulfate, but also in sulfate-free medium with ethanol as the limiting substrate; ethanol and CO_2 were fermented to propionate and acetate (Laanbroek et al., 1982). A simple method to isolate sulfate reducers that may be outcompeted in batch enrichments is the direct dilution of natural samples in agar or liquid media, without preceding enrichment. Bacteria predominating in the habitat will also be the most abundant in such dilution series, provided the artificial media are compatible.

Natural samples such as mud for enrichment and isolation of sulfate reducers should be kept under anoxic conditions. This can best be achieved by filling the vessels completely or by gassing the head space with nitrogen and sealing with a stopper. If not used immediately, samples are refrigerated but not frozen. The size of the inoculum should be based on the type of sulfate reducers to be enriched. For widespread, rapidly growing ones using common fermentation products (e.g., H_2, acetate, ethanol, lactate), an inoculum of $\leq 1\%$ (v/v) is usually enough for fast enrichment. For enrichment of slowly growing species, especially on less common electron donors (e.g., some aromatic compounds, alkanes), inocula of 5 to 10% are recommended. During incubation, the enrichments are briefly shaken once a day.

Enrichments should be transferred two to five times into new medium before pure culture isolation is attempted. In this way, sludge particles and the bulk of indigeneous non-sulfate-reducing bacteria are gradually diluted away. The transferred volume should be 1 to 10% of the culture volume. Many sulfate reducers, especially those from marine and brackish habitats, tend to form clumps or to stick to the sediment. Enrichments are therefore shaken immediately before inoculation of new medium to guarantee a transfer of some sediment also. More and more free bacteria will appear in the medium as the particulate fraction disappears. Enrichments are kept in the dark to prevent the appearance of photosynthetic, especially green sulfur, bacteria; by oxidation of sulfide to elemental sulfur, such phototrophs alter the redox conditions to the disadvantage of many sulfate reducers. Also, certain sulfate reducers are sensitive to light (Widdel, 1980).

The time for growth of sulfate-reducing bacteria in the first enrichment depends on the type of electron donor. For instance, enrichments on H_2 may grow within a few days, whereas sulfate reducers using phenolic compounds or alkanes may appear only after 1 to 4 months. The best proof of the positive growth of sulfate reducers is the production of H_2S. This can be detected by a simple chemical test. From the enrichment, 0.2 ml (or another defined amount) is added by means of a pipette or syringe to 1.0 ml of a reagent containing 5 mM $CuSO_4$ and 50 mM HCl in distilled water. The tip of the pipette or syringe should dip into the reagent to avoid loss of volatile H_2S. The reagent is gently shaken while the sample is added. The intensity of the brown color of the (initially) colloidal CuS gives a good estimate of sulfide production*; an enrichment without electron donor serves as

*Thiosulfate interferes with the test.

Table 1. Substrates and conditions for selective enrichment of representatives of Gram-negative sulfate reducers.

Species	Electron donor and carbon source (mM)	Medium used[a]	Comments[b]
Desulfovibrio species	H_2 plus CO_2 and acetate (2); lactate (20); ethanol (15)	F, B, S	
sulfodismutans	Thiosulfate (10) or sulfite (5) plus acetate (2)	F	Growth by sulfite or thiosulfate dismutation
Desulfomicrobium species	H_2 plus CO_2 and acetate (2); lactate (20)	F	No special selection versus *Desulfovibrio* known
Desulfobulbus species	Propionate (10); ethanol (10) without sulfate in a chemostat	F, B, S	
Desulfobacter			
Oval type	Acetate (10–20)	B, S	*D. hydrogenophilus* and *D. latus* isolated as acetate scavengers from a marine isovalerate enrichment
Curved type	Acetate (10–20)	B, S	May be promoted in NH_4^+-free medium under N_2; some strains obtained from naphthenic acid[c] enrichments, or by enrichment around 10°C
Desulfobacterium			
autotrophicum	H_2 plus CO_2	S	25°C; selective enrichment unlikely; direct dilution of marine mud in agar medium recommended
anilini	Aniline (0.5)	F, B	Lag phase of some months; portions of 0.5 mM aniline may be repeatedly added
indolicum	Indole (0.5–1)	S	Portions of 0.5 mM indole may be repeatedly added
phenolicum	Phenol (0.5–1)	S	Portions of 0.5 mM phenol may be repeatedly added
niacini	Nicotinate (4)	S	
vacuolatum	Isobutyrate (10)	S	May also yield other complete oxidizers
Desulfococcus			
biacutus	Acetone (10)	F	May also yield *D. multivorans*
multivorans	Benzoate (4), cyclohexanecarboxylate (3), acetone (10), 2-propanol (10)	F, B	35°C; acetone may also yield *D. biacutus*
Desulfosarcina			
variabilis	Benzoate (4)	S	
Desulfomonile			
tiedjei	No selective substrate reported	F	Isolated from a methanogenic 3-Cl-benzoate enrichment; 1,4-naphthoquinone required as special growth factor
Desulfonema			
limicola	Acetate (10) plus small amounts of additional substrates[d]; isobutyrate (5)	S	Not very selective; other sulfate reducers may become dominant
magnum	Benzoate (4)	S	≥5 mM Ca^{2+} to be added; enrichment may also yield other complete oxidizers
Desulfobotulus			
sapovorans	Palmitate (1.5), caproate (3), caprylate (2)	F	May yield other vibrioid or rod-shaped complete oxidizers. Further types obtained in saline medium
Desulfoarculus			
baarsii	Stearate (1)	F	36°C

[a]F, freshwater medium; B, brackish medium; S, saltwater medium.
[b]Unless indicated otherwise, the incubation temperature is 28–30°C.
[c]Organic acid fraction from oil (petroleum); is usually growth inhibitory, but some species seem to be resistant.
[d]Fermented peptone broth (20 ml/l) may be used (see text).

blank. If the substrates are relatively toxic, e.g., indole or phenol, only rather low concentrations can be used, which do not permit much growth or H_2S production (Bak and Widdel, 1986a, 1986b). In such cases, small portions of the substrate may be added a number of times during growth. An analytical test (UV absorption, gas chromatography, liquid chromatography, etc.) to prove substrate consumption can be useful. Sometimes, enrichments suffer from grazing by protozoa. They may be controlled by adding cycloheximide at a concentration of 10 to 50 μg/ml, which inhibits eukaryotic protein synthesis. Also, early transfer at the end of bacterial growth is recommended in such case.

Addition of complex nutrients such as yeast extract or peptone is not recommended for enrichments. These nutrients cause rapid development of various fermentative bacteria.

Isolation

ISOLATION USING AN AGAR DILUTION SERIES. The most frequently used method for the isolation of sulfate-reducing bacteria is serial dilution in anoxic agar medium.

Agar powder is first washed to remove soluble substances that may be inhibitory or favor fermentative bacteria. 3.3 g agar is suspended in approximately 300 ml distilled water in a calibrated flask or beaker and stirred for 10 min. The agar is then allowed to settle. After removal of the supernatant by slow decanting or suction with an aspirator, fresh water is added. The washing procedure is repeated four times. At the end, water is added to a final volume of 100 ml. The suspension is melted to homogeneity by stirring in a boiling water bath. The melted agar is dispensed in portions of 3 ml to test tubes that are sealed, e.g., with aluminum foil. The tubes are autoclaved and stored in plastic bags or sealed cans at 4°C to avoid drying.

For preparation of a dilution series, 6 to 8 agar tubes are heated in a boiling water bath to remelt the agar, which is then kept liquid in a bath at about 60°C. The aluminum seals are replaced by rubber stoppers using flamed tweezers; the stoppers are not fixed too tightly. Medium with substrate is prewarmed in another water bath at 41°C. From the prewarmed medium, 6 ml are added by means of a pipette to each tube to yield a 1% agar medium; to minimize contact with air during addition, the tip of the pipette is inserted into the agar. The mixture of agar and medium is kept liquid at 41°C. To each agar tube (liquid volume, 9 ml), 12 to 18 μliter of dithionite solution are added by means of a pipette which is used at the same time for gentle mixing. A sample of about 0.1 ml from the enrichment culture is added to the first tube; for mixing, the tube is slowly turned once or gently stirred with a pipette. A small, estimated amount of about 0.5 ml is transferred to the next tube by direct pouring or by means of a pipette and mixed again. The dilution is continued to the last tube. After each transfer, the previous tube is placed in a cold water bath. Immediately after solidification of the agar, the tubes are aseptically gassed with an N_2/CO_2 mixture, as shown in Fig. 5.

For isolation of brackish or marine sulfate reducers, the concentration of NaCl and other salts may become critical due to addition to the aqueous agar. This dilution can be compensated by addition of 13 or 35 ml of salt concentrate (solution 21) per liter of brackish or saltwater medium, respectively. After addition to the agar, the medium will regain its normal salt concentration. Addition of the salts to the agar before autoclaving is not recommended since hydrolysis may be promoted.

The method described allows slight contact with oxygen during dilution. However, this is not critical for most species of sulfate reducers; the exposure to air is brief and its dissolution is slowed down by the viscosity of the agar. However, for a completely anoxic procedure, the 3-ml portions of the concentrated agar are dispensed into tubes that have been provided with a 9 ml mark; the agar is allowed to solidify in an almost horizontal position. Tubes are then incubated under N_2 (in stoppered tubes or an anaerobic chamber) to allow desorption of O_2. Thereafter, stoppers are fixed with crimps or screw caps and tubes are autoclaved. The further procedure is in principal analogous to the aforementioned method. Medium is added to the melted agar by injection from the dispensing device shown in Fig. 2; the medium should be prewarmed in the device to avoid early solidification of the agar. Anoxically gassed syringes are used for addition of dithionite from the tube shown in Fig. 5 and also for transfers. For isolation of H_2-utilizing bacteria, an H_2/CO_2 mixture is used for gassing. In such case, the agar is allowed to solidify in an almost horizontal position.

Strictly anoxic dilution series may be also carried out with open tubes inside an anoxic chamber.

All tubes are inverted during incubation so that water exudate from the agar accumulates on the stopper; this water is removed when tubes are opened for isolation of colonies.

Colonies of sulfate-reducing bacteria are usually recognized by a yellowish, reddish, or brownish pigmentation. For isolation, the end of a Pasteur pipette is softened in a small flame,

taken out, and immediately drawn to a fine capillary by means of tweezers. The end is broken off and the capillary is filled with some medium. For isolation of colonies from tubes with horizontally solidified agar, the drawn Pasteur pipette should have a bent tip. Single, separated colonies are sucked into the medium-containing pipette by using a flexible tube connected to a mouth piece. The isolated bacteria usually need further purification via a second dilution series from which pure cultures may be picked and transferred into liquid medium. Part of the colonies may be used for microscopic control.

ISOLATION ON AGAR PLATES. Sulfate reducers may be also purified by streaking on agar plates that are incubated in anoxic jars containing some H_2 and a palladium catalyst. Preparation of plates, streaking, and transfer to jars is best carried out inside an anoxic chamber. If plates are handled in air, the reductant may be oxidized due to the large surface, and oxygen-sensitive cells may die off. If CO_2 is required as a carbon source, this is added to the atmosphere of the jar; the agar plates in such case should contain $NaHCO_3$.

Instead of plates and jars, anoxic flat bottles (100 ml) with an agar layer (10 ml) may be used ("bottle plates"). Problems caused by water exudate from the agar were solved with improved bottle plates (Hermann et al., 1986). Enrichments are streaked on the agar while the bottle is anoxically gassed. Some H_2S (approx. 1%, v/v) should be injected into the stoppered bottle. H_2S may be provided from a small steel bottle with a pressure regulator and a septum for withdrawal of gas samples by means of a syringe. The device has to be installed inside a fume hood with vigorous ventilation. Use of a gas mask is recommended.

ISOLATION IN LIQUID MEDIA. Instead of agar media, liquid media may be used for purification of sulfate-reducing bacteria via serial dilutions. The method is analogous to the dilution technique for determination of most probable numbers (MPN technique).

An alkane-utilizing sulfate-reducing isolate was purified in liquid medium under insoluble hexadecane by transfer of samples from both phases. In this way, alkane degraders attached to the hydrocarbon phase were gradually separated from free commensals (Aeckersberg et al., 1991).

ISOLATION OF FILAMENTOUS SULFATE-REDUCING BACTERIA. Isolation of the long, filamentous *Desulfonema* species by dilution or streaking is difficult since the numbers of the unicellular commensals or competitors are usually higher. For purification of *D. limicola* and *D. magnum,* the bulk of unicellular bacteria was removed by anoxic washing of the filaments (Widdel, 1983). This was achieved in a piece of glass tubing containing a fine-mesh copper grid (as used in electron microscopy); the latter acted as a sieve that allowed unicellular bacteria to pass through whereas filaments were retained. Washed filaments of *D. limicola* were further purified via dilution series in soft (0.8%, w/v) agar. For *D. magnum,* a pure culture was finally obtained from the washed filaments by transferring one of the relatively thick, visible filaments through a series of small portions of sterile anoxic medium (Widdel, 1983).

Maintenance

For short-term preservation, stock cultures are usually kept at 2–6°C. Since fully grown cultures easily die off or lyse if further incubated at optimal growth temperature, strains should be refrigerated before or right at the end of growth. However, *Desulfonema magnum* is very sensitive to refrigeration and is maintained at around 20°C. Also, sulfate reducers grown on alkanes may die off rapidly if refrigerated.

The interval for transfer depends on the tendency of stored cells to undergo lysis. Lysis is usually indicated by the presence of slime and a decrease in turbidity. For most species, transfer every 6 to 12 weeks is recommended.

For long-term preservation, cultures containing 5–10% (v/v) dimethylsulfoxide (DMSO) are kept in liquid N_2.

Taxonomy and Identification

Ribosomal 16S RNA sequences are generally accepted as decisive criteria for the definition of taxa at all levels and for the affiliation of new isolates to these taxa (Woese, 1987). This method has been applied to many mesophilic nonsporeforming sulfate-reducing bacteria. Derived relationships among the bacteria known as the delta subdivision of the proteobacteria are illustrated by the unrooted tree of Fig. 6. Wide-range sequencing of 16S rRNA of *Desulfonema* species has not yet been carried out. The older method of oligonucleotide cataloging indicated that *Desulfonema limicola* is closely related to *Desulfosarcina,* and thus it also is a member of the delta subdivision. Based on 16S rRNA analyses, *Desulfomonas* (Moore et al., 1976) groups with the genus *Desulfovibrio* (Devereux et al., 1989) and is therefore assigned to

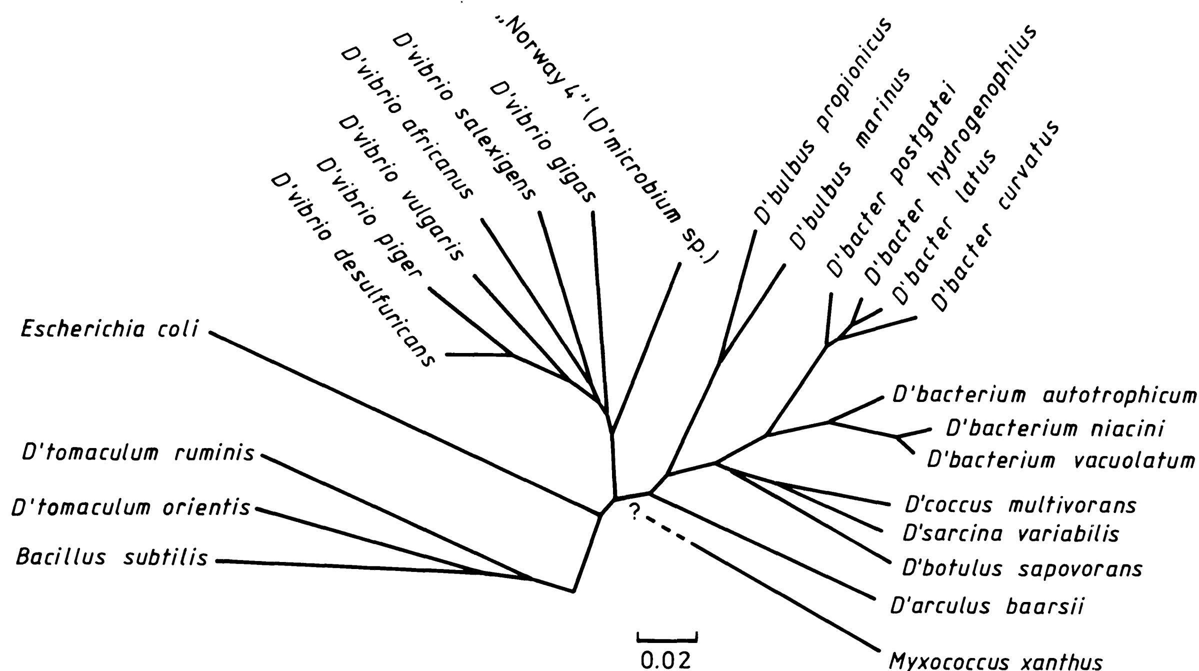

Fig. 6. Relationships of mesophilic nonsporeforming sulfate-reducing bacteria (delta-group) among themselves and to some other bacteria, as derived from 16S rRNA sequences. The unrooted tree of Devereux et al. (1990) and more recent, revised data (R. Devereux, personal communication) were combined into one figure. The scale bar is in units of fixed nucleotide substitutions per sequence position. Species with new names are: *Desulfobulbus marinus,* first described as *Desulfobulbus* strain 3pr10 (Widdel and Pfennig, 1982); *Desulfobacterium niacini,* formerly *Desulfococcus* (Imhoff-Stuckle and Pfennig, 1983); *Desulfobotulus sapovorans,* formerly *Desulfovibrio* (Widdel, 1980); *Desulfoarculus baarsii,* formerly *Desulfovibrio* (Widdel, 1980). The combining form *Desulfo-* is abbreviated *D'-*.

this genus.* The former *"Desulfovibrio" sapovorans* and *"Desulfovibrio" baarsii* are now listed as *Desulfobotulus sapovorans* and *Desulfoarculus baarsii,* respectively; establishment of these new genera appears appropiate because they resemble *Desulfovibrio* species only morphologically but not by other properties. By these rearrangements, genera of sulfate reducers become not only phylogenetically homogeneous, but also physiologically. A genus consists either of incompletely or completely oxidizing sulfate reducers. Morphology is not necessarily a good criterion for taxonomic assignments and it may not always agree with the 16S RNA groupings.

In view of the genealogy it seems justified to also define taxa above the genus level to the family level. The obvious separation of *Desulfovibrio* and *Desulfomicrobium* from the other members of the delta subdivision suggests the establishment of two families (Devereux et al., 1990); the designations Desulfovibrionaceae and Desulfobacteriaceae are proposed.

*This reclassification is done with permission from W. E. C. Moore (personal communication).

For determination of relationships at the species and genus level, other simpler methods based on nucleic acids may be useful. Competitive hybridization was measured between DNA from *Desulfovibrio vulgaris* and rRNAs from a number of other bacteria. The results confirmed that *Desulfovibrio* species were most closely related to each other, but less closely to *Desulfotomaculum* and non-sulfate-reducing Gram-positive and Gram-negative bacteria (Pace and Campbell, 1971). DNA-DNA hybridization revealed genotypic differences between *Desulfovibrio* species and nutritionally similar, but rod-shaped mesophilic or thermophilic sulfate reducers assigned with the genus. This led to the removal of *D. baculatus* and *D. thermophilus* from the genus *Desulfovibrio* (Nazina et al., 1987). The new genus *Desulfomicrobium* (Rozanova et al., 1988) was established for the mesophile, whereas the thermophile was affiliated with the formerly established genus *Thermodesulfobacterium* (Rozanova and Pivovarova, 1988; Zeikus et al., 1983). The exact relationship of *Thermodesulfobacterium* is not known. Preliminary sequencing indicated branching near the root of the eubacterial tree, at a point remote from the delta group (C.R. Woese, personal communication).

Since phylogenetic groupings were in good agreement with nutritional and biochemical traits (Fowler et al., 1986; Devereux et al., 1989), such characteristics are often useful for the identification and affiliation of sulfate-reducing bacteria to genera. Phenotypic properties of the classified mesophilic nonsporeforming sulfate reducers are listed in Table 2. The cell morphology of a number of strains is shown in Fig. 7 to 9 and the ultrastructure of some isolates is shown in Fig. 10. Besides nutritional and morphological characteristics, biochemical markers can be useful for the identification or affiliation of isolates to genera. Such markers are menaquinones (Collins and Widdel, 1986), lipid fatty acids (Boon et al., 1977; Dowling et al., 1986; Taylor and Parkes, 1983; Ueki and Suto, 1979), and pigments such as desulfoviridin. Most genera possess menaquinones MK-7 or MK-7(H_2); other different, characteristic menaquinones were found in *Desulfovibrio* species, *Desulfobulbus* species, and *Desulfonema magnum.* Since the presence or absence of biochemical markers may not always coincide with genera, they can only provide complementary criteria in addition to other characteristics.

The genera *Desulfovibrio, Desulfobulbus,* and *Desulfobacter* are phenotypically rather homogeneous, well-defined groups of Gram-negative sulfate-reducing bacteria. Affiliation to these solely by phenotypic characteristics is rather unproblematic. In the case of *Desulfonema,* the striking morphology allows easy identification.

The following brief description may help to identify sulfate-reducers of the delta group.

Descriptions of Genera and Families

Desulfovibrionaceae

DESULFOVIBRIO. Cells of *Desulfovibrio* are more or less curved and often motile. *Desulfovibrio piger* (formerly *Desulfomonas pigra*) has nonmotile, somewhat irregular, rod-shaped cells. The most commonly utilized organic substrates are lactate, pyruvate, ethanol, and in many cases also malate and fumarate. Electron donors are incompletely oxidized to acetate. The use of H_2 as electron donor is common; lithotrophic growth requires acetate as a carbon source in addition to CO_2. Oxidation of long-chain fatty acids is generally not observed. Growth in the absence of an external electron acceptor is possible by fermentation of pyruvate and in several cases also of malate or fumarate. Metabolism of lactate with concomitant formation of H_2 in the absence of sulfate has been observed (Pankhania et al., 1988). However, growth due to this reaction apparently does not take place unless hydrogen is kept at very low partial pressure, e.g., in co-cultures with methanogenic bacteria (Bryant et al., 1977). Such syntrophic growth is also possible with ethanol (Bryant et al., 1977) and choline (Fiebig and Gottschalk, 1983). Syntrophic growth has been observed so far only with *Desulfovibrio* species; *Desulfobacterium, Desulfosarcina* and *Desulfomaculum* species did not form active co-cultures with methanogens even though hydrogenase was present in these sulfate reducers (F. Widdel, unpublished observations). All species presently affiliated with the genus contain the bisulfite reductase desulfoviridin. Sulfate reducers that possess desulfoviridin but do not belong to the genus *Desulfovibrio* are the coccoid *Desulfococcus* species, *Desulfomonile,* and the filamentous *Desulfonema limicola.* The predominant menaquinone in *Desulfovibrio* species is MK-6; the isoprenoid side chain of the molecule is sometimes saturated in the terminal position (Collins and Widdel, 1986). Lipid fatty acids with an odd number of C atoms (mainly C_{15} and C_{17}) and iso- or anteiso branching* are characteristic for many *Desulfovibrio* species (Boon et al., 1977; Taylor and Parkes, 1983; Ueki and Suto, 1979).

DESULFOMICROBIUM. This genus is nutritionally very similar to *Desulfovibrio.* However, cells are rod-shaped and desulfoviridin is lacking. The bisulfite reductase desulforubidin (Lee et al., 1973) and MK-6 (Collins and Widdel, 1986) have both been detected in a strain that probably belongs to *Desulfomicrobium baculatum.*

Desulfobacteriaceae

DESULFOBULBUS. Most species have oval to lemon-shaped or onion-shaped (i.e., with pointed ends) motile or nonmotile cells. Some types form slender rods. A characteristic substrate is propionate, which is incompletely oxidized to acetate. Other commonly used electron donors are lactate, ethanol, or H_2; growth on dicarboxylic acids has not been observed. In contrast to *Desulfovibrio, Desulfobulbus* can grow by fermentation of lactate or ethanol and CO_2 in a sulfate-free medium. As in *Pelobacter* (Schink, 1984; Schink et al., 1987), propionate and acetate are formed in a ratio of 2:1 (Laanbroek et al., 1982; Widdel, 1980; Widdel and Pfennig, 1982) via a randomizing pathway (Stams et al., 1984). Fermentative growth of *D.*

*Methyl-branched, one or two C atoms, respectively, from the ω-end.

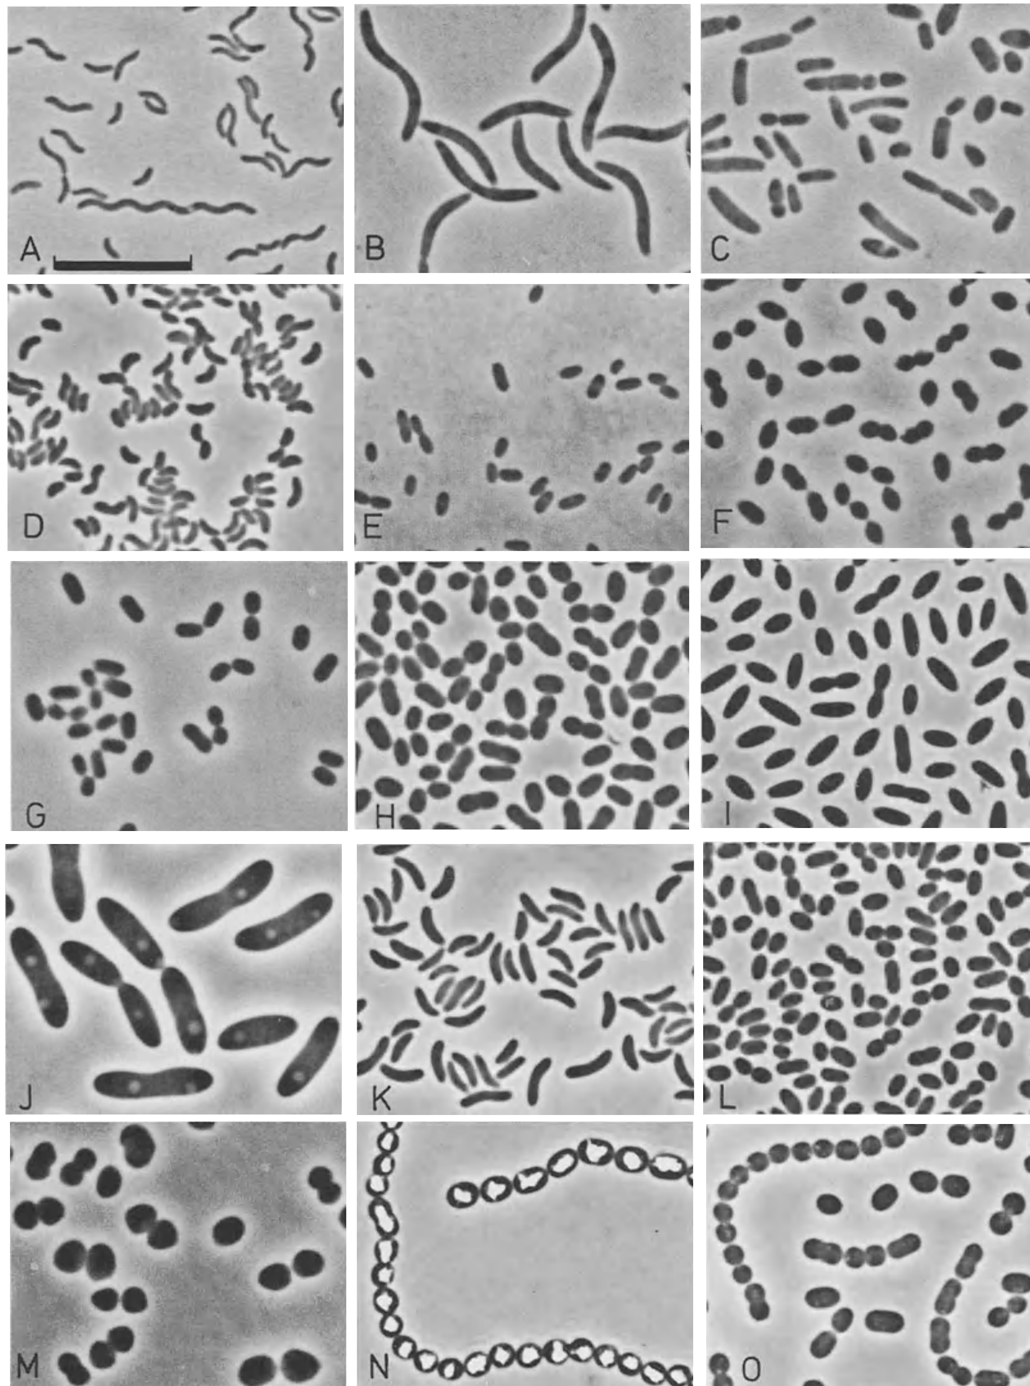

Fig. 7. Light micrographs of viable cells of some sulfate-reducing bacteria. (A) *Desulfovibrio desulfuricans.* (B) *Desulfovibrio gigas.* (C) *Desulfovibrio piger* (formerly *Desulfomonas pigra*). (D) *Desulfovibrio salexigens.* (E) Strain "Norway 4," probably a *Desulfomicrobium* species (formerly a *Desulfovibrio* species). (F) *Desulfobulbus propionicus.* (G) *Desulfobulbus marinus.* (H) *Desulfobacter postgatei.* (I) *Desulfobacter hydrogenophilus.* (J) *Desulfobacter latus,* with unidentified inclusions. (K) *Desulfobacter curvatus.* (L) *Desulfobacterium autotrophicum.* (M) *Desulfobacterium* (formerly *Desulfococcus*) *niacini.* (N) *Desulfobacterium vacuolatum.* (O) *Desulfobacterium vacuolatum,* after application of pressure which caused the collapse of gas vesicles. All photographs were taken by phase contrast. Bar in (A) = 10 μm; applicable to all photographs.

marinus is poor. Syntrophic growth with methanogens does not occur. The sulfite reductase desulforubidin has been detected in *D. elongatus* (Samain et al., 1984). The predominant, characteristic menaquinone is MK-5(V-H_2). Lipid fatty acids with straight, unbranched C chains are common (Taylor and Parkes, 1983).

DESULFOBACTER. Most species have oval, motile, or nonmotile cells. Motility may be lost after isolation. A few species with curved cells are known which morphologically resemble *Desulfovibrio* (Widdel, 1987). The most common and characteristic electron donor is acetate, which appears to be utilized by *Desulfobacter* species more effectively than by any other mesophilic, completely oxidizing sulfate reducer. The *Desulfobacter* species so far investigated are the only completely oxidizing sulfate reducers that possess an operative citric acid cycle (Chapter 24). The enzyme 2-ketoglutarate:ferredoxin (2-ketoglutarate:methyl viologen) oxidoreductase may be regarded as a key enzyme and indicator of the cycle. This enzyme has not been observed in completely oxidizing sulfate reducers of other genera, which cleave acetyl-CoA by means of carbon monoxide dehydrogenase; the latter is absent in *Desulfobacter. Desulfobacter* species seem to be typical brackish or marine organisms; they require NaCl (at $>$100 mM) and $MgCl_2$ (at $>$5 mM) for optimal growth. However, isolation of *D. postgatei* and some vibrio-shaped species was also possible from fresh water habitats; these isolates also required NaCl and $MgCl_2$ for optimal growth (Widdel and Pfennig, 1981; Widdel, 1987). Detection of desulforubidin has been reported (Odom and Peck, 1984). Lipids contain palmitic acid, 10-methylpalmitic acid, and cyclopropyl fatty acids as major characteristic components (Dowling et al., 1986; Taylor and Parkes, 1983).

DESULFOBACTERIUM. A number of completely oxidizing sulfate reducers that are nutritionally rather versatile and/or exhibit special degradative capacities, e.g., the oxidation of aromatic compounds) have been combined in the genus *Desulfobacterium.* Sequencing of 16S rRNA from *D. autotrophicum, D. vacuolatum,* and *D. niacini* (formerly *Desulfococcus*) indeed revealed close relationships among these three species and separate clustering from other genera. 16S rRNA analyses of other sulfate reducers described as *Desulfobacterium* species have not been carried out so far. *Desulfobacterium* species have rod-shaped to oval or almost spherical cells. Fatty acids, dicarboxylic acids, alcohols, or H_2 serve as electron donors for many species. Some may use lactate or aromatic compounds, e.g., benzoate, phenol, or indole. *D. indolicum* isolated on indole is less versatile than other species classified with the genus (Table 2). Autotrophic growth of H_2-utilizing *Desulfobacterium* species is common (Brysch et al., 1987). Like *Desulfobacter, Desulfobacterium* species are mainly brackish or marine organisms that require elevated NaCl ($>$150 mM) and $MgCl_2$ ($>$ 5 mM) concentrations.

DESULFOCOCCUS AND DESULFOSARCINA. Species of these two completely oxidizing genera are not only phylogenetically but also nutritionally related to each other. There are also striking nutritional and morphological similarities to many *Desulfobacterium* species. Obviously, neither phenotypic characteristics nor the GC content of the DNA permit clear distinctions among these three genera; hence, affiliation of sulfate reducers with these genera requires 16S rRNA sequencing. *Desulfosarcina* sometimes grows in dense cell packets; free cells are oval to rod-shaped. *Desulfococcus* contains desulfoviridin. *Desulfococcus* has been isolated from freshwater mud, but it will grow just as well or even slightly better in brackish or marine medium. *Desulfosarcina* is a marine organism.

DESULFOMONILE. A rod-shaped sulfate reducer that had originally been isolated as a pyruvate-utilizing organism capable of reductive dechlorination of 3-chlorobenzoate (Shelton and Tiedje, 1984) was later classified as *Desulfomonile tiedjei* (DeWeerd et al., 1990). According to 16S rRNA sequences compared so far, its closest relative is the sulfur reducer *Desulfuromonas acetoxidans,* followed by *Desulfosarcina variabilis. Desulfomonile* contains desulfoviridin, but otherwise it differs from *Desulfovibrio.* Experiments with defined mixed cultures suggested that dehalogenation is associated with energy conservation (Dolfing and Tiedje, 1987). The ability for the utilization of acetate and its complete oxidation has been demonstrated so far only with thiosulfate as electron acceptor, but not with sulfate. *Desulfomonile* was reported to utilize benzoate, which has been observed before only in case of completely oxidizing sulfate reducers. A special nutritional feature is the demand for 1,4-naphthoquinone as growth factor.

DESULFONEMA. Filamentous, gliding sulfate reducers have been classified in the genus *Desulfonema.* Their striking morphology rather than their other properties has been decisive for classification of these sulfate reducers. The relationship between *Desulfonema limicola* and *D.*

[a]nr, Not reported or not determined.
[b]A [T] following the species name indicates this is the type species.
[c]Flagellation type is given in parentheses: lo, lophotrichous; sp, single, polar.
[d]DV, desulfoviridin; O, other; 2, two further are known; DR, desulforubidin. The compound P582 is proposed from absorption spectra data.
[e]Terminal saturation in the isoprenoid side chain is indicated by (H$_2$).
[f]Oxid., extent of oxidation of organic substrates; I, incomplete; C, complete.
[g]Symbols: +, utilized; +*, autotrophic growth; ( ), poorly utilized; −, not utilized.
[h]This is not a complete list; for further substrates, see references.
[i]Symbols: bi, biotin; ni, nicotinate; nq, 1,4-naphthoquinone; pa, *p*-aminobenzoate; pt, pantothenate; th, thiamine.
[j]Also utilized by several other species of sulfate reducers (Folkerts et al., 1989).
[k]Formerly *Desulfomonas pigra;* reclassified with permission of W. E. C. Moore, Blacksburg, Virginia.
[l]Grows by dismutation of sulfite or thiosulfate.

[m]Desulforubidin was found in a similar isolate (strain "Norway 4", formerly regarded as a *Desulfovibrio* species) probably belonging to the same genus or species (Lee et al., 1973).

[n]Suggested new name of a marine isolate (Widdel and Pfennig, 1982).

[o]In addition, 1.2 to 3 g of $MgCl_2 \cdot 6H_2O$ per liter of medium required or routinely added.

[p]Type strain is nonmotile; other strains may be motile (single, polar flagellum).

[q]Motility may disappear after isolation.

[r]Formerly *Desulfococcus*.

[s]Addition is stimulatory, but not absolutely required.

[t]May be used with thiosulfate as electron acceptor.

[u]In addition, 5 g of $MgCl_2 \cdot 6H_2O$ and 1.3 g of $CaCl_2 \cdot 2H_2O$ per liter of medium are required.

[v]Formerly *Desulfovibrio*.

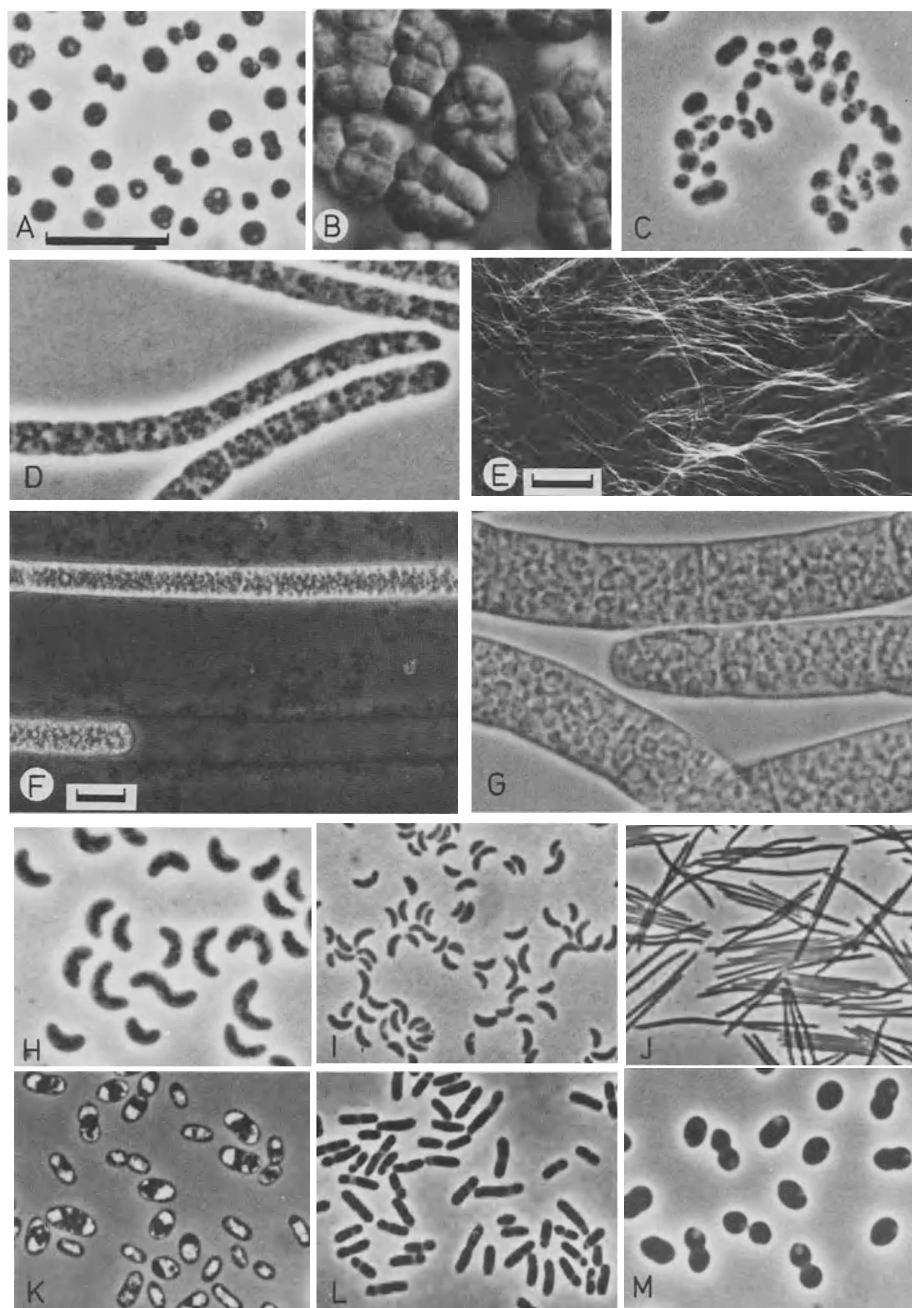

Fig. 8. Light micrographs of viable cells of some sulfate-reducing bacteria. (A) *Desulfococcus multivorans,* with granules of poly-β-hydroxyalkanoic acid. (B) *Desulfosarcina variabilis,* cell packets from an agar colony. (C) *Desulfosarcina variabilis,* single cells from liquid medium. (D) *Desulfonema limicola,* with granules of poly-β-hydroxyalkanoic acid. (E) *Desulfonema magnum,* layers of filaments at the wall of a culture bottle. (F) *Desulfonema magnum,* with granules of poly-β-hydroxyalkanoic acid; filaments glide in a synthetic sediment of aluminum phosphate which makes slime trails visible. (G) *Desulfonema magnum,* with granules of poly-β-hydroxyalkanoic acid. (H) *Desulfobotulus* (formerly *Desulfovibrio*) *sapovorans,* with granules of poly-β-hydroxyalkanoic acid. (I) *Desulfoarculus* (formerly *Desulfovibrio*) *baarsii.* (J) through (M) are unnamed isolates: (J) Long, thin cells nutritionally resembling *Desulfovibrio* species; the strain was isolated from an oil tank with H_2. (K) Cells with gas vesicles of a sulfate reducer nutritionally resembling *Desulfovibrio* species; the strain was isolated from marine sediment with H_2. (L) Cells of a species that preferentially grows by sulfite or thiosulfate dismutation. (M) Isolate nutritionally similar to *Desulfobulbus* species; the strain was isolated from freshwater sediment with 2-methylbutyrate. Photographs were taken by phase contrast, except for (B), (E), and (G). (B) Interference contrast; (E) dark field; (G) bright field. Bar in (A) = 10 μm; applicable to all photographs except for (E) and (F). Bar in (E) = 1 mm; bar in (F) = 10 μm.

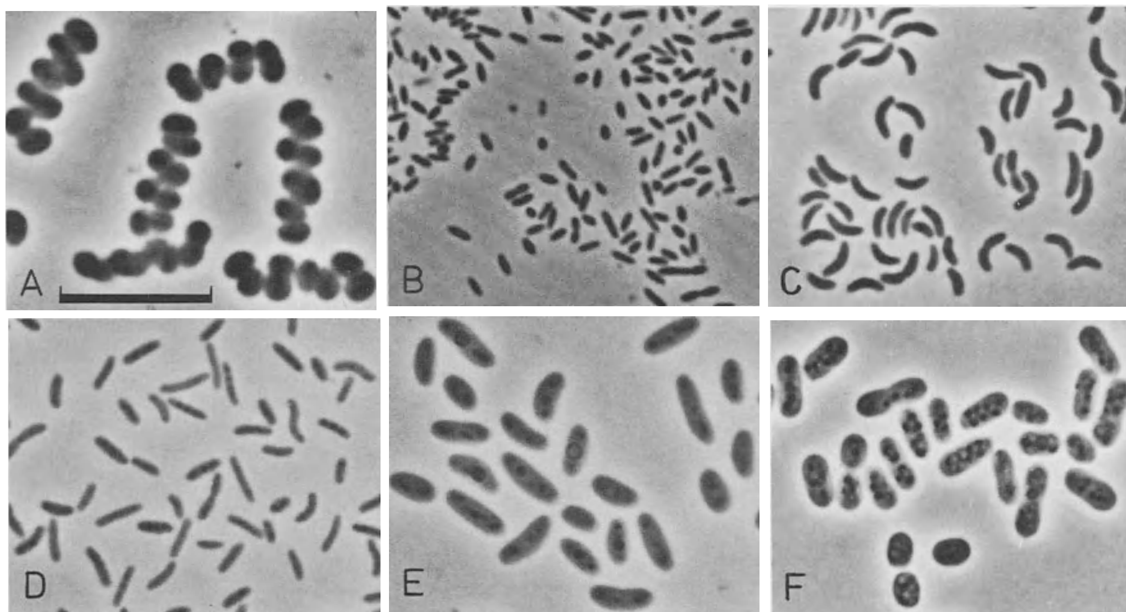

Fig. 9. Light micrographs of viable cells of some unnamed sulfate-reducing isolates. (A) Spirilloid, markedly screwed cells of an isolate nutritionally resembling *Desulfobacter* species; the species was isolated with acetate from marine sediment. (B) Hexadecane-degrading sulfate reducer, tentative name *Desulfobacterium oleovorans.* (C) through (F) are sulfate reducers nutritionally resembling *Desulfobotulus sapovorans.* (C) Vibrioid cells from marine sediment. (D) Rod-shaped to slightly curved cells from marine sediment. (E) Oval to slightly curved cells from marine sediment; inclusions are probably poly-β-hydroxyalkanoic acid. (F) Oval cells from freshwater sediment, with granules of poly-β-hydroxyalkanoic acid. All photographs were taken by phase contrast. Bar in (A) = 10 μm; applicable to all photographs.

magnum has not been confirmed yet by 16S rRNA analyses. Based on oligonucleotide catalogs, the closest relative of the former is *Desulfosarcina* (Fowler et al., 1986). Both *Desulfonema* species are versatile complete oxidizers; *D. magnum* is able to grow on benzoate. The mechanism of terminal oxidation has not been examined. *D. limicola* contains desulfoviridin. *Desulfonema magnum* contains MK-9, the menaquinone with the longest side chain found in sulfate reducers.

DESULFOBOTULUS. An incompletely oxidizing species originally named *Desulfovibrio sapovorans* (Widdel, 1980) branches off among completely oxidizing sulfate reducers, according to 16S rRNA sequences (see Fig. 6). The new genus *Desulfobotulus* is proposed. *Desulfobotulus sapovorans* utilizes lactate like *Desulfovibrio* species, but differs from them by the ability to use fatty acids from butyrate through palmitate, the inability to use H_2 or ethanol, and the absence of desulfoviridin. The curved cells of *D. sapovorans* are thicker than those of *Desulfovibrio* and usually contain granules of poly-β-hydroxyalkanoic acid.

DESULFOARCULUS. A completely oxidizing sulfate reducer originally named *Desulfovibrio baarsii* (Widdel, 1980) appears to represent a separate line within the delta group (Devereux et al., 1989), for which the new genus *Desulfoarculus* is suggested. Morphologically, *D. baarsii* is almost indistinguishable from the nutritionally completely different *Desulfovibrio desulfuricans* and other species of this genus. *Desulfoarculus baarsii* oxidizes monocarboxylic acids from C_1 to C_{18}, but no other compounds and thus differs nutritionally from the more versatile *Desulfobacterium, Desulfococcus,* and *Desulfosarcina* species.

Unclassified Types

A variety of nonsporeforming sulfate-reducing bacteria have been isolated and characterized but not definitely classified. Only a number of representatives can be briefly described in the following.

Two striking cell types physiologically resembled *Desulfovibrio* species, but were morphologically completely different. One of these types had long, thin cells (Cord-Ruwisch et al., 1986; Jones, 1971; Fig. 8J). The other type that was the predominant H_2-consuming sulfate reducer in a marine sediment consisted of ovals with gas vesicles (F. Bak, unpublished observations; Fig. 8K).

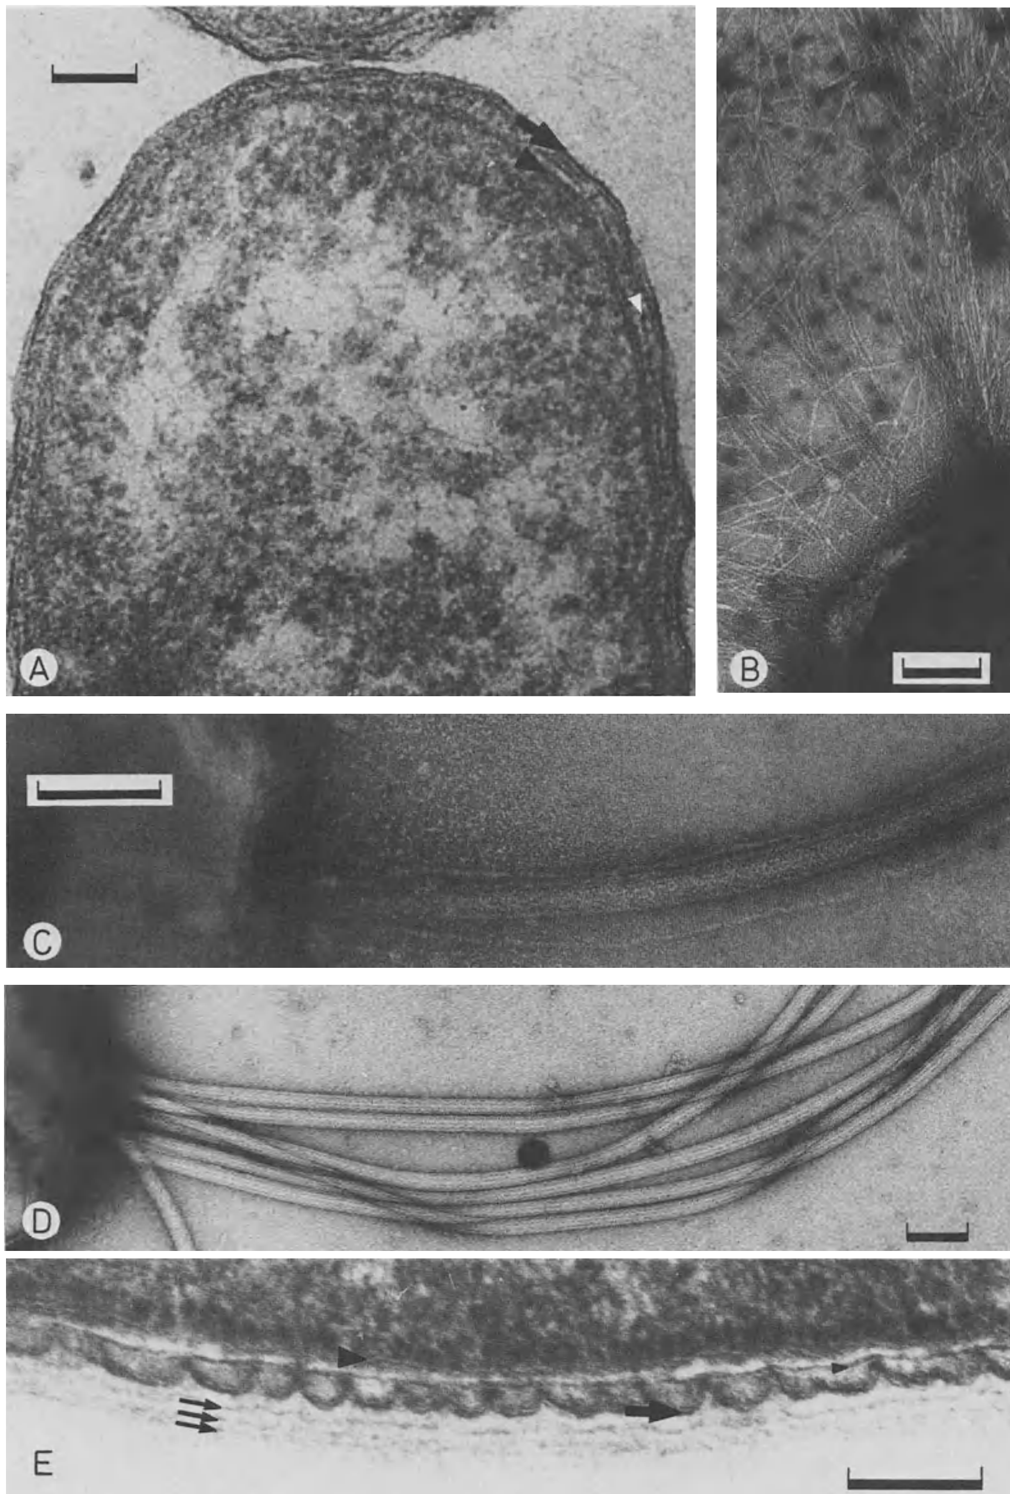

Fig. 10. Electron micrographs of some sulfate-reducing bacteria. (A) *Desulfomicrobium apsheronum;* ultrathin section. (B) Fimbria of *Desulfobulbus propionicus;* negative staining. (C) Sheathed flagellum of *Desulfobotulus sapovorans;* negative staining. (D) Polar bundle of flagella of an unnamed vibrio-shaped isolate that oxidized fatty acids incompletely; negative staining. (E) *Desulfonema magnum,* with waved outer membrane. Large arrowhead, cytoplasmic membrane; small arrowhead, peptidoglycan layer; large arrow, outer membrane; small arrows, outer wall layers. All bars = 0.1 μm. Photographs were kindly provided by the following authors: (A) T. N. Nazina and T. A. Pivovarova, Moscow; (B) and (C) F. Mayer, Göttingen; (D) E. Spiess, Heidelberg; (E) G.-W. Kohring and F. Mayer, Göttingen.

A great variety of incompletely oxidizing sulfate reducers have been isolated with palmitate or fatty acids of shorter chain lengths (Widdel, 1980). All of these vibrioid to rod-shaped isolates, except for one type, utilized fatty acids from C_4 through C_{16}, but not H_2, and did not contain desulfoviridin. Most motile species had single, polar flagella; a bundle of polar flagella in one species in shown in Fig. 10C. Due to their similarity to *Desulfobotulus sapovorans,* all these isolates were tentatively comprised as the "sapovorans group" (Pfennig et al., 1981). An exception was one type isolated on butyrate or 2-methylbutyrate that did not use fatty acids with chain lengths longer than C_5, but grew on H_2 and contained desulfoviridin (Widdel, 1980, 1988).

A rod-shaped sulfate reducer growing preferentially by dismutation of thiosulfate and sulfite was isolated from marine sediment (Bak and Pfennig, 1987; Fig. 8L).

An incompletely oxidizing sulfate-reducing bacterium with oval cells (Fig. 8M) that was enriched with 2-methylbutyrate from freshwater sediment also grew on H_2, ethanol, propionate, butyrate, and lactate and thus shared a number of nutritional properties with *Desulfobulbus* species (F. Widdel, unpublished observations).

A number of sulfate-reducing bacteria isolated with acetate nutritionally resembled described *Desulfobacter* species but were morphologically different (Widdel, 1987). A striking cell type with pronounced, narrow, spiral turns (Fig. 9A) was isolated from sediment from the Kattegat, Denmark (F. Bak, unpublished observations).

Completely oxidizing sulfate reducers differing morphologically and nutritionally from described species have also been isolated on H_2 (Brysch et al., 1987), benzoate (Cord-Ruwisch et al., 1986), catechol, and resorcinol (Schnell et al., 1989).

From an enrichment with hexadecane, a sulfate reducer with vey tiny cells (Fig. 9B) has been isolated (Aeckersberg et al., 1991). Complete oxidation of hexadecane was demonstrated by growth experiments in sealed (fused) glass ampules. The isolate grew on long-chain alkanes, hexadecane, long-chain alcohols, and fatty acids, but not on H_2, ethanol, or lactate. Its tentative name is *Desulfobacterium oleovorans.*

The Genus *Desulfuromonas* and Other Gram-Negative Sulfur-Reducing Eubacteria

FRIEDRICH WIDDEL and NORBERT PFENNIG

The ability to gain energy for growth by dissimilatory reduction of elemental sulfur in a respiratory type of metabolism (with the formation of sulfide) is found in several genera of eubacteria and archaebacteria. H_2 or organic substrates, mainly simple organic acids, serve as electron donors. There are, however, other organisms, including some eukaryotes, that reduce sulfur in a nonrespiratory manner; in this case, sulfur acts merely as a hydrogen sink in a "facilitated fermentation," or is reduced in a by-reaction without obvious bioenergetic significance. An overview and details of physiology and biochemistry of sulfur reduction are given in Chapter 24.

The concept of the sulfur-reducing bacteria as a physiological group was first advanced with the description of *Desulfuromonas acetoxidans*, an obligately anaerobic mesophile which grows by sulfur respiration (Pfennig and Biebl, 1976). Further well-characterized, sulfur-reducing eubacteria besides *Desulfuromonas* species include the obligately anaerobic moderate thermophile *Desulfurella acetivorans* (Bonch-Osmolovskaya et al., 1990), as well as facultatively microaerobic, spirilloid mesophiles such as the "spirillum 5175" of Wolfe and Pfennig (1977), the "free-living *Campylobacter* species" of Laanbroek et al. (1978), a similar strain of Zinder and Brock (1978), and *Wolinella* (formerly *Vibrio*) *succinogenes* (Macy et al., 1986; Wolin et al., 1961). Dissimilatory sulfur reduction has been observed even in bacteria that otherwise grow aerobically at normal O_2 tension, namely in a *Pseudomonas mendonica* subspecies (Balashova, 1985) and in *Alteromonas putrefaciens* (Loveley et al., 1989; Myers and Nealson, 1988). The latter two organisms have been studied mainly because of their ability to reduce ferric iron or manganese (IV). All of the above-mentioned sulfur reducers cannot reduce sulfate. In addition, there are a few sulfate-reducing bacteria that are able to use sulfur as alternative electron acceptor. These are *Desulfovibrio gigas*, another *Desulfovibrio* strain (tentatively named *Desulfovibrio multispirans*; He et al., 1986), and rod-shaped species most likely belonging to the genus *Desulfomicrobium* (Biebl and Pfennig, 1977; Rozanova et al., 1988), which is physiologically similar to *Desulfovibrio*. In the following, these will be briefly referred to as thiophilic sulfate reducers. The extremely thermophilic sulfur-reducing archaebacteria that can use H_2, most of which are obligate lithoautotrophs, are described in Chapter 24 and 28.

Analyses of 16S rRNA revealed that *Desulfuromonas* and the fermentative *Pelobacter* form a branch among the sulfate-reducing bacteria and are thus members of the delta subdivision and distant relatives of the purple bacteria (Fowler et al., 1986; Stackebrandt et al., 1989). *Wolinella* and the closely related *Campylobacter* species form their own branch, which on a deep level is also related to the purple bacteria (Lau et al., 1987; Romaniuk et al., 1987). *Alteromonas putrefaciens* is a member of the gamma subdivision of the purple bacteria (Schleifer and Ludwig, 1989). Genealogical relationships of *Desulfurella* and the facultatively sulfur-reducing bacterium assigned to *Pseudomonas mendonica* have not been elucidated. A summary of the eubacteria able to grow by sulfur respiration is given in Table 1. (For more details see "Taxonomy and Identification," this chapter).

Habitats and Cocultures

Desulfuromonas species are abundant and widespread in anoxic marine or brackish water sediments but occur less frequently in sediments of freshwater habitats (Pfennig and Biebl, 1981). Marine species usually require certain minimum concentrations of NaCl and Mg^{2+} ions. The predominance in marine or brackish habitats is understood in view of the intense sulfide production by sulfate-reducing bacteria, due to the high sulfate concentration (28 mM) in seawater (Chapter 183). Close to the sediment surface, sulfide is oxidized with O_2 (in a

chemical reaction or by thiobacilli) to yield free sulfur and more oxidized products. If light is available, phototrophic green sulfur bacteria in the upper zone of sediments excrete elemental sulfur as the primary oxidation product of H_2S. In fact, *Desulfuromonas* species do form well-growing, robust cocultures with green sulfur bacteria in the presence of acetate or another organic electron donor. Green sulfur bacteria of marine origin that tend to oxidize H_2S primarily to the level of sulfur (forming very little sulfate) have been shown to be ideal partners for *Desulfuromonas.* Green sulfur bacteria can only assimilate organic compounds (usually acetate) in the presence of an inorganic electron donor and CO_2 and therefore depend on H_2S formed by the sulfur reducer; and vice versa, the sulfur excreted by the green bacterium is immediately reduced back to sulfide by *Desulfuromonas* at the expense of the organic substrate, which is oxidized to CO_2. In such a syntrophism, the sulfur serves as an electron-carrying catalyst between both types of bacteria (Pfennig and Biebl, 1976; Fig. 1). As little as 0.25 mmol sulfide or sulfur per liter is sufficient to maintain optimal growth of both partners (Biebl and Pfennig, 1978).

The moderately thermophilic species *Desulfurella acetivorans* has been isolated from a cyanobacterial mat of a hot water pool in a solfataric field (Bonch-Osmolovskaya et al., 1990).

Thiophilic sulfate reducers occur in the same habitats as other sulfate reducers that cannot grow with sulfur (see Chapter 183). Thiophilic sulfate reducers have been enriched together with *Desulfuromonas* species in cocultures with green sulfur bacteria on ethanol. Syntrophism between such sulfate reducers and green sulfur bacteria has been verified with defined binary cocultures growing on ethanol, that was incompletely oxidized to acetate (Biebl and Pfennig, 1978). Lactate may function as well in these cocultures.

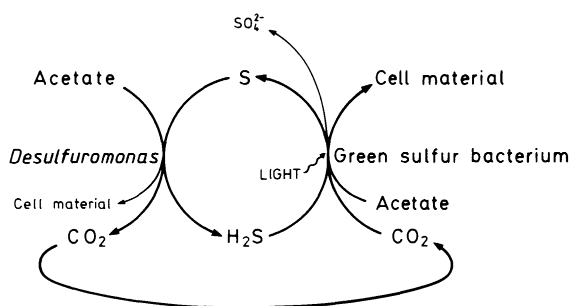

Fig. 1. The H_2S/sulfur cycle in a syntrophic coculture of acetate-oxidizing *Desulfuromonas* and a green sulfur bacterium that assimilates acetate only together with H_2S and CO_2 in the light. *Desulfuromonas* acting as a chemotroph forms less cell material in the coculture than the phototroph. If sulfur is also converted to sulfate, this cannot be recycled by the binary coculture; in sediments, however, sulfate is reduced by sulfate-reducing bacteria.

The spirilloid, facultatively microaerobic, sulfur-reducing bacteria are found in virtually all small or large accumulations of dirty fresh or brackish water (N. Pfennig, unpublished observations). So far, unnamed strains have been isolated from freshwater sediment (Wolfe and Pfennig, 1977; Zinder and Brock, 1978) and from an anaerobic digester fed with potato refuse (Laanbroek et al., 1977). *Wolinella* (originally *Vibrio*) *succinogenes* was obtained from bovine rumen (Wolin et al., 1961). The ubiquitous occurrence of spirilloid sulfur reducers may be due to their versatile respiratory metabolism (Table 1). In addition to *Desulfuromonas,* spirilloid sulfur reducers have also been shown to form robust cocultures with phototrophic green sulfur bacteria; formate was used as electron donor since these sulfur reducers cannot oxidize acetate.

A facultative sulfur-reducing subspecies of *Pseudomonas mendonica* was isolated from activated sludge, from an anaerobic sewage digester, and from river and swamp sediments with H_2 as electron donor and ferric hydroxide as electron acceptor (Balashova, 1985; Balashova and Zavarzin, 1979). Another facultative sulfur reducer, *Alteromonas putrefaciens,* was isolated as a manganese (IV)-reducing bacterium from lake sediment (Myers and Nealson, 1988).

Cultivation Techniques and Media

For cultivation of sulfur-reducing bacteria, the same anoxic media, cultivation vessels, equipment, and techniques may be applied as described in detail for sulfate-reducing bacteria (see Chapter 183). Occasional diffusion of some air into media during their preparation may be less critical than in case of sulfate-reducing bacteria, as long as sulfide is present as reducing agent. Polysulfide and sulfur formed by reaction of sulfide with oxygen may inhibit sulfate reducers, but are readily reduced by sulfur reducers. Spirilloid sulfur reducers may even be grown in nonreduced media; since they are able to grow microaerobically, growth may be started in media from which only the bulk of oxygen has been removed by sparging or flushing with anoxic gas.

For growth on H_2, sulfur-reducing eubacteria require CO_2 in addition to acetate (1 to 2 mM) as carbon source for cell synthesis. For growth of complete oxidizers on acetate or ethanol as electron donors, CO_2 should also be present,

even though it is formed during growth. Media are therefore prepared with $NaHCO_3$. If H_2 or another gas is used in the head space, this should contain 5 to 10% CO_2, depending on the required pH (see Chapter 183). With C_4-dicarboxylic acids or lactate as substrates, bicarbonate and CO_2 may be omitted.

Concentrations of NaCl and $MgCl_2$ should be varied, depending on whether the inoculum is of freshwater or marine origin.

Desulfuromonas, Desulfurella, thiophilic sulfate reducers, and spirilloid sulfur reducers grow in defined media without complex substrates such as yeast extract. *Desulfurella* may be stimulated by low concentrations of yeast extract (0.1 g/liter Schmitz et al., 1990). *Pseudomonas mendonica* exhibited significant reduction of sulfur with H_2 only in the presence of yeast extract (0.2 g/liter Balashova, 1985). For *Alteromonas putrefaciens,* a requirement for arginine, glutamine, and serine was reported (Loveley et al., 1989).

For preparation of media, NaCl, $MgCl_2$, $CaCl_2$, NH_4Cl, KH_2PO_4, and KCl are dissolved and autoclaved at concentrations indicated in Chapter 183 (see "Defined Multipurpose Medium"). Sulfate is omitted. Trace elements, $NaHCO_3$, vitamins, and Na_2S are added from separately sterilized stock solutions to the cold medium as described. Trace elements chelated with EDTA (ethylenediaminetetraacetic acid, used as the sodium salt) have been used most frequently for cultivation of sulfur reducers. Of the vitamins, isolated strains of sulfur reducers require, if at all, only biotin and B_{12}. In addition to the medium given in Chapter 183, two modifications have been used (Pfennig and Biebl, 1976, 1981). In the modified media, the concentration of KH_2PO_4 was 1 g/liter the concentration of $NaHCO_3$ was 2 or 4 g/liter for freshwater or marine species, respectively (corresponding to 24 and 48 ml, respectively, of the given 1 M $NaHCO_3$ solution per liter). Growth of completely oxidizing sulfur reducers with sulfur and acetate, ethanol, or other organic compounds causes a significant decrease of the pH. Media for growth on these substrates should therefore be adjusted to a pH between 7.6 and 7.8. Medium for the moderately thermophilic *Desulfurella,* which has a rather low pH optimum (6.8 to 7.0), is adjusted to a pH between 7.2 and 7.4. For growth of sulfate reducers on formate as electron donor when sulfur, fumarate, or malate is used as the electron acceptor, or for growth in cocultures with green sulfur bacteria, the pH is adjusted between 7.0 and 7.2. The medium is dispensed into 20-ml tubes or into 50- or 100-ml bottles, which are completely filled and sealed with screw caps fitted with soft rubber discs. Alternatively, culture vessels are filled so as to leave a head space which is gassed with an N_2/CO_2 mixture and sealed with rubber stoppers according to the Hungate technique (see Chapter 183, Fig. 5).

Depending on the type of sulfur reducer to be enriched and cultivated, organic substrates are added individually to tubes or bottles from the following, separately autoclaved stock solutions.

Medium Supplements for Sulfur Reducers

1. Stock solutions of acetate, ethanol, lactate, or other substrates of interest are prepared as described in Chapter 183 ("Defined Multipurpose Medium").
2. Formate solution, 2.0 M:
   13.6 g HCOONa are dissolved in distilled water to a final volume of 100 ml and autoclaved in a closed bottle with head space. Application: 10 ml per liter of medium.
3. Succinate, fumarate, or malate solution, 1.0 M:
   Sodium salts of the dicarboxylic acids are prepared from the free acids which are usually of higher purity than the commercial salts.

Distilled water	20 ml
Succinic acid (or fumaric acid, 11.6 g; or malic acid, 13.4 g)	11.8 g
NaOH (4.0 M)	48 ml

   The NaOH solution is added slowly under stirring. The pH is then adjusted to between 7 and 8 by dropwise addition of 1 M NaOH.
   Distilled water is added to a final volume of 100 ml. The solution is autoclaved in a closed bottle with head space.
   Application: 10 to 20 ml per liter of medium.

The electron acceptor, sulfur, is either added as a sulfur slurry or as polysulfide from the separately autoclaved stocks described in the following.

4. Sulfur slurry:
   Only highly pure (e.g., sublimized) flowers of sulfur should be used. This hydrophobic sulfur, which cannot readily be suspended in water, should be moistened by thoroughly grinding in a mortar with distilled water to give a slurry.
   Alternatively, flowers of sulfur can be moistened by stirring with water in a bottle that is repeatedly evacuated and reflushed with air or N_2. The resulting slurry is distributed in approximately 30- or 60-ml amounts into 50- or 100-ml screw-capped bottles, respectively, and excess water is decanted. Sulfur melts at 119.6°C, yielding an unusable compact clump, so the slurry should be autoclaved for 30 min at only 112 to 115°C.
   Application: Samples are taken with a flamed, cooled spatula and added individually to each culture tube or bottle. A pea-sized amount of sulfur in a very small volume of water is added per 50-ml bottle. A sterile glass bead should be also added to the culture bottle. If the culture is then incubated on a shaker, the bead keeps the sulfur partially in suspension.
5. Polysulfide solution:
   24 g $Na_2S{\cdot}9H_2O$ and 7.2 g flowers of sulfur are added

to water to yield a final volume of 100 ml. The mixture and a magnetic stirring bar are kept in a bottle under N_2 gas, with a tight rubber seal (see Chapter 183) to avoid autoxidation. The suspension is heated in a boiling water bath and stirred until the sulfur has dissolved (yielding an intensely yellowish-brown solution). In this way, a polysulfide solution with the average composition of $Na_2S_{3.25}$ at a concentration of 1 M is obtained. The solution is autoclaved under N_2 in the closed bottle.
Application: 6 ml per liter of medium.
Adding polysulfide increases the pH of the medium. If this is critical, medium with a relatively low pH (7.0 to 7.2) may be used. Alternatively, the pH is readjusted by addition of about 4 ml of sterile 2 M HCl or 1 M H_2SO_4 per liter of medium (see Chapter 183, "Defined Multipurpose Medium").

Enrichment, Isolation, and Maintenance

Selective Enrichment

Sulfur-reducing eubacteria can be selectively enriched in sulfate-free batch cultures with sulfur and a particular electron donor. Other important selective factors may be the salt concentration and the incubation temperature.

Samples from sediments or other types of sludge are kept under anoxic conditions (see Chapter 183). If not used immediately, samples should be refrigerated but not frozen. The size of the inoculum should be 1 to 2% of the culture volume.

There are essentially two methods for selective enrichment of sulfur-reducing bacteria:

1. The first and most direct method is the use of a sulfate-free, sulfide-reduced mineral medium with the electron donor of choice and an excess amount of moistened flowers of sulfur. An unequivocal proof of positive enrichment is H_2S production. This can be detected by testing with acidic $CuSO_4$ solution as described in Chapter 183 ("Selective Enrichment").
2. For the second method, the same culture medium and electron donor is used, but no sulfur is added. Instead, the medium is inoculated with the sediment sample and a pure culture of a green sulfur bacterium, e.g., *Prothecochloris aestuarii,* and incubated in dim light. Under these conditions, the *Prosthecochloris* forms elemental sulfur from sulfide; the sulfur is used directly by the sulfur reducers to be enriched. The successful enrichment culture is readily recognized by the abundant growth of the green sulfur bacterium as compared with a parallel culture that has not received the sediment sample as inoculum.

Enrichments should be subcultured two to five times before isolation is attempted. For inoculation, 1 to 2% of the culture volume is transferred from the previous positive enrichment.

ENRICHMENT OF *DESULFUROMONAS.* A generally suitable electron donor for enrichment of *Desulfuromonas* with sulfur is acetate, added at a concentration of 5 to 10 mM. Alternatively, 5 to 10 mM ethanol may be used. Enrichment of *Desulfuromonas succinoxidans* may be attempted with 5 to 10 mM succinate as sole electron donor. The concentration of NaCl and $MgCl_2 \cdot 6H_2O$ in the enrichment medium for freshwater types is 1 and 0.4 g, respectively, and for marine types 20 and 3.0 g, respectively. Intermediate salt concentrations have not been used so far. The incubation temperature is 30°C.

ENRICHMENT OF *DESULFURELLA. Desulfurella* is enriched on sulfur and acetate in freshwater medium at a temperature of 55°C. Thermophilic lithotrophic green sulfur bacteria that obligately depend on H_2S are not known and can therefore not be used to establish cocultures at this temperature.

ENRICHMENT OF SULFATE-REDUCING BACTERIA UTILIZING ELEMENTAL SULFUR. In addition to non-sulfate-reducing sulfur reducers, thiophilic sulfate reducers may appear in enrichments with lactate or ethanol and sulfur. The concentration of the organic substrate should be about 10 mM. Cultures are incubated at 28 to 35°C.

ENRICHMENT OF SPIRILLOID SULFUR-REDUCING BACTERIA. Successful enrichment of the spirilloid, facultatively microaerobic, sulfur-reducing bacteria is achieved with sulfur in the presence of 20 mM formate or under an atmosphere of H_2/CO_2 (90/10, vol/vol); acetate at a concentration of 1 to 2 mM has to be added as a carbon source. The incubation temperature may be around 30°C. Freshwater medium has been used most frequently. Tiny, highly motile vibrioid-to-spirilloid cells of the desired sulfur reducers usually appear within a few days. Enrichments may also be attempted with 10 mM dimethylsulfoxide (DMSO) as electron acceptor and formate, H_2/CO_2, or 10 mM lactate as electron donors (Zinder and Brock, 1978); with the former two electron donors, 1 to 2 mM acetate has to be added as the carbon source. Spirilloid sulfur reducers have also been enriched in a che-

mostat with aspartate as sole, growth-limiting carbon and energy source (Laanbroek et al., 1977).

Isolation

A simple, ideally suited method for the isolation of sulfur-reducing bacteria from enrichments is a serial dilution in agar deeps as described for sulfate-reducing bacteria (see Chapter 183). The agar dilutions with sulfide-reduced media may be carried out in open tubes. The brief contact with air does not affect the sulfur-reducing bacteria. Since flowers of sulfur are too coarse and inhomogeneous for agar dilutions, 0.15 ml polysulfide solution (see above) is added to a 50-ml bottle containing medium with the same electron donor as has been used for enrichment. Before the gradually precipitating sulfur forms flocs, the medium is distributed in 6-ml portions to tubes with the 3-ml portions of melted agar, as described in Chapter 183. Dithionite is not added. After serial dilution of an inoculum from the enrichment and gelling of the agar, tubes are anoxically sealed under N_2/CO_2 and incubated at the same temperature as the enrichment culture.

In case of obligate sulfur-reducing bacteria such as *Desulfuromonas thiophila* or *Desulfurella acetivorans,* elemental sulfur cannot be replaced by soluble electron acceptors. Isolation of facultative sulfur-reducing bacteria, however, may be attempted alternatively in agar dilution series with 10 to 20 mM fumarate or malate. Preferably, both electron acceptors are used in a parallel series. Acetate or ethanol is added as the electron donor in the case of *Desulfuromonas* species, and formate in the case of the spirilloid sulfur reducers. In this way, the turbidity caused by elemental sulfur is avoided, and the recognition of colonies at high dilution is facilitated.

Isolation of thiophilic sulfate reducers should be carried out in an agar dilution series with 10 to 20 mM sulfate instead of sulfur, while the electron donors are the same as in the enrichment. Such a counter-selection eliminates non-sulfate-reducing bacteria enriched together with the sulfate-reducing bacteria. After isolation, the pure cultures are tested for their capacity to use elemental sulfur in the sulfate-free culture medium.

In dilution series with sulfur precipitated from polysulfide, positive development is indicated by the disappearance of turbidity. At higher dilution, sulfur may only disappear around the colonies. Sulfur-grown colonies are usually rather small. Agar tubes are inspected under a dissecting microscope. In a dilution series with a soluble electron acceptor, colonies are bigger and easier to recognize. *Desulfuromonas* colonies are pink or intensely yellowish-brown (Pfennig and Biebl, 1976). *Desulfurella* does not possess cytochromes and forms whitish colonies (Bonch-Osmolovskaya et al., 1990; Schmitz et al., 1990). Colonies of sulfate reducers are brownish. Spirilloid sulfur reducers form yellowish-to-ochre colonies. With malate or fumarate as electron acceptor, these colonies appear chalky since they are interspersed with and surrounded by tiny whitish crystals of sulfur; this is produced by the oxidation of sulfide added as reductant, with fumarate or malate acting as electron acceptor (Macy et al., 1986; Wolfe and Pfennig, 1977).

Maintenance

For short-term preservation, stock cultures are kept at 2 to 6°C. Since grown cultures easily die off or lyse if further incubated at optimal growth temperature, strains should be refrigerated during or right after the end of active growth.

The interval of transfer depends on the tendency of stored cells to undergo lysis, which may be indicated by the presence of slimy layers or threads and a decrease in turbidity. For most species, a transfer every 6 to 10 weeks is recommended.

For long-term preservation, cultures containing 5 to 10% (v/v) DMSO are kept in liquid N_2.

Taxonomy and Identification

Relationships of a number of sulfur-reducing eubacteria among themselves and to other bacteria have been examined by oligonucleotide cataloging and by sequencing of 16S rRNA. As far as they have been analyzed, the phylogenetic groups coincide with those originally based on nutritional and morphological characteristics. Sulfur reducers assigned to the genus *Desulfuromonas,* mainly because of their ability to oxidize acetate, are also phylogenetically closely related to each other (Fig. 2; Fowler et al., 1986). However, there is the same degree of relatedness to fermentative, non-sulfur-reducing bacteria assigned to the genus *Pelobacter* (Stackebrandt et al., 1989). This interweaving of physiologically rather different groups at the genus and species level is difficult to interprete in terms of a biochemical evolution. Nevertheless, the genus designations *Desulfuromonas* and *Pelobacter* should be kept since they are in agreement with the physiological properties. The next relatives of this group are the completely oxidizing sulfate-reducing bacteria, *Desulfonema limi-*

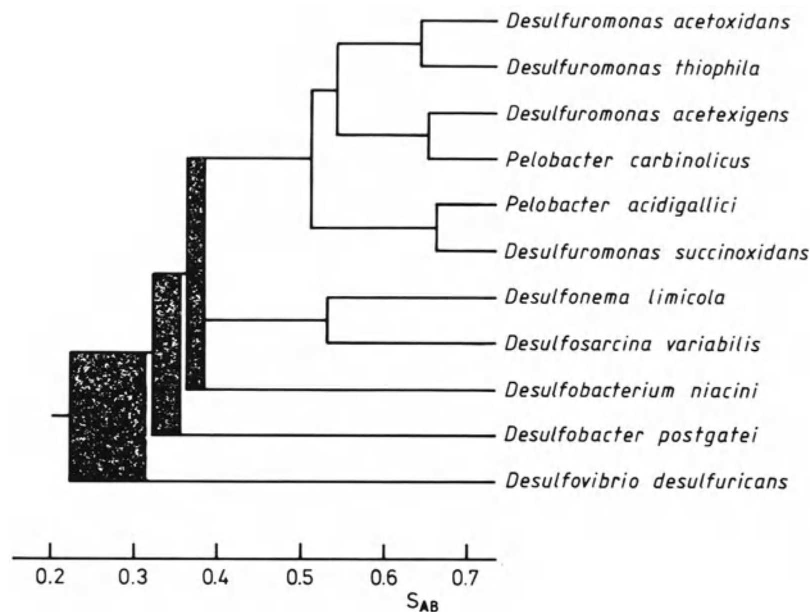

Fig. 2. Relationships of *Desulfuromonas* species among themselves and to other bacteria as revealed by 16S rRNA oligonucleotide cataloging. *D. acetexigens* and *D. thiophila* are tentative names. (Based on Fowler et al., 1986; Stackebrandt et al., 1989, and E. Stackebrandt, personal communication.)

cola, Desulfosarcina variabilis, and *Desulfobacterium niacini.* Desulfuromonas, Pelobacter, and the mesophilic sulfate-reducing bacteria together with *Myxococcus* and *Bdellovibrio* form the delta subdivision.

Nothing is known about the phylogenetic position of *Desulfurella acetivorans.* Its rather low GC content of 31.4 mol% distinguishes it from that of *Desulfuromonas* species (44 to 63 mol%).

Thiophilic sulfate reducers belong to the *Desulfovibrio* and *Desulfomicrobium* branch (tentatively comprised as Desulfovibrionaceae; see Chapter 183).

Spirilloid sulfur-reducing bacteria—originally isolated with formate and sulfur (Wolfe and Pfennig, 1977), aspartate (Laanbroek et al., 1977, 1978), or DMSO and lactate (Zinder and Brock, 1978)—and *Wolinella succinogenes* (Macy et al., 1986; Myers and Nealson, 1988) are physiologically very similar. Besides the latter, only the strain obtained with aspartate had been tentatively classified as a "free-living *Campylobacter* species." A genealogical relationship of this and the unnamed spirilloid isolates to authenticated *Campylobacter* species has not been demonstrated thus far. However, sequencing of 16S rRNA from *Wolinella* revealed that this species is closely related to the pathogenic *Campylobacter pylori,* which has a somewhat exceptional position in the genus. On a deeper level, a specific relationship exists to other pathogenic *Campylobacter* species (Fig. 3; Lau et al., 1987; Romaniuk et al., 1987). It is unknown whether any of the pathogenic *Campylobacter* species can grow by dissimilatory sulfur reduction, but it appears likely that the *Campylobacter* branch not only includes *Wolinella* but also some other hitherto-unnamed spirilloid sulfur reducers. The *Campylobacter* branch, with its presently known species, is related to the purple bacteria, but does not show any specific relationship to a particular member of the alpha, beta, gamma, or delta subdivisions (Lau et al., 1987; Romaniuk et al., 1987). *Campylobacter* and the spirilloid sulfur reducers probably form a fifth subdivision besides the ones mentioned (K. H. Schleifer, personal communication). The sulfur reducers await proper naming and classification.

Identification of sulfur-reducing bacteria by physiological characteristics, given in the following and in Table 1, is rather straightforward. Morphological features are shown in Fig. 4 and 5.

Dissimilatory Sulfur-Reducing Eubacteria (Physiological Group)

To be considered as a sulfur-reducing bacterium, an isolate must be able to grow with sulfur and produce sulfide over an indefinite number of subcultures. An unequivocal proof of a respiratory sulfur reduction is growth with H_2 or formate as sole electron donor, since neither of

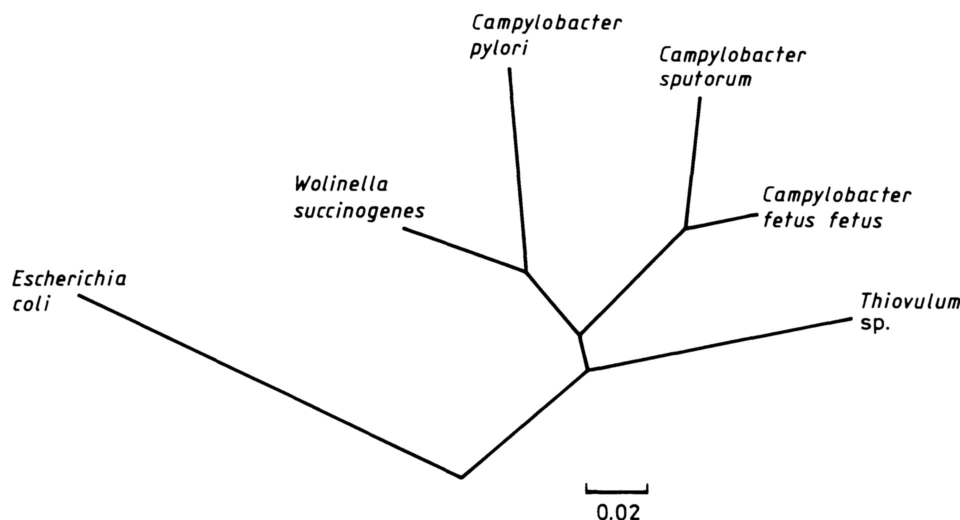

Fig. 3. Relationships of the sulfur-reducing bacterium *Wolinella succinogenes* to the pathogenic *Campylobacter* species as revealed by 16S rRNA sequencing. The scale bar represents the evolutionary distance measured as fixed nucleotide changes per sequence position. (Based on Romaniuk et al., 1987.)

these energy sources allows substrate level phosphorylation (see Chapter 24). Growth on H_2 or formate may require the addition of 1 to 2 mM acetate as carbon source for cell synthesis. According to present biochemical knowledge, oxidation of acetate with sulfur is also only possible in a respiratory metabolism (see Chapter 24). Sulfur reduction with sugars or lactate is not necessarily a respiration but may be only a facilitated fermentation or by-reaction.

DESCRIPTION OF *DESULFUROMONAS*. Cells are ovals or straight to slightly curved rods (Fig. 4A and B). Motility is common. Most species possess a single lateral (Fig. 5) or subpolar flagellum that cause a propellerlike movement. A few species have a single polar flagellum. Colonies and cell pellets are pink or yellowish-brown to reddish, due to a high content of cytochromes and other pigments (Bache et al., 1983; Pfennig and Biebl, 1976; Probst et al., 1977). *Desulfuromonas* species are obligately anaerobic, mesophilic bacteria. Acetate is the common electron donor and carbon source. Oxidation occurs via the citric acid cycle (see Chapter 24). Some species use, in addition, ethanol, 1-propanol, pyruvate, succinate, or some other simple organic acids. H_2 or formate are not oxidized. In the absence of sulfur, several species can grow with acetate as electron donor and malate or fumarate as electron acceptor, which are converted to succinate. After a certain adaptation period, especially in media with low bicarbonate and CO_2 concentrations, growth may occur on malate or fumarate alone. A few species obligately depend on elemental sulfur as electron acceptor. Sulfate, sulfite, or thiosulfate are never reduced. Nitrate is reduced in a few instances, nitrite being an intermediate and ammonia the end product. Growth with sulfur is usually rather rapid: *Desulfuromonas acetoxidans* has a doubling time of about 2.5 h on acetate and sulfur, while the doubling time on acetate and malate is around 7 h (Pfennig and Biebl, 1976, 1981).

DESCRIPTION OF *DESULFURELLA*. Cells are short rods that are motile by a single polar flagellum. Colonies and cell pellets are whitish, due to the absence of cytochromes (Bonch-Osmolovskaya et al., 1990; Schmitz et al., 1990). *Desulfurella* is an obligately anaerobic, moderately thermophilic bacterium. The optimum temperature for growth is 52 to 57°C. Growth occurs only on acetate and sulfur, the former being oxidized via the citric acid cycle. Growth of *Desulfurella acetivorans* can be rather rapid, with a doubling time of about 2 h (Bonch-Osmolovskaya et al., 1990).

DESCRIPTION OF SULFATE-REDUCING BACTERIA THAT REDUCE SULFUR. Cells are rod-shaped or vibrioid and are motile by polar flagella. Colonies or cell pellets are brownish. Growth occurs on lactate and in many cases also on ethanol in the presence of elemental sulfur. The capacity for indefinite growth on H_2 and sulfur has not been demonstrated, but is very likely, since H_2 is an excellent electron donor for growth on sulfate. Organic substrates are incompletely oxidized to acetate. Rod-shaped types usually do not contain desulfoviridin, but desulforubidin. They are considered as members of the genus

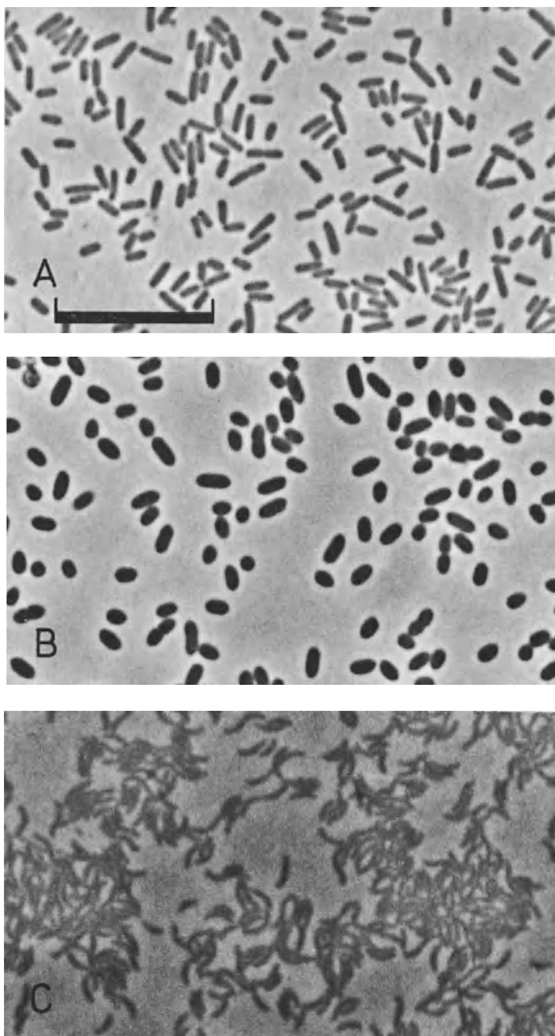

Fig. 4. Phase contrast micrographs of viable cells of sulfur-reducing bacteria. Bar = 10 μm. (A) *Desulfuromonas acetoxidans*. (B) *Desulfuromonas thiophila* (tentative name). (C) Spirilloid, facultatively microaerobic sulfur-reducing bacterium strain "spirillum 5175" (Wolfe and Pfennig, 1977).

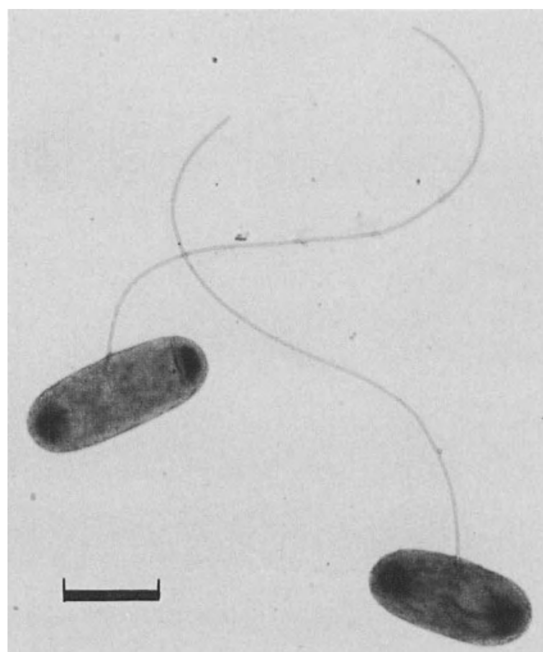

Fig. 5. Electron micrograph of negatively stained cells of *Desulfuromonas acetoxidans*, showing lateral flagella. Bar = 0.1 μm. (Courtesy of F. Mayer.)

Desulfomicrobium. Vibrioid types contain desulfoviridin and belong to the genus *Desulfovibrio*. Further descriptions are given in Chapter 183.

DESCRIPTION OF SPIRILLOID SULFUR REDUCERS INCLUDING *WOLINELLA*. Cells are vibrioid to spirilloid (Fig. 4C) and highly motile by a single polar flagellum. Colonies are yellowish to ochre. Growth occurs anaerobically or microaerobically (O_2 partial pressure, 1 to 5 kPa). The optimum temperature is between 30 and 37°C, depending on the type of isolate. Anaerobic growth occurs by oxidation of H_2 or formate with sulfur in the presence of 1 to 2 mM acetate as carbon source. Further electron acceptors are listed in Table 1. Dimethylsulfoxide is reduced to dimethylsulfide, nitrate is reduced to ammonia with nitrite as an intermediate. Reduction by *Wolinella* of N_2O to N_2 has been reported (Yoshinari, 1980). In the absence of an electron donor, spirilloid sulfur reducers, with the exception of *Wolinella*, are able to grow by fermentation of malate or fumarate; some species may ferment aspartate (Laanbroek et al., 1977).

OTHER SULFUR-REDUCING EUBACTERIA. A *Pseudomonas mendonica* subspecies and strains of *Alteromonas putrefaciens* were originally enriched as ferric iron- or manganese (IV)-reducing bacteria, respectively. Such types have never been enriched directly with sulfur as electron acceptor, probably because they utilize this electron acceptor more slowly and less effectively than the aforementioned sulfur reducers. For further descriptive information, the original literature should be consulted (Balashova, 1985; Loveley et al., 1989; Myers and Nealson, 1988).

The Genus *Thermodesulfobacterium*

FRIEDRICH WIDDEL

The genus *Thermodesulfobacterium* was established for a thermophilic sulfate-reducing eubacterium that grew optimally at 70°C (Zeikus et al., 1983) and possessed unusual nonisoprenoid ether-linked lipids (Langworthy et al., 1983). Later a sulfate reducer originally described as *Desulfovibrio thermophilus* (Rozanova and Khudyakova, 1974) was transferred to the same genus as *Thermodesulfobacterium mobile* (Rozanova and Pivovarova, 1988). The two *Thermodesulfobacterium* species are nutritionally relatively restricted, incomplete oxidizers using H_2, formate, lactate, or pyruvate as electron donors for sulfate reduction to H_2S. The morphology of *T. mobile* is shown in Fig. 1.

Preliminary sequencing of 16S rRNA of *T. commune* and *T. mobile* indicated that both species are related to each other and branch near the root of the eubacterial tree (C. R. Woese, personal communication; Chapter 24, Fig. 1). The genus is therefore phylogenetically entirely separate from other eubacteria and hence also from the delta group of Gram-negative sulfate reducers or from the genus *Desulfotomaculum.*

Habitats

T. commune was isolated from sediment of a hot spring (70°C) in Yellowstone National Park, USA. Morphologically identical thermophilic sulfate reducers were enriched from other hot pools or springs of this area (Zeikus et al., 1983). *T. mobile* (Rozanova and Khudyakova, 1974) and a similar isolate that could only use H_2 (Cord-Ruwisch et al., 1986) were isolated from warm-oil-field water.

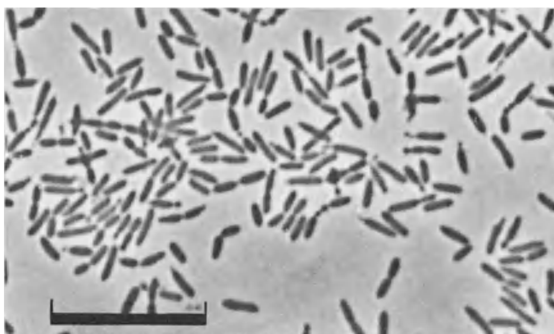

Fig. 1. Phase contrast photomicrograph of viable cells of *Thermodesulfobacterium mobile* (formerly *Desulfovibrio thermophilus*). Bar = 10 μm.

In their natural habitat, *Thermodesulfobacterium* species probably grow with H_2 derived from thermophilic fermentation processes or from geothermal reactions. Habitats of *Thermodesulfobacterium* probably also contain some acetate, since this organic compound is required for cell synthesis during growth on H_2 (Rozanova and Pivovarova, 1988; F. Widdel, unpublished observations).

Even though *Thermodesulfobacterium* strains were isolated from saline oil-field water, they do not appear to have a pronounced salt requirement or a significant salt tolerance.

Cultivation Techniques and Media

Thermodesulfobacterium species are grown under anoxic, reducing conditions in the lactate medium or the defined multipurpose medium described in Chapter 183; the latter is provided with lactate. Instead of lactate, pyruvate may be used for both media, the latter yielding less inhibitory H_2S than lactate and therefore allowing higher final cell densities. A pyruvate stock solution is prepared and applied as described in Chapter 80. For growth on H_2, the multipurpose medium is supplemented with 2 mM sodium acetate as carbon source for cell synthesis, and the culture is incubated under a head space of H_2/CO_2 (80/20, v/v).

The trace elements used (see Chapter 183, "Defined Multipurpose Medium") were either unchelated according to solution 1, with a threefold-increased $FeSO_4$ content (F. Widdel, unpublished observations), or they were chelated with NTA (nitrilotriacetic acid, neutralized), according to solution 3 (Zeikus et al., 1983). Growth occurs in a defined medium; however,

yeast extract (0.5 to 1 g/liter) is stimulatory, especially for *T. mobile.*

Enrichment, Isolation, and Maintenance

Selective Enrichment

For enrichment of *Thermodesulfobacterium* species, media with lactate are inoculated with sediment or mud samples from hot springs or oil production plants and incubated at 60 to 70°C. Parallel enrichments are carried out under a head space of H_2/CO_2 in the presence of 2 mM acetate; for this, the bicarbonate-buffered multipurpose medium should be used. Enrichments under H_2/CO_2 are carried out in tubes that are horizontally incubated, or in bottles that are gently shaken. Successful enrichment is recognized by sulfide formation (for test, see Chapter 183), the appearance of relatively small rod-shaped cells and, in the case of H_2 as electron donor, by the underpressure which develops. The underpressure is detected by piercing the stopper with a glass syringe lubricated with water and filled with H_2/CO_2 and observing retraction of the syringe barrel. Before isolation is attempted, two to five subcultures should be made.

Isolation

Thermodesulfobacterium species are isolated by the dilution techniques described in Chapter 183. Media with agar at the concentration used for mesophiles may be too soft at the relatively high incubation temperature, and the agar concentration should therefore be increased to 2% (this can be achieved by adding 3 ml of medium to tubes with 6 ml of 3% melted agar). The concentration of salts, reductants, and organic substrates in the medium to be added are increased by a factor of 3 to account for the dilution by the melted agar. Also, yeast extract (final concentration, 0.5 to 1 g/liter) is added to promote development of colonies. The dilution is carried out with tubes placed in a water bath at about 50°C. Before incubation at 60 to 70°C, the anaerobically sealed tubes are incubated for 30 min in a cold water bath to guarantee complete gelling of the agar.

Isolation is also possible via serial dilutions in liquid medium (see Chapter 183).

Maintenance

For short-term preservation, stock cultures are refrigerated or kept at room temperature. Since fully grown cultures easily die off or lyse if further incubated at 60 to 70°C, they should be cooled near to or at the end of active growth.

For most species, transfer every 3 to 5 weeks is recommended.

For long-term preservation, cultures with an addition of 5 to 10% (v/v) dimethylsulfoxide (DMSO) are kept in liquid N_2.

Taxonomy and Identification

Detailed studies on genealogical relationships among *Thermodesulfobacterium* species and of these species to other sulfate-reducing bacteria are lacking. Sequencing of 16S rRNA via reverse transcriptase could not be completed, probably due to modified bases, but the partial sequences obtained indicated a deep branching near the eubacterial tree, somewhere next to the branching point of *Thermotoga* (C.R. Woese, personal communication). Apart from these investigations, DNA-DNA hybridization studies were carried out with *T. mobile* and other sulfate reducers (Nazina et al., 1987). As might be expected, there was no hybridization with DNA from *Desulfovibrio* or *Desulfomicrobium.*

Thermodesulfobacterium species only resemble *Desulfovibrio* species nutritionally.

Thermodesulfobacterium species are identified by their high temperature optimum (65 to 70°C), rod-shaped cells that do not form spores, and the utilization of H_2, formate, lactate, or pyruvate as electron donors for sulfate reduction. However, some strains may use only H_2. Utilization of alcohols or fatty acids, as in case of thermophilic *Desulfotomaculum* species, has not been observed.

Thermodesulfobacterium species do not contain desulfoviridin. A new bisulfite reductase has been detected in *T. commune* (Hatchikian and Zeikus, 1983) and *T. mobile* (Fauque et al., 1986); the enzyme is named desulfofuscidin. Furthermore, cytochrome c_3 has been identified in this genus (Fauque et al., 1991; Hatchikian et al., 1984). The major menaquinone is MK-7 (Collins and Widdel, 1986).

A special biochemical feature of *Thermodesulfobacterium* species is the presence of ether-linked lipids, mainly phospholipids (Fig. 2). These were found in *T. commune* (Langworthy et al., 1983) and *T. mobile* (T.A. Langworthy, personal communication). However, in contrast to the isoprenoid lipids of archaebacteria, lipids of *Thermodesulfobacterium* contain alkyl chains with one subterminal methyl branch (anteiso branching). The lipid fraction also contains a certain portion of fatty acids and hydrocarbons (for details, see Langworthy et al., 1983).

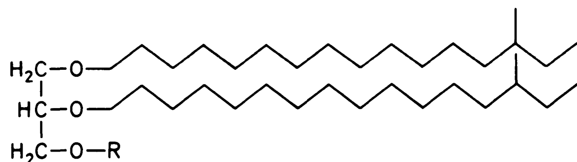

Fig. 2. Structure of the most frequently occurring lipophilic moiety (1,2-di-O-anteisoheptadecyl-*sn*-glycerol) in lipids of *Thermodesulfobacterium commune* (Langworthy et al., 1983). R, hydrophilic residue.

Thermodesulfobacterium commune, the type strain, has nonmotile cells, which are 0.3 μm in diameter and 0.9 μm in length. The optimum temperature is 70°C, the maximum 82°C. The GC content of the DNA is 34 mol%.

Thermodesulfobacterium mobile has motile cells with polar flagella. The cell diameter is 0.3 μm, the length 0.9 μm. The optimum temperature is 65°C, the maximum 82°C. The GC content of the DNA is 38 mol%.

CHAPTER 186

The Genus *Pelobacter*

BERNHARD SCHINK

The genus *Pelobacter* was proposed as a taxonomic entity consisting of strictly anaerobic, Gram-negative, nonsporeforming, rod-shaped bacteria that use only a very limited number of substrates. The members of the genus are all unable to ferment sugars and therefore cannot be grouped with any other genus in the family Bacteroidaceae (Krieg and Holt, 1984). The genus comprises five different species, *P. acidigallici* (Schink and Pfennig, 1982), *P. venetianus* (Schink and Stieb, 1983), *P. carbinolicus* (Schink, 1984), *P. propionicus* (Schink, 1984), and *P. acetylenicus* (Schink, 1985), which all are based on 3–5 described strains.

Comparisons of the various *Pelobacter* species by DNA-DNA hybridization experiments revealed that the genus is rather inhomogenous; therefore, a reorganization may perhaps be necessary in the future (J. P. Touzel and B. Schink, unpublished observations). Whereas the species *P. venetianus, P. carbinolicus,* and *P. acetylenicus* form a homogenous cluster, *P. acidigallici* and *P. propionicus* appear to be only distantly related to the others. These findings are consistent to some extent with the fermentation patterns of these species (see below). Comparison of three *Pelobacter* species with other anaerobes on the basis of 16S rRNA structure analysis supports this view. Whereas *P. venetianus* and *P. carbinolicus* exhibit a rather high similarity, with an S_{AB} of 0.70, *P. acidigallici* is related to both at an S_{AB} of only 0.53 (Stackebrandt et al., 1989). It is interesting to note that these three Pelobacter strains did not show any resemblance to other fermenting Gram-negative strict anaerobes; instead, they appeared to be highly related to several strains of sulfur-reducing anaerobes, namely, *Desulfuromonas succinoxidans, D. acetexigens,* and *D. acetoxidans,* to which they are even more closely related than *P. acidigallici* is to the other two *Pelobacter* species. Since *Pelobacter* species and the obligately sulfur-respiring bacteria are quite diverse metabolically and the latter are supposed to have derived directly from phototrophic ancestors, it has been suggested that the genus *Pelobacter* represents a group of fermenting bacteria that developed a fermentative metabolism as a "secondary" evolutionary event, and that they are separate from the first fermentative bacteria (Stackebrandt et al., 1989).

Habitat

All *Pelobacter* strains have been isolated so far from marine or freshwater sediments. The name *Pelobacter* was based on this origin (Greek *pelos* meaning mud, sediment). Enrichments from sewage sludges led to similar isolates as well. Viable counts using the characteristic substrates gallic acid, acetoin, polyethylene glycol, and acetylene showed that there were approximately 100 cells/ml of each of the *Pelobacter* species in sediment and up to 2,500 cells/ml in sewage sludge. Since their substrate ranges are comparably small, their ecological niche in such sediments can be understood rather well in most cases. *P. acidigallici* is restricted to the utilization of trihydroxybenzenoids, which are probably their only energy source in their natural habitat. *P. venetianus, P. carbinolicus, P. propionicus,* and *P. acetylenicus* were enriched and isolated with polyethylene glycol, 2,3-butanediol, and acetylene, respectively, but the ecological importance of these substrates in the respective environments is questionable. Since all these species can also ferment ethanol, either in syntrophic cooperation with hydrogen scavengers or in pure culture, it appears more probable that degradation of this important fermentation intermediate is their predominant function in these environments. *P. carbinolicus* has been identified as the dominant ethanol-degrading bacterium in digesting industrial sewage sludge (Dubourguier et al., 1986), and high numbers (10^6 - 10^7 cells/ml) of syntrophically ethanol-oxidizing anaerobes were detected also in other sewage sludges (Schink et al., 1985) and in freshwater creek

sediments (Eichler and Schink, 1985). *Pelobacter* has to compete for ethanol with certain homoacetogenic bacteria, e.g., *Clostridium aceticum* (Wieringa, 1940) or *Acetobacterium carbinolicum* (Eichler and Schink, 1984), which appear to be at least as successful in freshwater sediments (Schink et al., 1985), especially if the sediment is slightly acidic (Schink et al., 1985) or the temperature is low (Conrad et al., 1989). The ecological importance of ethanol fermentation to propionate by *P. propionicus* has been elucidated by enumerations and by tracer experiments (Schink et al., 1985). These studies revealed that up to 20% of the total ethanol turnover can go through propionate, and that bacteria forming propionate from ethanol contribute significantly to the total ethanol-metabolizing microbial community.

It has to be concluded that bacteria of the metabolic types represented by the various *Pelobacter* species make up a significant part of the anaerobic microbial population in sediments and sewage sludge. No *Pelobacter*-like bacteria have so far been isolated from the rumen. The numerically predominant, syntrophically ethanol-oxidizing *Pelobacter* species represent new isolates of the metabolic type of the S-strain in the mixed culture *"Methanobacillus omelianskii"* (Bryant et al., 1967). These *Pelobocter* species have become accessible to pure culture growth in our laboratory by the use of unusual substrates that all can be converted easily into acetaldehyde, the key intermediate in the energy metabolism of these bacteria (see next section).

Isolation

Growth Media

All *Pelobacter* strains have been enriched and isolated in a carbonate-buffered, sulfide-reduced mineral medium that contained only one organic energy and carbon source. Since they grow with substrates that yield 2-carbon intermediates exclusively, they have to form pyruvate and sugars via reductive carboxylation of acetyl coenzyme A and need carbon dioxide for this reaction. Use of a bicarbonate-buffered medium is therefore recommended for enrichment, isolation, and maintenance. Three different versions of this medium are described below for the isolation of *Pelobacter* from freshwater, estuarine, and marine sediment, respectively (after Widdel and Pfennig, 1981; Schink and Pfennig, 1982):

Pelobacter Growth Media

Dissolve in 1 liter of distilled water:

	Freshwater	Estuarine	Marine
KH_2PO_4	0.2 g	0.2 g	0.2 g
NH_4Cl	0.5 g	0.5 g	0.5 g
NaCl	1.0 g	8.0 g	20.0 g
$MgCl_2 \cdot 6H_2O$	0.4 g	1.2 g	3.0 g
KCl	0.5 g	0.5 g	0.5 g
$CaCl_2 \cdot 2H_2O$	0.15 g	0.15 g	0.15 g

Autoclave the complete mineral medium in a vessel equipped with 1) a filter inlet to allow flushing of the headspace with sterile oxygen-free gas; 2) screw-cap inlets for addition of thermally unstable additives after autoclaving; 3) a silicon tubing connection from the bottom of the vessel out to a dispensing tap (if possible with a protecting bell) for sterile dispensing of the medium (do not use latex tubing; it releases compounds which are highly toxic to many anaerobes); and 4) a stirring bar.

After autoclaving, connect the vessel with the still-hot medium to a line of oxygen-free nitrogen/carbon dioxide mixture (90%: 10%) at low pressure (< 100 mbar), flush the headspace and cool it under this atmosphere to room temperature, perhaps with the help of a cooling water bath.

The mineral medium is amended with the following additions from stock solutions that have been sterilized separately (amounts/l of medium): a) 30 ml of 1 M $NaHCO_3$ solution (autoclaved in a *tightly closed* screw-cap bottle with about 30% headspace; the bottle should be autoclaved inside another protective vessel, e.g., a polypropylene beaker, to avoid spills of carbonates if the bottle breaks in the autoclave); b) 2 ml of 0.5 M Na_2S9H_2O solution (autoclaved separately under oxygen-free gas atmosphere as above); c) 1 ml of trace element solution, e. g., SL 10 (Widdel et al., 1983); d) 0.5 ml of 10-fold concentrated, filter-sterilized vitamin solution (Pfennig, 1978); and e) adequate amounts of sterile 1 M HCl or 1 M Na_2CO_3 to adjust the pH to 7.1–7.3.

The complete medium is dispensed into either screw-cap bottles or screw-cap tubes which are filled completely to the top, leaving a lentil-sized air bubble for pressure equilibration. Enrichment cultures usually produce gas in the first enrichment stages and are better cultivated in half-filled serum bottles (50–100 ml volume) under a headspace of nitrogen: carbon dioxide mixture (90%:10%).

This mineral medium is amended with the respective organic substrates for enrichment and cultivation of pure cultures. The vitamin mixture is not really needed by all strains.

Selective Enrichment

All enrichment cultures were set up in our laboratory at 27–30°C in 50-ml fluid cultures inoculated with about 5 ml of sediment or sludge. Smaller inocula may also lead to isolation of the same bacteria, but this has not been evaluated in our lab. *P. acidigallici* can be selectively enriched with either one of its growth substrates (see Table 1) at 5–10 mM concentration. For enrichment of *P. venetianus,* either polyethylene glycol mol wt 106–20,000; 0.1% w/v) or meth-

oxyethanol (10 mM; Tanaka and Pfennig, 1988) is recommended. In this medium, 10 mM 2,3-butanediol enriches for *P. carbinolicus* from marine sediments, and for *P. propionicus* from freshwater sediments. *P. acetylenicus* is successfully enriched with mineral medium under the above-mentioned nitrogen: carbon dioxide atmosphere containing 5–10% acetylene in addition.

Isolation

After 3–4 transfers in liquid medium, a homogeneous microbial population should have become established in liquid enrichment cultures. Purification of *Pelobacter* species is most easily done by serial dilution in agar deep cultures ("agar shakes"; Pfennig, 1978). Roll tubes have not been used and are not necessary since these bacteria neither consume nor produce insoluble gaseous compounds. *P. acetylenicus* can be easily purified with 10 mM acetoin as substrate. Other procedures (streaking on agar plates in an anoxic glove box or on agar surfaces in flat agar bottles) have not been tried yet, but there is no reason why such methods would not be successful as well, if the solid media are incubated under a nitrogen/carbon dioxide atmosphere.

Preservation

Liquid cultures were maintained in our laboratory in 50-ml bottles at 4°C for 4–12 weeks between transfers. Longer storage intervals may be possible as well. Long-term preservation is easily accomplished by storage of dense cell suspensions in glass capillaries kept in liquid nitrogen.

Identification

Morphological and Cytological Properties

Cells of all Pelobacter species are Gram-negative, short rods that do not form spores (Fig. 1). The cell ends are usually rounded; however, *P. acetylenicus* cells can be slightly pointed (Fig. 1e). The cell sizes vary from 0.5 to 1.0 μm in width and from 1.2 to 6.0 μm in length. More exact cell sizes of the different type strains are listed in Table 1. The temperature optima for growth are in the range of 28–35°C; the pH optima are 6.5–7.5. On the basis of the GC content of the DNA, two clusters can be defined; the one *(P. acidigallici, P. venetianus, P. carbinolicus)* has a GC value at 50–53 mol%, the other one *(P. acetylenicus, P. propionicus)* at 57–58 mol%. It should be noted that this clustering does not agree with the subgroupings based on DNA and RNA homologies (see "Introduction," this chapter) or with physiological similarities.

Cytochromes have been found only in *P. propionicus*. A *b*-type cytochrome was detected at a very low level (Schink et al., 1987), but there is no evidence that this cytochrome plays any role in ATP-generating electron transport (see below).

Physiological Properties and Biochemistry

Table 1 presents a listing of all substrates used by the various *Pelobacter* species described so far. It is obvious from this table that *Pelobacter acidigallici* differs in its substrate spectrum from all other *Pelobacter* species. It utilizes only trihydroxybenzenoids for growth, and ferments them to acetate as sole fermentation product. With this, it resembles *Eubacterium oxidoreducens* (Krumholz and Bryant, 1986) to some extent, but does not depend on formate as an external co-substrate for degradation of these compounds. Growth experiments with increased substrate concentrations have revealed that the pathway of gallic acid fermentation leads via pyrogallol and phloroglucinol (Samain et al., 1986), and has nothing in common with the pathway of anaerobic benzoate degradation (Evans, 1977). Obviously, three hydroxyl groups in alternating position at the ring polarize the π-electron system sufficiently to permit selective reduction to dihydrophloroglucinol and ring opening by a thiolytic or hydrolytic mechanism. The isomerization of pyrogallol to phloroglucinol has recently been characterized as a unique transhydroxylase reaction involving a tetrahydroxybenzene as co-substrate (Brune and Schink, 1990). The third trihydroxybenzene isomer, hydroxyhydroquinone, is not metabolized by these bacteria, but it is fermented by other new anaerobic bacteria, also via phloroglucinol (A. Brune, S. Schnell and B. Schink, unpublished observations).

P. venetianus, P. carbinolicus, and *P. acetylenicus* have been enriched and isolated with polyethylene glycol, 2,3-butanediol, or acetylene, respectively. They can all grow with acetoin, some also with ethylene glycol or ethanolamine. All these substrates are converted to acetaldehyde, which is further dismutated to acetate and ethanol as final products. ATP is formed exclusively by substrate level phosphorylation via the acetate kinase reaction. The higher homologs of ethylene glycol, 1,2-propanediol, and 1,2-butanediol, are dismutated to propanol and propionate or butanol and butyrate, respectively, provided that the medium

contains some acetate (2–3 mM) for synthesis of cell material. Glycerol undergoes a similar dismutation to 3-hydroxypropionate and 1,3-propanediol. It is interesting to note that glycerol fermentation also requires the presence of acetate, and that this substrate cannot itself be assimilated.

In the presence of hydrogen-scavenging anaerobes, e.g., homoacetogens or methanogens, *Pelobacter* oxidizes primary aliphatic alcohols to the corresponding acids; with propanol and butanol, acetate is again required for cell matter synthesis. This syntrophic oxidation of ethanol via "interspecies hydrogen transfer" was first observed with the S-strain isolated from the syntrophic mixed culture *"Methanobacillus omelianskii"* (Bryant et al., 1967), which was lost many years ago. *Pelobacter* strains are the only representatives of this type of metabolism that are available today in pure cultures. Pure and mixed culture experiments have been carried out recently to understand the energetics

Table 1. Properties of the five *Pelobacter* species.

	P. acidigallici	*P. venetianus*	*P. carbinolicus*	*P. acetylenicus*	*P. propionicus*

Symbols: +, growth; −, no growth.
[a]Growth is possible only at very low concentration (<1 mM) or in continuous culture.
[b]Growth is possible only in the presence of a hydrogen-scavenging anaerobe, e.g., a methanogenic bacterium.
[c]Growth is possible only in the presence of small amounts of acetate for cell carbon synthesis.

and kinetics of interspecies hydrogen transfer in model cultures of *P. acetylenicus* and hydrogen-scavenging homoacetogenic and methanogenic partners (Seitz et al., 1988; Seitz et al., in preparation).

The biochemistry of polyethylene glycol degradation is not yet understood, neither in *P. venetianus* nor in other polyethylene glycol-degrading anaerobes (Dwyer and Tiedje, 1986; Wagener and Schink, 1988). *P. venetianus* degrades all polymers from the dimer up to a molecular weight of 40,000. Growth experiments in batch and continuous culture have shown that ethylene glycol can also support growth if it is provided at limiting amounts, and that acetaldehyde is the first free intermediate in both polymer and monomer degradation (Strass and Schink, 1986). Perhaps the polymer is attacked by a diol dehydratase-like reaction that transforms the terminal ether linkage into an unstable half-acetal linkage yielding acetaldehyde as product. Unfortunately, the cleavage reaction is very difficult to demonstrate in cell-free extracts, and a B_{12} compound of atypical structure appears to be involved (E. Schramm and B. Schink, unpublished observations). This cleavage reaction occurs inside the cells, and it is not clear how high-molecular-weight polyethylene glycols are able to cross the cytoplasmic membrane at sufficiently high transport rates.

Anaerobic degradation of polyethylene glycols is of major ecological concern because many industrially produced nonionic surfactants contain polyethylene glycols as hydrophilic moieties that maybe subject to anaerobic degradation in anoxic sediments and sludge (Wagener and Schink, 1987, 1988).

P. carbinolicus is related to *P. venetianus* and has basically the same biochemistry and physiology. It degrades ethylene glycol rather than polyethylene glycols, and it was originally enriched and isolated with acetoin or 2,3-butanediol as substrate. 2,3-Butanediol is oxidized to acetoin, which undergoes oxidative cleavage to acetyl CoA and acetaldehyde by a dichlorophenol indophenol-dependent enzyme analogous to pyruvate dehydrogenase (Oppermann et al., 1988). The physiological electron acceptor of this enzyme is not yet known. Acetaldehyde is either oxidized by a benzyl viologen-dependent enzyme to acetyl CoA or, depending on the electron balance, reduced to ethanol.

P. acetylenicus is the first strict anaerobe known to ferment an unsaturated hydrocarbon in pure culture. Again, the first intermediate of acetylene fermentation is acetaldehyde, which is further dismutated to acetate and ethanol. The enzyme that hydrates acetylene to acetaldehyde could not be demonstrated in a cell-free assay system; perhaps unusual cofactors are also

involved in this reaction. A report on an acetylene-hydratase enzyme in cell-free extracts of an aerobic *Rhodococcus* species (deBont and Peck, 1980) could not be reproduced in our hands either. The function of such an acetylene-hydrating enzyme in an anoxic environment is hard to understand since acetylene is probably not an important substrate in such environments. Perhaps its main role is hydration of other possibly toxic compounds, such as nitriles or cyanides, but there is no experimental evidence so far for such activities.

P. propionicus differs from the other *Pelobacter* species by producing propionate as one of its main fermentation products. Degradation of acetoin, 2,3-butanediol, and ethanol probably follows the same routes via acetaldehyde and acetyl CoA, as outlined above for the other species. The biochemistry of propionate formation from these C-2 compounds has been studied in detail (Schink et al., 1987). The key reaction is catalyzed by pyruvate synthase (pyruvate ferredoxin oxidoreductase), which operates here in the opposite direction to that predicted by its chemical equilibrium. The equilibrium is shifted by the exergonic propionate-forming reaction chain via methylmalonyl CoA; this chain is not coupled to ATP-yielding electron transport phosphorylation in these bacteria. This reaction in *P. propionicus* and other bacteria with similar biochemical capacities (Stams et al., 1984; Samain et al., 1982) is probably responsible for the formation of C-3 compounds from C-2 compounds in significant amounts in anoxic sediments and sludges (Goldberg and Cooney, 1981; Schink et al., 1985).

Applications

All *Pelobacter* strains discussed in this chapter may act as important syntrophic oxidants of primary aliphatic alcohols in sediments and sludges, where they have been found to be predominant (Dubourgier et al., 1986). Of technological interest may be the capacity of *P. venetianus* and similar isolates to degrade polyethylene glycols and to attack nonionic surfactants based on these compounds. These surfactants are of growing interest in the industrial manufacture of detergents, soaps, emulsifiers, etc. Aerobic degradation of polyethylene glycol-containing surfactant wastes creates enormous problems of foam formation in conventional activated-sludge sewage treatment and in natural waters. Anaerobic degradation of most of these compounds to methane can easily be achieved in packed column reactors, in which *P. venetianus*-like anaerobes ferment the polyethylene glycol moieties to substrates for the methanogenic microbial community (Wagener and Schink, 1987).

P. propionicus produces acetate and propionate from the substrates listed in Table 1. Propanol is fermented together with acetate exclusively to propionate. This fermentation may be of interest for biological production of propionate at high purity.

Acknowledgments

The author wishes to thank N. Pfennig and H. G. Trüper for their help on all questions concerning bacterial taxonomy, and in the establishment of this new genus. The assistance of Martin Bomar in compiling the phase contrast photomicrographs shown in Fig. 1 is highly appreciated.

CHAPTER 187

The Genus *Bdellovibrio*

EDWARD G. RUBY

Fewer than 30 years ago Stolp isolated the first representative of a group of bacteria that form plaques on lawns of other Gram-negative bacteria (Stolp and Petzold, 1962). Subsequently, this group of bacteriolytic microorganisms was described as a new genus, *Bdellovibrio* (Stolp and Starr, 1963). Since that time there has been a rapid increase in our understanding of the ecology, physiology, and biochemistry of the bdellovibrios, as well as the beginning of an understanding of their phylogeny and genetics.

The most significant characteristic that unifies bacteria defined in the genus *Bdellovibrio* is the presence of a distinctive growth phase within the periplasmic space of any of a variety of Gram-negative bacteria. This adaptation to growth in the interior of another bacterium has been accompanied by the evolution of a developmental life cycle that alternates between two (and sometimes three [Burger et al., 1968]) morphologically and physiologically differentiated cell types (Fig. 1). Thus far, all bdellovibrios isolated from nature require the presence of another bacterium to provide an intracellular growth environment, although it is possible to grow at least some bdellovibrios in the presence of extracts of other bacteria (Friedberg, 1978; Gray and Ruby, 1989). Also, as described below, variant strains can be selected that grow on simple nutrient media (Diedrich et al., 1970; Seidler and Starr, 1969b).

The distinctive life style of the bdellovibrios has led to a variety of somewhat confusing terminologies. They have been described both as "parasites" associating with "host" bacteria and as "predators" feeding upon "prey" bacteria.

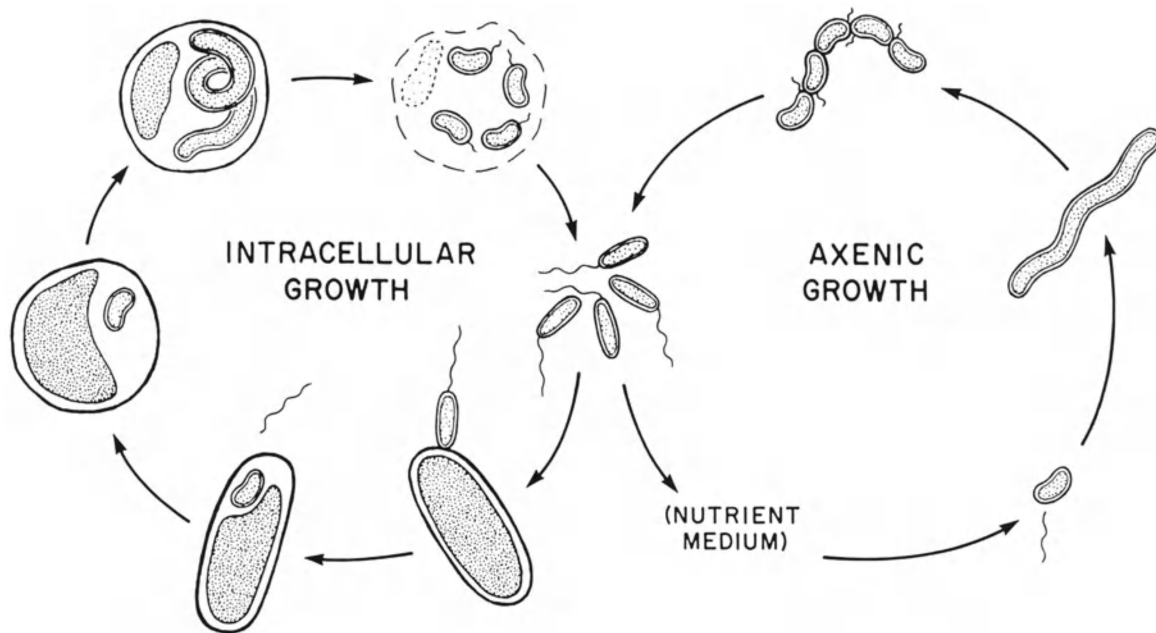

Fig. 1. The two growth patterns of *Bdellovibrio bacteriovorus* 109J. *Left:* wild-type bdellovibrios can grow only within another bacterium, alternating between an extracellular, attack-phase developmental form and an intracellular, growth-phase developmental form. *Right:* variant strains can be isolated that can grow axenically when inoculated into a complex nutrient medium. Many of these variants are facultative, i.e., able to grow either intracellularly or axenically.

This apparent controversy exists because the bdellovibrios express traits that fall within the definitions of both parasites and predators (Starr, 1975). The important point, however, is not what we call them, but that we realize that the success of the bdellovibrios derives from their unique combination of both "predatory" and "parasitic" traits. Our goal is to discover how those traits function together, without being prejudiced by restrictive labels. Accordingly, in this chapter the term "invaded cell" will generally be used, although occasionally "substrate cell" will appear. The latter term is used to emphasize that the invaded cell is used only as a source of organic substrates, and that its viability or metabolism is apparently unimportant to the successful growth and development of the bdellovibrios (Rittenberg, 1983; Varon and Shilo, 1969a).

Other terms that may need clarification, are the "attack-phase" and the "growth-phase," which are differentiated cell stages of the bdellovibrio life cycle. Attack-phase cells are flagellated, single-unit curved rods that do not exhibit chromosome replication or cell proliferation. Growth-phase (or "multiplication-phase" [Shilo, 1984]) cells have no external appendages, can initiate chromosome replication, and increase in size as single, elongating, spiral cells with unseptated cytoplasms. After a bdellovibrio enters a substrate cell it performs a number of degradative and biosynthetic modifications on the outer membrane and peptidoglycan of the invaded bacterium (Ruby, 1989). The resulting spherical structure, consisting of the inactive invaded cell and the developing bdellovibrio, is termed the "bdelloplast." Although the bdellovibrio remains within what was the periplasmic space of the invaded cell, the types and amounts of macromolecular components characteristic of the periplasm change, some being lost to the exterior, and others that are normally found in the cytoplasm becoming available to the bdellovibrio. Thus, the periplasmic compartment appears no longer to be distinctly separated from either the cytoplasm (Cover et al., 1984) or the extracellular environment (Crothers and Robinson, 1971; Ruby and McCabe, 1988). For this reason, the more generic term "intracellular," rather than "intracytoplasmic" or "intraperiplasmic," will be used in this chapter.

Since the publication of the first edition of *The Prokaryotes* (Stolp, 1981), there have been several general reviews of the bdellovibrio life style (Rittenberg, 1979; Thomashow and Rittenberg, 1979; Rittenberg, 1983), as well as more specific reviews dealing with ecology (Varon and Shilo, 1978; Rittenberg, 1979; Shilo, 1984), experimental methods (Rittenberg, 1982), and the cell envelope (Ruby, 1989). This present review treats the subjects of ecophysiology, isolation, identification, and application of the bacteria in the genus *Bdellovibrio,* and in particular reviews the (approximately) 60 papers published on the biology of the bdellovibrios since 1981.

Identification

The genus *Bdellovibrio* is defined in large part on the basis of a life style that includes the use of another Gram-negative cell as the sole source of nutrition (Burnham and Robinson, 1974). There are a number of other bacterial genera whose members prey upon or parasitize other microorganisms for their growth. Isolating bdellovibrios from, or studying them in, the natural environment requires an awareness both of the presence and characterisics of these other microbial bacteriovores, and of how they can be distinguished from the bdellovibrios. Such an awareness is of value not only for the valid identification of bdellovibrios in ecological studies (Enzinger and Cooper, 1976; Varon and Shilo, 1978, Germida and Casida, 1983; Mitchell et al., 1967), but also in providing a sense of the diversity of the organisms that should be considered in a comparative study of intracellular adaptations (Moulder, 1985; Ruby, 1989).

Table 1 lists seven genera of bacteria that have been reported to grow on unicellular organisms. With the exception of *Vampirococcus,* isolates have been maintained in laboratory culture, although often with some difficulty (I. Esteve, personal communication). Major metabolic and cellular characteristics by which they differ from each other and from bdellovibrios are noted (Table 1). While *Micavibrio, Vampirovibrio,* and *Vampirococcus* have been reported to be able to grow upon microorganisms of only a single genus, bdellovibrios as a group can utilize any of a wide variety of Gram-negative bacteria as a substrate cell. Any given strain of bdellovibrio usually has the ability to grow on bacteria of several different genera (Stolp and Starr, 1963; Taylor et al., 1974); for example, *Bdellovibrio bacteriovorus* 109J can be grown on certain strains of *Escherichia, Pseudomonas, Rhizobium, Chromatium, Spirillum,* as well as other genera. The basis for the specificity that is expressed within a strain of bdellovibrio and for the differences between bdellovibrio strains is still unknown, although the working assumption is that this specificity involves specific recognition of surface components of the attacked bacterium (Schelling and Conti, 1986).

Table 1. The characteristics of the major genera of bacteria that feed upon other microorganisms.

Genus	Motility	Metabolism	Association	Dependency[a]	Reference[b]
Myxococcus	Gliding	Obligate aerobe	Unattached	Axenic	1
Ensifer	Flagellar	Obligate aerobe	Attached	Axenic	2
Daptobacter	Flagellar	Facultative anaerobe	Cytoplasmic	Axenic	3
Micavibrio	Flagellar	Aerobe	Attached	Obligate (*Pseudomonas*)	4
Vampirovibrio	Flagellar	Aerobe	Attached	Obligate (*Chlorella*)	5
Bdellovibrio	Flagellar	Obligate aerobe	Periplasmic	Obligate (Gram-negative)	6
Vampirococcus	None	Anaerobe	Attached	Uncultured (*Chromatium*)	7

[a]The kind of host organism to which the parasite is restricted is given in parentheses.

Morphology and Ultrastructure

Bdellovibrios do not have any intrinsically distinctive morphological characteristics themselves and thus are usually recognized during microscopic examination of natural samples only by their association with the bacteria they have invaded (Caiola and Pellegrini, 1984; Wilkinson, 1979). Several excellent electron microscopic studies of the processes of penetration and growth by intracellular bdellovibrios have been reported using laboratory cultures (Abram and Davis, 1970; Abram et al., 1974; Snellen and Starr, 1974; Starr and Baigent, 1966) and have led to a better understanding of the topographical characteristics of this process (Rittenberg, 1983; Rittenberg and Thomashow, 1979).

The bdellovibrios exhibit two (or sometimes three [see below]) distinct cell morphologies that reflect their specific adaptations to either the attack phase or the growth phase of its life cycle. The attack-phase cell is a small (0.25 to 0.40 μm in width, 1 to 2 μm in length) vibrioid to rod-shaped bacterium. It possesses one polar flagellum of 28 nm diameter (Seidler and Starr, 1968) that is ensheathed by a continuous extension of the outer membrane of the cell (Thomashow and Rittenberg, 1985b). However, the flagellar sheath has been shown to be biochemically distinct from the rest of the outer membrane (Thomashow and Rittenberg, 1985a). The entire flagellum is lost from the attacking bdellovibrio after the bacterium attaches to a susceptible cell and before it enters that cell. The outer membrane of the bdellovibrio appears to be a strong structure that can maintain the osmotic integrity of the cell even when its peptidoglycan layer is experimentally removed (Thomashow and Rittenberg, 1978a).

The growth-phase bdellovibrio has the peculiar morphological characteristic of indeterminate growth. The extent of the length of an elongating cell is directly dependent upon the quality of the surrounding environment: intracellular bdellovibrios grow to lengths proportional to the volumes of the invaded cells (Kessel and Shilo, 1976), and the elongation of either axenic or prematurely released bdellovibrios depends upon the concentration of extracellular signals (Eksztejn and Varon, 1977; Gray and Ruby, 1989) that control bdellovibrio differentiation and growth. Cell elongation always occurs with the formation of a spiraling cell of strain specific compactness, and septa and flagella are elaborated only as the growth-phase cell differentiates into a number of attack-phase progeny (Fig. 1).

Bdellocysts

Almost all bdellovibrio strains that have been examined exhibit the simple, dimorphic life cycle illustrated in Fig. 1. However, the bdellovibrios of the *Bdellovibrio* sp. strain W not only are capable of the typical alternation between an attack and growth phase, but also can form a third, resting stage termed the bdellocyst (Burger et al., 1968; Hoeniger et al., 1972). Under unfavorable environmental conditions (Tudor and Conti, 1977a), strain W forms a resistant, multi-layered cyst inside the invaded cell and will eventually differentiate into an attack-phase cell upon the return of favorable conditions (Tudor and Conti, 1977b; 1978). A series of papers dealing with the synthesis and composition of the bdellocyst envelope has appeared (Tudor, 1980; Tudor and Bende, 1986; Tudor and DiGiuseppe, 1988). The significance of this encystment to the environmental biology of bdellovibrios has not been experimentally examined, but it would appear to offer a selective advantage to cells that frequently encounter harsh or changing conditions.

Bacteriophages of Bdellovibrios

There are presently three areas of interest concerning the characteristics of bacteriophages that parasitize bdellovibrios ("bdellophages"): 1) their abundance in the natural environment

may have some, as yet unknown, effect on the density and distribution of bdellovibrios in soil, water, and sewage (Varon, 1974); 2) they have been used in some taxonomic studies to group bdellovibrios with similar bacteriophage specificities (Althauser et al., 1972; Varon, 1974); and 3) their DNA has been used in studies of bdellovibrio transfection (Roberts et al., 1987; Roberts and Ranu, 1987).

Several laboratories have reported the isolation of bdellophages (Althauser et al., 1972; Hashimoto et al., 1970; Sagi and Levisohn, 1976; Varon and Levisohn, 1972), which are most easily obtained by their ability to form plaques on lawns of axenically growing bdellovibrios. Such bdellophages generally are able to attack and propagate within wild-type bdellovibrios provided that the bdellovibrios are grown together with cells that they can invade (so that they may initiate replication), and that the bdellophage attaches to the bdellovibrio just before the bdellovibrio invades another cell (Varon, 1974).

Taxonomy and Phylogeny

The difficulty of developing and applying a traditional taxonomic methodology to a group of bacteria that must be grown in a mixed culture has been responsible for the incomplete state of this area of bdellovibrio research. There are three described species of *Bdellovibrio*—*B. bacteriovorus* (Stolp and Starr, 1963), *B. stolpii,* and *B. starrii* (Seidler et al., 1972), as well as at least two unspeciated groups: the encysting forms represented by *Bdellovibrio* sp. strain W (Hoeniger et al., 1972), and the marine bdellovibrios (Marbach et al., 1976; Taylor et al., 1974). The three described species have been compared by DNA analysis (GC content, genome size, and DNA hybridization), as well as by cytochrome spectra and host range (Seidler et al., 1969; Torrella et al., 1978), and have been separated on the basis of three criteria that are variable and difficult to determine (Stolp, 1981).

The inadequacy of the methodology has resulted in very few attempts to identify large numbers of environmental isolates. Thus, no ecophysiological significance has been assigned to the various species of *Bdellovibrio,* and newly isolated strains are rarely taxonomically described. At present the nomenclatural type culture of *B. bacteriovorus* is strain 100 (ATCC 15356, DSM 5070); the type culture of *B. stolpii* is strain UKi2 (ATCC 27052, DSM 50722); and the type culture of *B. starrii* is strain A3.12 (ATCC 15145, DSM 50712) as described by Stolp (1981).

Further attempts have been made to elucidate the intrageneric arrangement of bdellovibrio strains by emphasizing passive, extracellularly located traits such as phage susceptibility (Varon, 1974), extracellular proteases (Gloor et al., 1974), antigenicity (Kramer and Westergaard, 1977), membrane proteins (Severin et al., 1981), and penicillin-binding proteins (Park and Mahadevan, 1988). Falkner et al. (1989) suggested that the marine and the terrestrial bdellovibrios have different surface antigens, and that this observation, as well as the relatively low GC content characteristic of the marine strains (Torrella et al., 1978), further supports the general consensus that they comprise two widely divergent groups (Stolp, 1981).

While there has been little recent progress in developing the taxonomy of the bdellovibrios, comparisons of sequence similarities of the 16S ribosomal RNAs of representatives of the three described species of *Bdellovibrio* and of the one marine isolate have allowed some speculation upon the phylogenetic relationship of the genus *Bdellovibrio* to other genera of bacteria (Hespell et al., 1984). The analyses of these data support two conclusions: 1) that the bdellovibrios probably form a single, ancient phylogenetic group that has experienced considerable divergence; and 2) that the closest existing relatives of the bdellovibrios are the myxobacteria and the sulfate-reducing bacteria. Further exploration of the molecular phylogeny of the bdellovibrios should provide thought-provoking information about their evolutionary relationships and may produce taxonomically useful probes for ecological studies.

Habitats

Distribution in the Natural Environment

The widespread distribution of bdellovibrios is evidenced by their ready isolation from samples of soil (Keya and Alexander, 1975; Klein and Casida, 1967; Mishustin and Nikitina, 1974; Parker and Grove, 1970), sewage (Dias and Bhat, 1965; Staples and Fry, 1973), freshwater (Fry and Staples, 1974; Guelin and Cabioch, 1970), and sea water (Marbach et al., 1976; Mitchell et al., 1967; Miyamoto and Kuroda, 1975; Taylor et al., 1974). Unfortunately, beyond the documentation of the presence and abundance of bdellovibrios in various natural samples, there have been few ecological investigations specifically designed to identify their normal habitats (Rittenberg, 1979). Rather little information is available to document experimentally what environmental factors may be important in the ecology of this group, except that oxic conditions and an abundance of

Gram-negative bacteria are positive correlating factors in many (Fry and Staples, 1976; Varon and Shilo, 1978), but not all (Williams and Falkner, 1984), studies.

The most complete studies of the ecology of the bdellovibrios are those reported by Williams and his co-workers, who examined the temporal and spatial distribution of these bacteria in estuarine waters. For most of this work, *Vibrio parahaemolyticus* was the prey species used to enumerate bdellovibrios; thus, the results may reflect the ecology of only a subset of all the bdellovibrios present in that environment i.e., those capable of growth on this species. The results of these studies indicated that bdellovibrios are more abundant in estuaries than in open ocean water (Williams et al., 1980). Bdellovibrios lytic to *V. parahaemolyticus* were found to occur at higher concentrations in the warmer, summer months than in the winter (Williams et al., 1980), and to be relatively uniformly distributed within the depth of the water column (Williams and Falkner, 1984). Most recently, a study of the abundance and distribution of bdellovibrios in estuarine sediments has suggested that they maintain their abundance and even appear to proliferate in this environment (Williams, 1988); warm water temperatures, low salinity, and a high concentration of other culturable Gram-negative bacteria are the environmental conditions that correlate positively with bdellovibrio abundance.

Because of the importance of the presence of substrate cells to bdellovibrio survival (Hespell et al., 1974), the biological (and not just the physical and chemical) characteristics of the microbial ecology of the bdellovibrios must be addressed. Several studies have attempted to determine experimentally the minimum concentration of substrate cells that is necessary to support a population of bdellovibrios (Fry and Staples, 1974; Hespell et al., 1974; Keya and Alexander, 1975; Varon, 1981; Varon et al., 1984; Varon and Zeigler, 1978). Of particular importance to this process are the kinetics of successful attachment of the bdellovibrio to a potential substrate cell (Varon and Shilo, 1968), a process in which the surface characteristics of that cell are of demonstrated importance (Varon and Shilo, 1969b). Applications of chemostat methods (Varon, 1979) and theoretical modeling (Dulos and Marchand, 1984; Marchand and Gabignon, 1981) to such questions have also been made.

An additional factor affecting the distribution and success of bdellovibrios in the natural environment is any potential for directed movement that would result in an increased likelihood of encountering a potential substrate cell (Rittenberg, 1979; Shilo, 1984). While bdellovibrios do not seem to express a measurable chemotactic response toward concentrations of suitable substrate cells (Straley and Conti, 1977), they have been reported to accumulate in the vicinity of high concentrations of organic solutes (LaMarre, et al., 1977; Straley and Conti, 1974; Straley et al., 1977). It has yet to be demonstrated whether or not this latter capability would itself direct the bdellovibrios to environments that attract or contain concentrations of actively metabolizing substrate cells.

The Intracellular Environment

A consideration of the natural environment of the bdellovibrios must be concerned both with the habitats and ecological distribution of the attack-phase cell and with the special intracellular environment of the growth-phase bdellovibrio. It has been observed that the intracellular environment may serve not only as a compact and complete nutrient source, but also as a protected environment (Rittenberg and Thomashow, 1979; Shilo, 1984). Thus, the bdelloplast is a relatively safe haven against lethal irradiation (Friedberg, 1977), phages (Varon and Levisohn, 1984), and environmental pollutants (Varon and Shilo, 1981). It seems clear, therefore, that their ability to produce an intracellular growth chamber exerts positive (and perhaps significant) effects on the ecology of the bdellovibrios.

The obligate nature of the intracellular life style of the bdellovibrios has another ecological consequence: it clearly limits the number of environments in which the bdellovibrio can reproduce. The question of why bdellovibrios normally proliferate only when they are within substrate cells has yet to be answered; however, two approaches to this problem are being actively pursued. The first approach is to define the genetic character of the mutation (or mutations) of the variant bdellovibrios that can proliferate in the absence of a substrate cell (Seidler and Starr, 1969b). The introduction of molecular genetics to the study of the bdellovibrios has made this goal feasible (Cotter and Thomashow, 1989). The second approach involves the identification of specific compounds in extracts of substrate cells that can promote axenic growth by these bdellovibrios that otherwise grow only within the intracellular environment of the substrate cell (Crothers et al., 1972; Horowitz et al., 1973; Gray and Ruby, 1989; Reiner and Shilo, 1969).

Isolation

The basic approach to the isolation of bdellovibrios from natural samples bears a resemblance to that used to obtain bacteriophages: dilutions of water, sewage, or soil are mixed with a susceptible bacterial suspension in soft agar and are plated and incubated at an environmentally appropriate temperature; the presence of a growing bdellovibrio clone is indicated by a plaque in the bacterial lawn (Rittenberg, 1982). In principle, two important considerations must be addressed for a successful isolation: 1) an appropriate choice of the lawn-forming prey bacterium must be made; and 2) some physical separation of the bdellovibrios from other plaque-forming microorganisms must be employed to facilitate screening and selection (Varon and Shilo, 1970).

Bdellovibrios, like bacteriophages, express some specificity for the species of their prey (Shilo and Bruff, 1965; Taylor et al., 1974), although the basis for such specificity is not yet well described (Chemeris et al., 1984; Schelling and Conti, 1986). In addition, the choice of a lawn-forming organism must take into account the physiological attributes desired in the isolated bdellovibrios (marine, psychrophilic, etc.). Schoeffield and Williams (1990) suggest that the selection of *Vibrio parahaemolyticus* as the lawn-forming bacterium will reproducibly maximize the efficiency of detection of bdellovibrios in some estuarine water samples. In contrast, the apparent usefulness of *Aquaspirillum (Spirillum) serpens* MW5 as a "universal host" (Torrella et al., 1978) has been recently disputed (S.F. Koval, pers oral communication). While these observations can be of great value in designing experiments, their interpretation in terms of the ecology of bdellovibrios must be approached cautiously (see below).

Because bdellovibrios usually are found in nature in rather low abundance (Klein and Casada, 1967; Fry and Staple, 1974; Williams, 1988) and often are mixed with bacteriophages, myxobacteria, protozoa, and other plaque-forming bacteriovores, a selective filtration step is used to eliminate large bacterial predators and protozoa, thereby enriching the sample in bdellovibrios (Starr and Stolp, 1976; Varon and Shilo, 1978). The relatively slow rate of formation of bdellovibrio plaques differentiates them from plaques formed by bacteriophages.

Enrichment and Direct Isolation of Bdellovibrio (Modified from Stolp, 1981)

An appropriate volume of water sample or a 50-g soil sample suspended in 500 ml of sterile buffer is shaken vigorously for at least 1 h and centrifuged briefly at 2,000 × g to remove large particles or soil. The resulting low-speed supernatant suspension is passed through a series of decreasing pore-sized membrane filters (3.0, 1.2, 0.65, and 0.45 μm). Samples of 100 μl serial dilutions of the final filtrate are combined with 200 μl of a suspension of potential substrate bacteria (10^{10} cells per ml) in 2.5 ml of 0.6% agar at 42°C. The mixture is well agitated and quickly overlaid on a room-temperature, dilute nutrient agar plate, allowed to solidify, and incubated at an appropriate temperature.

Within 24 h, the presence of any viable bacteriophages in the dilutions will be indicated by the appearance of plaques. Because none of these early plaques will be the result of bdellovibrio growth, they can be marked and disregarded. When the plates are viewed again after 2 to 4 days at 30°C, the additional plaques noted are presumptive bdellovibrio clones. Addition of a stain to the medium has been reported to aid in distinguishing bdellovibrio plaques (Williams et al., 1980)

After crushing a small bit of the plaque-containing agar between a cover slip and slide, it should be possible to discern small, rapidly motile bdellovibrio cells among the remains of the lawn bacteria. It should be noted that these numerous manipulations and fractionations of the sample may lead to the loss of an indeterminable portion of the total bdellovibrio population in the sample (Staples and Fry, 1973). Thus, this approach is not appropriate for the quantitative determination of the abundance of bdellovibrios in the sample.

When samples of the natural environment are not being used to estimate the abundance of bdellovibrios (Germida, 1987; Keya and Alexander, 1975; Parker and Grove, 1970; Sullivan and Casida, 1968), but instead to obtain an isolate of bdellovibrios that is lytic towards a particular strain or species of bacterium, the method of "specific enrichment" is most useful. In this approach the sample of water, soil, or sewage is added to a suspension of the desired substrate bacterium in a buffer solution. A period of incubation is chosen during which it is presumed that only those bdellovibrios that can grow upon the enriching bacterium will become enriched in the sample. Because of the lack of added nutrients, the growth of heterotrophic microorganisms in general is discouraged. Bacteriophage development is minimal because the growth of all of the bacteria in the enrichment (except for the bdellovibrios) is minimal.

Specific Enrichment Procedure for Obtaining Bdellovibrio Cultures (Modified from Stolp, 1981)

A culture of the desired substrate bacterium is suspended in DNB medium (0.08% Difco Nutrient Broth, 0.05% Difco Casamino Acid, and 0.01% Difco Yeast Extract in deionized water, adjusted to pH 7.6 with NaOH, supplemented with 1 mM $CaCl_2$ and 0.1 mM $MgCl_2$ after sterilization) or HM buffer (10 mM N-2-hydroxyethyl piperizine-N′-2-ethanesulfonic acid adjusted to pH 7.6 with NaOH, and supplemented with 1 mM $CaCl_2$ and 0.1 mM $MgCl_2$) to a density of 10^{10}

cells per ml. To 100 ml of this suspension is added the natural sample that is to be checked for the presence of bdellovibrios (e.g., 100 mg of soil, 0.5 ml of sewage, or 1 ml of river water). The enrichments are incubated with rapid shaking and checked daily by phase-contrast microscopy for the presence of either bdelloplasts or presumptive bdellovibrio cells. When bdellovibrios are apparent, the enrichment is centrifuged at low speed (2,000 × g) for 5 min to remove particles, and filtered through a 0.45 μm pore-sized membrane. The filtrate is diluted and plated onto lawns of the enriching substrate bacterium as described above, and the resulting plaques are checked for the presence of bdellovibrio cells.

There are two special considerations that must be addressed when attempting to isolate bdellovibrios from the marine environment. First, the media and buffers used should contain at least 25% sea water or an appropriate marine salts mixture (Bell and Latham, 1975; Marbach and Shilo, 1978; Taylor et al., 1974) to provide the specific ionic and osmotic requirements of marine bacteria. Second, the sometimes extremely low abundances of bdellovibrio cells in seawater samples require that large volumes of water be processed.

Procedure for Obtaining Marine Bdellovibrio Cultures (Varon and Shilo, 1976)

Either the direct or specific procedures for bdellovibrio isolation can be adapted to marine samples. Both should begin with the concentration of up to 1 l of sea water either by sedimentation in a centrifuge at high speed (10,000 × g for 30 min), or by collection on a 0.1-μm-pore-sized membrane filter. The concentrated material can be used to inoculate soft-agar overlay plates containing cultures of an appropriate prey organism, such as a strain of one of the luminous marine bacteria (Varon and Shilo, 1981).

Preparation of Pure Cultures

The plaques developing from an initial isolation must be purified of contaminating microorganisms by serial transfer. The result of such a process should be a mixed culture containing only the single clone of bdellovibrio, and the strain of bacterium upon which it was isolated and will be maintained. This approach is formally analogous to that applied to the purification of bacteriophage from plaques.

Procedure for Purifying Bdellovibrio Cultures (Modified from Stolp, 1981)

A sample of the bdellovibrios within a developing plaque is removed by inserting a sterile Pasteur pipette tip into the center of the plaque. The agar plug is removed and transfered to 2 ml of HM buffer or a dilute medium solution, and the cells are suspended by vortexing. The liquid suspension is passed through a sterile 0.45-μm-pore-sized membrane filter, and the filtrate collected. Serial dilutions of the filtrate are made in HM buffer and plated for the visualization of individual plaques. Plating is performed by combining 100 μl of bdellovibrio suspension, 200 μl of prey cell suspension (10^{10} cells per ml), and 2.5 ml of 0.6% agar at 42°C, and quickly pouring the mixture onto the top of a DNB agar plate. After incubating the plate for 4 to 7 days, a single plaque is reisolated from this plate, and the process is repeated three times, or until the culture shows no signs of contamination. If difficulties arise from the growth of contaminating heterotrophic bacteria, platings and dilutions can be made on an HM-buffer agar plate to discourage the growth of extraneous bacteria. With this method, substrate cells must be provided at a high turbidity in the soft-agar overlay in order to allow plaque development and visualization in the absence of significant lawn growth.

Manipulation

Cultivation

The success of many experiments using bdellovibrios relies upon the preparation of a healthy, predictably active suspension of attack-phase cells that can be either analyzed directly or combined with a suspension of substrate cells to initiate an intracellular growth cycle. The following procedures have been found to produce attack-phase cells in optimal condition.

Two consequences resulting from the high endogenous respiratory rate (Hespell et al., 1973) characteristic of bdellovibrios, should be remembered: 1) Suspensions of bdellovibrios should be incubated with vigorous agitation, preferably on a rotary shaker, to assure a ready supply of oxygen. Efficient aeration can also be encouraged if the nominal volume of the flask used is at least two to three times that of the cell suspension it contains. 2) Their high respiratory demand causes suspensions of attack-phase cells to lose viability rapidly when maintained in the absence of a source of cells upon which to grow (Hespell et al., 1974; Hespell and Mertens, 1978). Both the addition of a respirable substrate, such as 1 mM glutamate, and the reduction of temperature to 0°C, can ameliorate the effects of the requirements for high endogenous respiratory activity, and prolong both culture viability and synchrony of attack (see below).

The attack efficiency of bdellovibrios is enhanced both by keeping the concentration of organic nutrients (like nutrient broth or yeast extract) in the suspending medium below 0.1% (wt/vol), and by using washed suspensions of both bdellovibrios and substrate cells. Other viability-enhancing conditions for at least some strains include using substrate cell cultures with a low proportion of dividing cells (Rittenberg, 1982), maintaining high concentrations of Ca^{2+}

and Mg^{2+} ions in the suspending medium (Huang and Starr, 1973), the addition of osmoprotectants to cultures at low densities (Varon et al., 1983 and 1984), and the absence of strong irradiation (Friedberg, 1977). The following procedure is recommended for work with bdellovibrios:

Routine Cultivation of *Bdellovibrio Bacteriovorus* 109J (Modified from Thomashow and Rittenberg, 1978b)

Stock Culture. To a 125-ml flask containing 40 ml of HM buffer are added 10 ml of a culture of *Escherichia coli* ML35 (4×10^{10} cells) grown to stationary phase in NB medium (0.8% Difco Nutrient Broth, 0.5% Difco Yeast Extract in deionized water, adjusted to pH 7.6 with NaOH), and 50 to 100 μl of a 7 to 10-day-old stock culture of *Bdellovibrio bacteriovorus* 109J. The flask is shaken overnight at 30°C and, when the culture contains essentially only attack-phase bdellovibrios, it is stored at 4°C.

Large-scale Culture. To a 500-ml flask containing 200 ml of DNB medium is added 40 ml of a culture of *Escherichia coli* ML35 (total addition = 1.6×10^{11} cells) grown to stationary phase in NB medium, and 50 to 100 μl of a fresh *Bdellovibrio bacteriovorus* 109J stock culture. The flask is shaken at 30°C overnight, and the culture observed by phase-contrast microscopy until all of the bdelloplasts have lysed. The culture is cooled on ice, centrifuged at low speed (700 × g for 15 min), and the pellet discarded. The supernatant suspension, containing most of the attack-phase bdellovibrios, is centrifuged at high speed (10,000 × g for 15 min) and the resulting supernatant suspension discarded. The pellet is gently resuspended in HM buffer and harvested by recentrifugation at high speed. Resuspension of the pellet in HM buffer should yield about 6×10^{11} washed bdellovibrio cells.

Enumeration

There are three methods commonly used for enumerating laboratory cultures of bdellovibrios in liquid suspensions. Each method provides a different combination of degrees of accuracy, convenience, speed, and sensitivity. Direct microscopy, either of unstained (Snellen et al., 1978), or fluorescently labeled (Hobbie et al., 1977) cells can be performed on suspensions of bdellovibrios. Microscopy is effective even in the presence of substrate cells because there is usually a significant size difference between the substrate cells and the bdellovibrios. Electronic particle counting has also been used both to count and to size bdellovibrio cells in pure culture (Patinkin, 1975).

To determine the number of viable cells in a suspension, dilutions can either be mixed with a suspension of substrate cells in soft agar and pour plated, or spread on the surface of a nutrient agar medium if the cells are capable of axenic growth (see below). Bdellovibrios will form visible plaques in the lawn after 3 to 4 days and will continue to grow in diameter for a week or more. In the case of axenic strains, small, often yellow, colonies will be apparent within 4 days of incubation at 30°C.

The most convenient and routine method of estimating the concentration of bdellovibrio cells in a relatively dense suspension is by optical density. Both turbidimetric and spectrophotometric approaches have been useful in general laboratory procedures (Varon and Shilo, 1969a). Calibrating such measurements against microscopic counts or viable counts results in a reliable standard curve, especially if the bdellovibrios are cleaned of prey cell debris by washing with HM buffer before their optical density is determined.

Single-Cycle Growth Technique

One of the most intensely studied areas of bdellovibrio biology is concerned with the specific temporal events that make up their developmental cycle (Fig. 1). These events can best be investigated by using a method that produces a large number of bdellovibrios developing in a synchronous manner (Rittenberg, 1982). This is most easily achieved by mixing active, attack-phase bdellovibrios with susceptible substrate cells in a ratio of 2:1, which assures the attack and entry of all the substrate cells within a few minutes. The bdelloplasts formed can then be easily separated from the supernumerary, extracellular bdellovibrios by differential centrifugation, producing a suspension of bdelloplasts within which reside bdellovibrios that have begun, essentially simultaneously, a single, synchronized cycle of growth and development. Analyses of such developing populations at specific times between the initial attack and the final release from the spent bdelloplast can reveal the relative timing of stage-specific developmental events and activities (Matin and Rittenberg, 1972; Rosson and Rittenberg, 1979).

Procedure for Producing Developmentally Synchronized, Intracellularly Growing Bdellovibrios (Thomashow and Rittenberg, 1978b)

An overnight culture of bdellovibrios that have very recently been released from bdelloplasts is cooled to 0°C and harvested by centrifugation at 10,000 × g for 15 min. The resulting pellet of bdellovibrio cells is washed once with cold HM buffer to remove spent bdelloplast debris. A fresh overnight culture of substrate cells (such as *Escherichia coli* ML35) is similarly harvested and washed. Separate suspensions of the bdellovibrios (10^{10} per ml) and the *E. coli* cells (5×10^9 per ml) are maintained on ice until use. A synchronous developmental cycle is begun by mixing equal volumes of the two suspensions and shaking the mixture rapidly at 30°C.

Within 10 to 15 min, all of the *E. coli* cells should be visible as spherical bdelloplasts when viewed under phase-contrast microscopy. At this point the suspension is cooled in an ice bath, and the bdelloplasts are separated from any excess bdellovibrios by centrifugation at 1,000 × g for 5 min. The resulting pellet is resuspended and recentrifuged two more times or until the final pellet contains less than 5% of the excess bdellovibrio cells. The bdelloplast pellet is resuspended in one-half the original culture volume of HM buffer at 0°C. The intracellular bdellovibrios will resume their synchronous development when they are again shaken at 30°C.

Isolation of Axenic Variants

All the strains of wild-type bdellovibrios examined can spontaneously produce variants or mutants that have the ability to grow in the absence of substrate bacteria (Burnham et al., 1970; Stolp, 1981). Such variants arise at a frequency of approximately 10^{-6} to 10^{-8} (Seidler and Starr, 1969b) and can grow on a variety of nutrient media that contain at least a small amount of yeast extract (Ishiguro, 1974). While the frequency of generation suggests that only a single mutational event is required for the loss of substrate cell dependency, the pleiotropic nature of these strains suggests that lesions in any one of several regulatory genes may give rise to this phenotype. It is significant that these variants continue to express the morphological differentiation of the wild-type bdellovibrio, even in the absence of an intracellular life style (Fig. 1). These axenic growth-phase cells have been used to examine characteristics of bdellovibrio growth in the absence of any confounding influences of the invaded cell (Ishigura, 1973; Rosson and Rittenberg, 1981; Rayner et al., 1985; Ruby et al., 1985; Talley et al., 1987).

It has been noted (Diedrich et al., 1970; Varon and Seijffers, 1975) that most axenic variants are facultative and can grow in either of the two modes (axenic or intracellular) shown in Figure 1; however, maintenance of these variants in the absence of substrate cells for numerous transfers often results in the loss of the ability to grow intracellularly. This effect is probably related to the observation that obligately axenic strains have a selective advantage over facultatively axenic strains in chemostat culture (Varon and Seijffers, 1975).

Procedure for Isolating Axenic Bdellovibrio Strains (Modified from Seidler and Starr, 1969b)

The only significant difficulty that must be overcome to isolate axenic variants is that of separating them from the strain of substrate cell on which they have been maintained. Therefore, to obtain a selectable marker, an antibiotic (e.g., streptomycin) is added to a wild-type bdellovibrio culture, which is then propagated on substrate cells for several days until a spontaneously arising streptomycin-resistant bdellovibrio mutant completes lysis of the culture. The antibiotic-resistant bdellovibrios are concentrated by centrifugation and resuspension in HM buffer, and 10^7 to 10^9 cells are spread on NB agar medium containing streptomycin. Under these conditions, the only colonies that form are axenically growing bdellovibrios, which can be further purified by conventional streaking. An improvement in the growth rate of these axenic variants has been reported to occur in the presence of additional osmolytes (Varon and Seijffers, 1977), and the use of freshly poured agar medium and a humidified incubation chamber can enhance colony yields and growth.

Premature Release of Intracellular Bdellovibrios

Because of the unknown genetic nature of the axenic variants and their pleiotropic characteristics (Seidler and Starr, 1969b), these strains are not always appropriate subjects for examining the activities of wild-type, growth-phase bdellovibrios (Ruby et al., 1985). For this reason, a technique has been developed that allows one to obtain viable, wild-type growth-phase cells from the bdelloplast at any time during the intracellular portion of their life cycle (Ruby and Rittenberg, 1983).

Procedure for Premature Releasing Growth-Phase *Bdellovibrio bacteriovorus* 109J (Ruby and Rittenberg, 1983)

Bdelloplasts from a synchronously growing suspension of *Bdellovibrio bacteriovorus* 109J are produced as described above. At the desired stage of development these bdelloplasts are cooled in an ice bath and harvested by centrifugation (5,000 × g for 15 min). The resulting pellet is warmed to room temperature, rapidly resuspended in twice its volume of 10 mM ethylenediaminetetraacetic acid (EDTA) in 120 mM Tris buffer (pH 7.6), and incubated at 30°C for 3 min to permeabilize the bdelloplast's outer membrane. A crude enzyme preparation containing concentrated bdellovibrio lytic enzyme activity (obtained from lysed suspension of bdellovibrios) is added, and, within a few minutes, the growth-phase cells are released from their bdelloplasts. After washing in cold buffer, these cells are metabolically intact and are capable of either differenting into viable attack-phase cells, or responding to isolated substrate-cell signal compounds (Gray and Ruby, 1989). The release process can be enhanced if the bdelloplasts are formed from substrate cells that have a weakened cell envelope (for example, diaminopimelic acid [DAP]-requiring mutants grown for a generation in the absence of added DAP).

Genetic Manipulation

Recent efforts to find methods for transferring DNA into bdellovibrio cells have resulted in two promising approaches: conjugation and transfection. Cotter and Thomashow (1989) have reported a simple method by which anti-

biotic-resistance markers on plasmids in *Escherichia coli* have been mobilized into and expressed by *Bdellovibrio bacteriovorus.* This method is based on a procedure developed by Puhler and his colleagues (Simon et al., 1982) and has been successfully repeated and confirmed by this author (E.G. Ruby, unpublished observations). The advent of the capability to apply molecular cloning techniques to the bdellovibrios, coupled with the limited genetic techniques now in use (Dunn et al., 1974; Lania et al., 1976; Meier and Brownstein, 1976), is certain to be followed by a rapid advance in our understanding of the genetic mechanisms controlling bdellovibrio developmental biology.

The transfection of *Bdellovibrio bacteriovorus* with DNA isolated from the bdellovibrio-attacking bacteriophage MAC-1 (Roberts et al., 1987) has also been reported by one group (Roberts and Ranu, 1987). This procedure may be applicable to certain specialized gene-transfer problems with bdellovibrios, but has not yet been shown to allow transfer of DNA from sources other than MAC-1.

Storage of Cultures

The remarkably high endogenous metabolic rate of bdellovibrios can lead to a relatively rapid loss of culture viability at room temperature (Hespell et al., 1973, 1974). Storage of cultures in the cold (4°C) prolongs viability for weeks to months, and cell survival can be further enhanced by maintaining the bdellovibrios as bdelloplasts. Longer term storage is best achieved at temperatures well below −20°C, and with the addition of a cryoprotectant such as glycerol. It is important to note that although many laboratories maintain bdellovibrio cultures by transfer at weekly intervals, such a procedure may lead to the fixation of unknown variations in the activities or characteristics of the strain over time (Talley et al., 1987). Thus, it is best to prepare a large store of stock cultures in multiple vials, and to open a new vial for subsequent transfer of cultures at least once every few months.

Procedure for Long-Term Storage of Bdellovibrio Cultures (Gherna, 1981)

A freshly lysed culture of bdellovibrio cells is combined with an equal number of substrate cells, and incubated for 30 min at room temperature. One milliliter of the resulting bdelloplast suspension (about 10^9 bdelloplasts) is mixed with either 0.5 ml of sterile 50% glycerol or with 1 ml of a 10% solution of dimethyl sulfoxide in sterile DNB medium. The suspension is placed in a cryo-resistant plastic vial, and precooled by placing it at −20°C for 1 to 2 h. Vials can then be stored either in liquid nitrogen or in a deep freezer (−70°C) for periods of at least 10 years. The frozen specimen can be revived by diluting it at least 50-fold into a suspension of substrate cells and incubating the mixture until the resulting bdelloplasts lyse.

Metabolic Characteristics of Intracellular Growth

An important area of bdellovibrio biology concerns their metabolic adaptions to life in an intracellular environment (Rittenberg, 1983). There are several reasons behind an interest in such adaptions: 1) such adaptions help define the differentiated cell states of the attack-phase and the growth-phase bdellovibrios; 2) they have given us new insight into the range of bacterial metabolic versatility (Rittenberg and Langley, 1975); and, 3) there is evidence for considerable convergence among microorganisms that have chosen to exploit and become dependent upon the intracellular environment (Moulder, 1985; Ruby, 1989). Two classes of characteristic adaptations are among the most striking aspects of bdellovibrio intracellular metabolism: 1) a remarkably high efficiency of growth; and 2) an ability to modify the cellular structures that surround them in the bdelloplast.

All bdellovibrios examined to date are obligate aerobes. There is no obvious metabolic reason why the bdellovibrio life style should require such a restricted metabolism, and many bdellovibrios are able to use both facultative and obligate anaerobes as their substrate cells. Examination of axenically grown *Bdellovibrio stolpii* has revealed the presence of catalase, peroxidase, and an inducible superoxide dismutase activity (von Stein et al., 1982). With the exception of one study (Afinogenova et al., 1979), all indications are that the energy metabolism of most, if not all, bdellovibrios is nonfermentative (Hespell, 1976; Schoeffield and Williams, 1989; Simpson and Robinson, 1968) and is driven by a membrane-associated activity (Gadkari and Stolp, 1975; Friedberg and Friedberg, 1976) that maintains a high energy charge under aerobic conditions (Gadkari and Stolp, 1976). Preferred respiratory substrates include amino acids (Hespell et al., 1973) and the ribose moieties of transported phosphorylated nucleosides (Hespell and Odelson, 1978; Ruby et al., 1985), but not carbohydrates. The presence of glycolytic and tricarboxylic acid (TCA) cycle enzyme activities in bdellovibrio cell extracts (Hespell, 1976) suggests that the inability of these organisms to utilize sugars as a significant respiratory substrate may be due to the lack of an effective sugar transport capability (Ruby, 1989).

The efficiency with which respiration-derived energy is used to convert prey cell material into new bdellovibrio cell material has been calculated to be about twice as high as that typical of all other heterotrophic bacteria tested (Rittenberg and Hespell, 1975). It is clear, however, that the invaded cell rapidly and irreversibly loses its energy-generating and biosynthetic capabilities (Rittenberg and Shilo, 1970), and heat-killed cells are equally effective at supporting bdellovibrio growth and proliferation (Hespell, 1978; Ross et al., 1974). Therefore, the bdellovibrio achieves its high growth efficiency without the energy or biosynthetic parasitism characteristic both of viruses and of other intracellular bacteria (Moulder, 1985). Neither the physiological nor the bioenergetic basis for this phenomenon is known. However, the high growth effeciency may be due in part to the efficient coupling of energy generation and energy utilization (Rittenberg and Hespell, 1975), the unusual ability to transport and incorporate intact phosphorylated nucleosides (including ATP) from the prey (Rittenberg and Langley, 1975; Ruby et al., 1985; Ruby and McCabe, 1986), and the ability to incorporate rather complex portions of the structure of the invaded cell as anabolic precursors (Ruby, 1989).

One of the most striking features of bdellovibrio intracellular metabolism is their ability to modify the components of the prey cell structure. The results of some of these activities are new, functional structures, such as modified cell walls (Thomashow and Rittenberg, 1978d; Ruby and Rittenberg, 1984; Araki and Ruby, 1988). Alternatively, the bdellovibrio can incorporate various substances into its own growing cells: fatty acids (Kuenen and Rittenberg, 1975; Rittenberg and Langley, 1975); lipopolysaccharides (Nelson and Rittenberg, 1981a and 1981b): and possibly even intact and functional outer membrane proteins (Guerrini et al., 1982; Diedrich et al., 1983; Talley et al., 1987) derived from the invaded cell, although this last capability has been disputed (Rayner et al., 1985).

These modifications are believed to be performed by bdellovibrio-produced enzymatic activities (Engelking and Seidler, 1974; Hespell et al., 1975) that function in what was the periplasmic space of the invaded cell, altering the permeability and surface characteristics of the outer membrane (Odelson et al., 1982; Cover and Rittenberg, 1984; Ruby and McCabe, 1988), the peptidoglycan (Thomashow and Rittenberg, 1978b, 1978c, 1978d; Ruby and Rittenberg, 1984), and cytoplasmic membrane (Cover et al., 1984) of the invaded cell. Biochemical characterizations of some of these bdellovibrio activities have been reported recently (Araki and Ruby, 1988; M. Saier, personal communication).

Applications

There are three general classes of applications for which the bdellovibrios have either potential or actual use. The first of these has been described by Varon and Shilo (1981), who use the decrease in the bdellovibrio's ability to function as an attack-phase cell as an indication of the presence of certain pollutants, to which the bdellovibrios show a high sensitivity. This assay procedure is simple because the rate of bdellovibrio attack on a suspension of luminous bacteria is proportional to the loss of light emission by the cell suspension.

A second practical use, for which there appears to be some application for the bdellovibrios, is in the area of water quality. It has been suggested (Daniel, 1969; Fry and Staples, 1976; Guelin and Cabioch, 1970; Lambina et al., 1981) that the bdellovibrios may play a significant natural role in the self-purification of natural water systems. To date there has been no report of any successful efforts to supplement this natural level of activity by artificially increasing the abundance of bdellovibrios in a natural environment.

The area of application that has seen the most actual activity has been the use of members of the genus *Bdellovibrio* for the discovery of novel biochemical and physiological capabilities (e.g. transport, biosynthesis, differentiation control) that are adaptations to life in an intracellular environment (Moulder, 1985; Ruby, 1989). Recent studies, both of the biochemistry of signals involved in the control of bdellovibrio cellular differentiation (Gray, 1989) and of methods of molecular genetics (Cotter and Thomashow, 1989), have firmly established the bdellovibrio life cycle as an important model system for the study of prokaryotic developmental biology.

CHAPTER 188

The Myxobacteria

HANS REICHENBACH and MARTIN DWORKIN

The myxobacteria are Gram-negative, unicellular, gliding bacteria with rod-shaped vegetative cells (Fig. 1). Because of their gliding movement, colonies develop as thin, film-like, spreading swarms, particularly on media low in organic constituents (lean media) (Fig. 2). Under starvation conditions, the myxobacteria undergo an impressive process of cooperative morphogenesis: the vegetative cells aggregate and pile up, and the resulting cell mass differentiates into a fruiting body (Fig. 3). Myxobacterial fruiting bodies show various degrees of complexity, both morphologically and structurally. They typically measure between 50 and

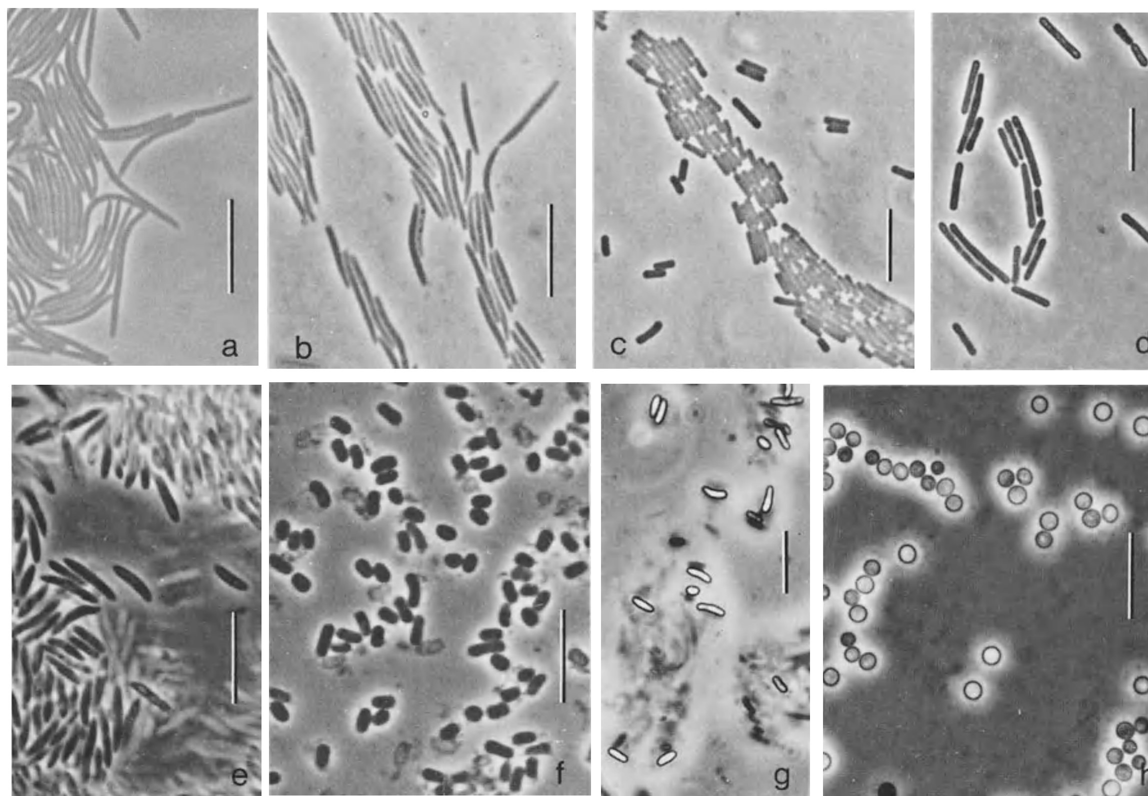

Fig. 1. Various types of myxobacterial cells. (a to d) Vegetative cells. (a and b) The Cystobacterineae type: (a) *Cystobacter ferrugineus,* cells from a liquid culture. (b) *Stigmatella aurantiaca,* cells in situ on agar surface in a chamber culture. (c and d) The Sorangineae type. (c) *Chondromyces crocatus* in a chamber culture. (d) *Sorangium compositum* in a chamber culture. (e to h) Myxospores of members of the Cystobacterineae. (e) Myxospores of *Cystobacter ferrugineus,* from a crushed, degenerated, *Archangium*-like, fruiting body; under oil immersion, the high optical refractility of the myxospores is not apparent. (f) Myxospores of *Cystobacter velatus* from a crushed fruiting body sporangiole; oil immersion. (g) Experimentally induced myxospores of *Stigmatella aurantiaca* on the agar surface in a chamber culture; under the 40× dry objective, the high optical refractility of the myxospores becomes very conspicuous. (h) Myxospores from a *Myxococcus xanthus* fruiting body; the optical refractility of these spherical myxospores is so high that it is recognizable even under oil immersion. All photographs are in phase contrast. Bars = 10 μm.

500 μm, and they can thus be easily seen with the naked eye. Within the maturing fruiting body, a cellular differentiation takes place during which the vegetative cells convert into short, fat, optically refractile myxospores (Figs. 1 and 3). The myxospores are desiccation resistant and allow the organism to survive unfavorable environmental conditions.

The phylogenetic position of the myxobacteria has been elucidated by a comparison of 16S rRNA sequences (Ludwig et al., 1983; Oyaizu and Woese, 1985). According to these data, the myxobacteria belong to the delta branch of the large assembly that has been called the purple bacteria, or the proteobacteria. The delta branch also contains the remotely related genus *Bdellovibrio* and certain sulfate reducers such as the genera *Desulfovibrio* and *Desulfonema* (Stackebrandt et al., 1988). The myxobacteria are currently assigned to twelve different genera (see "Taxonomy of Myxobacteria," this chapter).

Many myxobacterial fruiting bodies are large enough to be seen with the unaided eye and had already been observed by botanists early in the 19th century. However, they continued to be mistaken for fungi for almost a century. The first report in the scientific literature appears to be by Heinrich Friedrich Link (1809), who described a little "gasteromycete," *Polyangium vitellinum,* a taxon that is still valid. The description was accompanied by an exact and beautiful illustration (see Fig. 15) (Link, 1809; Ditmar, 1814). Two more species, *Stigmatella aurantiaca* and *Chondromyces crocatus,* were defined by the British mycologist, M.J. Berkeley (1857), who classified them as hyphomycetes (fungi imperfecti). Again, both taxa are still valid. *Stigmatella aurantiaca* was described two more times as a new fungus under different names and with different systematic positions before it was finally recognized as a myxobacterium by the U.S. botanist Roland Thaxter (1892); for the tortuous history of *Stigmatella,* see Reichenbach and Dworkin (1969). Thaxter was the first to elucidate the astonishing and unexpected life cycle of the myxobacteria, which he published, together with a substantial number of new species, in a series of brilliant articles (Thaxter, 1892, 1893, 1897, 1904). However, the reception by the scientific community was somewhat less than enthusiastic, and it took at least 20 years before Thaxter's work became widely accepted. In the first decade of the 20th century, however, four rather voluminous studies on myxobacteria were published (Baur, 1905; Quehl, 1906; Vahle, 1910; Kofler, 1913). Those articles are full of interesting observations and methods for the isolation and study of myxobacteria, and deal with many problems that later became important topics of research. It may be mentioned in passing that two of those four authors were later to become very influential scientists, one as a geneticist deeply involved in breeding research (Erwin Baur), the other as one of the founders of microchemistry (Ludwig Kofler). In the following decades, research was confined mainly to taxonomic, ecological, and morphological questions (Jahn, 1911, 1924; Krzemieniewska and Krzemieniewski, 1926, 1927a, 1927b, 1930). During that period, new species were discovered and the wide distribution of myxobacteria was recognized. Furthermore, it was recognized that there were two large subgroups that could be distinguished by the shape of their vegetative cells (Krzemieniewska and Krzemieniewski, 1928), and that some myxobacteria degrade cellulose and could be cultivated on a medium containing only cellulose and a few mineral salts (Imshenetski and Solntseva, 1936; Krzemieniewska and Krzemieniewski, 1937a, 1937b). For some time, cellulose decomposition by myxobacteria was a principal focus of interest, mainly in Russia, where it was studied mainly in the laboratory of A.A. Imshenetski (for a review, see Imschenezki, 1959).

Studies utilizing pure cultures of myxobacteria did not become common practice until the middle of the century. Also, until around 1960, it was generally believed that myxobacteria could not grow suspended in liquid media. Because of the difficulty of growing myxobacteria suspended in liquid media, their popularity with microbiologists was not high. Physiological studies were extremely tedious and only moderately conclusive, because the myxobacteria grew only as a film along the glass wall of the container and the surface of the liquid. Still, even under those experimental restrictions, some insights were gained into the nutritional requirements of myxobacteria (Norén, 1955). Loebeck and Klein (1956) and Mason and Powelson (1958) reported that at least some strains of *Myxococcus* grew well as suspension cultures. Subsequently, many more examples of myxobacteria growing in a dispersed manner have been described, so that most strains can now be handled as ordinary bacteria. Ironically, it later turned out (Dworkin, 1984) that dispersed growth of *Myxococcus* (*Mx.**) *xanthus* strains

*In the remainder of this chapter the following abbreviations sometimes are used for the genera of myxobacteria: *An., Angiococcus; Ar., Archangium; Cb., Cystobacter; Cc., Corallococcus; Cm., Chondromyces; Ha., Haploangium; Me., Melittangium; Mx., Myxococcus; Na., Nannocystis; Pl., Polyangium; Sg., Stigmatella; So., Sorangium.*

had been observed as early as 1948, but this information had never been published (Woods, 1948).

Beginning in the 1950s, the emphasis of myxobacterial research shifted more and more to problems in developmental biology, with *Mx. xanthus* as the preferred object. A major breakthrough was the discovery by Dworkin and Gibson (1964) that vegetative cells of *Mx. xanthus* in suspension cultures could be induced to convert into myxospores by the addition of certain chemicals, such as 0.5 M glycerol. This was the first clearly defined experimental system for the investigation of a morphogenetic process in a myxobacterium, and it led to a long series of studies on the morphological, physiological, and biochemical events that take place during induced myxospore formation.

Another major achievement of the past 15 years was the development in the laboratory of Dale Kaiser of an experimental system for the transfer of plasmids, transposons, and genes into and between strains of *Mx. xanthus,* based on the use of coli phage P1 and myxobacterial phages. This set the stage for the development in that organism of methods for the genetic analysis of various processes, including gliding motility and developmental programs, (for reviews, see Kaiser et al., 1979; Kaiser, 1984a, 1986, 1989). The availability of genetic techniques finally made the full potential of *Mx. xanthus* accessible as a model system for the study of morphogenetic processes on the prokaryotic level. While these methods are not easily adaptable to other myxobacteria, a more versatile system is under study that uses conjugation with *Escherichia coli* for the transfer of plasmids and transposons (Breton et al., 1985). This system has already been successfully applied to myxobacteria other than *Mx. xanthus.*

After this solid methodological basis was laid, progress in myxobacterial research gained considerable momentum. Completely unexpected findings have been made in the molecular biology of myxobacteria, e.g., the discovery of a multicopy single-stranded RNA-linked DNA (Dhundale et al., 1987), and the presence of two reverse transcriptases in *Mx. xanthus* (Inouye et al., 1990). Also, the discovery that many myxobacterial strains produce secondary metabolites, most of which are novel compounds, which may have practical applications, will most likely stimulate an even broader interest, in myxobacterial biochemistry, physiology, and taxonomy (for reviews, see Reichenbach et al., 1984, 1988; Reichenbach and Höfle, 1989).

Our knowledge of the myxobacteria has been summarized repeatedly in recent years. Apart from the articles mentioned above, the following reviews should be consulted for further details: 1) for general surveys and taxonomy—Rosenberg, 1984; Reichenbach, 1986; McCurdy, 1989; 2) for molecular biology—Sumiko Inouye et al., 1987; 3) for developmental biology—White, 1975, 1981; Zusman, 1980, 1984, 1990; Kaiser, 1984b; Dworkin, 1985, 1990; Dworkin and Kaiser, 1985; Shimkets, 1987, 1990b; and 4) for biotechnology—Reichenbach, 1988. In addition, several movies are available from the Institut für den wissenschaftlichen Film, Göttingen, Germany, that illustrate cell behavior, colony formation, and developmental processes in various species of myxobacteria (Reichenbach et al., 1965a, 1965b, 1965c, 1965d, 1980; Grimm et al., 1971; Kühlwein et al., 1971a, 1971b).

Habitats

The principal habitats of myxobacteria are soil, dung, decaying plant material, and the bark of living and dead trees. In addition, they are sometimes found in places where they most probably cannot live, but where their resting stages can survive for some time. Thus, several

Fig. 2. Swarm colonies of various myxobacteria. (a, b, d, f, and h). Swarms of members of the Cystobacterineae. (c, e, g, and i). Swarms of members of the Sorangineae. (a) *Stigmatella erecta* on CY agar; dissecting microscope, oblique illumination. Bar = 1 mm. (b) *Myxococcus xanthus,* very young colony on Casitone agar; dissecting microscope, oblique illumination. Bar = 0.5 mm. (c) *Polyangium* sp. on water agar, swarm edge; the spreading colony falls apart into cell clumps, which separate, thereby etching trenches into the agar surface; dissecting microscope, oblique illumination. Bar = 1 mm. (d) *Cystobacter violaceus* (formerly *Archangium violaceum*) on VY/2 agar; from the inoculum in the center, the swarm has spread over the whole agar plate. Bar = 30 mm. (e) *Nannocystis exedens* on Casitone agar; the swarm developed from the ridge in the center, and the agar plate has become deeply corroded; Leitz Aristophot. Bar = 5 mm. (f) *Corallococcus coralloides* on Casitone agar; the central part of the swarm is covered with rudimentary fruiting bodies; Leitz Aristophot; Bar = 5 mm. (g) *Polyangium* sp. on a streak of *E. coli* (which is still recognizable at the left) on water agar; the swarm edge is a compact, ridge-shaped mass of vegetative cells, behind which the agar surface is deeply corroded; dissecting microscope, oblique illumination. Bar = 1 mm. (h) *Stigmatella erecta* on Casitone agar, swarm edge with flamelike protrusions; dissecting microscope, oblique illumination. Bar = 1 mm. (i) *Nannocystis exedens* on a streak of *Micrococcus luteus* on water agar; the entire swarm has sunk into the agar, which is deeply corroded; dissecting microscope, oblique illumination. Bar = 2 mm.

species of myxobacteria have been isolated from seashore sediments (Brockman, 1967; Rückert, 1975b), although no myxobacterium is known that is able to grow at the concentration of salt found in seawater. Typically, in samples with a high salt content, such as salt marshes or certain desert soils, myxobacteria can only be demonstrated when the sample is first desalted before being cultured on a low salt medium (Rückert, 1983). The occurrence of myxobacteria in the peat of sphagnum bogs at a pH of 3.7 and at the low oxygen content of 2.6 mg/liter is also remarkable (Dawid, 1984), because, in cultures, myxobacteria are strict aerobes and without exception do not grow at a pH below 5.5. Of course, in complex habitats the existence of inhomogeneities among the microniches is always conceivable and could explain the presence of myxobacteria under seemingly unacceptable conditions. Another peculiar habitat is the leaf surface, or phyllosphere, of plants (Rückert, 1981). No leaf was sampled higher than 2 m above ground, but all 14 plant species investigated and 52% of the specimens were positive, mostly for *Myxococcus* species. Again, there is no proof that the myxobacteria can really grow on plant leaves, although this may not be totally inconceivable. The presence of myxobacteria deep within caves (Menne and Rückert, 1988) may seem less astonishing because the organisms could easily be washed in and then grow or remain dormant, depending on the local conditions.

A survey of common sources for different myxobacteria is given in Table 1. Most myxobacteria appear to be primarily soil organisms. However, almost all are "micropredators" (Singh, 1947) and are attracted by habitats with rich microbial communities, which they may colonize as secondary substrates. Even if certain myxobacteria can be isolated more easily from sources other than soil, their presence in the soil of the same environment can often be demonstrated. The preferred substrate of a particular species may vary under different climatic and edaphic conditions. Thus, in the central USA, *Chrondromyces* species are common inhabitants of bark and rotting wood, but are rare in soil (Nellis and Garner, 1964; H. Reichenbach, unpublished observations). In India, they are found regularly in soil, in the rhizosphere of plants, on rotting wood, bark, and dung (Agnihothrudu et al., 1959; Singh and Singh, 1971). In Europe, in spite of apparently similar climatic conditions to those found in the USA, they appear to be extremely rare organisms and

Table 1. Convenient and preferential sources for the isolation of different myxobacteria.[a]

Substrate	Myxobacterial species typically found[b]
Soil	*Nannocystis exedens*,[5] *Sorangium cellulosum*,[4] *Archangium serpens*,[4] *Corallococcus coralloides*,[4] *Polyangium* spp.,[3] *Cystobacter* spp.,[3] *Melittangium* spp.,[3] *Myxococcus fulvus*,[2] *Mx. virescens*,[2] *Mx. stipitatus*[2]
Dung of herbivores	*Myxococcus fulvus*,[5] *Corallococcus coralloides*,[5] *Mx. virescens*,[4] *Cystobacter fuscus*,[4] *Cb. ferrugineus*,[4] *Archangium serpens*,[4] *Nannocystis exedens*,[3] *Cb. violaceus*,[3] *Polyangium* spp.,[3] *Stigmatella erecta*,[2] *Mx. xanthus*,[2] *Melittangium* spp.,[2] *Cb. velatus*[1]
Bark and rotting wood	*Stigmatella aurantiaca*,[4] *Chondromyces apiculatus*,[4] *Sorangium cellulosum*,[4] *Corallococcus coralloides*,[4] *Myxococcus fulvus*,[3] *Cm. pediculatus*,[2] *Haploangium* spp.[2]

[a]As pointed out in the section on "Habitats," the frequency of myxobacteria on a specific substrate may vary substantially in different environments. Also, some species may be underrepresented from a certain source because the isolation technique usually applied may not result in the isolation of the particular organism.
[b]Frequency of the encountered species: [5], ubiquitous; [4], very frequent; [3], moderately frequent; [2], relatively rare; [1], rare.

have been found almost exclusively on dung, rotting wood, and bark (Zukal, 1896; Quehl, 1906; Jahn, 1924; Krzemieniewska and Krzemieniewski, 1946). Dawid (1979) tested several thousand samples from the Siebengebirge, a mountain ridge near Bonn, Germany, and obtained only one isolate of *Chondromyces,* a strain of *Cm. apiculatus,* from a piece of rotting wood. Similar results have been obtained by Krezemieniewska and Krzemieniewski (1946) and by one of us (H. Reichenbach) who isolated myxobacteria over decades from all kinds of samples collected at many different sites in Europe.

Myxobacteria are very common in soils of neutral or slightly alkaline pH (Brockman, 1976; Brockman and Boyd, 1963; Dawid, 1978, 1979; Hook, 1977; Kühlwein, 1960; Krzemieniewska and Krzemieniewski, 1927b; McCurdy, 1969a; Michoustine, 1968; Norén, 1950, 1952; Peterson, 1965; Peterson and Norén, 1967; Rückert, 1975a, 1976, 1979; Rückert and Heym, 1977; Sabadoš-Šarić, 1957). They have been isolated from samples collected in tropical rain forests and in the arctic tundra, in steppes, deserts, and in bogs, at sea level as well as at high altitudes. Warm and dry areas, such as the southwestern United States, Mexico, northern India, the Mediterranean countries, and the Canary Islands, have been found to be especially rich in different myxobacteria. The same is true for areas with underground limestone in temperate climates. Still, a myxobacterial species may show an unequal distribution even within the same climatic zone. The case of *Chondromyces* has just been mentioned. Another example is *Stigmatella aurantiaca,* which is common in the middle of the North American continent (Nellis and Garner, 1964; Reichenbach and Dworkin, 1969; McCurdy, 1969a), but very rare in Europe (Krzemieniewska and Krzemieniewski, 1946, isolated myxobacteria in Europe for 15 years before they found their first strain of *Sg. aurantiaca*) The decisive factor that controls the distribution may be the warm, humid American summers which are clearly contrasted in that respect with those in Europe. For unknown reasons, *Sg. aurantiaca* seems to be restricted to rotting wood and bark on both continents. Locations with acid soils and raw humus underground, such as the *Rhododendron* forests of West Virginia (H. Reichenbach, unpublished observations), can be totally devoid of myxobacteria. But under otherwise favorable conditions such as sufficiently high humidity and temperature, myxobacteria have also been isolated from soils with a bulk pH of below 5 (Rückert, 1975a, 1979). In cool, humid environments, such as in Finland, northern Minnesota, and mountain ranges, myxobacteria may be abundant, albeit limited to a few species. Tropical rain forests are not necessarily rich in myxobacteria, perhaps due to the nature of the underground material. Myxobacteria have also been isolated from Antarctic soil samples but at least in one case, the organisms had a temperature optimum around 30°C, which raises some doubts as to whether they were really indigenous (Rückert, 1985). In another instance, however, the isolated bacteria were true psychrophiles that developed, very slowly indeed, at temperatures between 4 and 9°C but did not grow at 18°C (Dawid et al., 1988). While the vegetative stages of the latter organisms closely resembled myxobacteria of the *Polyangium* and *Nannocystis* type, their identify could not be established with certainty since they did not produce fruiting bodies. No mesophilic myxobacteria were found in the Antarctic samples examined by Dawid et al. (1988).

Dung of various animals, especially of herbivores such as rabbit, hare, deer, moose, sheep, and goat, is an excellent substrate for myxobacteria. Rabbit dung in particular was the preferred source of myxobacteria for the early investigators, and in fact appears to serve as a

kind of natural bait. It seems, however, that myxobacteria can also pass unscathed through the digestive tract of animals (Kühlwein, 1950). Also, the observation of myxobacteria on dung pellets collected on the surface of deep snow layers suggests that, occasionally, they are deposited with the dung (Rückert, 1975a; H. Reichenbach, unpublished observations). However, the organisms primarily appear to arise in the surrounding soil after the dung has been dropped. This conclusion is based on the fact that aged dung is a better source of myxobacteria than is fresh dung, that dung collected on soil rich in myxobacteria results in a greater yield of strains than one from poor soil, and that the same species found on dung can also be found in the surrounding soil. A number of myxobacteria are regularly found on dung, such as *Myxococcus fulvus, Mx. virescens, Corallococcus coralloides, Cystobacter fuscus,* or *Stigmatella erecta,* but there is no myxobacterium that depends on dung-derived growth factors, as was thought for some time, and all strains isolated from dung can be cultivated on relatively simple media. Of course, occasional stimulation by substances such as vitamins found in dung extracts is conceivable.

Bark and rotting wood are good sources of certain myxobacteria. This includes the cellulose degraders of the genus *Sorangium,* but several noncellulolytic species are also regularly found in those habitats. Results vary with different species of trees: In Europe, relatively good yields have been reported with bark from living elder (*Sambus racemosa*), beech (*Fagus silvatia*), and black locust (*Robinia pseudacacia*) (Dawid, 1979). In Minnesota and other locations in the USA, bark and rotting wood are reliable sources for *Stigmatella aurantiaca* and *Chondromyces apiculatus.* The latter has also been found regularly on wood samples from southeast Asia, and on dry, rotten "leaves" of *Opuntia* cacti from the Canary Islands (H. Reichenbach, unpublished observations). The difference between the situation in Europe has already been pointed out. Clearly, there are other, less obvious, factors, perhaps climatic ones, that also play a role in the distribution of myxobacteria. However, there are no myxobacteria with an absolute dependence on bark and wood. The cellulose degraders are also common in soil and dung, and because the other species are bacteriolytic, they often grow well on dung, and, in culture, on media that contain peptone or protein. In fact, it is not understood why in nature they grow preferentially on wood and bark. Even when they are found on dung, they may be there mainly because the dung of herbivores is always abundant in plant residues. However, *Haploangium* has only been found on bark and wood so far. It has never been cultivated, so its nutritional requirements are unknown.

Although myxobacteria have repeatedly been isolated from freshwater habitats (Brauss et al., 1967, 1968; Geitler, 1925; Gräf, 1975; Hook, 1977; Jeffers, 1964; Tržilová et al., 1980, 1981), it seems probable that they are merely washed in from the soil. Myxobacteria have been used to classify rivers for the type of pollution present (Gräf, 1975; Tržilová et al., 1980, 1981). While myxobacteria appear not to be typical aquatic organisms, our experience with cultivated strains gives no reason to believe that they cannot survive and thrive in suitable niches in aquatic environments. A clear indication of this is the case of parasitism of a myxobacterium on the green alga *Cladophora,* with fruiting body formation inside the emptied-out algal cells (Geitler, 1925). Another example may be the occurrence of structures resembling myxobacterial fruiting bodies on eggs of the water beetle *Dytiscus marginalis* (Jackson, 1959).

Isolation

Although myxobacteria are common in many types of soil (a teaspoonful of soil is usually sufficient to isolate four or five species) they are rarely mentioned in articles on soil microbiology. The reason is that the usual dilution and plating techniques used for the isolation of soil microorganisms are unlikely to reveal the presence of myxobacteria. Due to the slime matrix they produce, myxobacterial cells do not disperse easily when the soil sample is shaken in water, so that the organisms are highly underrepresented in number when the suspension is plated. Even when other, more suitable methods are used, the estimated numbers probably are only approximate ones; depending on the type of soil, they are in the range of 10^3 to 4.5×10^5/g, and thus under favorable conditions seem to be a rather substantial component (McCurdy, 1969a; Sabadoš-Šarić, 1957; Singh, 1947). Another problem is that, on lean media, the myxobacterial colonies develop as delicate, spreading swarms that are easily overlooked, while on rich media they remain compact and are not recognized as myxobacteria. In addition, they grow relatively slowly so they are often overgrown by other soil microorganisms, particularly fungi. The fruiting bodies, however, are conspicuous and have probably been frequently observed by soil biologists and myxologists.

The isolation of myxobacteria can start from fruiting bodies that have developed on natural substrates, or from swarms growing in agar cul-

tures. These isolations can also be preceded by enrichment and baiting techniques. The methods have frequently been reviewed (Kühlwein and Reichenbach, 1965; McCurdy, 1969a; Peterson, 1969).

Collection and Treatment of Samples

Soil to be used for the isolation of myxobacteria should be taken from the upper few centimeters of the soil profile. Soils rich in higher organisms, and samples collected from between plant roots and near the base of stems, give the best yields. If the material cannot be processed soon after collection, it should be air-dried as quickly as possible because otherwise the sample may become moldy, creating problems later during isolation. A few cubic centimeters of soil are sufficient for most isolation techniques. In general, it is better to have several small samples from different localities than one large batch from a single spot. Dry material can be stored for long periods at room temperature. It appears that, in the natural substrate, myxobacteria are much more stable than, for example, fruiting bodies dried on filter paper. Thus, we have found essentially the same species over a 12-year period of sampling of stored soil samples, and we are regularly able to isolate myxobacteria from samples stored for 10 to 15 years (H. Reichenbach and M. Dworkin, unpublished observations).

With dung, better results are usually obtained if the samples are neither very fresh nor very old, but are completely free of low-molecular weight components. It is very important to dry the samples if they have to be stored for more than one day, and such dry dung will yield myxobacteria even after months and years of storage. Rabbit dung to be used for baiting (see below) should be taken from wild animals; pellets from laboratory or domestic rabbits are usually unsuitable, perhaps because they become soaked with urine in the cage.

Bark and wood for the isolation of myxobacteria must be taken from tree species that are low in resins and tannin compounds, and specimens have to be quickly dried if they are not to be processed immediately. Successful isolations are often obtained with wood that has already been decomposed to a rather soft state, and with bark from the base of the tree and from fallen trees.

Direct Isolation from Natural Substrates

Isolation can often be achieved directly from the natural substrate. Bark of living or dead trees, rotting wood, or dung pellets are kept in large petri dishes lined with two to three layers of filter paper. The samples are soaked in distilled water containing cycloheximide (up to 0.08 mg/ml) for a few hours to suppress the growth of molds. The water is then decanted and appropriate amounts of water are added at intervals during cultivation. If the culture is kept too dry, it may soon be covered with molds; if the substrates are inundated, no myxobacterial fruiting bodies will develop. The air in the incubator should be kept sufficiently humid, so that the crude cultures do not dry out too quickly. The initially saturated system is allowed to dry out gradually over a period of 14 to 21 days; in this way it will eventually pass through the optimum for the development of myxobacterial fruiting bodies. Such crude cultures are likely to contain a variety of fungi, mites, springtails, nematodes, and other organisms that may contaminate other cultures. The danger of a contamination with mites is especially serious and can quickly spoil a culture collection. The cultures should therefore be kept in tightly closed plastic bags or, more conveniently, in a separate incubator, which should frequently be sterilized.

The cultures can be incubated at room temperature (around 20°C) or at 30°C. We have never observed unequivocal differences in the yield of myxobacteria when parallel crude cultures were kept at different temperatures, but we have found that at room temperature, the development of myxobacteria proceeds more slowly and molds tend to spread more vigorously. Thus, we keep such cultures at 30°C (see also Krzemieniewska and Krzemieniewski, 1927b). However, samples from mountains at high altitudes or from arctic environments may contain myxobacteria that are adapted to lower temperatures (see "Habitats," this chapter), and even in forest soils in Central Europe strains are occasionally found that grow reasonably well at 30°C but produce fruiting bodies only at lower temperatures.

Initially, the crude cultures should be inspected for fruiting bodies every day, beginning with the third or fourth day of incubation, because fruiting bodies often spring up and then rapidly collapse and become very inconspicuous. Also, the fruiting bodies may soon become overgrown by other organisms. Most fruiting bodies will appear during the first 10 days, either on the substrate itself or on the filter paper lining; only rarely will anything of interest develop later than 18 to 20 days. Sometimes, fruiting bodies appear very early on the substrate, within hours after moistening; probably, in such cases, desiccated structures have simply been rehydrated and thus have become recognizable, while the fruiting bodies that appear later are produced de novo. In the later phases

of culture development, spherical or ridge-shaped masses of vegetative cells, which are usually bright yellow, orange, or red, can often be observed on the filter paper and can be used for isolation; in this way one may obtain species whose fruiting bodies are too small and inconspicuous to be recognized directly on the substrate. These organisms are almost always members of the Sorangineae, usually *Polyangium* and *Nannocystis* strains, which produce swarms with a massive ridge at the edge. Sometimes, cellulose decomposers may develop on the filter paper lining itself.

Isolation from Soil by Baiting

A baiting technique can be used to isolate myxobacteria from soil (Krzemieniewska and Krzemieniewski, 1926). A large petri dish is filled with soil which is moistened with distilled water up to its water-holding capacity. Autoclaved dung pellets from wild rabbits are partly buried in the soil. The culture is then incubated and examined as described above. Vegetative cells will migrate to the dung pellets, colonize them, and in time develop the characteristic fruiting bodies. Here, as with the technique described above, the discovery of the myxobacterial fruiting bodies is greatly facilitated by the fact that they tend to appear locally in large numbers and in addition often are brightly colored and glistening. With some experience, it is possible to locate them quickly with the unaided eye, despite their relatively small size (50 to 500 μm). For a more careful examination of the culture, a dissecting microscope with incident illumination and a magnification between 10 and 40 × is perfectly adequate (see Fig. 2).

Isolation from Swarms

The bacteriolytic properties of myxobacteria can be used for their enrichment from their natural substrates, particularly from soil and plant debris. Streaks of living food organisms on water agar (WAT agar, see below), either in the form of a cross-streak, three parallel streaks, or a number of circular patches, are inoculated with a small quantity (approximately the size of a lentil) of the material to be analyzed (Singh, 1947). The cross and the patches are inoculated in the center, the parallel streaks at the ends. Care should be taken not to scatter the inoculum over the plate. To facilitate application of the sample, the soil may first be moistened with sterile water and then applied with sterile swabs.

To restrict the development of fungi, the addition of the antibiotic cycloheximide (25–100 μg/ml) to the enrichment medium has been recommended (WCX agar, see below; Brockman and Boyd, 1963). Results are indeed superior when cycloheximide is included, and the cultures can be maintained for a longer period of time. The antibiotic does not control the growth of amoebae, a major nuisance with this isolation technique. Also, it does not result in the selection of particular myxobacteria or in the suppression of any other gliding bacteria, such as *Cytophaga*-like bacteria, flexibacters, *Taxeobacter*, or *Herpetosiphon*, that can also be isolated with this method.

WAT Agar and WCX Agar

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. After autoclaving, 25 μg cycloheximide may be added per ml from a filter-sterilized stock solution, yielding WCX Agar.

Many bacteria and yeasts can be used as food organisms by the myxobacteria. Food organisms that are readily recognized and can be easily eliminated later are, of course, preferred. Selection for myxobacteria works better if the prey microbes used are alive rather than dead. In the first study, an *Aerobacter* strain was used as the food organism (Singh, 1947). We have found the following bacteria to be useful: 1) *Micrococcus luteus* is easy to distinguish, is nonmotile, and is relatively large, so that it is not readily spread around; while it is not well utilized by soil amebae, neither will all strains of myxobacteria, specifically *Nannocystis* strains, grow on it. 2) *Escherichia coli* is a favorable substrate for myxobacteria, including *Nannocystis*, which can be subcultured indefinitely on it; but soil amebae also use it well, and this sometimes makes *E. coli* inconvenient. 3) Autoclaved yeast, *Saccharomyces cerevisiae*, can be cheaply prepared from commercial bakers' yeast; the pH of the suspension must be adjusted to 7.0, since the yeast cake is usually acidic; unfortunately, the autoclaved yeast is also a good substrate for many contaminants. Generally, living *E. coli* is our preferred food organism.

The cultures are incubated at 30°C and checked under a dissecting microscope for the appearance of myxobacterial swarms and fruiting bodies, at first daily, beginning at the second or third day, and later at longer intervals (See Fig. 2). After about 3 weeks, no additional myxobacteria are likely to appear, and the cultures can be discarded. Most myxobacteria appear within 8 to 14 days. The myxobacteria grow first on the lawn of the food organism, but later often spread over the agar surface between the smears. A fast-spreading organism such as

Cystobacter may reach the end of a streak within 1 to 2 days. If two streaks are made in a crossed pattern, different myxobacteria may develop on each of the four arms. Different organisms also may follow one another on the same streak. As a rule, species of the Cystobacterineae are seen first, while the Sorangineae develop later. Between two and five different myxobacteria can be expected on one plate. Three parallel plates are usually sufficient to secure most of the myxobacterial types that are readily isolated from a sample, with the exception of the cellulose degraders. Fruiting bodies are often produced within the swarms after a couple of days. Fruiting bodies may also appear on the soil crumbs or other particles of the inoculum. To be able to detect the delicate, filmlike, swarms of myxobacteria, one has to use a dissecting microscope with a tiltable mirror so that light can be applied at a shallow angle to the surface of the plate.

The sooner a swarm is recognized, the more easily a myxobacterium can be isolated, as at the beginning, the contaminants may still be confined to the site of the inoculum. Transfers are then made from the swarm edge, which is usually the purest part of the colony.

A disadvantage of isolating myxobacteria from the swarm stage is that most species cannot be identified by their swarm morphology. With some experience, however, at least certain genera or types can be differentiated (see Fig. 2). The ubiquitous *Nannocystis,* for example, produces a network of trails outside the streak of the food organism. These trails are deeply etched into the agar and end with a small cluster of cells. On the streak, there is often a heavy, meandering ridge. *Polyangium* shows a similar pattern, but with coarser structures. Swarms with an edge that consists of a massive, often brightly colored ridge are in general typical for the suborder Sorangineae. *Cystobacter* and *Archangium* swarms are usually tough slime sheets with a pattern of delicate, but conspicuous, branched, radiating veins. The swarms of the Myxococcaceae tend to be smooth, softslimy sheets, often with dense fields of tiny waves or ripples. If there are radial veins, they typically are wavy and meandering. Swarms of *Mx. stipitatus* show a bright yellow fluorescence in ultraviolet (UV) light of 366-nm wavelength (Lampky and Brockman, 1977). The shape of the vegetative cells under the microscope may also provide a clue to the identification of the swarm observed.

Isolation of Cellulose Decomposers

For the isolation of cellulose-degrading myxobacteria of the genus *Sorangium,* a mineral agar with cellulose as the only carbon source is used. While NH_4^+ is an excellent nitrogen source for *Sorangium,* much better results are obtained when NO_3^- is used in the isolation medium, as in ST21 agar. The cellulose is applied in the form of sterile filter paper which is placed on top of the agar surface. Since the cultures have to be incubated for a longer time before the cellulose decomposers can be recognized, it is essential to include cycloheximide in the medium.

ST21 Agar and ST21CX Agar

Solution A:

K_2HPO_4	0.1%
Yeast extract (Difco)	0.002%
Agar	1%

Make up in about two-thirds of the water volume.

Solution B:

KNO_3	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$FeCl_3$	0.02%
$MnSO_4 \cdot 7H_2O$	0.01%

Make up in the remaining water volume.

After autoclaving separately, solutions A and B are combined and 1 ml of trace element solution (see below) is added per liter of medium.

For crude and enrichment cultures, 25 μg of cycloheximide is added per ml from a filter-sterilized stock solution yielding ST21CX agar.

Trace Element Solution (Drews, 1974)

The following formulation is concentrated 10-fold over the original one given in Drews (1974).

$MnCl_2 \cdot 4H_2O$	100 mg
$CoCl_2$	20 mg
$CuSO_4$	10 mg
$Na_2MoO_4 \cdot 2H_2O$	10 mg
$ZnCl_2$	20 mg
LiCl	5 mg
$SnCl_2 \cdot 2H_2O$	5 mg
H_3BO_3	10 mg
KBr	20 mg
KI	20 mg
EDTA, Na-Fe^{3+} salt (trihydrate)	8 g

When dissolved in 1 liter of water and filter sterilized, this solution is stable for months at room temperature. The mixture is used at 1 ml/liter medium.

The filter paper is inoculated in the center with a pea-sized amount of soil or plant debris, either in one spot or in the form of a streak. The cultures are incubated at 30°C. Unequivocal cellulose decomposition cannot be expected before 8 to 10 days of incubation, and most *Sorangium* strains are seen only after 10 to 20 days. They are recognized as bright, more or less translucent patches, which are yellow, orange, brown, or even black, often several cm

across, and consisting of macerated cellulose, slime, and usually masses of densely packed fruiting bodies. The latter are responsible for most of the color, but also the vegetative parts of the swarms may be tinged yellow and orange, and at the edges, dense, orange ridges often develop. Besides the sorangia, other cellulolytic bacteria may also appear. The lysed areas always contain complex mixtures of a variety of bacteria, protozoa, and nematodes. In such cultures, particularly at later stages, often noncellulolytic myxobacteria also develop which obviously live off the cellulose degraders (Brockman and Boyd, 1963). They appear in the form of long, heavy, orange ridges, which are the edges of expanding swarms, and are usually strains of *Nannocystis, Polyangium,* or *Chondromyces.* Often fruiting bodies are also produced, not only in the macerated areas, but also on the edges of the intact filter paper, on the inoculum, and on the agar just beyond. Of course, these latter myxobacteria, not being cellulolytic, have to be subcultured on streaks of food bacteria and not again on filter paper. As the fruiting bodies observed in the lysis zones are not necessarily those of the cellulose degraders, in case of doubt, subcultures are best started both from fruiting bodies and from the swarm edge, using both types of substrates.

Isolation from Fresh Water

Sediments and plant and animal debris collected in lakes, ponds, rivers, etc., may be processed in the same way as described above. If free-floating myxobacteria are to be isolated, between 10 and 1000 ml of water is passed through a sterile membrane filter of small pore size (0.15 to 0.45 μm). The filter is then placed right-side up on the surface of rabbit dung agar (another lean medium, e.g., VY/2 agar with a reduced yeast content or CY agar with a lowered peptone concentration would also do). The cultures are incubated at a suitable temperature, e.g., 34°C. After 4 to 5 days, myxobacterial swarms and fruiting bodies may be observed (Gräf, 1975).

Rabbit Dung Agar

20 g of dry rabbit dung (wild rabbits) is boiled in 1 liter of distilled water for 20 min. The filtrate is made up to 1 liter again, and 1.5% agar is added. The pH is adjusted to 7.2, and the medium is autoclaved.

In summary, the various direct isolation techniques all have certain limitations, and each may be more or less appropriate for the isolation of a specific organism. For the cellulose degraders there is little choice. However, with some experience, they may also occasionally be found on dung pellets. Conversely, the cellulose plates are also useful for the isolation of *Chondromyces, Stigmatella, Polyangium,* and *Nannocystis.* While *Myxococcus* is most easily obtained on dung pellets, *Cystobacter fuscus, Stigmatella erecta, Archangium, Corallococcus, Chondromyces,* and *Melittangium* are also often found with this technique. The most generally effective technique is the use of bacterial smears; under these conditions, myxobacteria with small and inconspicuous fruiting bodies as well as strains that do not form fruiting bodies at all under the culture conditions, are reliably isolated. Bark and rotting wood incubated in a moist chamber are in some cases excellent sources for fast and reliable isolation of *Stigmatella aurantiaca* and *Chondromyces* species.

Purification Methods

In the simplest case, pure cultures of myxobacteria can be obtained in one step from fruiting bodies, which usually contain an uncontaminated population of myxospores, at least as long as they are young. By carefully transferring material from fruiting bodies to a suitable agar medium, such as CY or VY/2 agar (see below), pure swarms can be obtained. An excellent tool for such delicate work is a glass rod drawn out into a fine tip. More convenient for a swift operation is the sharp point of a disposable, 1-ml, injection syringe. Direct isolation from fruiting bodies is possible with *Myxococcus* species, because they produce soft-slimy fruiting bodies, and enough myxospores to start a culture can be obtained just by touching the fruiting body at the top. The fruiting bodies of *Chondromyces* and *Stigmatella* consist of sporangioles which are borne on a relatively long stalk that lifts them above the heavily contaminated substrate surface. The sporangioles can be plucked off and used as an inoculum. With all other myxobacteria, the chance of a selective transfer from fruiting bodies are low because they are too intimately interwoven with the substrate and the slime layer of the swarm.

VY/2 Agar

Bakers' yeast	0.5% (by weight of commercial yeast cake)
$CaCl_2 \cdot 2H_2O$	0.1%
Cyanocobalamin	0.5 μg/ml
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. The yeast may be stored as an autoclaved stock suspension for several weeks. In order to obtain a uniform suspension of the yeast cells in the agar medium, the yeast must be added to the molten medium.

CY Agar

Casitone (Difco)	0.3%
Yeast extract (Difco)	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

ENRICHMENT TECHNIQUES. If direct isolation is not possible, enrichment techniques have to be applied. Fruiting bodies or vegetative cells are transferred to streaks of a food organism on WCX agar. three parallel streaks can be made on one plate, and each streak can be inoculated at both ends. As the swarm is often firmly attached to the substrate or forms a very tough slime sheet, from which tiny bits cannot easily be removed, or because the myxobacteria migrate within the agar, the inoculum often must be cut out with a small piece of agar using the tools mentioned above. An inoculation loop would be much too coarse, and would risk carrying over too many contaminants. The bacterial smears are best inoculated at their edge so that the developing swarm also has a chance to spread over the free agar surface, which sometimes gives a better separation from the contaminants. New transfers can be made from the purest-looking sections of the developing swarms, preferentially from the swarm edge, until swarms are obtained that seem pure enough to justify a transfer to VY/2 or CY agar. A transfer to smears of autoclaved *E. coli* on WCX agar may be necessary as an intermediary step, particularly if the myxobacterium grows only *within* the streaks of the living *E. coli*. Much time can be saved later if the cultures are initially transferred within short intervals (1 to 2 days), before the contaminants have multiplied and spread. While it is advisable to make several transfers from the crude culture—by inoculating all three streaks of the enrichment plate, if possible from different sites—in order to enrich for the organism and to have a choice of contaminants to deal with, transfers can also be made one at a time, so that the three streaks of a plate can be used consecutively.

It may be mentioned that sometimes transferred fruiting bodies do not germinate. This may happen, for example, if fruiting bodies found on a dung pellet have erroneously been identified as a bacteriolytic species (which is indeed the case with almost all dung organisms) and therefore were transferred to a bacterial smear, while in reality the fruiting bodies had been produced by a cellulose degrader. The latter will readily develop if inoculated to filter paper on ST21 agar (see "Isolation of Cellulose Decomposers," this chapter). However, there are also bacteriolytic myxobacteria that do not always germinate on bacterial streaks, e.g., *Cystobacter fuscus*. With these strains it sometimes helps to transfer fruiting bodies directly to VY/2 agar. After germination, the swarms should be inoculated as soon as possible on bacterial streaks, because many contaminants can grow vigorously on VY/2 agar. If a sufficient quantity of fruiting bodies can be obtained from the crude culture, some of them should first be heated in water (see "Purification by Heating," this chapter) before they are inoculated to the growth medium. It should also be kept in mind that there is at least one myxobacterium (*Haploangium*) that will not germinate on any known medium and has not been cultivated so far.

If the myxobacteria are left growing on the streaks for a longer time, they usually will produce fruiting bodies. Fruiting bodies can be very useful as starting material for further, more sophisticated purification steps. Also, fruiting bodies are important for the identification of the isolated strains.

The main contaminants in the enrichment cultures are other bacteria. Occasionally, other gliding organisms, more often small Gram-negative rods, become trapped in the slime of the swarm and be carried around by the moving myxobacteria. These two types of contaminants are often difficult to eliminate. Nematodes, fungi, and especially soil amebae may also become a serious problem.

The first step in purification is to eliminate all animals from the culture because they move very actively and thus quickly spread bacterial contaminants over the plate. The transfer of nematodes can usually be avoided if some caution is observed, because they are large enough to be easily recognized and eliminated. Occasionally, however, a culture is heavily infested with nematodes; or the worms cannot be seen because an opaque substrate is used, e.g., cellulose plates. In these cases, the plate can be frozen by simply storing it in a −80°C deepfreeze for one or two days, which seems to kill all nematodes. After thawing the plate, it is important to make a transfer to a fresh plate immediately after the surface of the plate has softened sufficiently, because the thawed agar will be very runny and soft (Reichenbach, 1983). The amebae, which sometimes multiply extremely fast, can also be killed by exposing the plate to ammonia vapors (M. Aschner, personal communication). We use a 5% ammonia solution in a petri dish and place the culture plate upside down over the ammonia dish for 1 to 2 min. The plate is then left with a closed lid for another 2 to 5 min, and then the myxobacteria are transferred to a fresh plate because the old one is now strongly alkaline. The myxobacteria

usually survive the treatment very well, even when no fruiting bodies are present. A further transfer should be made as soon as possible from the fresh culture because a few amebae, probably encysted stages, sometimes survive. Soil amebae do not seem to be inhibited by cycloheximide, nystatin, or freezing.

Occasionally, cycloheximide-resistant fungi are present, but they can almost always be inhibited by dusting the inoculum with nystatin powder. The myxobacteria grow between the nystatin particles and can then be transferred to another plate.

The remaining contaminants are bacteria. By transferring pieces from the fast-spreading swarm edge, most of the larger and less motile organisms are quickly eliminated, in particular *Bacillus* species and their spores, but the slime matrix of the swarm may still shelter many small, mainly Gram-negative bacteria. Apart from the slime, the relatively slow growth of myxobacteria compared with that of typical contaminants is a major factor that makes purification time-consuming and difficult. Usually it takes 3 to 6 weeks before an isolated strain is pure; only rarely can it be accomplished in one to two days (by direct transfer of fruiting bodies). Fortunately, those isolations that may take one to two years (e.g., a cellulose degrader) are equally rare.

Often spreading growth under selective nutritional conditions is either not sufficient to shake off contaminants, or the procedure becomes too time-consuming. In such cases, a number of more specific purification steps may be tried.

PURIFICATION BY PLATING. Plating of diluted cell suspensions, the technique of choice for the isolation of most soil bacteria, is only partly useful with myxobacteria. The first difficulty is that the slime makes it difficult to suspend the cells homogeneously in water. We have sometimes had success using a small (1 ml) sterilized tissue homogenizer to overcome this problem. If fruiting bodies are available, treatment with ultrasound for 1 to 2 min may result in a suspension of myxospores. (The use of ultrasound to kill contaminants selectively, as suggested by Sutherland, 1976a, has not appeared very promising in our hands.) Cell suspensions can also be produced in a mixer with or without glass beads (McCurdy, 1963). The cell suspensions can be diluted without problems in sterile distilled water, although a special dilution medium (DM) has also been used.

Dilution Medium (DM; McCurdy, 1963)

Soluble starch	0.5%
$MgSO_4 \cdot 7H_2O$	0.05%
K_2HPO_4	0.025%

The second difficulty is that quite a few myxobacteria, particularly members of the suborder Sorangineae, do not readily produce swarms from single cells. Often a long and tedious optimization and adaptation procedure is required before single-cell colonies are obtained, even from pure strains. Nevertheless, with many myxobacteria, a reasonably high proportion of the cell population will grow to form colonies, so that plating may be successful. However, in our experience, plating has a chance only if the myxobacterium is already nearly pure. This may have to do with their relatively low plating efficiency and relatively slow growth rate. CY agar is often an appropriate medium for plating; sometimes the yield is improved if the peptone concentration is increased to 0.8 to 1.2% or if 0.5% glucose is added. ECM agar and SP agar have also been recommended. While VY/2 agar is a good growth medium, its turbidity reduces its utility and, in addition, myxospores sometimes do not germinate on this medium.

ECM Agar (McCurdy, 1963)

Washed cells of *Escherichia coli* (100 mg dry mass per 100 ml) are suspended in a medium containing: $MgSO_2 \cdot 7H_2O$, 0.05%; NaCl, 0.6%; agar 1.5%. The pH is adjusted to 7.2, and the medium is autoclaved. On this medium, myxobacterial colonies are surrounded by lysis zones.

SP Agar (McCurdy, 1963; McDonald and Peterson, 1962)

Raffinose	0.1%
Sucrose	0.1%
Galactose	0.1%
Soluble starch	0.5%
Casitone (Difco)	0.25%
$MgSO_4 \cdot 7H_2O$	0.05%
K_2HPO_4	0.025%
Agar	1.5%
Vitamin solution (see below)	2.5 ml/liter

Vitamin Solution (McDonald and Peterson, 1962)

Thiamine	100 mg
Riboflavin	75 mg
Pyridoxine	75 mg
Ca pantothenate	200 mg
p-Aminobenzoic acid	5 mg
Nicotinamide	75 mg
Choline HCl	200 mg
Folic acid	1 mg
Inositol	1,000 mg
Biotin	0.05 mg
Cyanocobalamin	0.05 mg

These ingredients are dissolved in 1 liter of ethanol. Add 2.5 ml per liter of medium.

It seems not to make much difference whether the diluted cell suspensions are spread on the agar surface or included in pour plates. In the latter case, the agar content of the medium should be reduced to about 1% and temperatures above 40°C of the molten agar should be avoided. Myxobacterial colonies may be recognized by their swarming behavior, which they also tend to show when embedded in agar. On rich media, swarming may be considerably reduced, and the colonies may become compact and look like those of ordinary bacteria. If they are dense enough, however, they may be brightly colored in shades of yellow, orange, red, or purple.

PURIFICATION BY HEATING. This procedure can be used if fruiting bodies with mature myxospores are present. The fruiting bodies are suspended in 1 ml of sterile water and incubated in a water bath. After 10, 20, and 40 min, samples are transferred to CY or VY/2 agar and carefully spread all over the plate. The useful temperature—too high for the contaminant, but still withstood by the myxobacterium—has to be found by trial and error. We usually work at 58°C, a temperature which is survived by most myxospores for at least 10 min. This temperature is often sufficient to kill contaminating bacteria, fungi, and amoebae. Only rarely do myxobacteria tolerate higher temperatures, and some do not withstand 58°C, in which case 56°C or less may still lead to success. It is, however, important to try this method in the later part of the purification process, because then the chances are higher that thermoresistant contaminants, e.g., *Bacillus* spores, will no longer be present. It may take a week or longer at 30°C, before swarms can be seen on the plates, as a substantial part of the myxospore population may also have been killed. However, often swarms are visible within 1 to 2 days.

PURIFICATION WITH ANTIBIOTICS. This procedure may also be useful if mature myxospores are present. Fruiting bodies are suspended in 1 ml of a rich growth medium, e.g., EBS medium (see below). To this is added 0.1 ml of a concentrated mixture of potent antibiotics, and the suspension is shaken overnight at 30°C (Reichenbach, 1983). The myxospores do not germinate in the rich medium, but the contaminants will grow and be killed. If a contaminant is resistant to the inhibitors, the culture will be turbid the next morning, and the procedure must be repeated with a different mixture of antibiotics. (Occasionally the liquid becomes turbid due to suspended dead cells. In this case, the culture fluid can be replaced by fresh medium and the culture incubated a few hours more.) We use three increasingly aggressive combinations of antibiotics, AB-1, -2, and -3 solutions, (see below) which we apply consecutively when necessary. If the supernatant is still clear on the next morning, it is replaced by sterile distilled water, and the fruiting bodies are washed by shaking them for 4 to 6 hr more. They are then transferred to VY/2 or CY agar, or to streaks of autoclaved *E. coli* on WCX agar. Usually swarms develop after 1 to 5 days. Sometimes an individual swarm is still contaminated, although no foreign colonies can be seen on the plate. Therefore, several swarms should always be isolated and tested separately for purity. Again, the procedure is less effective during the early stages of purification, before the majority of the contaminants have been removed. It should be emphasized that the vegetative growth of myxobacteria is, in general, as sensitive to inhibition by antibiotics as is the case with other Gram-negative bacteria. However, the metabolically quiescent myxospores within the fruiting bodies are resistant, and it is their germination that is prevented by the antibiotics.

EBS Medium

Peptone from casein (tryptic digest); Merck, Darmstadt, Germany)	0.5%
Proteose peptone (Difco)	0.5%
Peptone from meat (Merck)	0.1%
Yeast extract (Difco)	0.1%

The pH is adjusted to 7.0. The medium is autoclaved.

AB-1 Solution

Chloramphenicol	20 mg
Streptomycin sulfate	30 mg
Tetracycline HCl	25 mg
Na cephalotin	20 mg

The above ingredients are dissolved in 50 ml water and filter sterilized. The solution remains stable for several weeks at 4°C.

AB-2 Solution

Chloramphenicol	20 mg
Streptomycin sulfate	30 mg
Tetracycline HCl	25 mg
Kanamycin sulfate	35 mg
Erythromycin	25 mg
Polymyxin B sulfate	20 mg

The above are dissolved in 50 ml water and filter sterilized. The solution remains stable for several weeks at 4°C. It is often inhibitory to myxobacteria and should only be used as a last resort.

AB-3 Solution

Chloramphenicol	20 mg
Tetracycline HCl	30 mg
Neomycin sulfate	20 mg
Gentamycin sulfate	30 mg

Collistin methanesulfonate 30 mg

The above are dissolved in 50 ml water and filter sterilized. The solution remains stable for several weeks at 4°C. This mixture is specifically designed to eliminate pseudomonads. It usually serves that purpose but is less well tolerated by the myxobacteria than AB-1 solution.

It has also been suggested that inhibitors, e.g., neomycin and sulfanilamide, be included directly in the isolation medium (McDonald, 1967; McCurdy, 1969a). However, while some myxobacteria can be isolated in this way, we do not recommend this approach. (Cyclohexamide is, of course, an exception, as it does not inhibit prokaryotes. It is remarkable how many soil bacteria can grow in the presence of high doses of powerful antibiotics, and there is always the danger of a counterselection of some myxobacteria. Addition of antibiotics to purification media is a different story, however, as some groups of myxobacteria are naturally resistant to certain potent antibiotics (see later).

PURIFICATION OF CELLULOSE DECOMPOSERS. The purification of *Sorangium* strains is especially tedious and time-consuming because the organisms only grow slowly on the selective substrate, giving the contaminants ample time to multiply. Furthermore, within the water-soaked filter pad, many contaminants spread rapidly over the whole area, complicating the problem of separating the myxobacteria from the other organisms.

The first transfer from the crude culture should be made again to filter paper on ST21CX agar (see "Isolation of Cellulose Decomposers") to retain the selective conditions. For the preparation of subcultures, filter paper is cut into small rectangles, about 1.5 × 3 cm, three or four of which are placed at some distance from each other on the agar surface. The filter pads are inoculated from different parts of the original swarm. In this way, an initial reduction of the contaminants may be achieved. The next step is to remove nematodes and amebae, using the techniques recommended above. To eliminate bacterial contaminants, transfers can be made to streaks of autoclaved *E. coli* on WCX agar to which 250 mg kanamycin sulfate has been added per liter medium (after autoclaving, from a filter-sterilized stock solution: KAN4 agar). All *Sorangium* strains tested so far are completely resistant to kanamycin as well as to neomycin and gentamicin (H. Reichenbach, unpublished observations). Most sorangia grow reasonably well on autoclaved (but not on living) *E. coli*, often forming large, delicate swarms, another advantage of this purification step. Pieces from the swarm edge that appear to be uncontaminated can be transferred to VY/2 agar. The pure strain is reinoculated to filter paper to make sure that the desired organism has been isolated. We have never observed a *Sorangium* strain to have lost its ability to degrade cellulose during isolation. Addition of kanamycin initially to the crude culture would prevent the appearance of many other myxobacteria and at the outset, select for kanamycin-resistant contaminants.

If the method just described fails, heating of the fruiting bodies or treatment with the antibiotic solution may lead to success. If the *Sorangium* isolate is already relatively pure, it may also be transferred to chitin agar (CT7 agar; see Chapter 176) or to cellulose overlay agar (CEL3 agar, see below). Most but not all sorangia also decompose chitin and grow relatively quickly, producing large swarms on chitin agar with chitin as the only carbon, nitrogen, and energy source. Large swarms also arise on cellulose overlay agar, but development is delayed so that the contaminants have a better chance to predominate. On both media, the sorangia penetrate the agar, so that sometimes a pure inoculum can still be obtained from the deeper layers of the plate even though the surface is contaminated.

CEL3 Agar

Cellulose powder	0.5%
KNO_3 (autoclaved separately)	0.1%
Agar	1.0%

Cellulose powder MN 300 from Macherey & Nagel (Düren, Germany) works well. The pH is adjusted to 7.2. The medium is autoclaved and poured as a thin layer on top of ST21 agar plates.

Another strategy often helpful in the purification of sorangia is incubation at 38°C, e.g., on KAN4 agar + autoclaved *E. coli.* Most but not all strains are able to grow at this temperature, sometimes vigorously so, while growth of the contaminants is often prevented.

TESTING FOR PURITY. The final task in pure culture isolation is to check for purity of the culture. Some swarm material may be streaked on nutrient agar, on which myxobacteria, in contrast to most contaminants grow only slowly or not at all. Other media useful for purity control are CY and MYX agar. Although most myxobacteria grow on those media, they are usually easily distinguished from nonmyxobacterial colonies.

MYX Agar

Glutamate Na	0.5%
Yeast extract (Difco)	0.1%

$MgSO_4 \cdot 7H_2O$	0.1%
Glucose (autoclaved separately	0.2%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

In addition, some material may be inoculated into a liquid medium, e.g., nutrient broth or CAS medium and incubated with shaking for one day at 30°C. Under such conditions, myxobacteria usually grow in clumps, flakes, or as a ring around the glass wall, if at all. Dispersed growth at that stage is almost always an indication of contamination.

Myxobacteria can often be differentiated easily from other bacteria by their size, cell shape, and their inability to swim actively. Thus microscopic examination will also often quickly reveal contaminants, although this is not always reliable and requires some experience.

Counting Myxobacteria in Soil

The quantitative determination of myxobacteria in soil is not likely to give accurate results, because, in the swarm and in the fruiting bodies, the cells are always linked together by slime, and in the fruiting bodies cells are often surrounded by the tough walls of the sporangioles. Still, estimates are possible and have been performed in the following way: Small disks (about 2 cm in diameter) impregnated with a food organism are placed on a water agar or a silica gel plate, and each circle is inoculated with a small quantity of soil which has been carefully homogenized and weighed (Singh, 1947). Alternatively, the weighed and homogenized soil is made into a paste with sterile water, and small drops are applied to the ends and centers of cross-streaks of a food organism on water agar, or, for counting cellulose decomposers, to filter paper disks on mineral agar (Brockman, 1976). After incubation, the number of myxobacteria is calculated from the number of swarms and fields of fruiting bodies that have developed. Another approach is to add soil dilutions to ACE agar (McCurdy, 1969a). This method has severe limitations because the medium allows a rapid development of contaminants, and only *Myxococcus* and *Corallococcus* cells can be counted. Nevertheless, the numbers that have been obtained are sometimes quite impressive.

ACE Agar (Antibiotic Cell Extract Agar; McCurdy, 1969a)

SP medium (see "Purification by Plating," this chapter) is supplemented with:

Yeast extract	0.1%
Yeast (or *E. coli*) cells	0.5% (dry weight)
Neomycin	10 μg/ml
Sulfanilamide	10 μg/ml
Cycloheximide	100 μg/ml

The myxobacteria are detected by their swarm morphology and surrounding lysis zones.

Cultivation

Contrary to a belief that still seems widely held, myxobacteria are not particularly fastidious organisms. With the exception of *Haploangium,* all species have been cultivated, and all can be grown in axenic, pure culture. Of course, as with all other organisms, myxobacteria have their peculiarities, but no unusual requirements, and not even particularly complex ones, have been discovered to date. Exotic substrates such as the rabbit dung media that were so popular for a long time are not necessary. Although it is not always easy, fully defined, synthetic media have been developed for some myxobacteria. In connection with possible commercial antibiotic production, quite a few myxobacteria have been cultivated in large-scale fermentors (5 m^3 and greater), often on technical media, such as corn steep powder and soy meal.

Plate Cultures

Myxobacterial cultures are often incubated for extended periods, (1 to 4 weeks), where dehydration may occur, so that plates must be poured thicker than for the usual bacterial work. Also, a high humidity in the incubator is helpful.

All myxobacteria, including the cellulose degraders, seem to grow well on yeast agar (VY/2 agar). The yeast cells are usually decomposed, but not always completely, and sometimes not at all. Vitamin B_{12} is occasionally required (e.g., by many *Polyangium* strains) so cyanocobalamin is included in this standard medium. Typically, on VY/2 agar gliding motility is considerably stimulated, and the swarm colonies tend to become very large. Fruiting bodies are often formed even after several transfers on VY/2 agar, although sooner or later most strains cease fruiting on this medium as well as on most other growth media. Cultures on VY/2 agar are usually rather stable, and most strains need not be transferred more often than every 2 to 3 weeks (30°C). The reason is probably that VY/2 agar is relatively lean, nutrients are only gradually solubilized, and the pH does not change very much. The medium therefore is also well suited for stock cultures.

Another useful medium is CY agar (see "Purification Methods," this chapter). On this medium growth often is more vigorous, but the swarms do not spread so much, may become somewhat slimy, and often the cells die earlier (after 1 to 2 weeks) due to copious ammonia production. The choice of the peptone for media of this type is critical. In general, the most suitable products appear to be pancreatic and tryptic digests of casein, e.g., casitone (Difco), tryptone (Difco), or peptic digests (Marcor, Merck). But other peptones such soybean peptones can also be used. Meat peptones, on the other hand, are usually not useful, perhaps because their phosphate content is too high. In any case, the suitability of a peptone for the myxobacterial strain to be cultivated must first be tested. How critical the quality of the peptone can be is seen from the fact that even the specific batch of a particular peptone brand may make a difference. Thus, for example, not every batch of Difco casitone supported successful induction of myxospore formation with *Stigmatella aurantiaca* (Gerth and Reichenbach, 1978); similar observations have also been made with glycerol induction of myxospores of *Mx. xanthus.* Replacement of peptone by a total protein hydrolysate, e.g., casamino acids (Difco), is often not possible. But casamino acids are a perfect N source for *Cystobacter* and *Sorangium* strains.

Watson and Dworkin (1968) showed that *Mx. xanthus* lacked hexokinase and was unable to take up, metabolize, or grow on sugars. This, however, cannot be generalized for the myxobacteria, despite earlier impressions that this might be the case. Many myxobacteria are known that efficiently metabolize sugars, e.g., *Stigmatella* and *Cystobacter.* In fact, it seems that only the *Myxococcus* species and perhaps some *Corallococcus* strains are unable to use carbohydrates. In some cases, e.g., certain *Corallococcus* strains, polysaccharides such as starch can be utilized, although no mono- and disaccharides can be used. Apparently the starch is degraded to the trisaccharide, which can be metabolized (Irschik and Reichenbach, 1985). Thus, it may sometimes be useful to supplement a peptone medium with starch or glucose. Another beneficial effect of this may be that the pH rises more slowly, so that the culture can be maintained for a longer time. We have found the following formulations useful for plate cultivation:

CYG2 Agar

Casitone (Difco)	0.3%
Yeast extract (Difco)	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. After autoclaving, 0.3% glucose is added from an autoclaved stock solution.

STK2 Agar

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved and poured into petri dishes. After the agar has solidified, the following top agar is added:

Top agar: As base agar, but the agar concentration is increased to 1.5%, and the medium is prepared in about 85% of the final total water volume. In the remaining water is dissolved, as a percentage of the total volume of the top agar:

Soluble starch (see below)	0.2%
K_2HPO_4	0.02%

The starch solution is heated on a water bath under stirring before autoclaving in order to prevent clumping of the starch. The two solutions are combined after autoclaving.

In the form just described, STK2 agar can be used for checking starch degradation. If it is only to be used for cultivation, just the top agar (but with 1.2% agar) is required.

The cellulose decomposers utilize NO_3^- or NH_4^+ as the only N source and can be cultivated on simple synthetic media like CK6 and CA2 agar (see below). They respond favorably to the addition of an organic N source, such as peptone (0.1 to 0.2%), but usually they will not grow in the absence of a suitable carbohydrate, like glucose or starch. *Sorangium* strains thus can also be grown on VY/2, CEL3, and STK21 agar, and many strains will grow as well on CT7 agar, but for the reasons just mentioned, relatively few will grow on CY agar.

CK6 Agar (Modified from Couke and Voets, 1967)

Solution A:

$MgSO_4 \cdot 7H_2O$	0.15%
Fe^{3+} citrate	0.002%
Agar	1.5%

Prepare this solution in 80% of the final water volume.

Solution B:

KNO_3	0.2%
K_2HPO_4	0.025%

Prepare this solution in 10% of the final water volume.

Solution C:

Glucose	0.5%
$CaCl_2 \cdot 2H_2O$	0.15%

Prepare this solution in 10% of the final water volume.

After autoclaving, the three solutions are combined.

CA2 Agar (Mullings and Parish, 1984)

Base agar:

Agar	1.5%

Stock solution A:

KNO_3	7.5 g
K_2HPO_4	7.5 g

These ingredients are dissolved to give 100 ml.

Stock solution B:

$MgSO_4 \cdot 7H_2O$	1.5 g

This is dissolved to give 100 ml.

Stock solution C:

$CaCl_2 \cdot 2H_2O$	0.27 g
$FeCl_2$	0.15 g

These are dissolved to give 100 ml.

After autoclaving, the base agar is supplemented with 1% (v/v) of each of the three stock solutions, 1% (w/v) of glucose (from an autoclaved 20% stock solution) and trace elements.

Since myxobacterial swarms tend to spread quickly, cultures are more conveniently kept in petri dishes than on agar slants in tubes. In the latter, the swarm edge soon reaches the glass surface and the cells dry out and die; also transfer of sticky, tenacious swarms is easier from plates. The plates are inoculated best at one spot at the side to give the swarm as much space as possible. In large swarms, living cells are often found only in a rather narrow band along the edge. Therefore, the inoculum should always be taken from the edge, at least as long as there are no fruiting bodies in the interior zone. Many myxobacteria of the suborder Sorangineae tend to penetrate deeply into the agar, in which case an agar strip has to be cut out and used as an inoculum.

Viable Counting

Accurate viable counts are possible only with strains that grow in a dispersed fashion in liquid media. Plating efficiency has to be tested for every strain. Given below are some media that allow plating efficiencies close to 100%: CT and CTT agar for *Mx. xanthus* FB; PT agar for *Mx. fulvus* Mx f2; and SG agar for *Sg. aurantiaca* Sg a1. CF (clone-fruiting) agar supports the formation of colonies from single cells of *Mx. xanthus,* with the subsequent production of fruiting bodies (Bretscher and Kaiser, 1978). If a plating medium is not satisfactory for a specific strain, usually a modification of the peptone and ion concentrations or the addition of some yeast extract will make it suitable.

CT Agar (Dworkin, 1962)

Casitone (Difco)	2%
$MgSO_4 \cdot 7H_2O$ (autoclaved separately)	8 mM
Potassium phosphate buffer, pH 7.2	0.01 M
Agar	2%

A variation of the pH sometimes improves the results; it has been found that a pH of 7.6 is closer to the optimum than 7.2 (H. Reichenbach, unpublished observations).

CTT Agar (Bretscher and Kaiser, 1978)

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	8 mM
Potassium phosphate buffer, pH 7.6	1 mM
Tris buffer, pH 7.6	10 mM
Agar	1.5%

For semisolid media, agar is at 0.6%. The medium is autoclaved.

PT Agar (for *Mx. fulvus* Mx f2)

Casitone (Difco)	0.4%
Yeast extract (Difco)	0.4%
$MgSO_4 \cdot 7H_2O$	0.2%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

SG Agar (Gerth, 1975)

Casitone (Difco)	1.5%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.2%
Agar	1.5%

The pH is adjusted to 7.0. The medium is autoclaved.

CG Agar (Hagen et al., 1978)

Casitone (Difco)	0.015%
Na pyruvate	0.1%
Na citrate	0.2%
$(NH_4)_2SO_4$	0.02%
$MgSO_4 \cdot 7H_2O$	8 mM
Potassium phosphate buffer, pH 7.6	1 mM
Tris buffer, pH 7.6	10 mM
Agar	1.5%

The medium is autoclaved.

Excellent viable counts, e.g., for survival curves after treatment with mutagens, have been obtained by us with *Mx. fulvus* Mx f2 and *Sg. aurantiaca* Sg a1 by adapting a miniaturized counting technique recommended by Sharpe and Kilsby (1971). One of the plating media mentioned above is prepared with a reduced agar concentration of 0.6%. The bacteria are diluted directly in this soft agar at 40°C, and 0.1 ml drops of appropriate dilutions are put into petri dishes, covered with a drop of sterile agar of the same composition, and incubated at 30°C. It should be noted that vegetative cells of *Mx. xanthus,* and perhaps other myxobacteria as well, are sensitive to temperatures higher than 43°C. Microcolonies are counted under a dissecting microscope. Up to 150 colonies per drop can easily be counted (H. Reichenbach

and M. Dworkin, unpublished observations). The method has several advantages. Without difficulty, 40 drops can be placed into one petri dish, using the bottom and the lid. Besides enormous economy in materials and incubator space, results are obtained earlier (after 3 to 4 days instead of 5 to 8 days) and with superior accuracy (more replicates, e.g., 5 instead of 3; less divergence between replicates; and a better chance to hit the optimum dilution step, because a wide interval of dilution steps can conveniently be plated. Plating efficiency can be 100%. The peripheral drops often show a reduced colony count, probably because they dry more easily. Therefore a ring of sterile agar drops should be placed around the edge of the plate.

Production of Fruiting Bodies in Culture

Usually, fruiting bodies are not produced on media that allow good growth. High nutrient concentrations seem to repress the fruiting process. As already mentioned, on VY/2 agar, fruiting bodies are often produced during several transfers, but a vegetatively propagated strain normally stops fruiting soon after isolation and often cannot be made to fruit again. The reason for this is not really understood; perhaps there is a selection for nonfruiting variants. In several cases, induction conditions for fruiting have been found for certain individual strains. Such strains reliably form fruiting bodies even after many transfers of purely vegetative growth, but other strains of the same species usually do not respond to the same conditions. With freshly isolated strains, fruiting can often be induced by transferring swarm material from a lean growth medium, like VY/2 agar, to plain water agar (WAT agar) or to sterile filter paper pads on water agar. Also, fruiting may continue for some time on streaks of living *E. coli* cells on water agar. The nutrients carried over from the growth medium, and the low nutrient level provided by the lysing *E. coli* cells, respectively, allow reasonable growth for some time, leading to sufficiently high cell densities; the subsequent more-or-less-abrupt depletion of nutrients then somehow triggers development. The need for a high population density for fruiting has been established for several myxobacteria, e.g., *Mx. xanthus* (Wireman and Dworkin, 1975) and *Cm. apiculatus* (H. Reichenbach, unpublished observations).

Using some simple tricks, myxobacterial strains can sometimes be maintained in the fruiting state for a long period. We were able to do so with *Sg. aurantiaca* over a period of years by storing the strain in the form of fruiting bodies on WAT agar at room temperature (20°C). After 2 to 3 months, when the culture began to dry out, the fruiting bodies were inoculated to VY/2 agar and incubated to 30°C. The resulting swarms were immediately reinoculated to Wat agar, incubated for a few days at 30°C during which time the organism began to fruit again, and then stored at room temperature as before. One or two more transfers to VY/2 agar were possible, but after that the strain failed to produce fruiting bodies any longer. This procedure of cycling the culture between rich media that support growth and lean media that induce fruiting body formation will probably work with many different myxobacteria.

With several *Chondromyces* species (*Cm. apiculatus, Cm. crocatus, Cm. pediculatus, Cm. lanuginosus*) we have obtained fruiting bodies when the organism was kept in a mixed culture with cellulose degraders (not myxobacteria) on filter pads placed on ST21 agar plates. The cultures are incubated in the light (on the bench top in the laboratory) at room temperature (20–24°C). Transfers are made every 3 to 4 weeks by inoculating macerated cellulose and *Chondromyces* fruiting bodies together to fresh filter pads on ST21 agar. within 4 to 5 days, new fruiting bodies appear. Using this procedure, several of our strains have continued to produce dense populations of fruiting bodies over a period of years (H. Reichenbach, unpublished observations). The method can also be used with pure cultures of *Chondromyces.* The swarm material is simply inoculated into a developing culture of a cellulose degrader. While *Polyangium* strains often form fruiting bodies with this procedure, myxobacteria of the suborder Cystobacterineae rarely do so. In general, it seems that a slightly reduced temperature (24–28°C) is favorable for fruiting. Also, in two cases, a requirement of light for fruiting body differentiation has been demonstrated—with *Cm. apiculatus* (Reichenbach, 1974a, 1974b) and with *Sg. aurantiaca* (Qualls et al., 1978).

Chamber Cultures

For the study of the social behavior of myxobacteria and of morphogenetic events, chamber cultures that can be observed and followed under the microscope are extremely useful. Fig. 4 illustrates one procedure for making such cultures.

Liquid Cultures

If a freshly isolated myxobacterial strain is cultured for the first time in a liquid medium in a shake flask, the bacteria almost always grow in the form of flakes and nodules and as a film

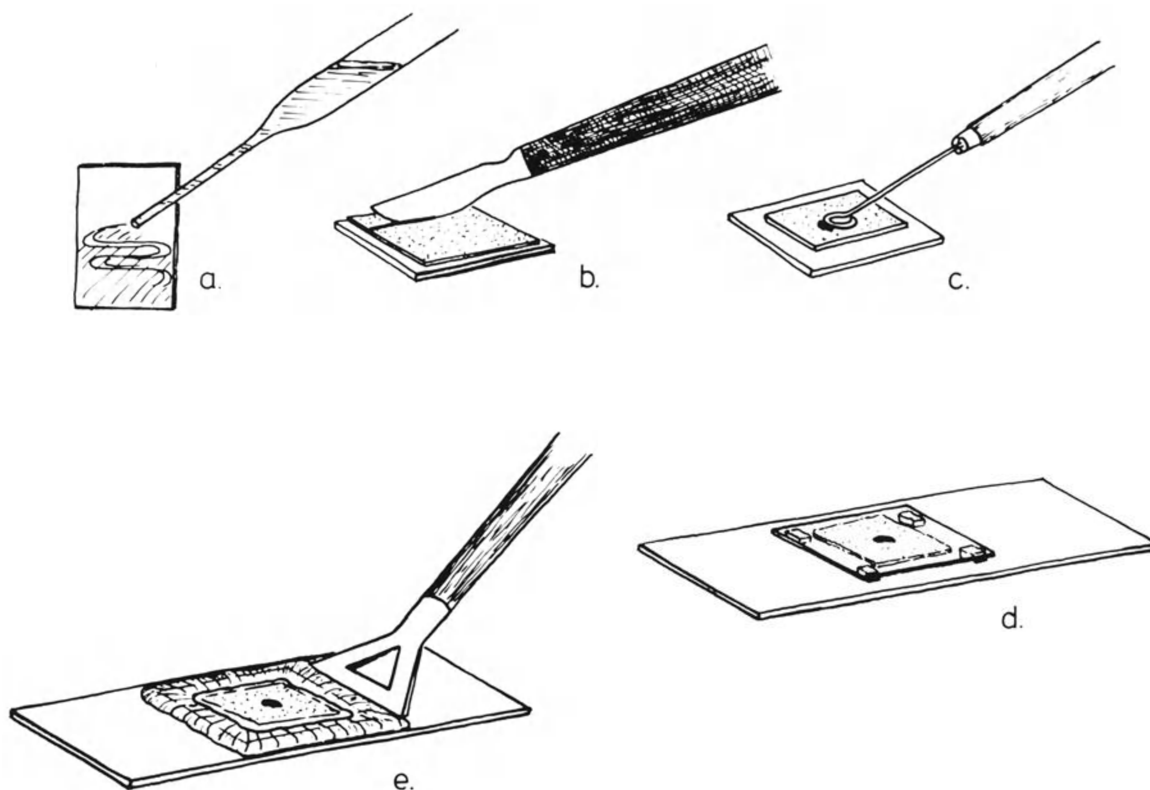

Fig. 4. Method for making a chamber culture: (a) Coat a sterile cover slip (e.g., 40 × 22 mm) with a thin agar layer. The molten agar is applied with a Pasteur pipette; the hotter the agar, the thinner the resulting layer. (b) Using a sterile scalpel, remove the agar layer along the edges of the cover glass. (c) Inoculate the agar film. (d) Mount the cover slip with the agar layer downwards on a sterile slide; tiny pieces of glass from a broken microscopic slide are used as supports. (e) Seal the chamber carefully with a molten mixture of paraffin and vaseline (2:1) and incubate at a suitable temperature. (From Heunert, 1973.)

along the glass wall. In static cultures, they grow as a sheet on the glass in the upper parts of the vessel and as a pellicle along the surface of the liquid. However, if repeated transfers are made from shake cultures, preferentially using the supernatant as an inoculum, strains that grow in a dispersed fashion may be obtained. While with many strains only a few such transfers are required, other strains may resist dispersed growth completely. Thus, for example, while most strains of *Myxococcus* can be grown in dispersed culture, we once transferred a strain of *Mx. fulvus* for months in a variety of liquid media without ever observing the slightest inclination to dispersed growth (H. Reichenbach, unpublished observations). Cells of most members of the suborder Sorangineae show a strong tendency to stick together, and in spite of many attempts, we have never been able to get *Chondromyces, Polyangium,* and *Nannocystis* to grow homogeneously in liquid cultures. The best that could be achieved was growth as tiny flakes with *Nannocystis* and *Polyangium.* With *Sorangium,* however, we have been able to select many completely dispersed strains. The list of myxobacteria that have been grown in a dispersed fashion is very long by now, and, with the exception of the last-mentioned organisms, comprises virtually all taxa. However, even the recalcitrant species which do not grow in a completely dispersed fashion, can at least be cultivated in suspension in liquid medium.

There is still no explanation for the factors which determine dispersed growth. One possibility is that the chemical structure and physicochemical properties of the excreted slime play an essential role. This hypothesis is consistent with several observations: 1) strains growing in a dispersed fashion often show a different swarm structure when returned to agar plates (soft-slimy swarms with rudimentary surface texture and reduced tendency to spread); 2) they usually have lost the ability to form fruiting bodies; and 3) the Sorangineae, which persistently fail to grow in a dispersed state, produce a slime that is chemically different from that of the Cystobacterineae (as shown by the fact that in contrast to the slime of the latter, the slime

of the former does not adsorb Congo red; McCurdy, 1969a).

An alternative possibility is suggested by the work of Kaiser's group. A large number of *Myxococcus* strains representing several different species were all found to possess pili when freshly isolated, and all of them failed to grow in a dispersed fashion in liquid media. This was examined in further detail in *Mx. xanthus* FB, where it was shown that a particular class of motility-deficient mutants had lost the ability to produce pili and now exhibited dispersed growth (Kaiser, 1979; D. Kaiser, personal communication). Of course, both slime and pili may be involved in dispersed growth, the pili reacting with a receptor in the slime at the cell surface. Also, not all myxobacteria may behave in the same way.

Work by Arnold and Shimkets (1988b) and in one of our laboratories (M. Dworkin, unpublished observations) indicates that the fibrils characteristically formed by *Mx. xanthus* (Dobson and McCurdy, 1979) play an important role in the cohesion and swarming behavior of the organism. These fibrils differ from the pili described by Kaiser (1979).

A homogeneously growing strain may start to clump again if growth conditions are changed, e.g., in a medium of different composition. Thus, cells of *Sg. aurantiaca* Sg a1, a strain which grows in a dispersed fashion, form tiny nodules if $CaCl_2$ is added to the medium. Freshly isolated *Cystobacter fuscus* cultures grow homogeneously almost immediately when inoculated into a casamino acids medium, but produces nodules and flakes for many transfers in casitone medium. Cells of *Sorangium cellulosum* strain So ce14 yield a homogeneous suspension when shaken overnight in casitone medium (in which they cannot grow, however); when reinoculated into AMB growth medium, they produce nodules again. It may also be mentioned in this connection that although the myxobacteria are the classical "slime bacteria" (*myxo* is a combining form meaning "slime"), they do not produce copious amounts of slime, either on plates or in liquid media, which rarely become recognizably viscous. Only on certain agar media is a larger quantity of slime sometimes seen, e.g., *So. cellulosum* on CA2 agar.

To facilitate the transition to dispersed growth, the addition of 0.1% agar to the liquid medium has been suggested (Schürmann, 1967). The agar forms tiny flakes that float in the liquid and are colonized by the myxobacteria. However, the selection of truly dispersed strains is not noticeably speeded up by this procedure. Sometimes it is helpful to replace the usual rotary shaker with a reciprocating shaker, since the slime sheets are broken up more efficiently on the latter, and the transition to dispersed growth may be faster, although patience is still required (K. Gerth, personal communication).

Liquid media used for cultivation of myxobacteria are of the same general composition as the agar media mentioned above (see "Direct Isolation" and "Purification," this chapter), but the nutrient requirements stand out more clearly in liquid media, and the organisms respond almost immediately to inadequacies of the medium. The prototype for the bacteriolytic myxobacteria is CT liquid medium, which was designed to provide the most rapid growth (3.5-h doubling time), maximum cell yield (4–5 × 10^9 cells/ml), and uniform cell suspension of *Mx. xanthus* FB (Dworkin, 1962; the medium has the same composition as the CT agar described in "Viable Counts," this chapter, only without the agar). However, most other myxobacteria grow better when the peptone concentration is reduced, as in CAS medium and in MD1 medium (see below). The latter medium was originally developed for *Nannocystis* but it is also often useful for *Archangium, Melittangium,* and *Cystobacter.* Also, in many cases it is superior for starting liquid cultures with newly isolated strains.

CAS Medium

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH is 6.8 and needs no adjustment if Difco casitone is used. The medium is autoclaved.

MD1 Medium (Behrens et al., 1976)

Casitone (Difco)	0.3%
$CaCl_2 \cdot 2H_2O$	0.07%
$MgSO_4 \cdot 7H_2O$	0.2%
Cyanocobalamin	0.5 μg/ml

Trace elements (see "Isolation of Cellulose Decomposers")

The vitamin solution is not needed for most strains. The medium is autoclaved.

What has been said about the choice of peptone in agar media holds also for liquid media. For many myxobacteria the addition of glucose (0.2 to 0.5%), starch, or another useful sugar to the peptone medium may be favorable. In general, the organisms do not grow faster with the carbohydrate, but they grow for a longer time, and they reach a higher cell density; also, the rise of the pH is delayed, so that the culture becomes more stable.

As already mentioned, some myxobacteria, e.g., *Cystobacter* strains, grow well on casamino acids, e.g., in CAC medium.

CAC Medium

Casamino acids, vitamin-free (Difco)	0.2%
Sodium glutamate	0.3%
$MgSO_4 \cdot 7H_2O$	0.1%
Cyanocobalamin	0.5 μg/ml
Trace elements	

After autoclaving, the medium is complemented from autoclaved stock solutions with:

Glucose	0.5%
Phosphate buffer, pH 6.5	0.5 mM

Sg. aurantiaca Sg a15 can be cultivated in the following defined medium:

STG Medium (Kunze et al., 1984)

Casamino acids, vitamin-free (Difco)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$(NH_4)_2SO_4$	0.1%
$CaCl_2 \cdot 2H_2O$	0.05%
Phosphate buffer, pH 7	1 mM
Trace elements	
Vitamins (see earlier)	

After autoclaving, the medium is complemented with 0.5% glucose from an autoclaved stock solution. Alternatively, fructose, maltose, starch, or dextrin 10 could also be used.

The cost of the medium is of considerable importance when large-scale culture is necessary. Many myxobacteria have been cultivated on various technical media, like corn steep powder, maize gluten, soy meal, skim milk, or yeast cells (Gerth et al., 1983; Kunze et al., 1984, 1985, 1987). Zein medium is an example of a production medium:

Zein Medium (Kunze et al., 1987)

Zein (maize gluten, Maizena, Hamburg, Germany)	1%
Peptone from casein, tryptic digested (Merck, Darmstadt, Germany)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH is adjusted to 7.3. The medium is autoclaved.

All myxobacteria of the bacteriolytic type rely totally, or to a large extent, on peptides and amino acids for nitrogen, carbon, and energy. As a consequence, relatively large quantities of ammonia are released, which seriously limits growth and productivity via regulatory mechanisms and by making the medium alkaline. Thus, in cultures of *Mx. virescens* Mx v48 concentrations of 35 to 42 mM NH_4^+ and more were measured in the culture supernatant, and 80 to 140 mM within the cells (Gerth and Reichenbach, 1986). On-line extraction of ammonia from a laboratory fermentor via hydrophobic-membrane hollow fibers maintained the NH_4^+ concentration in the medium between 3 and 7.5 mM with dramatic effects: the generation time was lowered from about 4 to 2 hr, the cell density increased by 233%, and the yield of the antibiotic myxovirescin rose from 8 to 115 mg/liter (K. Gerth, personal communication).

For a few strains of bacteriolytic myxobacteria, fully defined, synthetic media have been developed. Examples are given in Table 2. Generation times increase substantially in such media. Thus, with *Mx. xanthus* FB, the doubling times were: 3.5 h in CT medium, 8 h in S medium, and 6.5 in M1 medium; 6.5 h in M1 medium without lysine, 9.5 h in M1 medium without threonine, and 11.5 h in M1 medium without lysine and threonine (Filer et al., 1973).

The cellulose degraders can be cultivated on very simple media, such as CK1 and CK6 medium (see below). The addition of a small quantity of peptone, e.g., 0.05% peptone from a tryptic digest of casein (Merck, Darmstadt, Germany), usually improves growth and keeps the cells in the dispersed state, whereas without peptone they sometimes form cell clusters or tiny clumps (Irschik et al., 1987). Media with peptone as the only N source usually also allow good growth, e.g., AMB medium.

CK1 Medium (Kleinig et al., 1971; Modified from Couke and Voets, 1967)

$MgSO_4 \cdot 7H_2O$	0.3%
$CaCl_2 \cdot 2H_2O$	0.18%
Fe^{3+}-citrate	20 mg/liter
KNO_2	0.2%
K_2HPO_4	0.025%
Glucose	1%

Nitrate and phosphate, and $CaCl_2$ and glucose are each autoclaved together and separate from the other ingredients.

CK6 Medium (Irschik et al., 1987; Modified from Couke and Voets, 1967)

$MgSO_4 \cdot 7H_2O$	0.15%
$CaCl_2 \cdot 2H_2O$	0.15%
$FeCl_2 \cdot 7H_2O$	8 mg/liter
KNO_3	0.2%
K_2HPO_4	0.025%
Glucose	0.5%

Nitrate and phosphate, and $CaCl_2$ and glucose are each autoclaved together and separate from the other ingredients.

AMB Medium (Ringel et al., 1977)

Soluble starch	0.5%
Casitone (Difco)	0.25%
$MgSO_4 \cdot 7H_2O$	0.05%
K_2HPO_4	0.025%

The medium is autoclaved.

MD1 medium (see above) can also be used for cellulose degraders if it is supplemented with

[a]From Dworkin (1962).
[b]From Witkin and Rosenberg (1970).
[c]Minimal medium: from Bretscher and Kaiser (1978).
[d]From Mayer (1967). The organism is in fact *Cystobacter violaceus.*
[e]Reichenbach (1984); H. Reichenbach, unpublished observations. Some strains also require thiamine and/or biotin when growing in this minimal medium.

0.1% glucose or soluble starch (Irschik et al., 1987). There are even some strains that can grow in liquid media, like CB medium containing casitone as the only C, N, and energy source (Sarao et al., 1985), but this must be exceptional, because none of the many *Sorangium* strains we have tested would do so.

CB Medium (Casitone Broth: Sarao et al., 1985)

Casitone (Difco)	0.25%
$MgSO_4 \cdot 7H_2O$	0.05%
K_2HPO_4	0.0025%

For liquid cultures of myxobacteria, ordinary Erlenmeyer flasks are perfectly satisfactory as culture vessels. For agitation, a rotary shaker at about 150 rpm is sufficient. As the oxygen demand of myxobacteria is rather moderate, flasks with baffles give little or no improvement in growth and actually are unfavorable with peptone-containing media because they produce too much foam. Several types of antifoam can be used with myxobacteria, but the type of antifoam acceptable in a certain situation and tolerated by a specific strain must always be tested

first. We have found that with small culture volumes and limited foaming, a few drops of a 0.5% cholesterol solution in acetone works well. In fermentors, as a rule, more efficient antifoams must be applied (Mizrahi et al., 1977; Ringel et al., 1977). We have had good results in many different myxobacterial fermentations with polyoxypropylene-based antifoams at concentrations of 0.02 to 0.03%, for instance, antifoam agents LB625 or M115 (both from Brenntag, Mülheim/Ruhr, Germany; Gerth et al., 1980; Irschik et al., 1983a), or with silicone antifoam agent at 0.005 to 0.02% (Merck, Darmstadt, Germany; these sometimes require further additions later during fermentation; Irschik et al., 1983b; Kunze et al., 1984, 1985). Many, but not all, myxobacteria can be cultivated in the presence of an Amberlite adsorber resin, e.g., with 1% XAD-1180 (Röhm & Haas, Darmstadt, Germany; e.g., Gerth et al., 1983; Kunze et al., 1985). This strategy often is extremely useful for the production and recovery of secondary metabolites that are excreted by the cells.

Mass cultivation of myxobacteria in fermentors has not presented any serious problems. Mechanical stress seems not to be a limiting factor. If no continuous control and regulation of culture parameters is required, cultivation in large flasks (10 to 15 liters) also gives excellent results. The flasks are aerated with three air outlets of sintered glass at the ends of silicone tubings, which are lowered to close to the bottom of the vessel. The aeration produces enough turbulence in the liquid so that additional stirring is unnecessary. The appropriate temperature is achieved by placing the flask in an incubation room or by connecting a length of silicone tubing coiling within the culture broth to a thermostat with a pump. With such an inexpensive system, yields on the order of 8 to 12 g cells/liter (wet weight, corresponds to 2 to 3 g dry weight) can be obtained.

Cultivation in commercial fermentors permits the continuous monitoring of various culture parameters and allows them to be balanced and controlled. Although the optimum conditions depend on the type of fermentor used, the strain, and the medium, some generalizations are possible: In fermentations on the scale of 50 to 5000 liters, typical aeration rates are between 0.01 and 0.2 liter air per liter of medium per min, which, with stirring rates between 150 and 650 rpm, result in oxygen levels between 90 and 100% saturation (Gerth et al., 1980, 1982, 1983; Irschik et al., 1983a, 1983b, 1987; Kunze et al., 1984, 1985, 1987; Mizrahi et al., 1977). In a special study on myxovirescin production with *Mx. virescens* Mx v48 with fed-batch fermentations in a peptone medium, a cell yield of 0.5 g (dry weight) per g oxygen consumed, and of 0.31 g per g peptone was obtained (Nigam et al., 1984). The oxygen consumption was 6.25 g O_2 per liter culture in 55 h. Respiration quotients between 0.3 and 1.3 mol CO_2 per mol O_2 were calculated under different culture conditions, with values of 0.8 to 1.0 during logarithmic growth. The maximum dry weight yield was 3.1 g/liter. The specific growth rate, μ, varied between 0.05 and 0.12/h during exponential growth, depending on the feeding rate.

Other types of special fermentations have also been performed with myxobacteria; for instance, continuous cultures of *Mx. virescens* Mx v48 have been achieved in a chemostat with online extraction of myxovirescin in a vortex chamber (Hecht et al., 1987), and fermentations have been established with alginate-immobilized cells (Vuillemard et al., 1988; Younes et al., 1984, 1987). Cells of *So. cellulosum* So ce12 immobilized in 1-mm alginate beads are extremely stable and could be maintained in fermentors under continuous exchange of the medium for up to 75 days before the cells degenerated (Becker, 1990; K. Becker, personal communication). The system allowed the production conditions for the antibiotic sorangicin to be defined more clearly, and under optimal conditions, volume/time yields five times higher than those measured with suspended cells in batch cultures were obtained.

When fermentations are started with an inoculum of 5 to 10% (v/v), the results are almost always satisfactory. Sometimes the age of the inoculum is a critical factor, and beyond a certain, relatively early stage but still within the logarithmic phase, the cells will start to grow only after a long and erratic lag period or not at all. This has been observed with *Polyangium* and *Sorangium* strains (H. Reichenbach, unpublished observations).

Under optimal growth conditions the doubling times of myxobacteria are between 3.5 and 15 h, with the members of the suborder Sorangineae comprising the most slowly growing myxobacteria. Cell densities of up to 10^{10}/ml can be reached, for example, with *So. cellulosum.* Cell mass yields are in the range of 4 to 12 g wet weight per liter (e.g., Irschik et al., 1983a, 1983b, 1985). The dry mass is 20 to 25% of the wet weight.

The pH range for growth is rather narrow, approximately 6.5 to 8.5; in general, there is no good growth below a pH of 6.6 or above pH 8.0. While some of the cellulose decomposers will grow at a pH down to about 5.0 (Couke and

Voets, 1967; Krzemieniewska and Krzemieniewski, 1937a), below pH 5.8, growth is marginal (H. Reichenbach, unpublished observations). As with other bacteria, the pH in myxobacterial cultures can be stabilized by adding a buffer. HEPES and MOPS buffers (50 mM) are well tolerated by many myxobacteria, and Tris may also be used. (It should be noted that many of the media formulations do not contain phosphate; the low amount of phosphate contained in the peptones—in a 0.2% solution of peptone from casein, 0.5 mM phosphate was present (Becker, 1990)—are usually sufficient to satisfy the phosphate requirement of myxobacteria).

The temperature optimum for growth is usually between 32 and 36°C, and there is a sharp maximum around 38°C. The minimum is less clear. *Mx. xanthus* FB grew exponentially with a generation time of 14 h at 14°C, the lowest temperature tested (Janssen et al., 1977); the lower limit for cellulose decomposition by two *Sorangium* strains was found to be 11°C (Baur, 1905; Krzemieniewska and Krzemieniewski, 1937a; Quehl, 1906). *Mx. fulvus* Mx f2 grows, albeit slowly, at 6°C. However, there also are myxobacteria that obviously have a different temperature range: The psychrophilic myxobacteria from Antarctica have already been mentioned (Dawid et al., 1988), and at the other end of the scale, strains of *Archangium, Polyangium,* and *Sorangium* that are able to grow at 40°C have been known for some time (McCurdy, 1969a). About 70% of the *Sorangium* strains grow at 40°C, and about 80% at 38°C. A variety of other myxobacteria can grow at these somewhat elevated temperatures, e.g., most *Polyangium,* many *Archangium, Cystobacter, Chondromyces,* and some *Mx. virescens* strains, but usually not *Mx. fulvus* and *Corallococcus.*

Most myxobacteria do not require vitamins when growing in the usual complex media, but, as already mentioned, a vitamin dependence, usually for thiamine and/or biotin, may develop when the organism is transferred to a minimal medium. *Sg. aurantiaca* Sg a15 needs both thiamine and B_{12} (Kunze et al., 1984); B_{12} dependence is not unusual and has also been observed with many *Polyangium* (but not with *Sorangium*), some *Nannocystis,* and one strain of *Corallococcus macrosporus.*

The mineral requirements of myxobacteria are similar to those of other bacteria. Myxobacteria seem to need relatively high Mg^{2+} concentrations (the optimum is often around 5 to 10 mM, equivalent to 0.075 to 0.15% $MgSO_4 \cdot 7H_2O$). *Sorangium* strains require Ca^{2+} as well and grow better on media with Ca^{2+} than with Mg^{2+} (McCurdy, 1969a). The addition of Co^{2+} sometimes has a stimulating effect (Gerth et al., 1982; Ringel et al., 1977). *Mx. xanthus* is sensitive to elevated concentrations of monovalent cations (Mason and Powelson, 1958), and the salt tolerance of myxobacteria is generally low. An exception is *Mx. virescens,* which seems to form fruiting bodies better when 0.5% NaCl is added to the medium (Rückert, 1978). This organism can still grow on media containing 1% NaCl, although at a clearly reduced rate, and, in fact, it can be selectively isolated on streaks of *E. coli* on WCX agar at that salt concentration.

Usually, myxobacterial cultures are kept in the dark or, in an incubation room, under continuous illumination. As already mentioned, some myxobacteria produce fruiting bodies only when the cultures are illuminated. Also, a phototactic behavior has been reported for some myxobacteria (Aschner and Chorin-Kirsch, 1970). Illuminated cultures often are much more deeply colored than those grown in the dark, because carotenoid synthesis is induced by light (Burchard and Dworkin, 1966a). As color is sometimes a taxonomically relevant characteristic, cultures used for taxonomic work should at least be intermittently illuminated.

Isolation of Mutants

Mutant strains of myxobacteria can be isolated without difficulty by the standard techniques used with other bacteria, provided strains capable of dispersed growth and procedures for obtaining a high plating efficiency are available. Thus, carotenoid mutants, morphogenetic mutants, motility mutants, and metabolic mutants have been isolated in a number of laboratories. *M*-Methyl-*N'*-nitro-*N*-nitrosoguanidine (NTG) is often (but not always) an excellent mutagen for myxobacteria. The useful concentration range is 50 to 150 μg NTG/ml when the cultures are treated for 1 h. Killing curves can conveniently be determined with the miniaturized viable-count technique mentioned previously. Also UV irradiation has successfully been used to obtain mutants of myxobacteria. However, in contrast to NTG, UV was ineffective in generating carotenoid mutants in *Mx. fulvus* Mx f2. Further details on the application of different mutagens and a comparison of their effects on a variety of myxobacteria can be found in the literature (e.g., Burchard and Parish, 1975; Hodgkin and Kaiser, 1977; Grimm, 1978). In recent years, insertional mutations produced with transposons such as Tn5 lac, or with RP4 plasmids, have played an increasingly important role in the genetics of myxobacteria (e.g.,

Downard, 1988; Jaoua et al., 1987; Kaiser et al., 1985; Kroos and Kaiser, 1984; Kroos et al., 1986, 1990; Weinberg and Zusman, 1989).

Preservation Methods

Vegetative cultures of myxobacteria on agar plates kept at room temperature or at 30°C will usually remain viable for about 2 to 3 weeks. Storage of such cultures at 4°C leads to a rapid loss of viability.

If fruiting bodies are produced, the cultures remain viable for a much longer time. One has to be certain, however, that the fruiting bodies do indeed contain myxospores, since under some conditions, the fruiting bodies formed are empty or contain only vegetative cells.

Storage in the Form of Desiccated Fruiting Bodies

Pieces of agar that contain fruiting bodies can be placed on sterile filter paper in an empty petri dish, dried in an evacuated desiccator, and stored as such for years. This method is especially useful with myxobacteria such as *Nannocystis* whose fruiting bodies are mainly located within the agar.

Alternatively, vegetative cells can be transferred from a suitable growth medium, preferably VY/2 agar, to small rectangles of sterile filter paper, about 1.5 × 3 cm in size, on water (WAT) agar, and the cultures are incubated at 28°C. Usually, large numbers of fruiting bodies develop within 2 to 3 days. These fruiting bodies are allowed to mature for about 8 days. The filter pads are then placed into suitable containers, such as screw-cap tubes or small medicine bottles, and dried in an evacuated desiccator over silica gel for a few days. The containers are then tightly closed and stored at room temperature or at 6°C (it is not known which temperature is better). The dried fruiting bodies survive for about 5 to 15 years. This method has the advantage of being easy and cheap, and it conserves the ability of the strain to form fruiting bodies. It works, however, only if the strain has not been transferred too many times since its isolation. The method should therefore be applied as soon as a strain is pure, and, if fruiting is a desired feature, even earlier. Sometimes myxospores are still produced on the filter although fruiting bodies are not formed any more. In that case, the filter can still be dried and a viable preparation produced. The growth medium from which the vegetative cells are taken must not be too rich. Thus, for example, fruiting bodies usually do not appear after transfer from CY agar. Sometimes it is necessary to grow the organism directly on the filter paper in order to obtain fruiting bodies. This may be done on filter pads on water agar after streaking autoclaved yeast or food bacteria onto the filter. In this way, *Chondromyces* strains are sometimes induced to fruit. The cellulose decomposers almost always produce many fruiting bodies when growing on filter paper, which has been placed on ST21 agar. As the fabric of the filter paper is destroyed during growth, the paper can no longer be removed, but the macerated mass may be transferred to a fresh filter pad, which is then treated as described above.

To start a culture from dried fruiting bodies, the filter pad is placed upside down on CY agar, VY/2 agar, or WAT agar with streaks of autoclaved *E. coli*. After 24 h, the filter strip should be shifted to another place on the plate, because reduced oxygen access may prevent germination under the wet paper. When the paper is removed, many of the soaked and softened fruiting bodies will stick to the agar surface.

Alternatively, if a sufficient quantity of fruiting bodies is obtainable, e.g., after growth on VY/2 agar, they may be dried in skim milk after having been transferred to water agar, or, in the case of the cellulose degraders, to filter paper on ST21 agar. The fruiting bodies are suspended in skim milk, and a few drops of the suspension are applied to a freeze-dried milk plug in an ampule. The ampules are kept at 4°C for at least 10 min, and the plug is then dried again for about 5 h (this time at room temperature) in a desiccator connected to an efficient pump. After that, the ampules are filled with nitrogen gas and sealed. Strains thus preserved also retain their ability to form fruiting bodies and may remain viable for a longer time than on filter paper. While drying in skim milk also works well with myxospores, including those that were experimentally induced (Dworkin and Gibson, 1964), results with vegetative cells are highly erratic. Vegetative cells invariably die during drying and only those cultures which contained myxospores survived. Experiments with true lyophilization and with protective substances other than skim milk did not give better results.

An excellent and convenient method for the preservation of myxobacteria is freezing at −80°C. Samples of 1 ml are transferred from exponentially growing liquid cultures to screw-cap tubes and placed directly into the deep freeze. Alternatively, the bacteria may be scraped from the surface of a young agar culture, transferred to 1 ml CAS medium, and frozen. All of the myxobacteria that we have tested so far (26 species) have survived in the deep freeze for 8 to 10 years, the longest period over

which data have been collected. Storage at ultra-low temperature is the best way to preserve strains growing in the dispersed state, nonfruiting, nonsporeforming strains, and mutants. It is also a fast and reliable method for the storage of all kinds of strains of a culture collection. However, if the temperature rises above −30 to −25°C, the cells will die unless they are transferred to a growth medium within 5 to 10 h.

For safe long-term storage, freezing in liquid nitrogen is the method of choice. We use the same cell suspension as described above, but add 5% dimethyl sulfoxide (DMSO) to the suspension medium, which is usually CAS medium. We fill 0.5-ml amounts of the suspension into glass ampules, seal them, and immerse them in liquid nitrogen without further precautions. The DMSO may not be required since all the cells stored without DMSO have survived, thus far for 2 years.

Storage of frozen cell suspensions at −25°C is not recommended, because most myxobacteria will die within several days or, at the most, a few weeks.

To reactivate frozen cultures, the tubes or ampules are immersed in cold water to speed up thawing. The cells must be transferred to fresh medium immediately after they have thawed, because if the cells remain in the original medium after thawing, they will lyse within 15 to 30 min. We generally use VY/2 agar for the reactivation of the culture, usually with good results, but CY agar, CAS medium, and MD1 medium can also be used. If experience is lacking with a certain strain, the thawed suspension should always be inoculated into several different media, including a liquid medium. It sometimes happens, albeit rarely, that recovery will occur only on a specific medium, although the other media normally support growth. For example, we have observed that some strains can be reactivated only in a liquid medium or only on agar plates. If a liquid medium is used, care should be taken not to dilute the organisms too much, e.g., by inoculating a few drops into 100 ml. In some cases, for example with particularly fragile mutants, it is useful to reactivate the cells by embedding them in a growth medium containing 0.6% agar. The soft agar appears to provide a matrix which protects cells that have been slightly damaged by freezing and thawing (D. Zusman, personal communication).

At least some myxobacteria can be stored in a 1% NaCl solution at room temperature. The cell suspension must not be too dense: the liquid should be just visibly turbid, otherwise the cells will lyse overnight. For one strain of *Mx. xanthus,* a suspension of vegetative cells has been kept alive for 5 months in this way. In another case, we suspended vegetative cells and glycerol-induced myxospores of *Mx. xanthus* FB in 1% NaCl solution and kept the suspensions in sealed ampules for 7 years at room temperature. After that time, a culture could be started from the myxospores, but not from the vegetative cells. While the original strain was very sensitive to NaCl, the revived strain grew on CY agar with 1% NaCl. This clearly indicates that in such cases, the bacteria are not completely dormant, and that a selection for certain characteristics may have taken place.

Characterization

Considerable information has accumulated during the past 10 years on the composition, biochemistry, molecular biology, and genetics of myxobacteria.

Morphology and Fine Structure

The vegetative cells of the myxobacteria are rod-shaped, typically, 3 to 6 μm long and 0.7 to 1.0 μm wide. They are found in two morphological types: 1) slender, flexible rods with more-or-less tapering ends, and 2) cylindrical, somewhat rigid rods with bluntly rounded ends (Krzemieniewska and Krzemieniewski, 1928; Fig. 1a–d). These different cell types correlate with a number of other basic characteristics and represent two suborders of the Myxobacterales, the Cystobacterineae and the Sorangineae. The cell shape makes it possible to assign a strain at once to one of the two suborders.

Most electron microscopic studies on myxobacteria are rather old now, and a thorough reinvestigation would be desirable. In addition to *Mx. xanthus*, several other myxobacteria have been studied, including *Mx. fulvus, Mx. virescens, Cystobacter, Stigmatella, Sorangium,* and *Chondromyces* species (Abadie, 1967, 1968, 1971a, 1971b; Galván et al., 1986; Lampky, 1976; MacRae and McCurdy, 1975; McCurdy, 1969b; Reichenbach et al., 1969; Schmidt-Lorenz and Kühlwein, 1968; Voelz, 1965, 1966a, 1966b, 1967; Voelz and Dworkin, 1962). Cytologically, the myxobacteria are typical Gram-negative bacteria. Both the tapered and the cylindrical cell types appear to be identical in fine structure, ultrathin sections revealing a typical triple-layered outer membrane and a thin peptidoglycan sheet. The cells divide by septum formation (Abadie, 1971b; MacRae and McCurdy, 1975). Within the cells, mesosomes and mesosomelike membrane bodies are often seen (Abadie, 1967, 1968, 1971b; Galván et al., 1986; Lampky, 1976; MacRae and McCurdy, 1975;

Voelz, 1965). The visualization of ribosomes was initially a problem, because they were difficult to fix properly (Voelz, 1967), but it later turned out that they are of the usual type. At low phosphate levels, the formation of polysomes seems to be induced in *Mx. xanthus* (Voelz, 1966b). Polysomes were also observed in cells of *Cm. crocatus,* and they were often attached to the cytoplasmic membrane and arranged in a helical fashion (Abadie, 1971b). Unusual disk-shaped, membrane-associated structures have been described from *Cm. crocatus* (MacRae and McCurdy, 1975). In cross-sections they appear as two double tracks, each 7.5–11 nm wide and between 55 and 130 nm long, connected to the interior of the cytoplasmic membrane by 11- to 15-nm-long, fibrillar extensions. Several classes of intracellular granules, or inclusion bodies, have been found. Black granules, apparently produced by all myxobacteria, have been identified as polyphosphate (Voelz et al., 1966). Electron-transparent granules are of at least two types: 1) granules that are pale gray, containing material that does not contrast well; these have been suggested to be polysaccharide (Reichenbach et al., 1969), "slime vacuoles" (Abadie, 1971b; Schmidt-Lorenz and Kühlwein, 1969), or "glycogen" (Voelz et al., 1966). This has been corroborated by light microscopy after performing the periodic-acid Schiff reaction (Schmidt-Lorenz and Kühlwein, 1969). 2) Completely empty, large, circular areas, which are sudanophilic under the light microscope, have been seen in the cells of *So. cellulosum* (Lampky, 1976) and may be lipid material. Also, poly-β-hydroxybutyric acid has been demonstrated chemically in *So. cellulosum* (H. Jansen, personal communication). In cells of *Mx. xanthus* grown under suboptimal conditions, large parts of the cytoplasm sometimes appear to have a crystalloid pattern (Voelz, 1966b, 1967, 1968).

In many myxobacteria, intracellular microtubules and fibrils may be seen (Abadie, 1971b; Burchard et al., 1977; MacRae and McCurdy, 1975; Schmidt-Lorenz and Kühlwein, 1968). The diameter of the microtubules is 10 to 16 nm (with *Cm. crocatus* 15 to 19 nm), that of the fibrils, 4 to 5 nm (with *Cm. crocatus* 7.5 to 10 nm). Once it was thought that microtubules and fibrils were just two different aspects of the same structure depending on the plane of sectioning (Schmidt-Lorenz and Kühlwein, 1968), but this is not the case. The fibrils are usually arranged in bundles which may be 40 nm wide and 3.5 μm long. The bundles usually lie close to the cytoplasmic membrane and often follow the long axis of the cell, sometimes to the cell poles, but they also may cross the cell from one side to the other. A herringbonelike periodicity with a 12-nm spacing has occasionally been seen (Burchard et al., 1977). Also, transverse bands with a very regular, crystal-like pattern may occur (Burchard et al., 1977). Originally, fibrils were found only in cells from swarming agar cultures (Schmidt-Lorenz and Kühlwein, 1968), but they were subsequently found in cells from liquid cultures as well (Burchard et al., 1977; H. Reichenbach, unpublished observations). These systems of fibrils and microtubules have been interpreted as contractile elements responsible for gliding motility by producing contraction waves (Burchard et al., 1977; Schmidt-Lorenz and Kühlwein, 1968), but there is no evidence that those structures can really contract, and they could have some other function or even be artifacts. In *Cm. crocatus,* those structures were assumed to be composed of ribosomes (paracrystalline system: Abadie, 1971b).

An extremely complex structure has been discovered in the surface layers of *Mx. fulvus,* just below the outer membrane, suggested to be the apparatus of gliding motility (Lünsdorf and Reichenbach, 1989). One or several belts with an intricate substructure appear to run helically around the periphery of the cell, beginning at or close to the cell pole. From isolated material, it was deduced that the unit element consists of a long series of tiny rings at a regular, periodic distance, connected to each other by two longitudinal structures, perhaps two fibrils. Several of these unit elements, or strands, form a ribbon, and it could be shown that the rings in those ribbons can change their conformation thereby producing a reduction of the transverse dimension of the ribbon by 40%. The belt is composed of about seven ribbons, and conceivably a coordination of the conformational changes occurring in the ribbons could produce a travelling wave in the belt and concomitantly in the cell surface, which would propel the cell. Nothing is known yet about the biochemistry of the system, and not even the structural details are fully understood. However, the components of the apparatus have been seen also in other myxobacteria, including *Mx. xanthus.*

Gliding Motility

From the very beginning, investigators have been intrigued by the mechanism of gliding motility in the myxobacteria. There are numerous hypotheses, including contractile fibrils (Burchard et al., 1977), a travelling wave along a complex belt below the outer membrane of the cell (Lünsdorf and Reichenbach, 1989), and the polarized excretion of surfactant (Keller et al.,

1983), but none have been proven so far (for reviews, see Burchard, 1980, 1981, 1984). Genetic analysis of the motility system of *Mx. xanthus* has revealed a very complex situation involving at least 33 genes (Hodgkin and Kaiser, 1979a, 1979b; for review, see Shimkets, 1990b). Two almost completely separate motility systems exist. The A system (A for adventurous) controls the movements of individual, independent cells. It comprises 22 loci and may be related to the lipopolysaccharide (LPS; Gill and Dworkin, 1986, 1988). The S system (S for social), comprising 10 loci, controls the gliding movements of groups of cells. If the S system is to operate, the cells must not be farther apart than one cell length. They obviously have to be in contact with one another, and the contact is mediated by pili (Kaiser, 1979) and by strands of LPS (see below). The S system seems to be of central importance in all social activities of the myxobacteria, as in the coherence of the swarm colonies, in the rippling phenomenon, and in fruiting. Usually, a mutant is only nonmotile under all circumstances if it is A^-S^-. A single mutation in one further locus, *mgl*, has the same effect, so that *mgl* appears to be required in the A system as well as the S system. Another set of genes, the "*frizzy*" (*frz*) genes, determine the frequency with which the cells change the direction of their movements (Blackhart and Zusman, 1985). They were discovered because the colonies of Frz mutants differ substantially in size and organization from wild-type swarms, and the cells show an aberrant aggregation behavior. While wild-type cells may reverse their movements every 6 to 7 min, there are some Frz mutants that do so every 2 h or every 2 min. The genes and their gene products have been analyzed in considerable detail. Surprisingly, the Frz CD protein is 40% homologous with the Tar protein, which controls the direction of movement in *Salmonella typhimurium* (McBride et al., 1989). As in the enteric bacteria, *Mx. xanthus,* the direction of movement is controlled by methylation and demethylation reactions (McCleary et al., 1990).

The speed of gliding of myxobacterial cells varies, depending on the substrate and the temperature; typically, it is between 3 and 13 μm/min (*Mx. virescens,* 32°C, on peptone agar, measured in movie frames; Reichenbach, 1966). Gliding cells always deposit slime tracks (Fig. 5). When placed in a liquid such as water, the cells sometimes attach themselves to the glass with one pole and perform relatively fast gyrating movements.

While *Mx. xanthus* cells show directed movements towards latex beads and clumps of prey bacteria (Dworkin, 1983), it has not been possible to demonstrate a chemotactic response to any of a number of chemicals tested (Dworkin and Eide, 1983). Nevertheless, myxobacterial cells clearly have some sensory mechanism that enables them to move toward one another over a distance of at least 10 cell lengths. Gliding cells also respond to delicate structural disturbances in the substrate surface, such as are produced in agar plates by mechanical stress. This results in distorted swarms and unusual fruiting body patterns, a phenomenon which has been named elasticotaxis (Stanier, 1942b). This is interesting insofar as the movements of the cells in this case are not coordinated by intercellular communication but by an external factor, such as the structural pattern of the substrate surface, via a purely physical mechanism. The same mechanism may also play a major role in determining the behavior of cells in the swarm and during fruiting.

Occasionally, branched cells are seen in myxobacterial cultures; they can also translocate, albeit clumsily (Reichenbach, 1965a, 1966).

The nature of the outer surface of the myxobacterial cell is of interest, because it can be assumed that the organization of the surface may be directly involved in gliding motility as well as in certain types of intercellular communication. It seems that the appearance of the cell surface may change substantially with the preparation technique, the culture conditions, and, of course, also with different types of mutants. The underlying rules are only partly understood at the moment. In thin sections, the outer surface appears essentially smooth or, at the most, slightly wavy. The same is normally the case in freeze-etched preparations (Burchard and Brown, 1973). In negative contrast and in shadowed mounts, however, the surface often appears to be covered by short, vesicular blebs and long, irregular, seemingly tubular extensions, approximately 50 nm wide, which are probably protrusions of the lipopolysaccharide (LPS) layer (e.g., Arnold and Shimkets, 1988b; MacRae and McCurdy, 1975, 1976; Schmidt-Lorenz and Kühlwein, 1969). The excretion of this material can be prevented by adding the diazo dye Congo red (5 μg/ml, a concentration which does not interfere with growth) to the culture; as a consequence, *Mx. xanthus* cells are no longer able to agglutinate (Arnold and Shimkets, 1988a, 1988b). This also implies a loss of social (S) gliding and of fruiting. The Congo red-treated cells behave in all these respects like a class of A^+S^- mutants, the Dsp mutants, which indeed do not bind Congo red. It may thus be concluded that the major Congo red receptor is controlled by genes of the S sys-

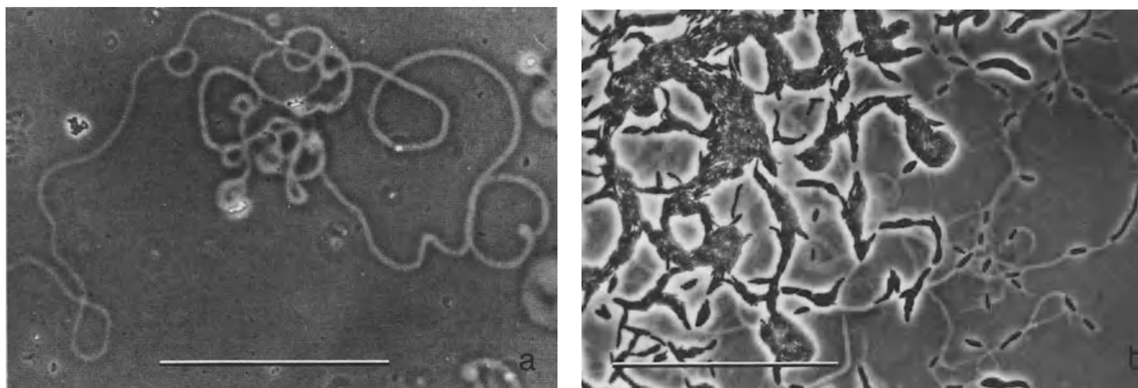

Fig. 5. Slime tracks as seen on thin agar layers in chamber cultures. (a) *Nannocystis exedens.* (b) *Myxococcus fulvus;* the spots seen on the left are cell clusters, not single cells. Bar = 100 μm. Phase contrast.

tem. If the Congo red is removed, wild-type cells begin to produce the tubular material again within 30 min, and their cohesiveness and all associated properties are restored.

Surface Structures

Scanning electron micrographs of mycobacteria often show a system of extracellular strands and fibers which may even form a dense network connecting the cells to each other and to their environment (Arnold and Shimkets, 1988b; Burnham et al., 1981; Lampky, 1976). Some of that material may be identical with the tubular LPS strands discussed above, but some may also be excreted slime. It seems that such networks can also be used by the myxobacteria to entrap prey organisms (Burnham et al., 1981).

Another type of appendage is the thin, polar fimbria, which is 5 to 8 nm wide and may exceed the length of a cell (Arnold and Shimkets, 1988b; Dobson and McCurdy, 1979; MacRae and McCurdy, 1975, 1976; MacRae et al., 1977). Fimbriae have been observed with many different species of both suborders; the only negative result was with *Nannocystis,* but this may have been due to technical problems. The fimbriae may be restricted to one of the two cell poles, and up to six have been seen per cell. In *Mx. xanthus,* two types of fimbriae were distinguishable, a rigid (R) and a flaccid (F) type (Dobson and McCurdy, 1979). The two could be separated and purified and turned out to be very similar in many respects (e.g., in the apparent molecular weight, which was about 7,750 Da; and in their amino acid composition). Only their dissociation behavior differed. The R type disintegrated into 2-nm microfibrils at pH 3.5 to 4.5. Both species of fimbriae agglutinated guinea pig erythrocytes. The F type may be the contracted form of the R type.

Tiny holes in the outer membrane, 6.5 to 8.5 nm wide and surrounded by a collar of 2.6 nm, which sometimes shows a ring of 12 spikes, have been proposed to be the insertion sites of the fimbriae (MacRae et al., 1977). As fimbriae could not be demonstrated on nonmotile mutants (MacRae and McCurdy, 1976), and, in particular, not on mutants lacking S motility (Kaiser, 1979), it has been suggested that the fimbriae may be involved in social motility. In *Mx. xanthus,* four genetic loci (*sglA, sglB, sglG,* and *tgl*) seem to control fimbriation. If *tgl*$^-$ cells come in contact with *tgl*$^+$ cells, their S gliding is restored (Kaiser, 1979). But as pointed out above, S motility is also correlated with the presence of the LPS-containing fibrils. Thus, the cell-cell interactions required for social motility may require the participation of both the fimbriae and the fibrils.

Chemical Composition

Much has been learned in the last decade about the chemical composition of the myxobacterial cell. However, the precise nature of the extracellular polysaccharides characteristically excreted by the myxobacteria remains undetermined, as it is usually accompanied by a variety of other large and small excreted molecules (Sudo and Dworkin, 1972; Hanson and Dworkin, 1974). The excreted slime appears usually to be a heteropolysaccharide containing, among others, *N*-acetyl aminosugars (Sutherland, 1979; Sutherland and Thomson, 1975). Slime from fruiting bodies resembles in its overall composition that produced in vegetative cultures. A large extracellular protein-polysaccharide-lipid complex with proteolytic activity has been isolated from culture supernatants of *Mx. virescens* (Gnosspelius, 1978b). A glycopeptide with a heat-stable blood anticoagulant activity,

named myxaline, has been obtained from the culture broth of *Mx. xanthus* (El Akoum et al., 1987; Masson and Guespin-Michel, 1988). The glycan part contains *N*-acetyl aminosugars, and the peptide is rich in glutamic acid and serine. The excreted slime must be chemically different in the two suborders of myxobacteria, since Congo red (0.01% aqueous solution) stains the slime of the Cystobacterineae, but not that of the Sorangineae (McCurdy, 1969a).

LIPOPOLYSACCHARIDES AND CELL WALLS. There are several studies on the chemistry of the lipopolysaccharides (LPS) of various myxobacteria (Rosenfelder et al., 1974; Sutherland, 1979; Sutherland and Thomson, 1975; Weckesser et al., 1971). Contrary to the statement of Ruiz et al., (1987), myxobacterial LPS, including lipid A, can be readily and completely extracted from the cells by the usual phenol procedure (e.g., Panasenko, 1985; Rosenfelder et al., 1974; Sutherland and Smith, 1973; Sutherland and Thomson, 1975). Typical LPS yields are 0.5 to 1.0% (up to 1.9%) of the cell dry weight. Chemically, the LPS of the myxobacteria resembles that of the enterobacteria. The LPS of *Mx. fulvus* contains mannose, galactose, glucose, rhamnose, arabinose, glucosamine, and 3-O-methyl-D-xylose, a sugar only very rarely seen in bacterial LPS (Rosenfelder et al., 1974; Weckesser et al., 1971). The LPS of other myxobacteria may differ somewhat in its sugar composition, but 2-keto-3-deoxyoctonic acid is always present, and heptose is never present. The 3-O-methyl-D-xylose may or may not be found, and, in some cases, similar nonpolar but thus far unidentified sugars have been observed (Sutherland, 1979; Sutherland and Smith, 1973; Sutherland and Thomson, 1975). While the scant data do not really allow generalizations, a complete lack of rhamnose seems to be characteristic for *Sorangium* and may be another distinguishing characteristic of that suborder. The lipid A moiety contains glucosamine and the usual 3-hydroxy fatty acids, mostly iso-3-OH-C_{15} and iso-3-OH-C_{17} (Rosenfelder et al., 1974). During sporulation of *Mx. xanthus,* the LPS, or at least its polysaccharide part, is completely lost (Sutherland, 1976b), and a capsule composed of an α-1,3-glucan is produced (Sutherland and Mackenzie, 1977). That capsule is ruptured and discarded during germination rather than enzymatically solubilized (Voelz, 1966a). Monoclonal antibodies have also been obtained against O-antigens and against a core antigen of *Mx. xanthus* LPS (Fink and Zissler, 1989a; Gill and Dworkin, 1988). Several O-antigen mutants were defective in the A system but not in the S system of gliding. They were still able to form normal fruiting bodies (Fink and Zissler, 1989b). Endotoxinlike effects (anticomplement test and Shwartzman skin reaction) could be produced with whole cells and myxospores of *Mx. xanthus* (Ruiz et al., 1987).

Mx. xanthus, the only myxobacterium for which the organization of the cell wall has been investigated, has a thin peptidoglycan layer that seems to be organized in patches rather than in a homogeneous sacculus (White et al., 1968). The composition of the peptidoglycan resembles that of *E. coli,* with diaminopimelic acid at the cross-links. It appears that during sporulation, the degree of cross-linking increases. At the same time, galactosamine and glycine accumulate in the wall layer. The pepotidoglycan content of vegetative cells and myxospores is, however, the same (0.6% of the dry weight).

LIPIDS. The fatty acid spectra of the myxobacteria show characteristic differences between the two suborders (Fautz et al., 1981). While all myxobacteria contain iso-branched fatty acids in substantial quantities, mainly saturated $C_{15:0}$ and $C_{17:0}$, the pattern is dominated by them only in the Cystobacterineae (usually between 50 and 70%) (Fautz et al., 1979, 1981; Schröder and Reichenbach, 1970; Ware and Dworkin, 1973; Yamanaka et al., 1988). *Na. exedens* (suborder Sorangineae) is the only myxobacterium so far in which larger amounts (about 30%) of iso-$C_{15:1}$ and iso-$C_{17:1}$ are found.

Even more characteristic is the distribution of hydroxy fatty acids. Although it was overlooked in the earlier studies, a 2-hydroxy (OH) fatty acid iso-2-OH $C_{17:0}$, was first seen as a contaminant from phospholipid in LPS preparations of *Mx. fulvus* and *Cb. ferrugineus* (Rosenfelder et al., 1974). The LPS contains 3-OH fatty acids, exclusively. Later, proof was presented for the chemical structure of the 2- and 3-OH fatty acids of *Mx. fulvus* and *C. ferrugineus,* and it was demonstrated that, in total cell hydrolysates, 2-OH fatty acids, mainly iso-2-OH $C_{17:0}$, constitute a respectable share of the total fatty acids (10 to 12%), while 3-OH fatty acids only play a minor role (2.5 to 4.5%: Fautz et al., 1979; later analyses of Yamanaka et al., 1988, give somewhat lower values of 1 to 10% for 2-OH, and 0.2 to 0.3% for 3-OH). In members of the Sorangineae, no hydroxy fatty acids are seen at all in total cell hydrolysates (Fautz et al., 1981). In members of the Cystobacterineae, two types of phosphatidylethanolamine have been demonstrated, one of which contains exclusively nonhydroxy fatty acids; the other, however, contains 50 to 70% 2-OH fatty acids (Yamanaka et al., 1988). Another major component of the fatty acid pattern of the Cystobacterineae is the

$C_{16:1}$ fatty acid (15 to 39%). This component, too, seems much reduced in the Sorangineae. While all investigators found only iso-branched fatty acids in myxobacteria, one laboratory did report anteiso fatty acids in *Mx. xanthus* (Ruiz et al., 1985). In another study, a clear difference was seen between the fatty acid patterns of *Corallococcus* and those of *Myxococcus* species (Monteoliva-Sanchez et al., 1987): branched and unbranched $C_{17:0}$ fatty acids were present in large quantities in the latter (27 to 38%) but completely absent in the former. While such a clear difference would be useful for taxonomic reasons, it is highly unlikely and is not supported by other investigations (Yamanaka et al., 1988).

The earliest analysis of the phospholipid pattern of a myxobacterium, that of *Mx. fulvus* Mx f2, demonstrated phosphatidylethanolamine as the main component (72%), but phosphatidylglycerol (9%), phosphatidylinositol (7%), and an unknown, ninhydrin-positive phospholipid (8%) were also present (Kleinig, 1972). A small proportion of the phospholipids were alk-I-enyl-acyl (1–15%) and alkyl-acyl compounds; however, they comprised 22% of the phosphatidylinositol compounds. The phospholipid content of the isolated membranes was 25% (dry weight). The occurrence of two species of phosphatidylethanolamine in myxobacteria has already been mentioned (Yamanaka et al., 1988). In another study concerning the membrane composition of *Mx. xanthus,* the inner and outer membranes could be separated (Orndorff and Dworkin, 1980). The outer membrane showed an unusually low buoyant density (1.221 g/ml) which was probably due to an exceptionally high phospholipid content. The main phospholipid in both membranes was phosphatidylethanolamine (60 to 70% of total phospholipid). The other major phospholipids were phosphatidylglycerol and two unknown phospholipids. Phosphatidylserine and cardiolipin were found only in the cytoplasmic membrane. Substantial amounts of lysophospholipids were found in both membranes, although somewhat more in the outer membrane. They obviously indicate lipase activities, which here seem not to be restricted to the outer membrane.

In *Sg. aurantiaca,* too, the main phospholipid was phosphatidylethanolamine (50%), followed by phosphatidylglycerol (12%), and phosphatidylinositol (20%) (Caillon et al., 1983). Very high amounts of lysophosphatidylethanolamine were also found. Each phospholipid had a different fatty acid composition. Alkyl ether linkages were common; phosphatidylinositol occurred only as the dialkyl compound. The structural details of an alk-I-enzyl-acyl-phosphatidylethanolamine, i.e., a plasmalogen, from *Mx. stipitatus* have recently been elucidated (Stein and Budzikiewicz, 1987).

From the amount of phosphorus in the lipid fraction of *Sg., aurantiaca* it has been estimated that only about 40% of the fatty acids are bound in phospholipids (Schröder and Reichenbach, 1970), and, in fact, several nonphospholipids with fatty acids on them have been identified. Ceramides and cerebrosides have been isolated from *Cystobacter fuscus* and chemically characterized (Eckau et al., 1984; Dill et al., 1985). Ceramides are long-chain, 1,3-dihydroxy-2-amino bases (sphinganine) with an amide-bound fatty acid. Cerebrosides are sphingolipids consisting of a ceramide with a C-1-bound sugar. The compounds are common in eukaryotes and, interestingly, they play a role in cell-cell recognition and cell adhesion and also have been found to be fruiting-body inducers in basidiomycetes. Perhaps they play similar roles in myxobacteria. The myxobacterial ceramides all contain 2-hydroxy fatty acids. Also, a novel, long-chain base, 17-methylsphinga-4E,8E-dienine, was found in two of them. The cerebrosides are all galactosides.

The capnoids discovered as a characteristic constituent of the lipids of another group of gliding bacteria, the cytophagas, have not been found in myxobacteria (Godchaux and Leadbetter, 1983). The capnoids are C-1 sulfonic acids of sphinganine bases and their ceramides.

Pigments and Respiratory Components

Carotenoids are the main pigments of most myxobacteria. With the exception of *Na. exedens,* the main compounds are always monocyclic carotenoid glycosides, usually containing glucose, with a fatty acid attached to the sugar via an ester bond (Kleinig et al., 1970, 1971; Reichenbach and Kleinig, 1971). Pigments of this type are rather unusual, but they have been found, for example, in *Nocardia kirovani* (Bacheron et al., 1970). The structure of myxobacton, which is the main pigment of many myxobacteria including *Mx. xanthus,* has been reinvestigated and corroborated (Eckau et al., 1984). It appears that certain pigment types are characteristic for taxonomic subgroups (for a review, see Reichenbach and Kleinig, 1984). *Nannocystis* contains aromatic carotenoids but no glycosides. Members of the suborder Sorangineae produce glucosides with hydroxyl but not with keto functions on the chromophore, and the Cystobacterineae have glucosides with keto but not with hydroxyl functions. In all cases, complex mixtures of carotenoids are found, but only

monocyclic and acyclic compounds occur. The carotenoid content of exponentially growing, late log-phase cultures of *Mx. fulvus* Mx f2 has been determined. Acetone extracts typically represent 0.03% of the dry weight of dark-grown cells and 0.03–0.06% of the dry weight of light-grown cells (Reichenbach and Kleinig, 1971). The carotenoids are located in the (cytoplasmic) membrane, and their concentration there is consequently much higher (0.14% in a membrane preparation of *Mx. fulvus* containing both membranes; Kleinig, 1972). The carotenoid synthesis of myxobacteria is induced by light (Burchard and Dworkin, 1966; Burchard and Hendricks, 1969; Reichenbach and Kleinig, 1971). The genetics of light-induced carotenogenesis has been studied in *Mx. xanthus* and has been found to comprise various control mechanisms. Also, a light-induced promoter has been identified and cloned (e.g., Balsalobre et al., 1987; Martinez-Laborda et al., 1990). The only demonstrated role of carotenoids in myxobacteria is to provide protection against photooxidation (Burchard and Dworkin, 1966a). This has also been demonstrated with carotenoid-free mutants of *Mx. fulvus* Mx f2. The killing effect is seen only if the mutants are illuminated with daylight intensities (about 40,000 lux; H. Reichenbach, unpublished observations). In *Mx. xanthus,* protoporphyrin IX has been found to be a photosensitizer (Burchard and Dworkin, 1966a). Dark-grown cultures, which produce only small amounts of carotenoid, lyse quickly if illuminated. It is not clear, however, that all myxobacteria accumulate protoporphyrin IX as a photosensitizer; it could not be detected, for example, in *Mx. fulvus.* The effect of various inhibitors on the cyclization reaction of carotenoid synthesis has also been studied (Kleinig, 1974, 1975; Reichenbach and Kleinig, 1971). In normally growing laboratory cultures, there is virtually no turnover or degradation of carotenoids. A system for the in vitro synthesis of C_{15} to C_{60} polyprenols from isopentenylpyrophosphate with a crude enzyme preparation from *Mx. fulvus* has been developed (Beyer and Kleinig, 1985).

Pigments other than carotenoids are also produced by myxobacteria. A fluorescent, pale-yellow pigment is characteristic for *Mx. stipitatus* (Lampky and Brockman, 1977) and similar pigments are also found in *Mx. xanthus* (Gerth et al., 1983). On certain media, the colonies of *Cb. violaceus* (= *Ar. violaceum*) develop a deep purple-violet color, probably due to melanoid pigments (Kühlwein and Gallwitz, 1958; Reichenbach, 1965a). Melanoid pigments are also relatively often seen with individual strains of many other species, especially on peptone-containing media, e.g., with *Cystobacter, Archangium, Corallococcus,* and *Stigmatella.* Liquid cultures of *Sg. aurantiaca* in peptone medium turn a deep black color within 1 to 2 h after reaching the stationary phase (Reichenbach and Dworkin, 1969). The slimy swarms of some strains of *So. cellulosum* on CA2 agar become deep violet to black after 2 to 4 weeks. *Mx. virescens* and *Pl. vitellinum* are bright greenish-yellow, especially on protein-containing media. Often the various shades observed with different strains and species are only due to differences in the quantitative proportions of the same pigments. Fruiting bodies, and especially the walls of the sporangioles, are often very intensely colored, but the chemical nature of these pigments is not known.

The respiratory quinones of the myxobacteria are exclusively menaquinones (Kleinig, 1972; Kleinig et al., 1974). A survey of 11 genera and 20 species of both suborders showed that the menaquinone pattern of the myxobacteria is completely uniform and comprises virtually only MK-8 (M.D. Collins, personal commuinication). *Nannocystis* contains substantial quantities of squalene (0.4%) and steroids (0.4% of the dry weight), mainly 3-OH-cholest-8(9)-en-3β-ol (Fig. 6; Kohl et al., 1983). Because these compounds are synthesized de novo, *Nannocystis* is one of the very few prokaryotes that are known to be able to synthesize steroids.

Membranes and Membrane Proteins

A few interesting proteins that have been isolated and characterized from myxobacteria will be briefly mentioned. Most of these are surface proteins that seem somehow to be involved in cell-cell contacts and morphogenetic events.

The membranes of *Mx. fulvus* consist of about 64% protein and 29% lipid, the latter comprising mainly (25%) phospholipid (Kleinig, 1972). About 40 polypeptides could be resolved in membrane extracts of *Mx. xanthus* (Orndorff and Dworkin, 1980). Of those, about 26 were enriched in the cytoplasmic membrane fraction, and 8 to 10 major proteins were found

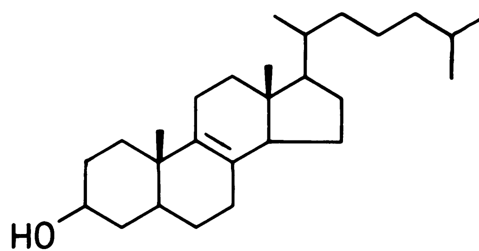

Fig. 6. The sterol 3-OH-cholest-8(9)-en-3β-ol, which is synthesized by *Nannocystis exedens.*

in the outer membrane fraction. None of the latter were, however, identical to the 32-kDa and 44-kDa proteins that are the principal proteins of the outer membrane of *Escherichia coli.* Many membrane and soluble proteins change in amount and rate of synthesis during fruiting. Six of the membrane polypeptides changed substantially during aggregation (Orndorff and Dworkin, 1982): during the early stages of fruiting, protein T disappeared from the soluble fraction of *Mx. xanthus,* when proteins S and U first appeared and then increased dramatically. Protein S (Inouye et al., 1979a) has been particularly well studied. In vegetative cells it amounts to less than 1% of the soluble protein, but during fruiting body formation, its rate of synthesis rises to 15% of total protein synthesis. In the presence of Ca^{2+}, protein S assembles on the surface of the maturing myxospores (Inouye et al., 1979b). Certain domains in the amino acid sequence of protein S show homologies to the Ca^{2+}-binding sites of calmodulin. The functional correspondence of those areas was demonstrated by site-specific mutations, which eliminated the Ca-binding property of protein S together with its ability to accumulate on the myxospores. Protein S also has some homology with the bovine-lens protein, α-crystallin (Inouye et al., 1983a; Teintze et al., 1988; Wistow, 1990). Protein S is coded by two tandem genes which closely follow one another and show an 88% amino acid homology. It appears that the protein species synthesized during fruiting comes exclusively from (downstream) gene 2 (Inouye et al., 1983a, 1983b).

Another development-specific protein is a myxobacterial hemagglutinin, a lectin that is induced during the developmental aggregation of *Mx. xanthus* (Cumsky and Zusman, 1981). It appears to be localized in the periplasmic space or loosely bound to the cell surface and to recognize a galactose-containing, complex receptor. Its distribution over the cell surface is uneven, as it is found in patches mainly at the cell poles (Nelson et al., 1981). The 28-Da protein contains four highly conserved domains of 67 amino acids each, which are reflected in four strong internal homologies in its gene (Romeo et al., 1986).

Several nucleotide-binding proteins have been described. They are of great interest because they could be involved in signal transduction, e.g., during development. In the soluble-protein fraction of sporulating *Mx. xanthus,* a single protein has been discovered that specifically binds cyclic AMP (cAMP). The binding capacity did not change during myxospore development (Orlowski, 1980). Vegetative cells of *Mx. xanthus* contain a cyclic GMP- (cGMP-) and a cAMP-binding protein in the periplasm, and a second cAMP-binding protein in the cytoplasm. The latter appears to be identical with the cAMP-binding protein mentioned above. All three activities varied substantially during aggregation (Devi and McCurdy, 1984a). In the membrane fraction of *Sg. aurantiaca,* a single, GTP- and GDP-binding protein was identified. Proteins of this kind are very common in eukaryotes, but have only rarely been found in prokaryotes. It was suggested that the protein plays a role in the phosphoinositide metabolism of *Stigmatella* (Dérijard et al., 1989).

Using an iodination technique, substantial changes in the pattern of accessible surface proteins of *Mx. xanthus* were shown to take place during development (Maeba, 1983). A glycoprotein, probably a peripheral membrane protein that is present only in vegetative cells, was further characterized (Maeba, 1986). The 74-Da protein contained about 15% carbohydrate, mainly neutral sugars, but also some hexosamines and uronic acids. It made up 1% of the total cell protein and might play a role in cell-cell interactions.

A different approach to the study of the dynamics of the cell surface during development has been the use of monoclonal antibodies against cell-surface antigens (CSAs) of vegetative and developing cells (Gill et al., 1985). In this way, many different CSAs of *Mx. xanthus* have been identified (e.g., Gill and Dworkin, 1986, 1988). While most of the antibodies are directed against cell-surface proteins, some are directed against LPS or, in the case of CSA 1604, against a large, 150-Da complex consisting of at least two protein subunits and LPS (Jarvis and Dworkin, 1989a, 1989b). CSA 1604 is of special interest, because antibodies directed against it block certain stages in the fruiting body development of *Mx. xanthus.* Other monoclonal antibodies are directed against cell-surface proteins that appear uniquely during development (Gill and Dworkin, 1986).

Some proteins have been identified by transfer and expression of myxobacterial genes in *E. coli.* An 18.7-Da, basic protein coded by the *vegA* gene of *Mx. xanthus* turned out to have amino acid homologies with certain histones and may function as a DNA-binding protein. It is essential for vegetative growth (Komano et al., 1987). Also, the *Mx. xanthus* gene *fprA* was shown to code for a protein that binds flavin mononucleotide. This protein, too, is essential for growth. Overexpression of the gene in *E. coli* leads to a spectacular increase in flavin biosynthesis, but the FprA protein seems not be an enzyme in the biosynthetic pathway (Shimkets, 1990a).

The product of the *csgA* gene of *Mx. xanthus,* C factor, which is required for several steps during fruiting body development, was recovered from developing fruiting bodies and characterized (Kim and Kaiser, 1990). The 17-Da protein restores the developmental capacities of *csgA* mutants, acts in a very low and narrow concentration range (1 to 2 $\times$ 10^{-9} M), and appears to represent a signal factor.

Nucleic Acids

The GC content of myxobacterial DNA is between 67 and 72 mol% (as measured by buoyant density and thermal melting, respectively). The GC content appears to be slightly higher (70 to 72 mol%) in the Sorangineae than in the Cystobacterineae (67 to 70 mol%) (Behrens et al., 1976; Mandel and Leadbetter, 1965; McCurdy and Wolf, 1967). The GC content may vary considerably between different DNA segments in the genome; in *Mx. xanthus,* for example, it varies from 36 to more than 80 mol% (Komano et al., 1987).

Repeated efforts have been made to determine the genome size of *Mx. xanthus,* applying widely differing techniques, including cloning of the entire *Mx. xanthus* genome into 141 artificial yeast chromosomes (YACs) (Kuspa et al., 1989; Yee and Inouye, 1981, 1982; Zusman et al., 1978). The most reliable estimate of 9,450 kilobase pairs (kbp) comes from a recent construction of complete physical genome maps of several independent *Mx. xanthus* strains (Chen et al., 1990). The *Myxococcus* genome is thus approximately the same size as the *Streptomyces* genome, and it is twice as large (4,700 kbp) as that of *E. coli.* The genome of *Sg. aurantiaca* appears to be nearly the same size as the *Myxococcus* genome (Yee and Inouye, 1981). It has been reported that exponentially growing cells of *Mx. xanthus* contain just one replicating chromosome with 1.5 genome equivalents (Zusman et al., 1978). The amount of DNA in a freshly divided cell was estimated to be 14 $\times$ 10^{-9} μg, while a logarithmically growing cell contains 20 $\times$ 10^{-9} μg.

The DNA of *Mx. xanthus* strain FB has been found to be methylated at cytosine sites (Yee and Inouye, 1982). In rapidly growing cells, the DNA is undermethylated, and the degree of methylation increases when growth slows. A vegetative promoter and two development-specific promoters have also been characterized (Komano et al., 1987; Inouye, S., 1984).

Mx. xanthus RNA polymerase shows the usual $\alpha\beta\beta'$ subunits composition, but two slightly different sigma factors have been obtained from vegetative cells (Rudd and Zusman, 1982). Gene *rpoD* for a major vegetative sigma factor from *Mx. xanthus* has been characterized (Inouye, S., 1990). It probably corresponds to the previously described protein, sigma I (see above) and consists of 708 amino acids (80,391 Da). The amino acid sequence derived from the base sequence is in excellent agreement with that of *E. coli* sigma-70, but the *Myxococcus* sigma has an additional 100 residues at the amino end. The last 242 amino acids at the carboxy end show 78% and 72% homology with *E. coli* sigma-70 and *Bacillus subtilis* sigma-43, respectively. *Myxococcus* sigma-80 contains an extremely high proportion (40%) of charged amino acids. The polypeptide corresponding to *rpoD* has also been identified. It showed a somewhat higher apparent molecular weight (86 kDa), and there was evidence of a second sigma factor—apparent molecular weight 80 kDa, calculated from the putative gene (73,117 Da). Gene *rpoD* was used as a probe to find other genes for sigma factors in the *Myxococcus* genome, and a developmental sigma factor has thereby been discovered.

A most unusual kind of nucleic acid, msDNA, which was first discovered in *Mx. xanthus,* has raised many intriguing questions (Yee et al., 1984). msDNA has been found in almost all myxobacteria investigated (Dhundale et al., 1985). It is a single-stranded DNA and is present at 500 to 700 copies per genome. The DNA is 162 bases long, and its 5′-end is linked via a 5,′ 2′-phosphodiester bond with a guanidine residue in a branched RNA, msdRNA, which is 77 bases long and comes from a much longer precursor. The RNA has an extremely stable stem-and-loop structure. The coding regions for msDNA and msdRNA are found side by side at one specific site in the *Myxococcus* genome but they are oriented in opposite directions and overlap with 8 bases at their 3′-ends (Dhundale et al., 1987). A very similar msDNA (81% sequence homology) with a corresponding genome structure has been found in *Sg. aurantiaca* (Furuichi et al., 1987a, 1987b). A second species of such DNA, mrDNA, was later discovered in *Mx. xanthus* (Dhundale et al., 1988b). mrDNA is, however, much shorter, and it has a completely different base sequence in the DNA as well as in the RNA, but the RNA still has a similar secondary structure to that of msRNA. Also, there seem to be only 100 copies of mrDNA per genome.

The msDNA is synthesized by a reverse transcriptase with an associated ribonuclease H activity. The enzyme uses a folded RNA precursor as a primer and a template (Lampson et al., 1989). The gene of the reverse transcriptase has been found immediately downstream from the

msdRNA region and codes for 485 amino acids, which show sequence homology with retroviral reverse transcriptases (Inouye, S., et al., 1989). In fact, *Mx. xanthus* actually contains two reverse transcriptases (Inouye, S., et al., 1990). The wide distribution of msDNA in myxobacteria, as well as a comparison of codon usage in the reverse transcriptase gene and in other *Myxococcus* genes, suggests that the system is very old and was not acquired recently (in contrast to a similar system in certain *E. coli* strains). By deletion mutation, msDNA synthesis could be eliminated, but this had no significant effects on growth, motility, and morphogenesis compared to the wild-type strain (Dhundale et al., 1988a).

No evidence has been found for the presence of a poly(dT-dG)·poly(dC-dA) (TG) element in *Mx. xanthus* (Morris et al., 1986).

While the half-life of mRNA is about 3.5 min in vegetative cells of *Mx. xanthus,* 5 to 10 species of mRNA with a much longer half-life (20 to 30 min) could be demonstrated during fruiting body formation (Nelson and Zusman, 1983). One of the long-lived mRNAs is for protein S. The stable mRNA can amount up to 30 to 40% of the total mRNA.

Although no clear evidence has been presented for free, self-replicating plasmids in myxobacteria, several early reports suggest that extrachromosomal DNA may be present. Thus, after induction of chloramphenicol resistance in *Mx. xanthus* RB, a burst of synthesis of circular, covalently linked, extrachromosomal DNA was observed (Brown and Parish, 1976). The resistance was due to chloramphenicol acetylation (Burchard and Parish, 1975). Also, it was possible to transfer resistance to several different antibiotics from R factor-containing strains of *E. coli* to several *Myxococcus* species by conjugation (Parish, 1975). In some cases, extrachromosomal DNA could be demonstrated in the resistant *Myxococcus* strains, and the resistance could be transferred to other *Myxococcus* strains by conjugation.

It is now possible to introduce foreign plasmids into myxobacteria, usually via *E. coli* phage P1 as a suicide vector (Kaiser and Dworkin, 1975; Kuner and Kaiser, 1981; Morris et al., 1978), or by direct conjugation with *E. coli* (Parish, 1975; Breton et al., 1985). The plasmids often survive in the myxobacterial cells but seem always to be integrated in the genome. The genetic information contained in such plasmids is often expressed. A particularly useful approach is the random insertion of Tn*5 lac* segments into the genome of *Mx. xanthus,* which may be turned on by external promoters (Kroos and Kaiser, 1984). In this way, promoters could be identified that became active at certain stages of the developmental program (Kroos et al., 1986). Also, site-specific insertion of external plasmids has been possible, e.g., by incorporating into the plasmid, the *attP* attachment site of lysogenic phage MX-8 (Orndorff et al., 1983), which recognizes only one site, *attB,* in the *Mx. xanthus* genome. Thus, the plasmid is integrated only once and at one specific site (Li and Shimkets, 1988). A useful strategy to increase the integration of plasmids is to insert pieces of the myxobacterial genome into the plasmid (Jaoua et al., 1987). For a survey of the vast literature on myxobacterial genetics, the reader is referred to review articles on this topic (Kaiser et al., 1979; Kaiser, 1984a, 1986, 1989; Shimkets, 1990b).

Phages and Bacteriocines

There are some problems with the isolation of phages for myxobacteria, perhaps because wild strains are usually lysogenic and therefore restrictive. In fact, when the ultracentrifugal pellets of culture supernatants were examined under the electron microscope, all six strains of *Mx. xanthus, Mx. virescens,* and *Mx. fulvus* produced small quantities of phage particles (Brown et al., 1976a). Restriction of phage MX-1 has been shown directly with a strain of *Mx. virescens* (Morris and Parish, 1976). The strain became fully sensitive after curing by UV irradiation. Also, two restriction endonucleases have been demonstrated in the restrictive strain. Such enzymes have been found in many different myxobacteria (Mayer and Reichenbach, 1978). Furthermore, defective phage particles, originally described as rhapidosomes (Reichenbach, 1965b), have been seen in several myxobacteria (Brown et al., 1976a; McCurdy and McRae, 1974; Reichenbach, 1967). Nevertheless, infective phages have been isolated from soil and dung of various animals; these are most likely virulent mutants of temperate phages (Brown et al., 1976a). The first myxobacterial phage to be isolated was MX-1 of *Mx. xanthus* (Burchard and Dworkin, 1966), which has been extensively studied (Brown et al., 1976a, 1976b; Burchard and Voelz, 1972; Tsopanakis and Parish, 1976; Voelz and Burchard, 1971). Like all myxobacterial phages known so far, it is a DNA phage with a genome size of 130 to 150 $\times 10^6$ Da and a GC content of 56 mol% (using buoyant density, a reinvestigation with a chemical method gave 50 to 52 mol%; Brown et al., 1976b). The phage particle has an icosahedral head and a tail with a contractile sheath. MX-1 is a lytic phage with a host range restricted to *Mx. xanthus.* Several more *Mx. xanthus* phages

have been isolated (Brown et al., 1976a; Campos et al., 1978; Geisselsoder et al., 1978; Martin et al., 1978) which often resembled MX-1, but other morphological types with very short tails have also been obtained. A strategy was applied to isolate transducing phages from a collection of *Mx. xanthus* strains using certain sensitive strains as indicators, such as strain FB, which is probably a phage-free and nonrestrictive strain (Morris and Parish, 1976). In this way, several useful transducing phages have been found (Martin et al., 1978), such as MX-8, which has been particularly well characterized (e.g., Orndorff et al., 1983; Stellwag et al., 1985). MX-8 is a generalized transducing phage with a linear, double-stranded DNA (56 kbp). The genome has a terminal redundancy of 8% and is circularly permuted over at least 40% of its length. MX-8 can start a lysogenic cycle in *Mx. xanthus* strains, and its prophage is integrated into the bacterial genome by a site-specific recombination between the *attB* and *attP* sites already mentioned. Another well-studied transducing phage with similar morphology is MX-4 (Campos et al., 1978; Geisselsoder et al., 1978).

During the search for myxobacterial phages, bacteriocinlike activities have also been discovered. In one case, two antibacterial activities have been described, but one was directed against the homologous producer strain, and the other against the totally unrelated genera *Salmonella* and *Cytophaga*; thus, neither conforms to the definition of a bacteriocin (Brown et al., 1976a). In another case, an activity termed xanthacin was obtained from *Mx. xanthus* FB. The enriched preparation inhibited *Cystobacter* and *Melittangium,* but not *Mx. xanthus* or any other *Myxococcus* strains, which again seems not to fit the explicit definition of a bacteriocin (McCurdy and MacRae, 1973). Xanthacin appeared to be a particulate membrane fraction. True bacteriocins were, however, discovered in *Mx. fulvus* strain Mx f16 (Hirsch, 1977). The strain produced three bacteriocins, which could be precipitated from the culture supernatant with $(NH_4)_2SO_4$. They were not inducible by mitomycin. One of them, fulvocin C, was further characterized. As expected for a bacteriocin, it only essentially inhibited *Mx. fulvus* strains (all 16 strains tested), the producer excluded. The chemical structure of fulvocin has been fully elucidated, and it was the first bacteriocin for which this could be achieved (Tsai and Hirsch, 1981). It is a very compact and stable protein (4672 Da, 45 amino acids) with four disulfide bridges. In sensitive strains, fulvocin C leads to a fusion of the outer membranes of adjacent cells. The minimal inhibitory concentration is 0.25 μM.

Myxobacterial Colonies

On media with a relatively low nutrient content, like VY/2 and CY agar, colonies of myxobacteria spread over the agar surface. Such colonies are called swarms. The swarm does not behave like a pseudoplasmodium, as has sometimes been stated in the older literature; that is, the colony does not move as a whole, but simply increases in diameter due to gliding motility and cell division. An exception are the tiny swarmlets that emerge from germinating *Chondromyces* sporangioles, which have already been described in connection with chemotaxis. Also, as discussed earlier, there are obviously mechanisms that keep the cells together.

The appearance of a swarm is a particular function of the species and the medium. On rich media, such as those with a high peptone content (around 1%), myxobacterial colonies may remain small and more or less compact; sometimes they are even circular, convex, and with an entire edge like ordinary bacterial colonies. The typical myxobacterial colony is, however, a swarm sheet consisting of cells and excreted slime; much of the latter is probably composed of interwoven slime trails. The swarms often contain conspicuous veins, rings, and ridges, or even depressions in the agar surface. Such patterns can be very characteristic for specific taxonomic groups (see below). The swarm sheet can sometimes be loosened from the agar surface with water (e.g., for *Cystobacter* and *Stigmatella*); sometimes, however, it sticks tenaciously to the agar surface, occasionally to such an extent that the agar is torn into pieces when the aging swarm sheet contracts (especially for *Sorangium*). In some cases, the swarm sheet becomes so tough and leathery, or rubberlike, that it is very difficult to cut with the inoculating loop (for *Archangium, Cystobacter,* and *Melittangium*); in other cases, it is soft and slimy and can easily be scraped off the plate (for *Myxococcus*). Often the myxobacteria penetrate the agar (even 1.5% agar), and the swarm spreads below the agar surface, sometimes penetrating to the very bottom of the dish (often for *Polyangium*). In such cases, the swarm may completely disappear below the surface, and its former position can be recognized only by a shallow depression. All members of the Sorangineae tend to grow within the agar. However, some members of the Cystobacterineae also do so, although here it is often a consequence of swarm degeneration. Some myxobacteria corrode the agar surface to the extent that they

produce long tunnels or large, cavernlike holes in the plate. This is typical of *Polyangium* and especially of *Nannocystis.*

The swarm edge usually shows characteristic flamelike protrusions, or flares. Sometimes wide, tonguelike depressions are produced (by *Chondromyces* and other members of the Sorangineae), or isolated narrow trenches radiate from the swarm center far into the surrounding agar surface (*Polyangium, Nannocystis*). Occasionally, massive ridges are also seen at the swarm edge (*Chondromyces, Polyangium, Cystobacter*). At such a swarm edge, the swarm may consist of only one cell layer, but as a rule the swarm sheet is composed of many layers on top of one another that quickly pile up behind the margin. When growing on very lean media, most of the swarm may be only one cell thick, although even then the bacteria tend to concentrate themselves in certain areas, such as along radial tracks. In large swarms, most of the cell population may be found in the outer regions, and if no fruiting bodies or myxospores have been produced, the interior may be completely deserted. The speed of the advancing edge is in the range of 1 mm in 9 h (*Cb. violaceus* at 22°C; Reichenbach, 1965) to about 1 mm in 1.6 h (*Cystobacter* and *Stigmatella* strains at 30°C).

Various taxa may be recognized by their swarm morphology. When plate cultures are flooded with an aqueous 0.01% Congo red solution for 5 to 10 min, the swarm sheets of the Cystobacterineae stain a deep violet-red, while those of the Sorangineae remain unstained (McCurdy, 1969a). The swarms of *Myxococcus, Corallococcus,* and *Angiococcus* typically develop meandering radial veins, which may be particularly conspicuous on CY agar; the swarm sheet usually remains soft and slimy. In contrast, long, more or less straight, branching veins are seen in the swarms of *Cystobacter, Archangium, Melittangium,* and *Stigmatella*; the sheet is usually tough. On VY/2 agar, the swarms of most Sorangineae are sunk into the agar and appear as wide shallow depressions at the surface. *Chondromyces* and *Sorangium* often develop long, cablelike veins, on the surface which sometimes curl into a ring at one end. Also, isolated rings are often seen in those swarms. With *Chondromyces* swarms, the swarm edge typically consists of a series of tongue- and shell-like shallow depressions. *Polyangium* swarms on VY/2 agar often penetrate the agar to the bottom and characteristically are surrounded by a more or less perpendicular, curtainlike zone composed of tiny, well-separated cell clumps. *Polyangium* and *Nannocystis* growing on streaks of autoclaved *E. coli* often produce long, radiating, narrow trenches in the agar surface, with small cell clusters (and, later on, fruiting bodies) at the end. The two can often be distinguished because the tracks and cell clumps of *Nannocystis* are more delicate. On mineral salts-glucose media, like CA2 and CK6 agar, *Sorangium* often produces swarms with a beautiful, dense network of branching cablelike veins.

It should be emphasized that the swarm structures described above are usually only seen with strains that have recently been isolated. The swarms of strains that have been transferred many times, or that have been adapted to growth in liquid media, are often very different. Such swarms may be soft-slimy, lacking all morphological differentiation, and, in the case of the Cystobacterineae, sometimes no longer grow on the surface but are sunk into the agar. In addition, a colony dimorphism has been described for *Cb. violaceus* and *Mx. xanthus* and is probably quite common among myxobacteria (Burchard et al., 1977; Grimm and Kühlwein, 1973a, 1973b, 1973c; Reichenbach, 1965a). This dimorphism may be a function of cell motility and consequently the spreading behavior of the colonies (K/G or K/S in *Cb. violaceus*, as well as the amount and consistency of the slime produced, and, probably directly connected to that, the capacity to fruit, and, after transfer to a liquid medium, to grow as a homogeneous cell suspension (*Cb. violaceus*). Also, pigmentation can be affected (deep and pale violet in *Cb. violaceus,* tan/yellow in *Mx. xanthus*). Usually, one colony type is more stable than the other, but segregation in both directions is possible. An explanation at the genetic level is still lacking, but it may involve a recombinase system (Jaoua et al., 1990). Of course, any mutations in genes of the motility system can be expected to have some effect on the appearance of myxobacterial colonies, e.g., the *frizzy* genes of *Mx. xanthus* discussed earlier (see "Gliding Motility") (Blackhart and Zusman, 1985).

In myxobacterial swarms, a very peculiar and striking feature has occasionally been observed: dense fields of regularly arranged, tiny ridges, or ripples. These ridges are usually found in long, parallel rays. They are positioned parallel to one another and perpendicular to the direction of the ray. The distance between the ridges is uniform and is approximately equal to the width of the ridges (Fig. 7). In *Mx. xanthus,* a distance of 45 μm from crest to crest has been measured (Shimkets and Kaiser, 1982). The phenomenon was discovered when movies of developing *Corallococcus* and *Myxococcus* swarms were first made. They showed that the ridges actually move, so that the whole field ap-

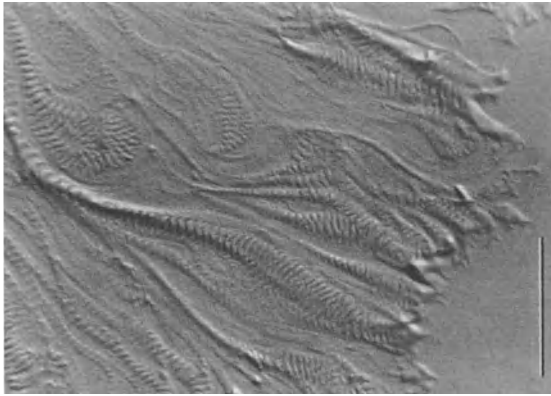

Fig. 7. Oscillating ridges, or ripples. *Stigmatella erecta* on casitone agar; dissecting microscope, oblique illumination. Bar = 200 μm.

pears to oscillate; hence, the ridges were called oscillating waves (Reichenbach, 1965b; Reichenbach et al., 1965a, 1965c). In fact, the movements of the ridges may even speed up and slow down, or pulsate, over a period of several hours. The movement of the ridges is fast enough to be recognized under the dissecting microscope; a speed of about 2 μm/min has been measured in *Mx. xanthus* (Shimkets and Kaiser, 1982). Oscillating waves were later found in many other myxobacteria. They appear to occur with all Cystobacterineae, and occasionally are also observed with members of the Sorangineae, e.g., *Chondromyces.* With *Sg. aurantiaca,* even waves travelling in opposite directions along the same path have been seen (Reichenbach et al., 1980). In *Mx. xanthus,* rippling can be induced by purified peptidoglycan and peptidoglycan components, such as *N*-acetyl-glucosamine, *N*-acetylmuramic acid, diaminopimelic acid, and D-alanine (Shimkets and Kaiser, 1982). The mechanism of cell movement in the oscillating waves and the biological significance of rippling are not understood.

Finally, the shape of myxobacterial swarms may become distorted by stress lines in the agar plate produced, for example, by mechanical pressure and stretching, a phenomenon known as elasticotaxis (Stanier, 1942).

Fruiting Bodies and Myxospores

The outstanding trait of the myxobacteria is their ability to form fruiting bodies and myxospores (Figs. 8, 9, 10, and 11). These morphogenetic processes make the myxobacteria by far the most sophisticated prokaryotes, and the object of considerable scientific interest as model systems for the study of the mechanisms of development. Studies of morphogenesis have provided extensive insights into the biochemistry and genetics of communication, as well as differentiation and morphogenesis on the prokaryotic level, and have also provided clues to the origin of important control mechanisms of eukaryotic development. These are several examples of such clues, including GTP-binding proteins, phosphoinositol cycle, steroid biosynthesis, stress proteins, and retrons. The literature on myxobacterial development is already very voluminous, and many excellent reviews on this topic are available (Dworkin, 1985, 1990; Kaiser, 1984b, 1986, 1989; Kaiser et al., 1979; Shimkets, 1987, 1990b; White, 1975, 1981; Wireman and Dworkin, 1975; Zusman, 1980, 1984, 1990).

The simplest myxobacterial fruiting bodies are mounds of either soft or hardened slime, the latter often having bizarre shapes (*Corallococcus, Archangium*), the former typically having a nob or head with a constriction or a stalk at the base (*Myxococcus*). Most myxobacteria enclose their myxospores in sporangioles, i.e., containers with well-defined walls; the interior of the sporangioles is always hard and tough. The sporangioles may occur singly or in groups; they may rest either directly on or in the substratum, or on simple or branched slime stalks. The fruiting bodies of several species are structures of considerable complexity, and some were mistaken for fungal fruiting bodies for a long time. The following key gives a survey of the different fruiting body types and their relation to the various myxobacterial taxa. It must be kept in mind, however, that fruiting body structure and morphology often degenerate quickly after a few transfers upon isolation. Also, strains may be isolated that produce degenerate fruiting bodies from the very beginning. In such cases, only completely atypical nobs and ridges of slime and myxospores are formed. It may be added here that the fruiting bodies of several myxobacteria have also been studied with the scanning electron microscope, and some very impressive pictures have been obtained in this way (e.g., Brockman and Todd, 1974; Galván et al., 1981; Stephens and White, 1980a; Stephens et al., 1982).

Key to the Fruiting Body Types of Myxobacteria

1. Naked masses of slime and myxospores 2
1′. Myxospores encased in sporangioles 3
2. Fruiting body soft-slimy .... *Myxococcus*
2′. Fruiting body hard, cartilaginous
.... *Corallococcus, Archangium*
3. Sporangioles single 4

3′. Sporangioles in groups 5
4. Single sporangiole located on or in the substrate
.... *Nannocystis, Haploangium*
4′. Single sporangiole on top of a stalk
.... *Melittangium, Sg. erecta*
5. Group of sporangioles on or in the substrate
.... *Angiococcus, Cystobacter, Polyangium, Sorangium, Nannocystis*
5′. Cluster of sporangioles on top of an unbranched stalk
.... *Sg. aurantiaca,* most *Chondromyces* species
5″. Clusters of sporangioles on a branched stalk
.... *Cm. crocatus*

More or less the same types of fruiting bodies are found in both suborders (with the qualification that the Sorangineae produce only fruiting bodies with sporangioles). Still, the course of morphological differentiation may be different with seemingly identical fruiting body types. Thus, *Chondromyces* and *Sg. aurantiaca* both form little treelets, but the stalks and sporangioles are produced in a different way in the two cases. While *Chondromyces* excretes a slime stalk that lifts the undifferentiated cell mass upward, and differentiation of the sporangioles occurs as the last step, *Sg. aurantiaca* piles up a mass of cells with approximately the shape and size of the final fruiting body, then the cells either withdraw from the stalk area or degenerate and lyse in that part, and the sporangioles mature (Fig. 12).

As has already been mentioned, stalks, sporangiole walls, and pigments are produced during fruiting but nothing is known about the chemical composition of these structures and substances. Under the electron microscope, the stalk of *Cm. crocatus* is seen to consist of numerous parallel tubes which are approximately the diameter of a cell and run in direction of the long axis of the stalk (Abadie, 1971b; McCurdy, 1969b). The stalk of *Sg. aurantiaca* was found to be composed of tubules wedged against each other and containing cell debris but only rarely a cell or myxospore; the stalk was surrounded by a thin, dense surface layer resembling the wall that surrounds the sporangioles (Voelz and Reichenbach, 1969). The stalk of *Sg. erecta* also was found to be cell free and to consist of slime, although in this case tubules could not be distinguished (Galván et al., 1987). In contrast, scanning electron micrographs suggested that the stalk of *Sg. aurantiaca* is cellular (Stephens and White, 1980). The contradiction is not yet resolved; perhaps the fruiting bodies examined with the scanning electron microscope had not yet fully matured. In any case, under the light microscope the stalk of *Sg. aurantiaca* looks translucent, unpigmented, and white, and thus completely different from the opaque, dark brown sporangioles.

The base of fruiting body stalks is often clearly disk-shaped. The disks apparently arise early during fruiting body development when the aggregated cells move on a circular path at the site of fruiting.

Little is known about the arrangement of the cells within the developing fruiting body, but it appears that this arrangement, and perhaps rearrangements by migrations of certain cell populations, may play a major role during fruiting body morphogenesis. In *Me. boletus,* a very regular pattern of three or more layers of strictly parallel cells has been observed (Jahn, 1924). The cells are perpendicularly arranged on the outer surface of the fruiting body, and it has been suggested that they are responsible for the secretion of the sporangiole wall. In developing *Cb. fuscus* sporangioles, the cells in the outer layers lie parallel to the surface. There are two hypotheses to explain the formation of sporangioles: Cells either secrete the sporangiole wall (Jahn, 1924) or they fuse together into a wall layer (Vahle, 1910). The sporangioles of the *Cb. fuscus* fruiting body are embedded in a communal, thick, translucent, unpigmented layer, called the matrix or glass envelope (called "Glashülle" by Jahn, 1924). Such additional envelopes are found with most of the genera that produce fruiting bodies in the form of clusters of sporangioles sitting directly on the substrate surface (*Cystobacter, Polyangium,* and *Sorangium*).

The fruiting bodies are produced by the coordinated action of a large number (10^5 to 10^7) of swarm cells that retain their physical individuality throughout this process of cooperative morphogenesis (Fig. 13). Formation of fruiting bodies can schematically be divided into a number of developmental stages: 1) environmental signal(s) to convert the vegetatively growing cells to a developmental path; 2) cell aggregation or accumulation; 3) emergence of molecules on the cell surface that mediate cell adherence; 4) rearrangement or clustering of the cells within the original undifferentiated mass; 5) production of special structural elements (stalks, sporangiole walls); 6) creation of the specific shape of the fruiting body, perhaps the most fascinating event in the whole sequence; and finally, 7) during the maturation phase, conversion of the vegetative cells into myxospores. Under optimal conditions, the bacteria may go through the whole developmental cycle within 12 to 24 h. It has been demonstrated that fruiting body induction as well as the individual steps of differentiation are subject to control by environmental factors such as nutrients, pH, divalent

cations, and temperature. As has already been mentioned, in at least two cases (*Cm. apiculatus* and *Sg. aurantiaca*), normal development takes place only in illuminated cultures (Qualls et al., 1978; Reichenbach, 1974a, 1974b; Stephens and White, 1980). The course of fruiting body formation has been documented for different genera and species in several scientific films (cited earlier), which show the sequence of events during fruiting.

It may be mentioned in passing that, for many myxobacteria, fruiting bodies can also be obtained on submerged substrates; this has been demonstrated with *Polyangium parasiticum* (Geitler, 1925), *Mx. fulvus* (Fluegel, 1963, 1965), and *Mx. xanthus* (Kuner and Kaiser, 1982). *Nannocystis, Polyangium,* and *Sorangium* strains often produce fruiting bodies deep within the agar plate, which is in some sense analogous to submerged conditions. There are, however, other myxobacteria, that seem not to form fruiting bodies under submerged conditions, e.g., *Cm. apiculatus* (H. Reichenbach, unpublished observations).

The distribution of the fruiting bodies on the culture plate is often more or less random, but occasionally striking patterns are observed. Thus, an arrangement in so-called witches rings is often seen in *Myxococcus* and *Corallococcus* cultures. This may perhaps be explained by a periodic depletion of nutrients which then induces fruiting but also a concomitant reduction of the metabolizing cell population. As mentioned, elasticotaxis may also lead to unexpected arrangements.

The terminology used to describe the structural components of myxobacterial fruiting bodies is illustrated in Fig. 14. Although complete consistency with usage of terms in other biological systems is not possible, terms that have already acquired a well-defined meaning in other systems should be avoided if they are inappropriate. The term "fruiting body" has a long tradition of use and may be acceptable in connection with myxobacteria, although in biology, fruiting usually implies sexual processes, and no such events seem to be involved in the case of the myxobacteria. The term "sporangium" has also been applied to these structures, but this term is even more suggestive of sexuality and is best avoided. Most types of fruiting bodies are composed of myxospores and the walled portions containing these myxospores are in fact communal cysts; they have traditionally been referred to as cysts. However, since the term "cyst" in microbiology is applied to quite a different structure, dormant, encapsulated single cells, we propose to use the term "sporangiole" instead, and to accept its obvious shortcomings. The advantage of the term sporangiole over sporangium is that it is a relatively unusual term and has been used only in connection with a restricted group of fungi (Mucorales) where it is not even used with a consistent meaning. Its use here is thus less likely to cause confusion. Incidently, the term sporangiole was applied to these myxobacterial structures by Link (1809) in the very first description of a myxobacterium, *Pl. vitellinum* (Fig. 15).

Inside the maturing fruiting body, the vegetative cells are converted into myxospores. Up to 85 to 90% of the dry weight of a fruiting body may consist of myxospores, the remaining 9 to 15% consisting of polysaccharide (Sutherland, 1979). However, these proportions vary within wide limits even with the same species. In the process of cellular morphogenesis, the slender rod-shaped cells of the Cystobacterineae shorten and fatten substantially and become optically refractile. Also, they surround themselves with an additional layer, a spore coat, or capsule. The capsule is usually so thin that it can be detected only under the electron microscope: it may be only 20- to 30-nm thick in the fruiting body and in glycerol-induced myxospores of *Sg. aurantiaca* (Reichenbach et al., 1969; Voelz and Reichenbach, 1969), and 100-

Fig. 8. Myxobacterial fruiting bodies. (a) *Cystobacter ferrugineus* on VY/2-agar; culture is 4 weeks old; the organism has spread all over the plate and produced numerous dark brown fruiting bodies; the diameter of the plate is 9 cm. (b to d) *Corallococcus coralloides:* (b) swarm on VY/2 agar, with numerous fruiting bodies; the delicate swarm edge and the clear lysis zone in the yeast agar are well recognizable; (c) field of fruiting bodies at higher magnification; (d) a single fruiting body, in situ on the agar surface. (e) *Myxococcus stipitatus,* fruiting body at the edge of a piece of filter paper, in situ. (f) *Myxococcus fulvus,* fruiting bodies on a soil crumb, in situ. (g to j) *Archangium*-like fruiting bodies: (g) *Archangium serpens,* large fruiting body in situ on agar surface; (h) *Cystobacter ferrugineus,* fruiting body with only rudimentary differentiation into sporangioles, in situ on agar surface; (i) *Cystobacter,* probably *Cb. ferrugineus,* with totally degenerated fruiting bodies, in situ on agar surface; (j) *Cystobacter* strain with typical *"Archangium"* fruiting bodies, in situ on agar surface. (k) *Cystobacter velatus,* fruiting bodies in situ on agar surface, covered with a delicately plicated slime sheet. (l) The same organism; at the lower magnification, one can see some of the enormous number of fruiting bodies that may be produced under suitable conditions. Bar = 5 mm in (b), 500 μm in (c), 200 μm in (l), and 100 μm in the remaining micrographs.

nm thick in *Sg. erecta* (Galván et al., 1987). Only the spherical myxospores of *Myxococcus* and *Corallococcus* develop a capsule that is thick enough to be recognized under the light microscope, particularly in negative contrast (Voelz and Dworkin, 1962) or after germination when the capsule remains intact (Reichenbach, 1966). In electron micrographs of thin sections, the laminated capsule of *Mx. xanthus* was found to be up to 350 to 400 nm thick (Voelz and Dworkin, 1962). In the Sorangineae, the morphological changes during myxospore conversion are much less dramatic. The rod cells may shrink a little, and they become optically refractile. The capsule remains very thin (60 nm; Abadie, 1971b) or is not developed at all (McCurdy, 1969b). Physiologically, however, both types of myxospores are equivalent; they are both dormant resting cells.

In the past, the resting cells of myxobacteria have also been named spores and microcysts (or pseudo-microcysts in the case of *Cm. crocatus*; Abadie, 1971b). More recently, the term myxospore has been adopted (Dworkin, 1977), because it emphasized the specific nature of the myxobacterial resting cell (in contrast to the term spore, which in bacteria is generally assumed to refer to the endospore) and eliminated the confusion with fruiting body macrocysts and microcysts in the older literature. After what has been said above, there is hardly a need to distinguish the two types of myxobacterial resting cells terminologically, and the term myxospore is now almost universally used for myxobacterial resting cells, regardless of shape and fine structure.

Myxospore formation and fruiting body formation are not always well coordinated. Sometimes only dark myxospores are found in fruiting bodies, which is probably due to strain degeneration. Such myxospores are usually not resistant to desiccation. Also, well-developed fruiting bodies may be found that are, however, completely empty, particularly in older cultures. In such cases, the cells either never converted into myxospores, or they germinated again and left the fruiting body. Especially with *Chondromyces,* fruiting bodies often arise on top of other fruiting bodies, sometimes repeatedly, so that in the end the whole cell mass of the aggregate is used up in the production of stalk material. In these cases, the cells obviously never enter the resting stage.

The myxospores are completely desiccation resistant, in contrast to vegetative cells which are extremely sensitive to desiccation. In addition, they show substantial resistance to ultrasound and UV irradiation. Their temperature resistance is only modest, although clearly above that of vegetative cells; in aqueous suspensions, they can survive at 58 to 62°C for 10 to 60 min (Sudo and Dworkin, 1969).

Cytological changes during myxospore formation have been studied on the ultrastructural level with four species, *Mx. xanthus* (Voelz, 1966a; Voelz and Dworkin, 1962), *Sg. aurantiaca* (Reichenbach et al., 1969; Voelz and Reichenbach, 1969), *Sg. erecta* (Galván et al., 1987; McCurdy and Khouw, 1969), and *Cm. crocatus* (Abadie, 1971b; McCurdy, 1969b). In all four cases, dark granules of polyphosphate and light areas containing some other kind of reserve material can be observed. The latter usually seems to be polysaccharide; in *Sg. aurantiaca,* these polysaccharide granules are coated with a dense layer of ribosomelike particles (Reichenbach et al., 1969). In *Cm. crocatus,* lipid inclusions have been suggested (McCurdy, 1969b). The outer

Fig. 9. Myxobacterial fruiting bodies. (a to c) *Stigmatella aurantiaca:* (a) fruiting body in situ on an agar surface; (b) fruiting body with its sporangioles on exceptionally long peduncles, in situ; (c) early developmental stage of a fruiting body, mounted in "Miracle Mount" (Cunningham, 1972) to make it transparent; the stalk still consists mainly of cells that later migrate into developing sporangioles or degenerate; the young sporangiole in the upper left corner shows the developing sporangiole wall that ends in a collar at the base of the sporangiole; phase contrast. (d) Although this fruiting body strikingly resembles those of certain *Polyangium* (see h) or *Sorangium* species (see g), it still is that of a *Cystobacter, Cb. minor,* as is clearly shown by the shape of the vegetative cells; interference contrast. (e) *Stigmatella erecta,* fruiting bodies in situ on agar surface. (f) *Melittangium lichenicola,* fruiting bodies in situ on a piece of wood. (g) *Sorangium cellulosum* on filter paper, cautiously squeezed slide mount; the shape of the fruiting bodies is often controlled by the orientation of the remnants of the wood fibers and tracheids, along and within which they develop; phase contrast. (h) *Polyangium* sp., fruiting body in crude culture in situ on agar surface; note the deep path that has been etched into the agar surface by the migrating bacterial mass (compare with Fig. 2c) before it encased itself in sporangioles; the tiny dots all over the agar surface are encysted amebae. (i) *Polyangium thaxteri,* fruiting bodies on filter paper, in situ. (j to m) *Chondromyces apiculatus:* (j) cluster of fruiting bodies on surface of filter paper, in situ; dissecting microscope; (k) early (club) stage sporangiole differentiation; dissecting microscope; (l) mature fruiting body; (m) small, mature, fruiting body in "Miracle Mount" (Cunningham, 1972) to make it transparent; the myxospores within the turnip-shaped sporangioles can just be recognized; the slime stalk, in contrast, is cell free; phase contrast. (n) *Nannocystis exedens;* the fruiting bodies are single sporangioles of very variable size and are embedded in the (agar) substrate; slide mount, phase contrast. Bar = 50 μm in (c), 200 μm in (i), 400 μm in (j), and 100 μm in the remaining pictures.

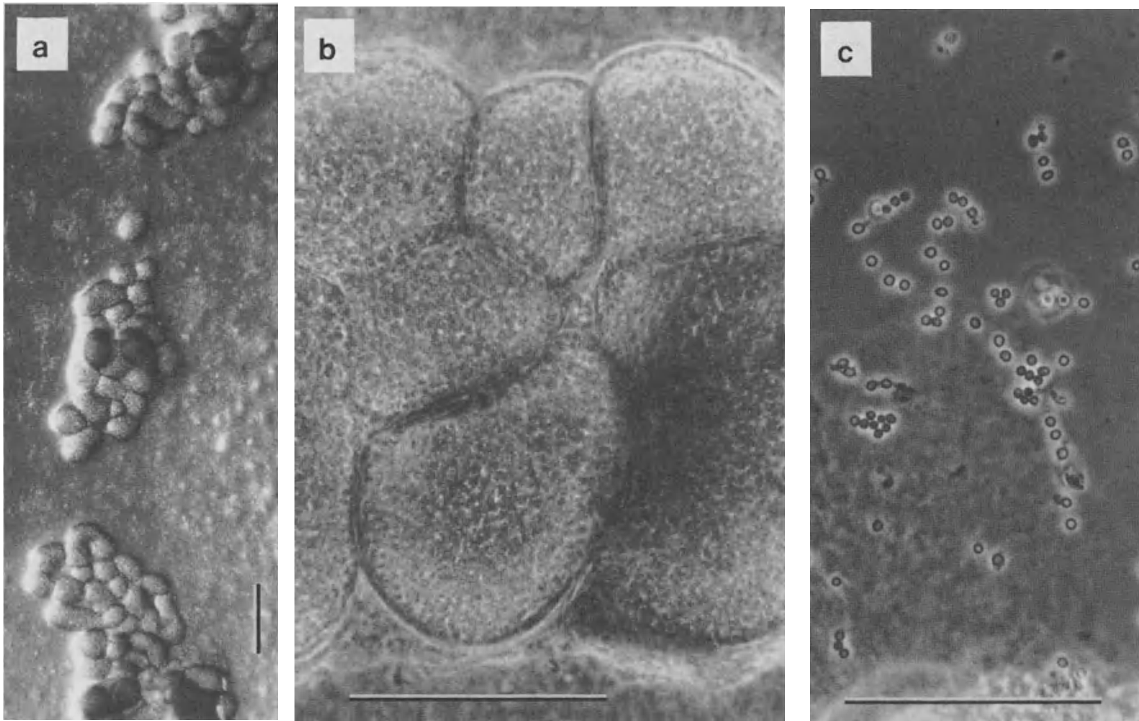

Fig. 10. Myxobacterial fruiting bodies: *Angiococcus disciformis.* (a) In crude cultures and on natural substrates the sporangioles tend to be disk-shaped and loosely stacked but, as shown here, in pure culture, they are more or less spherical and tightly attached to each other. (b) At high magnification, the walls of the sporangioles, although only about 1 μm thick, become clearly recognizable. (c) When the sporangioles are crushed, they release optically refractile, spherical myxospores, shown here at the same magnification as the sporangioles in (b), which look exactly like *Myxococcus* myxospores. (b) and (c) are in phase contrast. Bar = 100 μm in (a), 50 μm in (b) and (c).

membrane, but not the cytoplasmic membrane, is often intensively folded, particularly in glycerol-induced myxospores (Bacon and Eiserling, 1968; Reichenbach et al., 1969; White, 1975); in *Sg. aurantiaca,* tight, budlike membrane bodies sitting in pockets of the cytoplasmic membrane may be seen; in *Cm. crocatus,* the outer membrane may be folded in a concertinalike fashion (Abadie, 1971b). Perhaps the relatively rigid outer layer is not able to adapt itself quickly enough during the fast change in shape of the vegetative cell and responds by folding itself. Otherwise, the cell envelope appears to remain morphologically intact during sporulation and germination.

The chemical composition of myxospores shows some differences from vegetative cells. When myxospores of *Mx. xanthus* and other *Myxococcus* species, or of *Cb. velatus* and *Archangium* species, were extracted with acetic acid, virtually all of the polysaccharide could be removed from the cells. In the extracts, mainly glucose (50 to 70%) and galactosamine (15 to 48%) have been identified. The glucose is part of an α-1-3-glucan. Binding studies with the lectin concanavalin A demonstrated that the glucan is on the outer surface and only present (or accessible) in myxospores. The myxospores of *Cb. velatus* were the only ones that also bound soybean agglutinin (Sutherland and

Fig. 11. Myxobacterial fruiting bodies. (a) *Sorangium cellulosum,* on VY/2 agar in situ (compare with Fig. 9). (b and c) *Polyangium thaxteri;* (b) on agar surface in situ; a mass of tightly packed sporangioles is situated on a stalklike cushion of slime: the whole fruiting body looks like a false morel; (c) when mounted in "Miracle Mount" (Cunningham, 1972), the individual sporangioles can easily be distinguished. (d) *Chondromyces pediculatus,* fruiting body on a soil crumb, embedded in Miracle Mount. (e and f) *Chondromyces crocatus,* both in Miracle Mount: (e) a young, not yet fully differentiated stage; in dark field illumination, the translucent, cell-free stalk and the densely packed cell masses on its top are clearly distinguished; (f) mature fruiting body; at the base of the stalk some encysted soil amebae are seen. (g and h) *Chondromyces lanuginosus,* both in Miracle Mount: (g) survey of the whole fruiting body; (h) view from above showing the end face of the sporangioles covered with little tails. (f to h) in phase contrast. All bars = 100 μm.

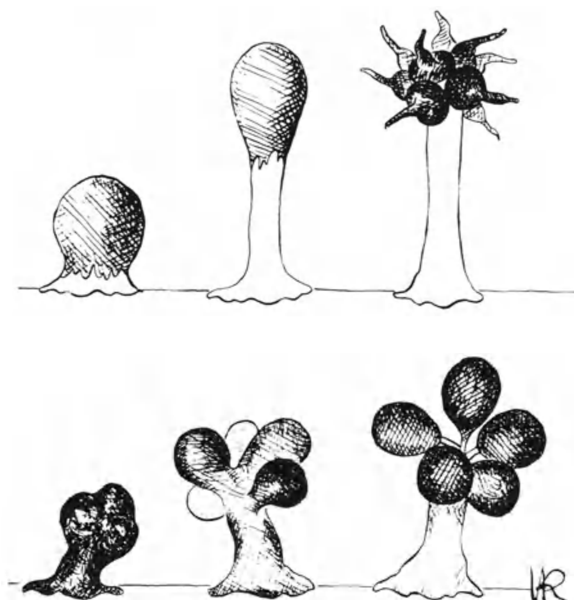

Fig. 12. Similar fruiting body shapes may be reached in different ways, as shown here for *Chondromyces apiculatus* (above) and *Stigmatella aurantiaca* (below), two organisms formerly thought to be closely related. The hatched areas indicate where the cells are located at the various stages.

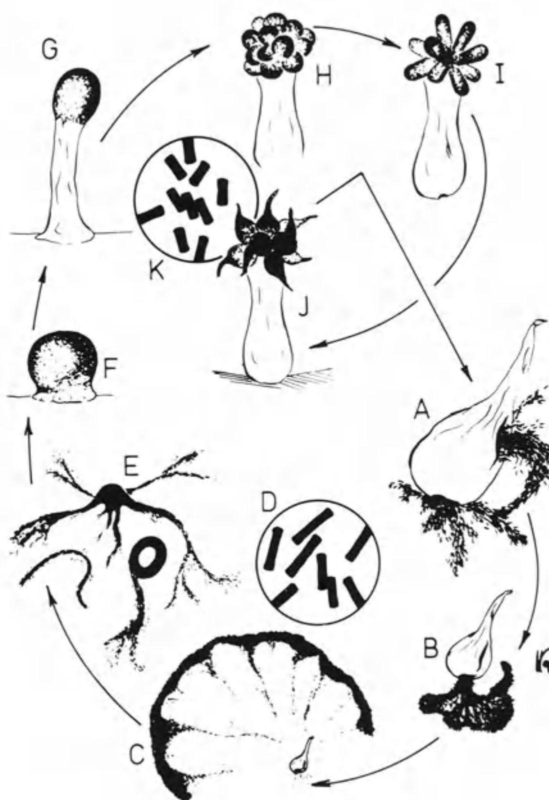

Fig. 13. Cooperative morphogenesis in myxobacteria. The organism shown in the diagram is *Chondromyces apiculatus*. Symbols: A, germinating sporangiole; B, C, development of a swarm colony; D, vegetative cells; E, aggregation of vegetative cells at various places within the swarm. F to J, fruiting body development; F, knob stage; G, excretion of the slime stalk, cells all concentrated in the terminal knob; H, the terminal mass begins to differentiate, forming wartlike protrusions which later elongate into (I) clublike structures and finally mature into (J) turnip-shaped sporangioles; K, myxospores.

Mackenzie, 1977). The coats of glycerol-induced myxospores of *Mx. xanthus,* which, in contrast to fruiting body myxospores, were only 25 to 50 nm thick, could be isolated and chemically analyzed (Kottel et al., 1975). They consisted of 75% polysaccharide (23 to 28% glucose, 50 to 58% galactosamine), 14% protein, 8% glycine, and 0.4% organic phosphorus. While one portion of the coat is already complete 5 to 6 h after induction, another part consisting mainly of glucose is added only after 8 h; perhaps this is the glucan mentioned above. During cell conversion, beginning about 50 min after induction, a rapid accumulation of some galactosamine-containing material on the cell and a concomitant rise in sonication resistance is seen. Quite obviously, this reflects the synthesis of the capsule. The capsule is highly resistant to chemical and enzymatic attack. During germination it is probably broken open mechanically and remains as an empty husk. During the phase of shape change, the degree of cross-linking of the peptidoglycan decreases transiently. It appears to be substantially higher in mature myxospores than in vegetative cells (White et al., 1968). Myxospores of *Mx. xanthus* accumulate large quantities of trehalose: fruiting body myxospores up to 1.1 mg, glycerol-induced myxospores up to 0.3 mg per mg of protein (McBride and Zusman, 1989). The trehalose disappears rapidly during germination and seems to be metabolized in some unknown way. This sugar may be responsible for the high osmotic strength of the myxospores and their elevated resistance to desiccation. In this connection, it is of interest that vegetative cells also store trehalose (up to 0.2 mg per mg of protein) when they are grown in the presence of 0.1 to 0.3 M of certain solutes [sucrose, KCl, NaCl, $(NH_4)_2SO_4$]. *Myxococcus* cultures appear to be unable to utilize added trehalose (H. Reichenbach, unpublished observations). The DNA content of myxospores is higher (27×10^{-9} μg) than that of vegetative cells and corresponds to that of three to four chromosomes (Zusman and Rosenberg, 1968).

Under natural conditions, myxospores are probably produced primarily inside fruiting bodies. In culture, myxospores are sometimes found on the substrate in the immediate neighborhood of fruiting bodies, as if a sporulation

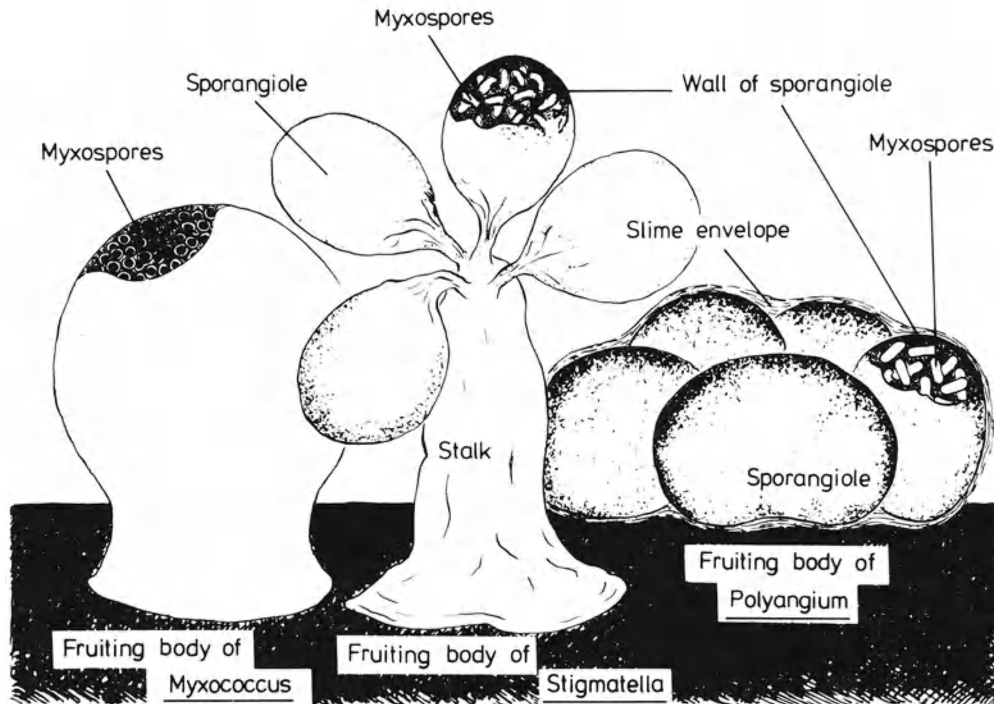

Fig. 14. The terminology for myxobacterial fruiting bodies and their structural components.

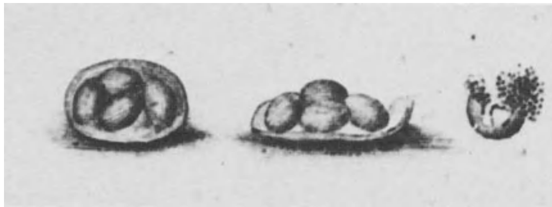

Fig. 15. *Polyangium vitellinum,* probably the first drawing of a myxobacterium to be published (Link, 1809). The original description of this still-valid genus and species reads as follows: "Among the Gasteromycetes in front of *Endogene* is to be inserted: *Polyangium.* Sporangium spherical or distortedly ovoid. Sporangioles very large in relation to the sporangium, ovoid, crammed full with a granular material. The sporangium consists of a thin, translucent, gelatinous, vesicular membrane enclosing four to six ovoid sporangioles which are filled with a colored granular mass. Sporidia could not be distinguished. *P. vitellinum,* with small yolk-colored spots, is to be counted among the smallest (species) of the order. It is found on old tree trunks, either singly or in groups of two or three, and can be recognized by its intense yolk color. Discovered by my friend Ditmar. Is to be inserted among the Gasteromycetes after *Tremella.*" (Translated from the Latin.)

signal had emerged from the maturing fruiting body. This signal seems also to diffuse through cellophane membranes, because, if a swarm is covered with cellophane and the latter is inoculated with the same organism, piles of myxospores are found on the cellophane at exactly the same sites where fruiting bodies have arisen below. Experiments of this kind were an early approach to the study of communication and the mechanisms of fruiting body formation (Fluegel, 1963; McVittie and Zahler, 1962; Reichenbach, 1966). A good experimental system for the study of myxospore formation became available when it was discovered that cellular morphogenesis can be triggered by the addition of glycerol (final concentration 0.5 M) to suspensions of growing cells of *Mx. xanthus* (Dworkin and Gibson, 1964). This became the starting point for biochemical research into cellular morphogenesis (e.g., Dworkin and Sadler, 1966; Sadler and Dworkin, 1966; White, 1975). It was soon found that many other myxobacteria also respond to glycerol induction. *Sg. aurantiaca* is another well-characterized experimental system (Gerth, 1975; Gerth and Reichenbach, 1978; White, 1981). In this organism, almost 40 chemicals have been found that induce sporulation, including monovalent cations (Reichenbach and Dworkin, 1970), various alcohols and amino acids, choline, benzene, indole, and indole derivatives; the latter two are active at particularly low concentrations. The most efficient inducer is 3-methylindole, with an optimal concentration of 0.07 mM. With the aid of mutants that were resistant to one kind of inducer but still responded to another one, the inducers could be divided into

three or four classes. Apparently each class participates in a distinct induction mechanism, each probably acting on a specific receptor. In *Sg. aurantiaca,* sporulation can also be induced by supraoptimal temperatures (40 to 41°C: the temperature has to be controlled very carefully). The change in shape that accompanies the change from vegetative cell to myxospore begins 60 min after the temperature shift, at the same time that it begins after induction with chemicals. Induction by high temperature and by glycerol (130 mM) both have the same effect on the elapsed time to the change in shape; for example, if the temperature is shifted down to 30°C after 20 min at 40.5°C, and glycerol is added at the same time, the shape change begins 40 min later. Heat induction is also possible with other myxobacteria, e.g., *Mx. fulvus* (Gerth and Reichenbach, 1978). The complementation experiment seems to corroborate the idea that the induction event, which may be initiated in different ways, sets in motion a common biochemical pathway, which then leads to cell conversion. The explanation for the effect of elevated temperatures may have to do with the heat shock proteins (HSP) that have been discovered to be induced in *Mx. xanthus* when it is transferred to temperatures above 36°C (Nelson and Killeen, 1986). If cells were heat-shocked at 40°C for 1 h, the time schedule of a following glycerol induction was accelerated, and the myxospore yield improved. It could be shown that the heat shock elicited the expression of genes normally involved in development; thus, 9 out of 18 proteins produced after glycerol induction, including alkaline phosphatase, could also be induced by heat shock (Killeen and Nelson, 1988). In this respect, *Mx. xanthus* appears to be different from *Sg. aurantiaca,* in which the complete developmental program is induced at 40.5°C. Conceivably, myxospore induction by high temperatures reflects an evolutionary root of an ancient stress reaction system which has become connected to the developmental program. In fact, in other organisms, HSP are also induced by stress factors other than heat, like alcohols or oxidants. Also, HSP are expressed during developmental processes in many eukaryotic systems. Therefore, it has been suggested that the HSP stress response system may have been directly involved in the evolution of certain developmental processes (Kurtz et al., 1986). In the case of myxospores, the connection between stress and development is particularly convincing.

The case of the artificial inducers may also be relevant for myxospore formation within fruiting bodies. Natural inducers are perhaps produced and excreted by the isolated, starving cell population crowded together inside the maturing fruiting body. The cellophane experiments discussed above and the presence of myxospores just outside of fruiting bodies may be explained by the occurrence of a diffusible inducer. In this connection, it is of interest that indole derivatives such as formylindole have been isolated from several myxobacteria (W. Trowitzsch, personal communication; Reichenbach et al., 1988), and an increase in the intracellular concentration of glycerol has been correlated with the formation of myxospores in *Mx. xanthus* (Mueller and Dworkin, unpublished observations).

Myxospore germination is induced by the transfer of the dormant cells to a suitable growth medium. Myxospores inside fruiting bodies do not always germinate readily under such conditions, however, especially those with a very thick sporangiole wall like *Cb. fuscus*; perhaps the sporangiole wall delays diffusion of some critical compound. In fact, these walls are so stable and resistant to enzymatic attack that they often remain fully intact as an empty husk long after the germinated cells are gone. As has already been mentioned, high nutrient concentration may also prevent germination (see "Purification," this chapter). Glycerol-induced myxospores of *Mx. xanthus* can be induced to germinate not only by the full growth medium, but also by certain individual amino acids (Gly, Ala, Val, Asp, Glu; at about 10 mM) and inorganic ions (HPO_4^{2-}, Mg^{2+}, Ca^{2+}, NH_4^+; at about 10 mM); heat activation is not required (Ramsey and Dworkin, 1968). It appears that a specific type of early DNA synthesis is essential during germination (Kimchi and Rosenberg, 1976).

Clearly, the function of myxospores is to help the organism survive unfavorable environmental conditions, mainly periods of dry or cold weather and starvation, but, as we have seen in the section on "Habitats," occasionally also other factors such as high salt concentrations, acid pH, and anaerobic conditions. The function of fruiting bodies is more difficult to explain. One hypothesis is that they ensure that a new life cycle is started by a population of cells rather than by single cells (Dworkin, 1973). This property could be essential for organisms that obtain their nutrients by solubilizing extracellular macromolecules with excreted enzymes. A population of cells, in contrast to an individual cell, maximizes the efficiency of extracellular enzymes. Thus, a high cell density will result in higher levels of excreted enzymes, and the utilization of the solubilized substrate will be considerably improved because losses by diffusion into directions not occupied by cells

will be minimized (Dworkin, 1973; Reichenbach, 1974a; Rosenberg et al., 1977).

Nutrition and Energy Metabolism

All myxobacteria are characterized by their ability to decompose biomacromolecules. There are two sharply separated metabolic groups: Group 1 myxobacteria depend on the decomposition of cellulose. They are all classified in one genus, *Sorangium*. The few strains that have been studied in detail are all able to grow on inorganic nitrogen (NH_4^+ or NO_3^-) as the only nitrogen source, although their growth is stimulated if a small quantity (0.05 to 0.1%) of peptone is added. They also grow on organic nitrogen compounds as the only nitrogen source, provided a carbohydrate is also present. A few strains appear even to grow on peptone alone (Sarao et al., 1985). These organisms utilize cellulose and sugars such as glucose equally well, but cellulase production is more or less repressed in the presence of sugar (Couke and Voets, 1967; Krzemieniewska and Krzemieniewski, 1937a, 1937b; Pronina, 1962).

Group 2 myxobacteria, by far the majority of species, depend on an amino acid-containing medium such as peptone for growth. They obtain the required oligopeptides by hydrolyzing proteins. Their dependence on peptides may be such that it becomes difficult, in some cases impossible, to develop defined amino acid media for them. In other cases, the organisms grow on remarkably simple media with glucose, glutamate, and two essential amino acids (see "Cultivation," this chapter). In nature, these organisms seem to subsist mainly on other organisms, which they degrade by means of a variety of hydrolytic exoenzymes. Proteases, nucleases, lipases, glycanases, and cell wall lytic enzymes have been demonstrated. These myxobacteria are particularly efficient in the destruction of other bacteria and of yeast cells, and therefore have been called "micropredators" (Singh, 1947). However, they do not depend on living organisms and could as well be regarded as scavengers. Their association with animal dung is probably due to its rich mixture of living and dead cells of all kinds and to its content of organic matter at every level of decomposition.

All known myxobacteria are strictly aerobic organotrophs. As a prerequisite for aerobic energy generation, *Myxococcus* possesses *a*-, *b*-, and *c*-type cytochromes as well as NADH-oxidase (Dworkin and Niederpruem, 1964; Kleinig, 1972) and a complete tricarboxylic acid cycle (McCurdy and Khouw, 1969; Sarao et al., 1985; Watson and Dworkin, 1968). The genus *Myxococcus* cannot utilize mono- and disaccharides (Watson and Dworkin, 1968), and therefore completely depends on amino acids (or pyruvate) as an energy source (Bretscher and Kaiser, 1978). However, as has already been mentioned, some myxobacteria are able to take up and metabolize oligosaccharides, which they produce from polysaccharides such as starch through the action of special hydrolytic enzymes (Irschik and Reichenbach, 1985). This ability may be more common than presently believed, for virtually all *Myxococcus* and *Corallococcus* strains are able to degrade one or another polysaccharide, e.g., yeast cell wall β-glucan, xylan, and starch.

An overview of the metabolism of myxobacteria has been given by Shimkets (1984). It appears that myxobacterial metabolism is similar to that of other bacteria, and unique biochemical pathways have not been discovered. Of course, myxobacterial metabolism has often been studied mainly in relation to biochemical reorganization during morphogenesis, and many enzymes have been described that are turned on or off at certain stages of development. These data will be found among the reviews cited earlier.

The glycolytic pathway seems to play a major role in the glucose metabolism of *So. cellulosum* (Sarao et al., 1985; D. Hofmann, personal communication). In *Mx. xanthus,* glucose is not metabolized, presumably because hexokinase (ATP-dependent) and pyruvate kinase are absent (Watson and Dworkin, 1968). Nevertheless, an intact phosphofructokinase and a fructose-1,6-diphosphatase are present (Watson and Dworkin, 1968), implying that glycolysis and gluconeogenesis are both possible. The explanation for this apparent contradiction is not obvious. In *Corallococcus coralloides* strain Cc c127, fructose-1,6-diphosphate aldolase activity is very weak, and intracellular hexose seems to be metabolized via the pentose phosphate pathway (Irschik and Reichenbach, 1985). The latter pathway is present in other myxobacteria, e.g., *So. cellulosum* (D. Hofmann, unpublished observations). In fact, this pathway must be present in all myxobacteria, because all are able to synthesize the pentoses required in anabolic reactions. In *Mx. xanthus,* the initial enzyme, phosphoenolpyruvate carboxylase, has been shown to be present (Watson and Dworkin, 1968). The conversion of fructose-6-phosphate into cell wall precursors has also been demonstrated (Filer et al., 1977). In *So. cellulosum,* gluconeogenesis appears to be blocked, which may explain the dependence of this organism on external carbohydrates (D. Hofmann, unpublished observations).

Lysis of Other Bacteria

The capability of myxobacteria to disintegrate whole cells of other microorganisms has attracted much attention (e.g., Beebe, 1941; Imshenetski and Kusjurina, 1951; Norén, 1960a, 1960b; Oxford, 1947), and comparative studies on the kinds of organisms that can be attacked by various myxobacteria have been carried out (Mathew and Dudani, 1955; Nolte, 1957; Oetker, 1953; Singh, 1947). It became apparent from these studies that living as well as dead bacteria could be degraded, and it was suggested that antibiotic substances could be involved in the killing and inactivation of living prey (Finck, 1950; Oxford, 1947; Oxford and Singh, 1946). While bacteriolytic activities of myxobacteria do not depend on the production of growth-inhibiting substances (Norén and Raper, 1962), myxobacteria do indeed synthesize a host of secondary metabolites, and many of them exert strong biological effects (see "Applications," this chapter). The predator-prey relationship between *Myxococcus* strains and the cyanobacterium *Phormidium luridum* in aqueous environments has also been studied in some detail (Burnham et al., 1981, 1984; Daft et al., 1985).

Studies on bacteriolytic activities led to the first studies on myxobacterial exoenzymes (e.g., Bender, 1962; Hart and Zahler, 1966, Haskå, 1969; Hüttermann, 1969; Norén, 1960b; Sudo and Dworkin, 1972). Some of the responsible enzymes have since been purified to varying degrees and have been biochemically characterized. While a complete bacteriolysis obviously requires many different enzymes, all of the studies on bacteriolytic enzymes of myxobacteria have concentrated on peptidoglycan-degrading enzymes. A glucosaminidase, an amidase, and an endopeptidase cleaving D-Ala/diaminopimelic acid and D-Ala/Lys bonds and proteases have been obtained from culture supernatants of *Mx. xanthus* (Sudo and Dworkin, 1972). Three bacteriolytic enzymes have been isolated and highly purified from *Mx. virescens* (Haskå, 1972a, 1972b, 1974); two of them proved to be endo-β-*N*-acetylglucosaminidases. The third enzyme, an endopeptidase, could be purified by adsorption to montmorillonite followed by selective desorption (Haskå, 1974, 1975). The fact that the bacteriolytic enzymes retain some of their activity when they are adsorbed to clay minerals may be of ecological relevance (Haskå, 1981). The addition of C_{11} through C_{15} fatty acids (about 2mM) to suspensions of the target bacteria increased the efficiency of the bacteriolytic enzymes substantially (Haskå et al., 1972). In contrast to the two myxococci, *Cc. coralloides* excreted an enzyme with a muramidase (= lysozyme) activity (Harcke et al., 1972). It may be added here that the "*Sorangium,*" isolate whose enzymes are often discussed in this connection, was in reality a species of *Lysobacter.*

Little is known about the enzymes with which microorganisms other than bacteria are attacked. Living cells of four yeast species could not be degraded by *Mx. xanthus* enzymes, but they were digested after a prior treatment with cysteine or organic solvents, or after heating; in contrast, living cells of the yeastlike fungus *Pullularia (Dematium) pullulans* were partially decomposed (Bender, 1963). Isolated cell walls of *Saccharomyces cerevisiae* also could not be degraded by enzymes from *Mx. fulvus* Mx strain f80 without a brief heat treatment (Borchers, 1982). It appears that the mannoprotein layer on the outside of the yeast cell wall protects the susceptible material. Two inducible enzymes have been demonstrated in the culture supernatant of *Mx. fulvus* Mx f80; 1) a laminarinase with a high specificity for β-1,3-glucosidic bonds cleaving laminaran endolytically with laminaritriose as the main product; and 2) a β-1,3-glucanase that can remove a high-molecular-weight polysaccharide other than β-1,3-glucan from the cell wall. The yeast cell wall is not completely broken down by *Mx. fulvus* Mx f80: The inner, fibrillar, glucan layer and the bud scars remain undigested, as can be seen under the electron microscope.

Most myxobacteria excrete strong, diffusible proteases, as can be readily seen through the clearing action that occurs around colonies growing on skim milk agar. A few of these enzymes have been further characterized: From the culture supernatant of *Mx. virescens,* at least three proteases have been obtained (Gnosspelius, 1978b). One of them has been purified and was found to be an alkaline serine protease (26 kDa) which preferentially cleaved peptide bonds between hydrophobic amino acids. Three different proteases have also been demonstrated in the culture supernatant of *Mx. xanthus* FB (Coletta and Miller, 1986). They have tentatively been classified as alkaline serine proteases. There were qualitative differences among the proteases of different *Mx. xanthus* strains. A coagulase, myxocoagulase (57 kDa), has been isolated from the culture broth of *Mx. fulvus* strain NK35 (Bojary and Dhala, 1989). The enzyme was clearly different from *Staphylococcus* coagulase; it did not contain sugar and was active only on rabbit plasma.

In those cases that have been examined, the bacteriolytic enzymes disappeared from the culture broth during the late exponential phase of

growth while protease activity remained long into stationary phase, either because the proteases were more stable, or because they continued to be produced and/or released (Bender, 1962; Harcke et al., 1971; Haskå and Ståhl, 1971; Nicaud et al., 1984; Sudo and Dworkin, 1972).

In contrast to the extracellular proteases of *Mx. xanthus,* the intracellular proteases appear to be mostly (80%) neutral metalloproteases. During glycerol-induced conversion of vegetative cells into myxospores, a transient increase of two protease activities (at pH 6 and pH 8) was observed (Orlowski and White, 1974).

While it is well established that myxobacteria are able to hydrolyze many other macromolecules by means of diffusible exoenzymes, those enzymes have not been characterized so far. Thus, many myxobacteria decompose starch; quite a few are potent chitin degraders, e.g., all strains of *Cb. fuscus, Cb. ferrugineus, Sg. aurantiaca,* and *Sg. erecta,* and many strains of *Me. lichenicola* and *So. cellulosum.* Also, many myxobacteria appear to attack xylan. Two enzyme activities could be demonstrated in the culture supernatant of the cellulose degrader *So. compositum,* growing in a liquid medium with suspended cellulose powder. The enzymes produced only glucose and cellobiose from cellulose. One was a cellobiase and was destroyed by heating at 55°C for 10 min. After that, an enzyme releasing cellobiose from cellulose was still intact (Couke and Voets, 1968). These two enzymes probably did not constitute the entire cellulase complex of the organism; rather there may exist another endocellulolytic enzyme that was not released from the cells. In fact, in plate cultures of *So. cellulosum* on filter paper or on cellulose powder agar, the lysis zone always exactly coincided with the size of the swarm colony. Thus, there seems to be no diffusible cellulase efficient enough to break down the crystalline cellulose completely.

Antibiotic Sensitivity

There exist relatively few data on the response of myxobacteria to antibiotics. In one study, all myxobacteria tested proved resistant to penicillin and ristocetin, and all were sensitive to erythromycin, chloramphenicol, and tetracycline; most were also sensitive to kanamycin, neomycin, and streptomycin (McCurdy, 1969a). As already mentioned, members of the Sorangineae, and specifically *So. cellulosum,* are resistant to kanamyxin, neomycin, and gentamicin. It was found that almost all myxobacteria are highly sensitive to actinomycin D, which is unusual for Gram-negative bacteria and suggests that they have an unusual, probably more lipophilic, cell surface (Dworkin, 1969). If transposon Tn*5* is introduced into *Mx. xanthus,* it confers on the organism a streptomycin resistance which is not expressed in *E. coli* (Breton, 1984).

Taxonomy and Identification

General Principles

Classification of myxobacteria still rests almost entirely on morphological characteristics, in part for historical reasons, and in part because most of the physiological information is restricted to only a few species of myxobacteria, mostly *Mx. xanthus.* Moreover, the complex morphology of myxobacteria suggests that a morphological classification is more feasible than is the case with most other bacteria. Nevertheless, the present solution does leave quite a few unsolved problems, as will be discussed.

Although some efforts have been made to support and supplement morphological classification by physiological characteristics, the results are relatively scant so far. Comparison of a number of standard physiological tests did not identify useful key characteristics other than the Congo red reaction of slime (McCurdy, 1969a; see also "Characterization," this chapter). This may simply mean, however, that the taxonomically relevant physiological characteristics of the myxobacteria have not yet been recognized, rather than that they do not exist. One taxonomically useful physiological characteristic appears to be cellulose decomposition, and we therefore suggested its use for the definition of the genus *Sorangium.* Investigations with the potentially useful techniques of immunology (Grilione, 1968) and DNA-DNA hybridization (Johnson and Ordal, 1969) have not been pursued beyond a preliminary stage. More recent research has shown that an in-depth investigation of a certain group may indeed reveal chemosystematic and biochemical characteristics of taxonomic weight. Thus, bacteria of the genus *Nannocystis* are unique among the myxobacteria in synthesizing steroids (Kohl et al., 1983) and aromatic carotenoids, and by not producing carotenoid glycosides, as all other myxobacteria do (Reichenbach and Kleinig, 1984). *Mx. stipitatus* appears to be the only myxobacterium that lacks carotenoids, so that its cell mass is colorless; instead, it produces compounds with a strong yellow fluorescence (Lampky and Brockman, 1977). While these compounds may also be produced by other *Myxococcus* species,

in them the fluorescence is masked by the carotenoids unless the cultures are grown strictly in the dark. Furthermore, as has already been discussed in detail, there are significant differences between the fatty acid and carotenoid spectra of the Cystobacterineae and the Sorangineae.

The most serious shortcoming of our present diagnostic scheme of the myxobacteria is that it rests primarily on fruiting body morphology. Although the shape of the vegetative cells and myxospores and the morphology of the swarm colony often permits the assignment of a strain to a suborder, a family, or sometimes even a genus, an exact determination and reliable classification still requires the production of typical fruiting bodies. But many strains form aberrant fruiting bodies, or no fruiting bodies at all, after continued cultivation. If we do not know which species we are dealing with from the crude culture or the early isolation steps, it may be impossible to find out later. The production of atypical fruiting bodies is particularly a problem in connection with the genus *Archangium,* as will be discussed later in more detail.

Another, more basic problem with morphological classification is the apparent convergent evolution which results in more or less identical fruiting body types being produced by taxonomically diverse myxobacteria. A good example is the case of *Chondromyces* and *Sg. aurantiaca* discussed earlier. Similar relationships are found among the genera *Angiococcus, Cystobacter, Polyangium,* and *Sorangium* and have led to considerable confusion in the past. A meaningful taxonomy has to reflect phylogenetic relations, and therefore possible errors in classification due to such convergences have to be carefully tracked down and corrected. However, if other morphological and biochemical characteristics are considered in addition to fruiting body morphology, it should not be too difficult to achieve this.

Another continuing source of confusion in the literature is the inappropriate application of the term myxobacteria to all kinds of unicellular gliding bacteria, such as *Cytophaga* and the *Cytophaga*-like bacteria of the genera *Sporocytophaga* and *Lysobacter.* The lysobacters in particular have often been called myxobacters or classified in the genus *Sorangium* and are consequently often discussed in articles on myxobacteria, e.g., in connection with enzymes and antibiotics.

The phylogenetic position of the myxobacteria is now being put on a solid base by 16S rRNA studies (Ludwig et al., 1983; Oyaizu and Woese, 1985). These studies have shown that the myxobacteria are a phylogenetically coherent group. They further suggest that the nearest, though rather remote, relatives of the myxobacteria are the sulfate-reducing bacteria and the genus *Bdellovibrio,* and that these three groups of organisms cluster in a branch of their own, the delta branch, within the class Proteobacteria (Stackebrandt et al., 1988) (see Chapters 2 and 24). It also has become apparent that there are two deep division lines within the myxobacteria, the major one separating two large groups, which correspond to the two suborders suggested by us earlier, and the minor one allocating a special position to *Nannocystis* within the Sorangineae (Ludwig et al., 1983).

Taxonomy of Myxobacteria

All known myxobacteria are united in the single order Myxococcales. The name has recently been changed from Myxobacterales (McCurdy, 1989) in accordance with Rule 9 of the International Code of Nomenclature of Bacteria (which requires that the name of an order be derived from the name of the type genus). The order may be subdivided into two suborders: Cystobacterineae and Sorangineae (Reichenbach, 1974a). As discussed earlier in this chapter, the members of the suborders differ in cell shape, myxospore development, colony structure, fatty acid, and carotenoid pattern, and in the chemical composition of their slime (Congo red reaction). The suborders are divided into families based on the organization of the fruiting bodies and the shape of the myxospores. The definition of genera and species is based on the same characteristics and on a few complementary physiological facts. There are different possibilities for splitting and rearrangement, and in the absence of more compelling arguments, personal preference must still determine which route to follow. All in all, we can distinguish 12 genera and about 40 different species of myxobacteria, a number that is not likely to increase dramatically in the future. It must be emphasized, however, that myxobacterial taxonomy cannot yet be regarded as settled and we are still confronted with major problems in distinguishing species, e.g., in the genera *Corallococcus, Archangium, Cystobacter,* and *Polyangium.*

A survey of the taxonomy of myxobacteria as favored by us is given in Table 3; it differs in some respects from the taxonomy presented in *Bergey's Manual* (McCurdy, 1989). An annotated and illustrated key to the genera follows below.

Illustrated Key to the Genera of Myxobacteria*

1. Vegetative cells are slender rods with more or less tapering ends, cigar-, boat-, or needle-shaped, about 3.5 to 7 μm long and 0.6 to 0.8 μm wide. Swarms (e.g., on VY/2 agar) tend to remain thin, filmlike, and often show a striking surface structure in form of radial veins and fields of tiny ridges or waves. Swarm edge usually has delicate fringes and flamelike protrusions. Myxospores arise through a striking cellular morphogenesis: the vegetative cells always shorten and fatten substantially. Myxospores always seem to have a capsule, which, however, is often seen only under the electron microscope. Slime and swarm sheets are stained with Congo red. The fatty acid pattern is dominated by branched-chain fatty acids; 2- and 3-hydroxy fatty acids are present in substantial amounts. All species are of the bacteriolytic type.
Suborder: Cystobacterineae 2

1′. Vegetative cells are stout, cylindrical rods, sometimes almost cube-shaped, with broadly rounded ends, about 2.5 to 6 μm long and 0.6 to 1.0 μm wide. Swarms (e.g., on VY/2 agar) tend to sink into and to penetrate the agar, sometimes to the bottom of the plate; they usually form shallow pits and bowllike depressions; their surface structure is often less pronounced, although radial veins, ring-shaped ridges, and fanlike structures may be produced. The agar surface in the swarm area may be more or less corroded. Often, the cells concentrate at the swarm edge as a band or a massive ridge, or they form spherical or kidney-shaped clusters that migrate away from the center and leave deeply etched paths in the agar surface. Myxospores differ only slightly from vegetative cells in shape and seem to possess no capsule or, at the most, a very thin one; they are, however, optically refractile. Slime and colonies do not stain with Congo red. Branched-chain fatty acids are reduced in the fatty acid pattern, and hydroxy fatty acids are completely absent. Several species are cellulose decomposers.
Suborder: Sorangineae 7

2. Myxospores are regular spheres or ovoids with a smooth surface and a heavy capsule, diameter 1.2 to 2.5 μm. Vegetative cells are 3 to 5 μm long, boat- or cigar-shaped. Swarms often consist of a relatively soft slime sheet, although occasionally tough and tenacious sheets are also produced. The surface structure of the swarm is often rudimentary, but characteristic meandering radial veins may develop. Fruiting bodies are simple, spherical, soft-slimy mounds, or cartilaginous columns and ridges that are sometimes branched, both without a distinct outer wall. In the case of *Angiococcus* they consist of spherical or disk-shaped sporangioles.
Family: Myxococcaceae 3

Fig. 16 illustrates the various forms given in the key. The numbers in the figure refer to those in the key.

Comments. The differentiating characteristic of the family is the smooth, spherical myxospore. Myxospores that are nearly spherical are found with three other myxobacteria (*Archangium, Cystobacter, Nannocystis*), which can, however, easily be distinguished by the characters mentioned below.

3. Fruiting bodies are soft-slimy spherical heads or drops, often constricted at the base, in one species with a long slime stalk .... *Myxococcus*
Comments. In agar cultures the shape of the fruiting body often deviates from the type, and only flat, cushionlike mounds or ridges are produced. There are four species: *Mx. fulvus* has white, pink, brick red, or even violet fruiting bodies with small myxospores (1.2 to 1.8 μm). *Mx. xanthus* and *Mx. virescens* produce orange and greenish yellow fruiting bodies, respectively, and have large myxospores (1.8 to 2.5 μm); they may be only one species, although it appears that typical *Mx. virescens* strains produce very large myxospores and often grey, fruiting bodies on VY/2 agar. *Mx. stipitatus* has white-to-brownish fruiting bodies with a long slime stalk; they are often found in groups on a common cushionlike base. Its myxospores are small and they are often, but not always, clearly oval in shape. The swarms show a strong yellow fluorescence with UV light illumination at 366 nm; it is, however, not yet established whether this quality is exclusive for the species.

3′. Fruiting bodies are tough cartilaginous columns or ridges, sometimes staghorn- or coral-branched, very variable in shape, often more or less deeply rooted within the agar .... *Corallococcus*
Comments. This genus has formerly been called *Chondrococcus*. The name is improper because it has been previously used for an alga. In *Bergey's Manual* (McCurdy, 1989), the genus is united with *Myxococcus*, but we prefer to retain it and suggest a new generic name.
Because of its enormous variability, many species have been described in this genus, only two or three of which may be realisitc. But a final decision will require more information. *Cc. coralloides* has small myxospores (1.2 to 1.8 μm) and produces relatively large pink or red fruiting bodies that are often branched or bear finger- or hornlike projections. Strains that also have small myxospores and produce large numbers of tiny, brownish fruiting bodies in dense fields have been described as *Cc. exiguus*. They either represent a species of their own or a variety of the former. *Cc. macrosporus* has large myxospores (1.8 to 2.4 μm) and sturdy, yellow fruiting bodies. In contrast to the other two species, it is relatively rare.

3″. Fruiting bodies consist of tiny, spherical or disk-shaped sporangioles with a definite outer wall
.... *Angiococcus*
Comments. There is only one species, *An. disciformis*. The species as such, has long been absent from descriptions of the myxobacteria although its original description by Thaxter (1904) was very clear. It has since been isolated again, and in fact it is not even particularly rare. The sporangioles appear in dark brown clusters that superficially resemble *Corallo-*

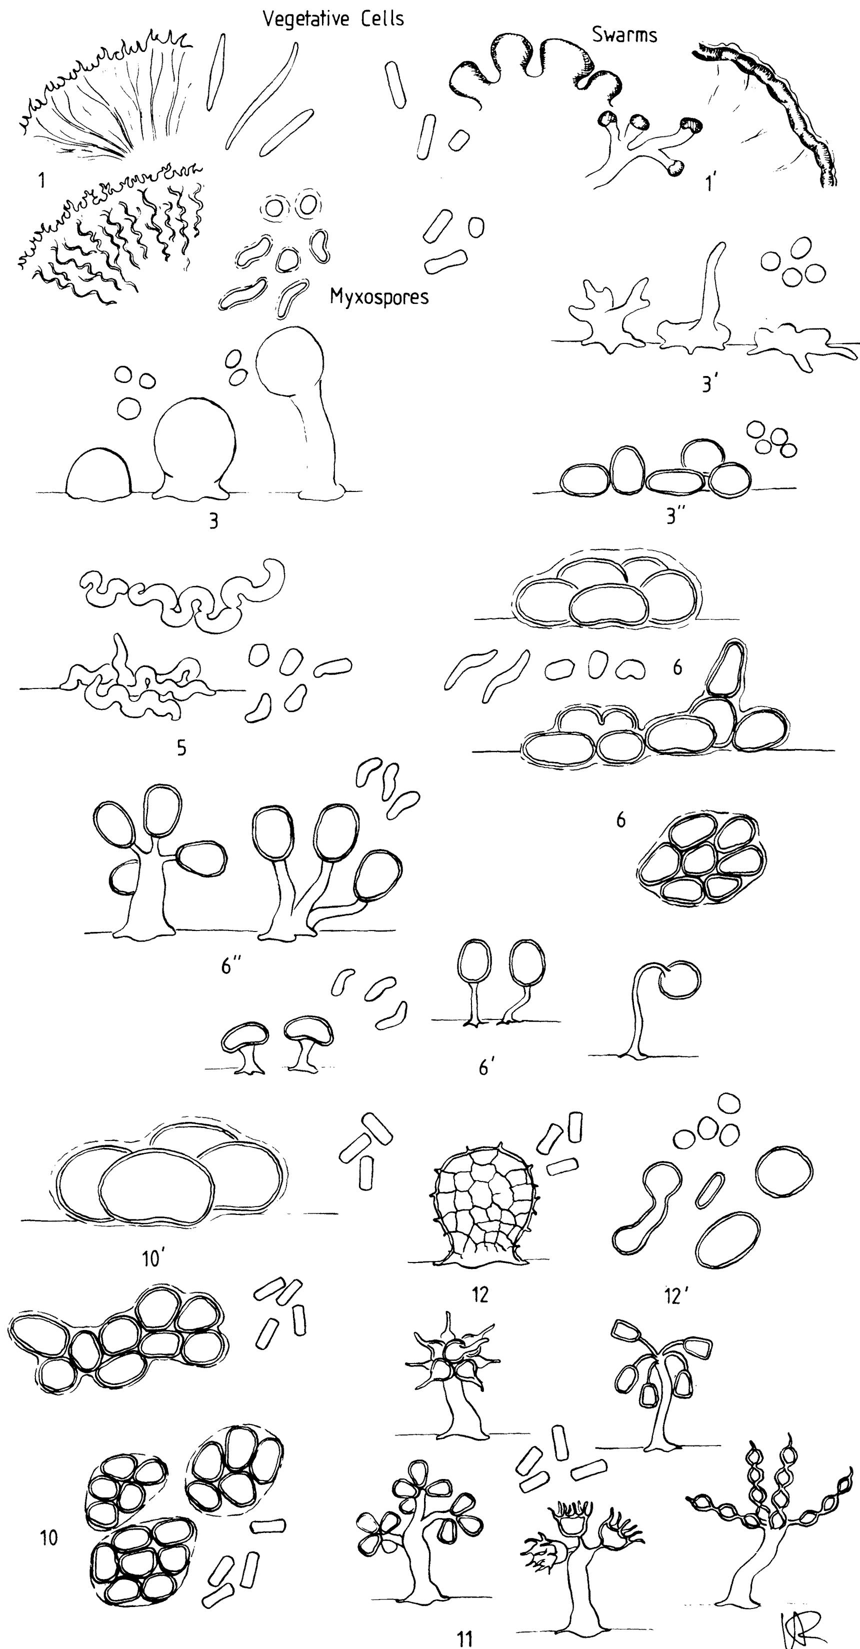

Fig. 16. A diagrammatic illustration of the key to the myxobacterial genera. The numbers in the figure refer to those in the key. The cells shown next to the fruiting bodies are myxospores.

Table 3. Taxonomic survey of the myxobacteria.

Order: Myxococcales	
Suborder:	Cystobacterineae
Families and genera:	Myxococcaceae
	Myxococcus
	Corallococcus (formerly *Chondrococcus*)
	Angiococcus
	Archangiaceae
	Archangium
	Cystobacteraceae
	Cystobacter
	Melittangium
	Stigmatella
Suborder:	Sorangineae
Families and genera:	Sorangiaceae
	Sorangium
	Polyangium
	Haploangium
	Chondromyces
	Nannocystis

coccus fruiting bodies, with which they may often have been confused. It is not yet clear whether this bacterium belongs to the Myxococcaceae, although its swarm resembles that of the other members of the family, and not that of *Cystobacter* to which genus the species has been transferred in the most recent edition of *Bergey's Manual* (McCurdy, 1989). The myxospores are spherical and small (1.2 to 1.8 μm).

4. Fruiting bodies consist of irregular masses of hardened slime, in which the myxospores are embedded, and lack an outer wall. They are either cushions with a bulging brainlike surface, or ridges that consist of meandering rolls, often with rising, fingerlike projections. Myxospores are short, fat rods, often bean-shaped or almost spherical, but clearly less regular than the myxospores of the myxococci. Vegetative cells are long, slender rods with tapering ends. Swarm is thin and spreading (e.g., on VY/2 agar), usually with a pattern of densely crowded, long, radial veins and a tough slime sheet.
Family: Archangiaceae 5
Comments. The family is characterized by the shape and structure of its fruiting bodies, myxospores, and vegetative cells. However, many myxobacteria may form degenerate fruiting bodies that resemble those of the Archangiaceae exactly. This tendency is especially true for the members of the Cystobacteraceae, and if no typical fruiting bodies are observed during isolation and cultivation, there is often no way to discriminate between an *Archangium* and a degenerated *Cystobacter* or *Melittangium.* The situation is further complicated by the fact that the vegetative cells and myxospores of these organisms are of similar shape. It may even be argued that a separate genus *Archangium* does not exist, but this conclusion is probably not correct; because, on natural substrates, one often observes large *Archangium* fruiting bodies side by side with typical *Cystobacter* fruiting bodies, and both organisms retain their original character when isolated. A careful study with modern taxonomical methods would be helpful. Although *Archangium*-type fruiting bodies are also produced by members of the Sorangineae, in this case, the different shape of the vegetative cells allows an easy differentiation from the Archangiaceae.

4′. Fruiting bodies consist of sporangioles with a distinct outer wall, often with stalks. Myxospores are short, fat rods. Vegetative cells are slender rods with tapering ends, either boat- or needle-shaped.
Family: Cystobacteraceae 6
Comments. Aberrant fruiting bodies are common in cultures (see Archangiaceae).

5. The family contains only one genus, *Archangium.* Several species have been described in the genus. However, the variability of *Archangium* fruiting bodies, and the degeneration of the fruiting bodies of other myxobacteria to *Archangium*-like structures, makes it impossible at the moment to distinguish these different species. In fact, it is not even possible to recognize *Archangium* reliably, and it would be more honest to name such strains "*Archangium*-like myxobacteria." *Ar. serpens* is the first species for which *Archangium*-type fruiting bodies have been described, and in the absence of clear, distinguishing characteristics, we prefer to label all relevant strains with this name. *Ar. violaceum* must be regarded as a degenerated *Cystobacter, C. violaceus,* under which name the organism was originally described.

6. Fruiting bodies are clusters of sporangioles that sit directly on the substrate, often embedded in a clearly recognizable, common, transparent slime envelope or covered by a slime sheet .... *Cystobacter*
Comments. There are myxobacteria with very similar fruiting bodies in the suborder Sorangineae, and some of these were originally united with the present *Cystobacter* species in a common genus, *Polyangium,* which, incidently, is the oldest generic name in myxobacterial taxonomy (Link, 1809). The original family name was Polyangiaceae. Subsequently, it was realized that the genus *Polyangium* was heterogeneous. It was therefore split, and the Sorangineae-type species were united with species of the genus *Sorangium.* For reasons of priority, the name of the newly defined genus was *Polyangium,* and for the remaining species the old generic name *Cystobacter* Schroeter 1886 was reactivated. The genus *Sorangium* disappeared completely, and as a consequence the family name Sorangiaceae was also eliminated and replaced by Polyangiaceae, which now, of course, had a completely different meaning than before. We feel this change has led to unnecessary confusion, and therefore shall no longer use the family name Polyangiaceae. Rather we shall redefine the genus *Sorangium* and reintroduce the family name Sorangiaceae.

The species of the genus *Cystobacter* are not well studied, and it is not clear at the moment how many there are. The type species, *Cb. fuscus,* is readily recognizable from its large, glistening, chestnut brown sporangioles. *Cb. ferrugineus* has large, elongated,

dull, dark brown sproangioles; they are often arranged in chains that tend to curve upwards in a fingerlike fashion. Both species have relatively long and slender, often slightly curved myxospores and are strongly chitinolytic. There are strains that produce light to reddish brown and often kidney-shaped sporangioles that are covered by a thin, translucent, and delicately plicated slime sheet; the myxospores are short, fat rods; these strains clearly represent a separate species, *Cb. velatus.* Other strains form somewhat smaller but still large, dull, dark brown, spherical sporangioles that contain myxospores in the shape of short, fat rods; they often produce a deep violet pigment, and appear to constitute the species *Cb. violaceus.* Still other strains form tiny, light to golden brown, spherical sporangioles that are tightly packed together in small clusters and are often embedded in the agar substrate, resembling *Sorangium* or *Polyangium* fruiting bodies in all these respects; but the vegetative cells are long, slender needles, the myxospores short, fat rods, and the swarms of the *Cystobacter* type. These organisms belong to *Cb. minor.* The problem of *An. disciformis* has already been discussed.

6′. Fruiting body consists of a tiny sporangiole sitting on a delicate, white stalk .... *Melittangium*
Comments. Most species were formerly attached to the genus *Podangium.* The type species of *Podangium, Pd. erectum,* has since been transfered to *Stigmatella*; the remaining species have been united in the genus *Melittangium,* so that the genus *Podangium* is now dissolved. There are at least three *Melittangium* species: *Me. boletus* has sporangioles that resemble mushroom caps and are located on very short stalks. *Me. lichenicola* forms spherical, dark brown sporangioles on short and relatively sturdy stalks. *Me. alboraceum* is described as having a spherical sporangiole on a long and bent stalk. There are also strains that produce very tiny and delicate fruiting bodies; they may represent still another species, *Me. gracilipes.* The myxospores are always short, fat rods, the vegetative cells long, slender needles.

6″. Fruiting bodies consist of dull, orange-brown to dark brown, ovoid sporangioles, which are arranged either as several on a common stalk or each on a stalk of its own .... *Stigmatella*
Comments. *Stigmatella* is easily distinguished from *Melittangium*: its fruiting bodies are much coarser, and the vegetative cells are boat-shaped and of moderate length. The myxospores are short, fat rods and often S- or C-shaped. There are two species: *Sg. aurantiaca* with several sporangioles attached to a common stalk, often via tiny peduncles; and *Sg. erecta* with one sporangiole on each stalk. Clear as this may appear, the two species still are sometimes difficult to differentiate, because *Sg. erecta* often produces several fruiting bodies side by side on a common base and sometimes with partially fused stalks, so that the resulting structure may be confused with a *Sg. aurantiaca* fruiting body. These two species occupy different ecological niches: While *Sg. aurantiaca* almost always appears on rotting wood, *Sg. erecta* is found preferentially on dung and sometimes in soil. *Sg. erecta* was formerly classified as *Podangium erectum* (see "Comments" on *Melittangium*), *Sg. aurantiaca* as *Chondromyces aurantiacus.*

7. Characters of the suborder.
Family: Sorangiaceae 8
Comments. See *Cystobacter.*

8. Fruiting bodies consist of several sporangioles clustered together 9

8′. Fruiting bodies consist of solitary sporangioles 12

9. Sporangioles located directly on or within the substrate 10

10. Fruiting bodies consist of tiny sporangioles that are tightly packed together and consequently are often polyhedral rather than spherical. A large number of the small parcels thus formed may lie together in more or less densely packed masses, but also the parcels themselves may become rather large. The fruiting bodies are often produced in enormous quantities, especially on digested filter paper, so that they determine the color of the swarm: bright yellow, orange, all shades of brown, and even pitch black. The vegetative swarm is usually more or less bright orange. Decomposes crystalline cellulose (filter paper) .... *Sorangium*
Comments. We propose to restrict this genus to the cellulose decomposers. Cellulose degradation is such a unique and stable character, and in addition parallels a series of other morphological, physiological, and biochemical characteristics in the respective strains, that a separation of the cellulolytic species seems justified. The organisms have not been sufficiently studied to allow satisfactory classification of species. In addition, it is not always apparent from the original descriptions whether an organism was a cellulose decomposer, because not all strains have been cultivated. Also, the organisms are very variable. There appear to be at least two species: *So. compositum* produces yellow-orange fruiting bodies, *So. cellulosum* brown, gray, or black ones, but this characteristic appears insufficient to differentiate the two species reliably. There are many other morphological, chemosystematical, and physiological differences among strains, but the taxonomic relevance of these observations is presently still under study.

10′. Fruiting bodies consist of more or less spherical sporangioles, that may be yellow, orange, brown, or grey. Several of them may be embedded in a common, translucent slime envelope .... *Polyangium*
Comments. For some time, this genus also contained the species of *Cystobacter* (see there for further comments). *Pl. vitellinum* produces large, golden yellow sporangioles in groups of 1 to 20 in a common envelope. It appears that in culture the color often changes to greenish yellow. *Pl. luteum* has smaller, golden yellow sporangioles embedded in a yellow slime envelope. *Pl. aureum* may be another species of this group of polyangia with orange sporangioles. *Pl. thaxteri* produces large, golden yellow sporangioles that are typically borne as a convoluted mass on a short, stout slime stalk; the whole

structure then resembles the fruiting body of a false morel (*Gyromitra*); often the sporangioles are, however, found directly on the substrate. There are further strains with small sporangioles that are densely clustered together in the same way as with certain *Cystobacter* and *Sorangium* strains. The fruiting bodies are light brown or gray in color and usually are embedded in the agar substrate. Probably, all strains of this type can be classified as *Pl. fumosum* and *Pl. spumosum*. *Pl. parasiticum* seems to parasitize fresh-water algae; it produces red-brown sporangioles within the emptied alga cells. This species has not been reported since its first description in 1925, and its parasitic growth and even its appearance in freshwater may have been an exceptional situation. The polyangia are somewhat difficult to handle and are not well-studied organisms. There are some doubts whether the present genus is really homogeneous.

11. Fruiting bodies consist of a conspicuous, unbranched or branched slime stalk, bearing cluster of bright orange sporangioles .... *Chondromyces*
Comments. The myxobacteria with the most beautiful and complex fruiting bodies are found in this genus. There are five species. One species, *Cm. aurantiacus* had to be transferred to the genus *Stigmatella*. *Cm. crocatus* has a branched stalk with clusters of small, ovoid sporangioles at the ends of the branches. All other species have unbranched stalks. *Cm. apiculatus* produces conspicuous, turnip-shaped sporangioles, and *Cm. pediculatus* produces bell-shaped sporangioles, often drooping on long, delicate peduncles; both species are relatively common, the former especially on rotting wood, the latter often in soil and decaying plant material. *Cm. catenulatus* produces chains of sporangioles, and several chains originate from one stalk. *Cm. lanuginosus* (formerly *Synangium*) has a cluster of a few large sporangioles each of which ends in a ring of long tips; the sporangiole thus resembles the young fruit of a hazelnut.
12. Fruiting bodies are large, solitary sporangioles, golden yellow, with a wrinkled or netlike surface structure when mature, found on bark and decaying wood .... *Haploangium*
Comments. This genus is easily recognized by its peculiar fruiting bodies that so far have only been encountered on the bark of living or dead trees in North America and in Europe. It also has a special position in that these are the only myxobacteria that have resisted all efforts to cultivate them. (The "*Haploangium*" species described and cultivated by Singh and Singh, 1971, were obviously misnamed because their vegetative cells were long, slender rods with tapering ends.) There may be two species that differ in size: *Ha. rugiseptum* with large sporangioles, and *Ha. minus* with small ones.

12′. Fruiting bodies are tiny, ovoid or spherical, solitary sporangioles that are produced in large numbers and are mostly embedded in the substrate. Myxospores are spherical or ovoid. Vegetative cells are often very short, stout, almost cube-shaped. Swarm is etched more or less deeply into the agar. The agar plate may become completely corroded .... *Nannocystis*
Comments. Presently only one species, *Na. exedens*, is known, but probably other species do exist. *Na. exedens* is easily recognized by its typical swarm pattern, which is especially conspicuous on water agar with streaks of living or autoclaved *E. coli*, and by its unique fruiting bodies. The latter may become considerably larger and very irregular in shape when they are produced on the agar surface. On an agar surface, some strains produce composite fruiting bodies that consist of clusters of small sporangioles that are more or less tightly squeezed together. Such strains may represent a different species ("*Na. aggregans*"). *Nannocystis* is perhaps the most common myxobacterium, although it is often overlooked; it is present in virtually every soil sample that contains any myxobacteria. While *Nannocystis* fits, in general, rather well to the other members of the suborder, it shows certain peculiarities that clearly set it apart, such as the nature of its carotenoid pigments and its synthesis of steroids.

Applications

Although myxobacteria have not been used in any industrial process, they do have some potential for biotechnological application. There are also some aspects of their biology which may have economic or environmental impact, even if this has not always been obvious, as described below.

There are no known myxobacterial pathogens for humans, animals, or plants. The fish pathogen *Chondrococcus columnaris* is a *Cytophaga*-like bacterium and has been wrongly classified as a myxobacterium. Because of their many aggressive enzymes, myxobacteria may occasionally contribute to the deterioration of materials such as rawhide or cellulose fabrics (e.g., Heyn, 1957), but it is doubtful that they are an important factor in that respect. However, although not yet demonstrated experimentally, it seems reasonable that they play a substantial role in nature in solubilizing large macromolecules, cell carcasses, and other biological detritus. As myxobacteria may reach rather high population densities in soil, it has been argued that they could become antagonistic to useful soil organisms like *Azotobacter* (Callao et al., 1966). However, although a suppression of *Azotobacter* by *Mx. xanthus* can indeed be demonstrated in the laboratory, it is an open question whether this occurs in nature. Myxobacteria are obviously able to destroy cyanobacteria in mixed cultures in aqueous environments, and it has been suggested that they could perhaps be used to control cyanobacterial water blooms (Burnham et al., 1981, 1984; Daft

et al., 1985). However, that potential has not yet been demonstrated under practical conditions. Still another application of myxobacteria in environmental problems may be their use as pollution indicators (Gräf, 1975; Tržilová et al., 1980, 1981). This scheme is presently being perfected and may eventually become a useful addition to conventional biological water analysis.

Certain chemical compounds produced by myxobacteria may occasionally become troublesome. Many myxobacteria produce a strong earthy smell, which, in the case of *Na. exedens,* has been demonstrated to be due to geosmin (Trowitzsch et al., 1981). While that smell may be pleasant in connection with soil, it is extremely disagreeable in drinking water, from which it has to be removed. The omnipresent myxobacteria could be a major source of that odor.

A good opportunity for application may lie in the field of myxobacterial enzymes, a potential that has not yet been thoroughly investigated. Thus, restriction endonucleases (Mayer and Reichenbach, 1978; Morris and Parish, 1976) and special proteases could become of interest in the future.

The efficient secretion of proteins observed with myxobacteria is unusual for Gram-negative bacteria and points to another conceivable application, as unusual expression hosts for foreign proteins (Breton et al., 1984, 1986; Nicaud et al., 1984). *Mx. xanthus* has been shown to secrete more than 50 different proteins into the medium, amounting to about 4% of the intracellular protein. This is impressive even if the actual number may be somewhat lower because some of the bands may have been due to proteolytic activity (Nicaud et al., 1984). It appears that the outer membrane of the myxobacterial cell is less of a barrier than in most other cells, perhaps due to its more dynamic behavior. It has been demonstrated that two *E. coli* periplasmic enzymes, acid phosphatase and TEM2 β-lactamase, leave the periplasm quickly when they are expressed in *Mx. xanthus* and appear in the extracellular medium (Breton and Guespin-Michel, 1987). The extracellular pectate lyases of *Erwinia* are also expressed in *Mx. xanthus* and secreted into the medium, although in this case the myxobacterial proteases inactivate the lyase (Breton et al., 1986).

Finally, there are some myxobacterial products that could become of interest. The lectin produced by *Mx. xanthus* during aggregation has already been mentioned (Cumsky and Zusman, 1981; Nelson et al., 1981), and there may be more of them. *Mx. xanthus* also secretes a blood anticoagulant, myxaline, which is a heat-stable glycopeptide (El Skoum et al., 1987; Masson and Guespin-Michel, 1988). The same or a similar compound is also produced by other myxobacteria.

The most promising opportunities for biotechnological applications with myxobacteria are at present in the production of secondary metabolites, especially compounds with biological activity such as antibiotics and other inhibitors. Although the ability of the myxobacteria to produce antibiotics has been known for some time (Katô, 1955; Norén, 1953; Norén and Raper, 1962; Oxford, 1947), apart from trivial fatty acids that were found to inhibit the germination of fungal spores (Norén and Odham, 1973), until relatively recently, no chemical structure was proposed for any of these inhibitors. The first myxobacterial antibiotic for which the chemical structure has been elucidated was ambruticin, a potent antifungal compound from *So. cellulosum* (Ringel et al., 1977). In the past decade, about 40 basic structures and 200 structural variants have been discovered in myxobacteria and have been fully characterized chemically. As most of these results have been reviewed (Reichenbach and Höfle, 1989; Reichenbach et al., 1984, 1988), this material is not discussed here in detail. The more significant insights can be summarized as follows: 1) A high proportion of myxobacterial strains produce some kind of compound with biological activity: about 50% among the Cystobacterineae, almost 100% of the *Sorangium* strains. 2) The substances produced are chemically very different, including aromatic, heterocyclic, and polyenic compounds, alkaloids, macrocycles, polyethers, and peptides. A few examples are shown in Fig. 17. 3) Most of these compounds have not been isolated from other organisms and thus appear to be unique to the myxobacteria. The only exceptions are pyrrolnitrin and althiomycin; saframycin has been found with a new variant. 4) The ability to produce a specific compound is typical for a certain strain, and not for all strains of that species. In fact, different strains of the same species may produce totally different antibiotics, but the same antibiotic may also be found in different species and even genera. Interestingly, the border between the two suborders is also a division line for the secondary metabolism, and so far no compound has been found that is produced by representatives of the two different suborders. 5) A strain may produce, at the same time, two or more compounds that are totally different chemically. 6) Often a family of chemical variants of the same basic structure is synthesized by a strain; up to 40 different variants have been isolated from one single strain. 7) The initial yields are usually low, between 0.5 and 20

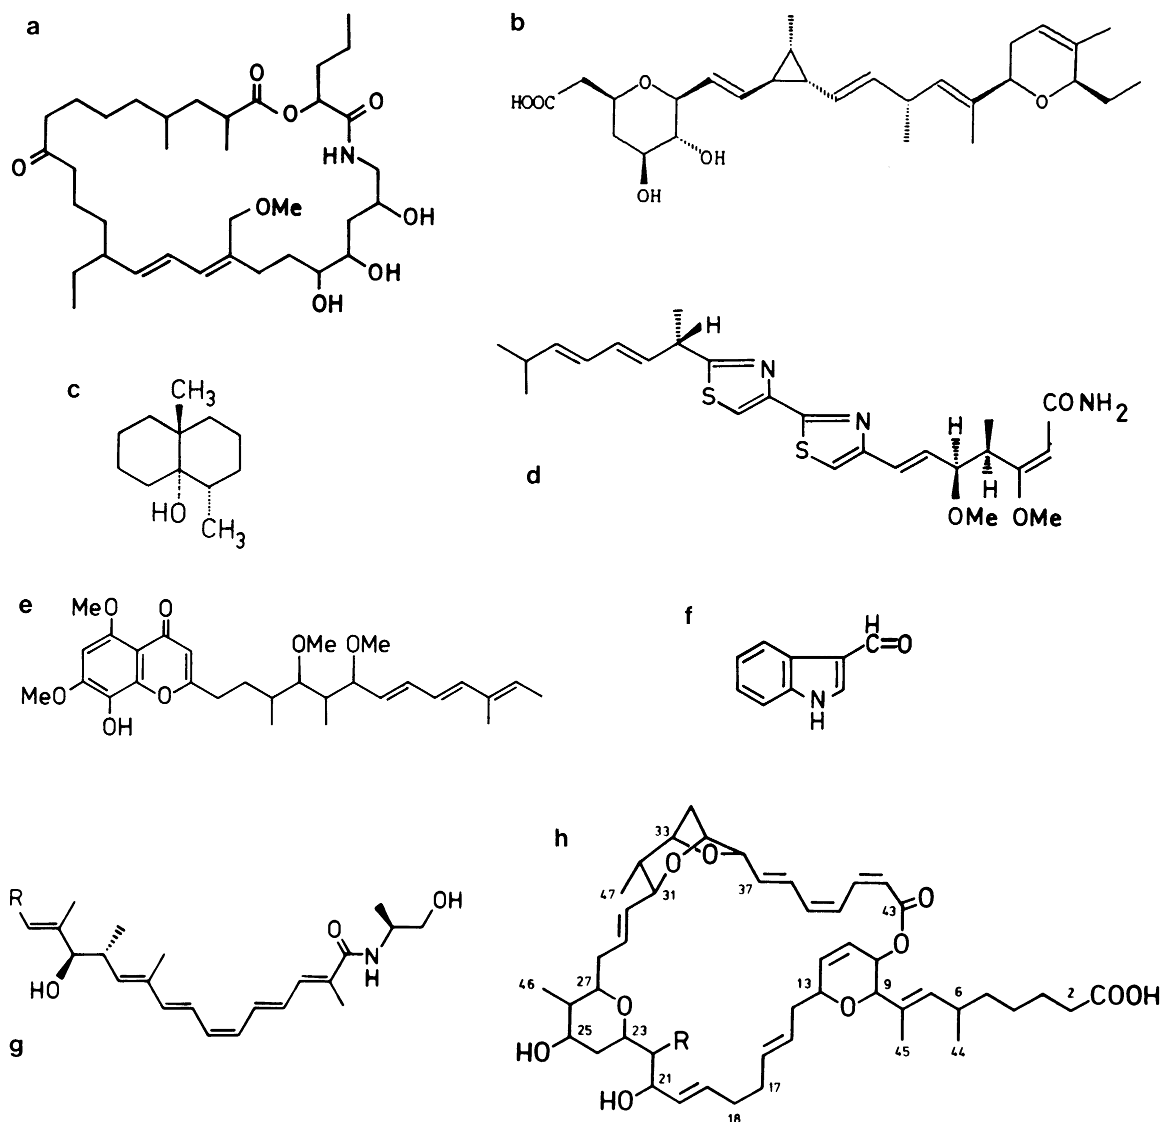

Fig. 17. A few examples of secondary metabolites produced by myxobacteria. (a) Myxovirescin A; the compound, or variants of it, has been described as antibiotic TA and as megovalicins; (b) ambruticin; (c) geosmin; (d) myxothiazol; (e) stigmatellin; (f) 3-formylindole; (g) myxalamid; R is 2-butyl, 2-propyl, ethyl, and methyl for myxalamids A, B, C, and D, respectively; (h) sorangicin; R is OH and H for sorangicin A and B, respectively.

mg/liter, but with conventional methods, yield increases to more than 1 g/liter have already been achieved. 8) Interesting mechanisms of action have been discovered; compounds have been discovered that are specific inhibitors of eubacterial RNA and protein synthesis or are extremely efficient inhibitors of electron transport in respiration and photosynthesis. Two of the latter are used as specific biochemical probes and are commercially available (myxothiazol, stigmatellin). Antitumor and antiviral substances including substances active against the human immunodeficiency virus) have also been found. Among the compounds discovered also are iron transport metabolites of the myxobacteria (myxochelin, nannochelin). At the moment, several of the myxobacterial inhibitors are being intensely studied for potential application and large-scale production.

Antibiotic TA was discovered in *Mx. xanthus* strain TA (Rosenberg et al., 1973), but its structure has not been elucidated so far. Published chemical data, specifically NMR data (Rosenberg et al., 1982) suggests that the compound may be identical to one of the 20 variants of myxovirescin (Gerth et al., 1982; Trowitzsch et al., 1982; Trowitzsch-Kienast et al., 1989). This identification is further supported by the observation that, myxovirescins are produced by many *Mx. xanthus* and *Mx. virescens* strains

(H. Reichenbach, unpublished observations). In fact, the same antibiotic has been described a third time from another *Mx. xanthus* strain (Onishi et al., 1984). Furthermore, the megovalicins (Miyashiro et al., 1988; Takayama et al., 1988) are identical with previously published variants of myxovirescin; a new species, *Mx. flavescens,* has been created to describe the producing organism (Yamanaka et al., 1987), which cannot, however, be distinguished from existing species. Novel compounds with antitumor activity, the glidobactins, have recently been discovered in what seems to be a *Nannocystis* or a *Polyangium* strain (Oka et al., 1988a, 1988b, 1988c). These compounds are acylpeptides with a variable fatty acid moiety and a constant cyclic dipeptide nucleus consisting of two new amino acids. Finally, antibacterial activity has been reported in a strain of *Cc. coralloides,* but chemical data that allow an identification of the compound have not so far been produced (Arias et al., 1979a, 1979b).

The Genera *Campylobacter* and *Helicobacter*

FRED C. TENOVER and CYNTHIA L. FENNELL

Introduction

The genus *Campylobacter* encompasses a diverse group of organisms that are either commensals for pathogens for both humans and animals. Thirteen species are currently included in the genus (Table 1). The new genus *Helicobacter* contains two species previously classified as Campylobacter (Table 1). All of these organisms are Gram-negative, nonsporeforming, oxidase positive, indole negative, asaccharolytic organisms that neither ferment nor oxidize carbohydrates (Smibert 1978, 1984; Penner, 1988). Energy is produced through respiration and the metabolism of amino acids. The GC content for members of the genus falls between 29–39 mol% (Fox et al., 1989; Owen, 1983; Owen and Leaper, 1981; Harvey and Greenwood, 1983b; Ursing et al., 1983). All these organisms are slender, helically curved Gram-negative rods that are 0.2–0.5 μm wide and 0.5–8.0 μm long (Fig. 1). Pairs of cells have an S-shaped or gull-wing morphology while longer chains of cells form spirals. The shorter campylobacter forms move in a rapid, darting manner while spiral forms rotate along the long axis like corkscrews. The wavelength, amplitude, and length of the spirals vary among species. With the exceptions of *Helicobacter pylori* and *H. mustelae,* the organisms are motile by means of a long single, polar flagellum found at one or both ends of the cell (Smibert 1984). *H. pylori* has multiple flagella located at only one end of the cell while *H. mustelae* has both polar and lateral flagella (Fox et al., 1989).

Table 1. Current *Campylobacter* and *Helicobacter* taxonomy.

Species	Subspecies	Biovar
C. fetus	*fetus, venerealis*	
C. jejuni	*jejuni, doylei*	
C. coli		
C. laridis		
"C. upsaliensis"		
C. hyointestinalis		
C. mucosalis		
C. cinaedi		
C. fennelliae		
C. sputorum		*sputorum, bubulus, faecalis*
C. concisus		
C. cryaerophila		
C. nitrofigilis		
H. pylori[a]		
H. mustelae[a]		

[a]The new genus name *Helicobacter* has recently been accepted for these species (Goodwin et al., 1989).

Historical Review of Taxonomy

Campylobacters were originally thought to be members of the genus *Vibrio* and were first cited in the literature by McFadyean and Stockman (1913) as a cause of abortions in ewes. Smith (1918) and Smith and Taylor (1919) associated these curved bacilli, which they named *Vibrio fetus,* with abortion in cattle, thus extending the known host range of this group of organisms. Jones and Little (1931) added winter dysentery in calves to the list of diseases attributable to the new vibrios, calling their isolates *V. jejuni* and Doyle (1944) ascribed swine dysentery to the organism he called *V. coli.* Thus, by 1944, the epithets *V. fetus, V. jejuni,* and *V. coli* had all appeared in the literature and the organisms were well established as veterinary pathogens. It was shortly thereafter that Levy (1946) noted the presence of spiral organisms in the blood of some of 350 people affected with gastrointestinal disease. Unfortunately, the organism seen by microscopy was not recovered by culture from any of these cases. However, in the following year Vinzent et al. (1947) were successful in isolating the organism known as *V. fetus* from the blood of three pregnant women, two of whom went on to have spontaneous abortions. This marked the beginning of the association of these novel vibrios with human disease.

The key observation that initiated the current interest in this group of organisms in human

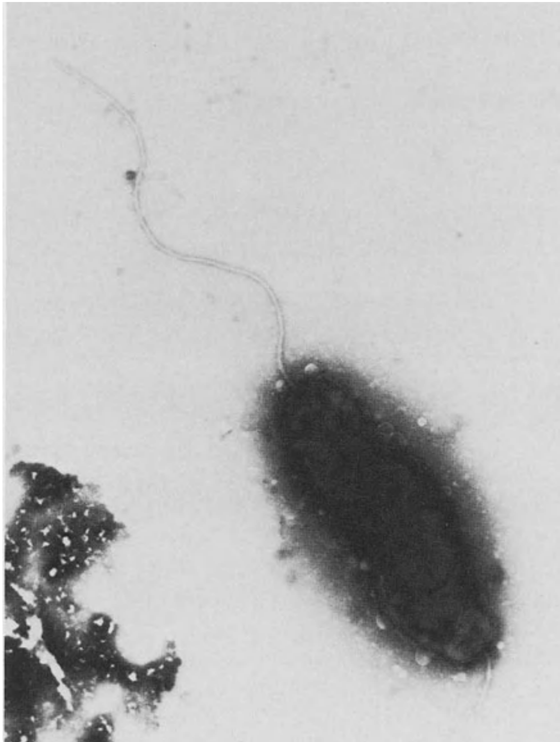

Fig. 1. Electron micrograph of *Campylobacter jejuni* subsp. *jejuni*. Magnification 17,000 ×. Diameter of cells is 0.6 μm.

disease was made by King (1957) who isolated from the blood of a patient an organism that was similar in morphology to the *V. fetus* described by Vinzent et al. (1947) but that differed biochemically and antigenically from *V. fetus*. King named the organism, which grew at 42°C, a "Related Vibrio" and hypothesized that the organism would someday be recovered from the stool of humans with diarrheal illness (King, 1962). This would not be accomplished, however, until 1972 (Dekeyser et al., 1972).

The differentiation of species within the genus *Vibrio* was undertaken by Florent (1959) who described *V. fetus* subsp. *intestinalis*, the pathogen causing septic abortion in sheep, as a spiral organism capable of growing in the presence of 1% glycine and able to produce H_2S, vs. *V. fetus* subsp. *venerealis*, the cause of infectious infertility in cattle, which does not show these characteristics.

Sebald and Véron (1963) demonstrated that the new group of organisms bearing the designations of *V. fetus*, *V. jejuni*, and *V. coli* could be distinguished biochemically and by DNA-base composition from the traditional members of the genus *Vibrio*. They designated a new genus, *Campylobacter*, meaning "curved rod," to encompass the new group. Véron and Chatelain (1973) published a comprehensive taxonomy of the genus *Campylobacter*, designating the organism described as *V. fetus* subsp. *intestinalis* by Florent (1959) as the type species and renaming it *Campylobacter fetus* subsp. *fetus*. Although Smibert took a different view of the taxonomy, designating *V. fetus* subsp. *venerealis* as the type species and renaming it *Campylobacter fetus* subsp. *fetus* (Smibert, 1974), the nomenclature of Véron and Chatelain (1973) has been selected as that which appears in the list of approved bacterial names (Skerman et al., 1980). After a careful review of the literature, Karmali and Skirrow (1984) confirmed that the original description by McFadyean and Stockman (1913) most closely resembles *C. fetus* subsp. *fetus*, which is thus given the position of type species. The name *C. fetus* subsp. *intestinalis* is now defunct and does not appear in Skerman's list of approved bacterial names.

The status of the genus *Campylobacter* continues to be in flux. For example, *C. pylori* and *C. mustelae* have been renamed *Helicobacter pylori* and *H. mustelae* (Goodwin et al., 1989). This change was based on the results of rRNA analysis and other features of the organisms (Lau et al., 1987; Romaniuk et al., 1987; Thompson et al., 1988). Based on 5S and 16S rRNA sequence data, other members of the genus *Campylobacter* may well be moved to other genera in the near future (Thompson et al., 1988), while organisms such as *Wolinella recta*, *W. curva*, *Bacteroides gracilis*, and *B. ureolyticus* may someday be included in the *Campylobacter* genus (Lau et al., 1987; Paster and Dewhirst, 1988). Because these changes are difficult to predict, this chapter will not address those issues but rather will focus on those organisms that currently are accepted in the genus.

Descriptions of Campylobacter Species

C. fetus is the type species of the genus and has two recognized subspecies, *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis*. *C. fetus* subsp. *fetus* is a cause of sporadic abortion in cattle and sheep (Bryner et al., 1964, 1971; Garcia et al., 1983). Animals are thought to acquire the organism through contaminated food and water. After intestinal colonization, the organism is apparently spread hematogenously to the uterus where infection causes spontaneous abortion of the fetus. *C. fetus* subsp. *fetus* is an unusual pathogen of humans, although cases of septicemia in immunocompromised hosts have been described (Guerrant, 1978). The organism

also has been recovered from human stool samples (Devlin and McIntyre, 1983; Harvey and Greenwood, 1983a) but the incidence in humans may be underestimated due to the use of selective media and the inhibitory growth temperatures commonly employed for the recovery of *C. jejuni*.

C. fetus subsp. *venerealis*, on the other hand, has a clear tropism for the bovine genital tract where it is a cause of epidemic sterility (Bryner, 1964) and, in some cases, abortion (Garcia et al., 1983). The organism often is carried asymptomatically in the prepuce of infected bulls and is passed to the bovine female genital tract where it causes inflammation and subsequent infertility (Samuelson and Winter, 1966; Hoffer, 1981; Garcia et al., 1983).

C. jejuni has been noted to cause diarrhea (Campbell and Cookingham, 1978; Firehammer and Meyers, 1981) and mastitis in cattle (Lander and Gill, 1985); abortion in sheep (Smibert, 1978); and is a significant cause of enteritis in humans (Butzler and Skirrow, 1979; Blaser and Reller, 1981). *C. jejuni* also has been associated with a wide variety of other human illnesses including septicemia, meningitis, arthritis, urinary tract infection, and Guillain-Barré syndrome (Blaser and Reller, 1981; Blaser et al., 1986a) although these occur less frequently than does enteritis. *C. jejuni* is found in healthy and diarrheic dogs and cats (Fleming, 1983; Fox, 1985; Blaser et al., 1978) and nonhuman primates (Morton et al., 1983) and is part of the normal flora of chickens, turkeys, and many wild birds (Lander and Gill, 1985; Prescott and Bruin-Mosch, 1981; Prescott and Munroe, 1982). It also has been recovered from retail chickens, beef, pork (Harris et al., 1986) and retail mushrooms (Doyle and Schoeni, 1986). In studies where *C. jejuni* subsp. *jejuni* and *C. jejuni* subsp. *doylei* have been distinguished, *C. jejuni* subsp. *doylei* has been isolated from the feces of children (Steele et al., 1985) and from gastric biopsies of adults (Kasper and Dickgiesser, 1985; Owen et al., 1985).

C. coli is isolated routinely from the intestines of healthy pigs, cattle, and sheep (Gebhart et al., 1983; Manser and Dalziel, 1985) and can be recovered from a variety of other domestic animals with and without enteric disease (Prescott and Bruin-Mosch, 1981). It is a significant cause of enteritis in humans (Blaser and Reller, 1981; Steele et al., 1985). However, the incidence of human infection may be underestimated due to the inhibition of some *C. coli* isolates by the selective antimicrobials used to recover *C. jejuni* from clinical samples (Ng et al., 1985).

C. laridis (Benjamin et al., 1983) was originally isolated from seagull feces and is often referred to as the nalidixic-acid-resistant thermophilic campylobacter (NARTC). This organism is an infrequent agent of enteritis and bacteremia in humans (Nachamkin et al., 1984; Tauxe et al., 1985; Simor and Wilcox., 1987) and occasionally is recovered from sheep (Manser and Dalziel, 1985), dogs, monkeys and other avian species (Skirrow and Benjamin, 1980b).

C. hyointestinalis was originally recovered from pigs with proliferative ileitis (Gebhart et al., 1983), although its role in the disease is uncertain. Neither *C. hyointestinalis* nor *C. mucosalis*, a frequent co-isolate of *C. hyointestinalis*, produce the symptoms of the disease when given in pure culture to pigs (Boosinger et al., 1985.) *C. hyointestinalis* is rarely recovered from healthy pigs but has been isolated from the feces of cattle and the intestines of hamsters (Gebhart et al., 1985). This organism also has been recovered from the stool of humans with enteritis or proctitis, although its role in either disease is unclear (Fennell et al., 1986; Edmonds et al., 1987). The use of selective media containing cephalothin or other antimicrobials active against *C. hyointestinalis* and nonoptimal incubation temperatures (i.e., 42°C) limits the recovery of these organisms from human cases.

C. mucosalis (Roop et al., 1985b) was previously classified as *C. sputorum* subsp. *mucosalis* (Lawson et al., 1981) and has been isolated primarily from the intestinal mucosa of pigs (Rowland et al., 1973). This organism may have a role in porcine intestinal adenomatosis or proliferative ileitis although Koch's postulates have not been fulfilled (Lawson and Roland, 1974; Gebhart et al., 1985). It has not been recovered from humans.

"C. upsaliensis," the catalase negative or weak (CNW) campylobacter, was originally isolated from dogs with and without diarrhea (Sandstedt et al., 1983). The name of the organism is in quotation marks since it has yet to be accepted by the International Committee on Systematic Bacteriology and validly published in the International Journal of Systematic Bacteriology. More recently, it has been isolated from the feces of cats and from the feces and blood of humans (Lastovica et al., 1989; Megraud and Bonnet, 1986; Patton et al., 1989; Steele et al., 1985; Taylor et al., 1989; Walmsley and Karmali., 1989).

C. concisus was originally isolated from the oral cavity and gingival crevices of humans with periodontal disease, although no association with oral pathology was established. (Tanner et al., 1981). More recent work has focused on rapid identification and chemotactic responses

of this organism (Tanner 1986; Paster and Gibbons, 1986) as well as its potential role in human enteritis (Vandamme et al., 1989).

C. fennelliae and *C. cinaedi* are associated with enteritis, proctitis, and proctocolitis in homosexual men (Quinn et al., 1984; Totten et al., 1985). Both organisms also have been recovered from the blood of patients with human immunodeficiency virus infection (Pasternak et al., 1984; Cimolai et al., 1987; Ng, V. L. et al., 1987). In addition, *C. cinaedi* is known to be part of the normal flora of hamsters (Gebhart et al., 1989).

C. sputorum is divided into three biovars that can be distinguished phenotypically and by host preference, but not by genetic means (Roop et al., 1985a). *C. sputorum* biovar *sputorum* is a commensal of human gingival crevices (Loesche et al., 1965) and has been recovered from stool samples of humans (Karmali and Skirrow, 1984; Steele et al., 1985). *C. sputorum* biovar *bubulus* appears to be strictly a commensal of cattle and is found in the prepuce of the male and in the female genital tract. It has not been isolated from humans. Finally, *C. sputorum* biovar *faecalis* (Roop et al., 1985a), originally known as *"C. faecalis"* (Firehammer, 1965), has been isolated from sheep feces and bovine genitalia and may be associated with enteritis in cattle (Al-Marshat and Taylor, 1980). There are no human isolates to date.

C. cryaerophila was originally recovered from aborted fetuses of cattle and pigs (Neill et al., 1978; Higgins and Degre, 1979). It also has been recovered from cattle with mastitis, although its role in this disease is uncertain (Logan et al., 1982). Tee et al. (1988) reported the recovery of *C. cryaerophila* from a human fecal sample. In most laboratories isolation temperatures above the optimal growth temperature of this organism (30°C) may prevent the recovery of *C. cryaerophila* (Neill et al., 1980).

Campylobacter nitrofigilis is a nitrogen-fixing organism isolated from the roots of plants growing in salt marshes (McClung and Patriguin, 1980). It has not been recovered from humans or animals. *H. pylori* initially was isolated by Marshall and Warren (1984) and was subsequently named *C. pyloridis* (Marshall et al., 1984). The epithet, however, was grammatically incorrect and was changed to *C. pylori* (Marshall and Goodwin, 1987). It has recently been changed a third time to its current epithet, *H. pylori* (Goodwin et al., 1989). This organism is a cause of type B gastritis in humans and is isolated most frequently from biopsies of the antral region of the stomach (Buck et al., 1986; Marshall, 1990; Rauws and Tytgat, 1989). *H. pylori* also has been recovered from the nonhuman primate *Macaca nemestrina* (Bronsdon and Schoenknecht, 1988). A second species, *H. mustelae,* previously named *C. mustelae* (Fox et al., 1989; Goodwin et al., 1989), has been recovered from the stomachs of ferrets (Fox et al., 1988).

Identification

The individual biochemical, growth, and susceptibility patterns used to distinguish members of the genus *Campylobacter* and the genus *Helicobacter* are shown in Table 2. A discussion of the morphologic and biochemical traits of each species is presented below.

C. fetus

There are two subspecies of *C. fetus,* designated *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis.* These organisms can be distinguished in the laboratory by their cellular morphology and ability to grow in the presence of 1% glycine. The spirals of *C. fetus* subsp. *fetus* have an average wavelength of 1.8 μm and an average amplitude of 0.55 μm, while the spirals of *C. fetus* subsp. *venerealis* are more loosely coiled, with an average wavelength of 2.43 μm and an amplitude of 0.73 μm (Karmali et al., 1981). *C. fetus* subsp. *fetus* can grow in the presence of 1% glycine, although Chang and Ogg (1971) noted that glycine tolerance was bacteriophage-mediated and thus may be a poor test to differentiate these two organisms.

Colonies of *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis* can be observed after 24–48 h of microaerobic incubation at 25 or 37°C; some strains of *C. fetus* subsp. *fetus* will grow at 42°C (Harvey and Greenwood, 1983b; Edmonds et al., 1985). These organisms will not grow under aerobic conditions but may grow anaerobically if the medium is supplemented with 0.2% fumarate (Veron et al., 1981). Trimethylamine N-oxide (TMAO) will not serve as a terminal electron acceptor for *C. fetus.* Colonies grown on blood agar are 1–2 mm in diameter, smooth, round, convex, entire, shiny, grayish white to tan, and are nonhemolytic. They do not swarm on moist agar and coccoid forms are not observed when these organisms are exposed to air.

Strains of both subspecies are positive for catalase production, nitrate reduction, and growth in 1% bile. They do not reduce nitrite, nor do they hydrolyze urea or hippurate. They are negative for hydrogenase activity by the benzyl viologen assay (Goodman and Hoffman, 1983). H_2S is not produced in triple sugar iron (TSI) agar, and growth is not observed in the presence

of 3.5% NaCl or 0.04% triphenyltetrazolium chloride (TTC). Both subspecies are resistant to nalidixic acid but are susceptible to cephalothin.

C. jejuni

There are two subspecies of *C. jejuni*, *C. jejuni* subsp. *jejuni*, and *C. jejuni* subsp. *doylei* (Steele and Owen, 1988). The latter subspecies, which is likely the organism first described as *Vibrio coli* by Doyle (1944), is unable to reduce nitrate to nitrite. This is the major difference between the two groups of organisms.

The spiral forms of *C. jejuni* are tightly coiled and have an average wavelength of 1.12 μm and an amplitude of 0.48 μm when measured by phase contrast microscopy (Karmali et al., 1981). This characteristic is shared with *C. coli* and *C. laridis* and distinguishes them from both subspecies of *C. fetus*, whose spirals are less tightly coiled. Cells of *C. jejuni* become coccoid when exposed to atmospheric air.

Colonies of *C. jejuni* subsp. *jejuni* appear after 24–48 h of microaerobic incubation at 37 or 42°C. *C. jejuni* subsp. *doylei* grows well at 37°C but poorly, if at all, at 42°C. No growth of either subspecies is observed at 25°C and anaerobic growth cannot be achieved by the addition of 0.2% fumarate or 0.1% TMAO to the medium (Roop, 1984). Two different colony types have been described (Smibert, 1984). The first measures 1–2 mm in diameter, is raised, round, glistening, and entire, with an opaque center and translucent edge. The second type is flat, with an irregular border and a smooth to ground-glass appearance. These colonies tend to spread along the lines of inoculation producing elongated, coalescing growth. Most strains of *C. jejuni* readily form spreading colonies when grown on moist, freshly prepared media. Both colony types are nonhemolytic on blood agar, are gray to tan in color, but pinkish tan when collected on a loop.

C. jejuni is the only campylobacter capable of hydrolyzing hippurate, making this the key differential test for the species (Harvey, 1980; Hébert et al., 1984). However, hippurate-negative strains of *C. jejuni* have been identified by DNA hybridization (Totten et al., 1987). Most strains of *C. jejuni* subsp. *jejuni* are catalase positive although catalase negative or weakly positive strains of *C. jejuni* subsp. *doylei* occur (Steel and Owen, 1988). *C. jejuni* grows in the presence of 1% glycine and 1% bile but does not produce H_2S on TSI slants. Tolerance to 0.04% TTC is variable. *C. jejuni* is usually susceptible to nalidixic acid, although nalidixic acid resistant mutants have been described (Taylor et al., 1985). *C. jejuni* subsp. *doylei* is susceptible to cephalothin, while *C. jejuni* subsp. *jejuni* is resistant. Strains of *C. jejuni* produce large

amounts of C19:0 fatty acid (Blaser et al., 1980c).

C. coli

The microscopic and macroscopic appearance of *C. coli* are indistinguishable from those of *C. jejuni.* Biochemically, these organisms also are quite similar with the exception of the hippuricase activity of *C. jejuni.* In addition, Roop et al. (1984) reported that the isolates of *C. coli* they examined produced small bands of H_2S in TSI agar if the medium was fresh and adequate water of syneresis was present at the junction of the slant and the butt. He also found that *C. coli* strains grew in a minimal medium while *C. jejuni* strains did not (Roop et al., 1984).

C. laridis

The microsopic morphology of *C. laridis* is similar to *C. jejuni* in that the cells form tightly coiled spirals of relatively short wavelength and amplitude (Benjamin et al., 1983). Upon exposure to air, the cells undergo a rapid transformation to the coccoid shape.

C. laridis produces colonies after 24–48 h of incubation at either 37 or 42°C. Growth of most strains is enhanced at 42°C. Colonies are 1–1.5 mm in diameter, low convex, smooth, translucent, gray to tan, and entire. They are nonhemolytic on blood agar. Some strains may spread on moist agar.

Isolates of *C. laridis* are catalase positive, reduce nitrate but not nitrite, and grow in the presence of 1% glycine, 1% bile or 1.5% NaCl, but do not hydrolyze hippurate or urea, do not produce H_2S on TSI agar, and are resistant to cephalothin. *C. laridis* can be differentiated from *C. jejuni* and *C. coli* based on its resistance to nalidixic acid, growth in 1.5% NaCl, and growth under anaerobic conditions when 0.1% TMAO is added to the medium. Since nalidixic-acid-resistant mutants of *C. jejuni* and *C. coli* have been described, the use of multiple tests to confirm the identification of these species seems warranted. Urease-positive, nalidixic-acid-susceptible variants of *C. laridis,* confirmed by DNA-DNA hybridization studies, have been reported by Megraud et al. (1988).

"C. upsaliensis"

"C. upsaliensis" strains are slender, curved rods similar to those of *C. jejuni.* They become coccoid after extended incubation.

Colonies appear after 48–72 h of microaerobic incubation at 37°C. Most strains also will grow at 42°C, but not as luxuriantly and there is no growth at 25°C. Colonies are nonhemolytic on blood agar, measure 0.5–1.0 mm in diam-

eter, are translucent, smooth, convex, gray to tan, entire, and are similar in appearance to the colonies of *C. jejuni* and *C. coli*. "*C. upsaliensis*" is either catalase negative or demonstrates a weakly positive reaction. These organisms reduce nitrate but not nitrite and grow in the presence of 1% bile. They do not hydrolyze either hippurate or urea, do not grow in the presence of 1.5% NaCl or 0.04% TTC, and do not produce H_2S in TSI agar. Growth in 1% glycine is variable. These organisms are susceptible to both nalidixic acid and cephalothin (Patton et al., 1989; Walmsley and Karmali, 1989).

C. hyointestinalis

Cells of *C. hyointestinalis* are similar in morphology to those of *C. fetus* subsp. *fetus* (Gebhart et al., 1983). Organisms grow best at 37°C although most strains also grow at 42°C. Some may grow at 25°C. The cells do not become coccoid upon exposure to air.

After 48 h of incubation, colonies measure 1.5–2.0 mm in diameter, are round, convex, shiny, slightly mucoid, and are gray to yellow. The color of colonies gathered on a loop is dirty yellow. These organisms are nonhemolytic on blood agar and do not swarm on moist agar.

C. hyointestinalis strains are potent producers of H_2S as detected in TSI agar. This is a characteristic shared with *C. concisus*, *C. mucosalis*, and *C. sputorum*. Isolates of *C. hyointestinalis* are catalase positive, reduce nitrate but not nitrite, and will grow in the presence of 1% glycine and 1% bile. These organisms do not hydrolyze either hippurate or urea, and will not grow in the presence of 1.5% NaCl or 0.04% TTC. They do not grow aerobically but can grow anaerobically in the presence of 0.1% TMAO (Gebhart et al., 1985). *C. hyointestinalis* strains also produce hydrogenase, which can be detected by the viologen method (Goodman and Hoffman, 1983). They are resistant to nalidixic acid and susceptible to cephalothin.

C. fennelliae and C. cinaedi

Cells of *C. cinaedi* and *C. fennelliae* are slender, curved rods that appear more delicate than those of *C. jejuni*. S-shaped forms can occur but spirals up to 5.0 μm in length predominate. Coccal transformation occurs after prolonged incubation.

C. cinaedi and *C. fennelliae* grow more slowly on primary isolation than other campylobacters; up to 6 days of incubation may be required before colonies are visible. On subculture, after 48 h of incubation, colonies are pinpoint and translucent on blood agar. After additional incubation the colonies appear nonhemolytic, gray to grayish white, translucent, flat, regular, watery, and are less than 1 mm in diameter. Colonies of *C. fennelliae* are whiter and less watery than those of *C. cinaedi* and have a distinctive odor similar to that of bleach. Colonies of both species swarm readily on moist agar, producing a thin translucent film. Growth occurs at 37°C but not at 25 or 42°C. Incubation in a microaerobic environment containing hydrogen enhances growth but growth does not occur either aerobically or anaerobically (Fennell et al., 1984).

In addition to the difference in the odor of the colonies produced on solid media, *C. fennelliae* is nitrate negative. Both *C. fennelliae* and *C. cinaedi* are catalase positive, tolerate 1% glycine and 0.04% TTC, but neither organism tolerates 3.5% NaCl nor produces H_2S in TSI agar. Neither organism hydrolyzes hippurate or urea nor do they grow in the presence of 1% bile. They are susceptible to both nalidixic acid and cephalothin.

C. mucosalis

C. mucosalis is a short, slender rod 0.25 to 0.35 μm in diameter and 1.0 to 2.8 μm long. Coccoid forms and filamentous rods up to 8.0 μm long may be found in older cultures.

Colonies of *C. mucosalis* are 1.5 mm in diameter, round, raised with a flat surface, and are grayish yellow in color. The yellow pigment is observed best when colonies are spread on white paper. The colonies tend to spread on moist agar. *C. mucosalis* will grow between 25 and 42°C.

C. mucosalis are catalase negative, produce H_2S in TSI agar, reduce nitrate, and grow in the presence of both 1% bile and 1% glycine. They do not hydrolyze hippurate or urea, and do not grow in the presence of 1.5% NaCl or 0.04% TTC. While all strains are susceptible to cephalothin some strains have been noted to be resistant to nalidixic acid. Some strains reduce nitrite and tolerate glycine, but these results may vary depending on the basal medium used (Roop et al., 1985b). Growth at 25°C distinguishes this group of organisms from the other catalase-negative campylobacters. The requirement for either hydrogen or formate when the organism is grown under microaerobic conditions is a trait shared only with *C. concisus* and distinguishes them from *C. sputorum*. Anaerobic growth can be achieved in the presence of fumarate and either formate or hydrogen. The cellular fatty acid profile of *C. mucosalis* contains large amounts of lauric acid, a fatty acid which is not found in other campylobacters (Moss et al., 1984).

C. sputorum

Cells of the three biovars of *C. sputorum* are morphologically similar. Cells may be comma-shaped, gull-winged or straight rods, and some filamentous forms up to 8.0 μm in length may be found, primarily in older cultures. These organisms do not exhibit the tightly coiled spiral cells typical of *C. jejuni*. Young cultures may show some darting motility but older cultures are often nonmotile (Roop et al., 1985a).

Colonies of all three *C. sputorum* biovars are 1 to 2.5 mm in diameter, are shiny, round, convex, smooth, gray, and may have an entire or irregular spreading edge. On blood agar some strains exhibit slight alpha hemolysis. These organisms do not swarm on moist agar. The preferred growth temperature is 37°C, although most strains will grow at 42°C and no growth is observed at 25°C. Unlike *C. concisus* and *C. mucosalis,* hydrogen and formate are not required for microaerobic growth although fumarate alone will support anaerobic growth.

C. sputorum biovar *sputorum* is catalase negative, reduces nitrate, produces H_2S in TSI agar, tolerates 1% glycine, and grows in the presence of 1% bile. Most strains grow on 1.5% NaCl but not 3.5% NaCl. They hydrolyze neither hippurate nor urea. Most strains are resistant to nalidixic acid but susceptible to cephalothin.

C. sputorum biovar *bubulus* is catalase negative and *C. sputorum* biovar *faecalis* is catalase positive; this is the only major phenotypic difference between these two biovars. They both reduce nitrate, produce H_2S in TSI agar, grow in 1.5% and 3.5% NaCl, tolerate 1% glycine, and grow anaerobically in the presence of 0.1% TMAO. They do not hydrolyze hippurate or urea and, unlike *C. sputorum* biovar *sputorum,* they do not grow in the presence of 1% bile. Most strains are resistant to nalidixic acid but susceptible to cephalothin.

C. concisus

C. concisus cells are slender, curved, straight, or helical rods 0.5–1.0 μm in diameter and 4.0 μm long.

Colonies of *C. concisus* are 1.0 mm in diameter, convex, translucent, and entire. *C. concisus* will grow at 37 or 42°C but not at 25°C. Either hydrogen or formate is required to sustain growth when incubated microaerobically, while fumarate, in addition to formate or hydrogen, is necessary for growth under anaerobic conditions. No aerobic growth is observed.

C. concisus is catalase negative, produces H_2S in TSI agar, reduces both nitrate and nitrite, and tolerates 1% glycine and 1% bile but not 3.5% NaCl. Neither hippurate nor urea are hydrolyzed and 0.1% TMAO does not support anaerobic growth. Strains are resistant to both cephalothin and nalidixic acid (Tanner et al., 1981; Roop et al., 1985a).

C. cryaerophila

The cells of *C. cryaerophila* are curved rods with loosely coiled spirals that resemble *C. fetus* subsp. *venerealis,* although cells up to 20 μm may be observed.

After 48–72 h of incubation at 30°C, colonies are less than 1 mm in diameter, nonpigmented, smooth, convex, and entire. On subculture, colonies may become flattened and irregular. For primary isolation, organisms require microaerobic conditions and incubation at 30°C. However, on subculture, growth can occur aerobically, microaerobically, or anaerobically. Aerobic growth in this species is unique among campylobacters. Although 30°C is the optimal growth temperature, all strains will grow at 15°C and some may grow in temperatures as low as 5°C or as high as 40°C (Neill et al., 1985).

C. cryaerophila is catalase positive and reduces nitrate. Most strains can reduce nitrite as well, although this is not a universal feature. They tolerate 2.0% NaC1, but not 1.0% glycine or 0.1% TTC. They cannot hydrolyze hippurate or urea nor do they produce H_2S in TSI agar. They do not grow anaerobically in 0.1% TMAO (Neill et al., 1985). These organisms are resistant to cephalothin but susceptible to nalidixic acid.

C. nitrofigilis

C. nitrofigilis, the nitrogen-fixing campylobacter, is a slender, curved rod similar in morphology to *C. jejuni*. In young cultures, the cells are typically short, curved rods, while coccoid forms predominate in older cultures. However, the transition to coccoid forms is slow and apparently is not due to exposure to oxygen, as occurs with *C. jejuni, C. coli,* and *C. laridis* (McClung et al., 1983).

After 72 h of incubation at room temperature, colonies are tan to gray, glistening, low convex, entire, and measure 1 mm in diameter. They are nonhemolytic on blood agar.

The optimum growth temperature for these organisms is 30°C with a range from 10–37°C. *C. nitrofigilis* requires a minimum concentration of 0.5% NaCl for growth in artificial media. The optimum salt concentration is between 1 and 4%, but concentrations as high as 7% can be tolerated. Anaerobic growth of *C. nitrofigilis* can be achieved with the addition of either fumarate or aspartate to the culture medium, but

not with the addition of nitrate. There is no growth under aerobic conditions.

All strains of *C. nitrofigilis* produce catalase, grow in the presence of 3.5% NaCl and reduce nitrate to nitrite. Many isolates can split urea. H_2S formation is not observed in TSI agar. In addition, these organisms are unable to hydrolyze hippurate, do not grow in the presence of 1% glycine or 0.1% TTC, but do, however, have a nitrogenase enzyme and produce pigment from tryptophan (McClung et al., 1983). Isolates of *C. nitrofigilis* are susceptible to both cephalothin and nalidixic acid.

H. pylori and H. mustelae

The cells of *H. pylori* are 0.5–1.0 μm wide and 2.5–5.0 μm in length and are curved rods. On subculture, horseshoe-shapes and gull-wings can be seen. Motility is darting and rapid due to multiple, sheathed flagella with terminal bulbs occurring at only one end of the cell (Fig. 2). The organisms grow best at 37°C under microaerobic conditions. Anaerobic growth does not occur. Rare strains can grow at 42°C, but no growth is observed at 25°C (Fox et al., 1989).

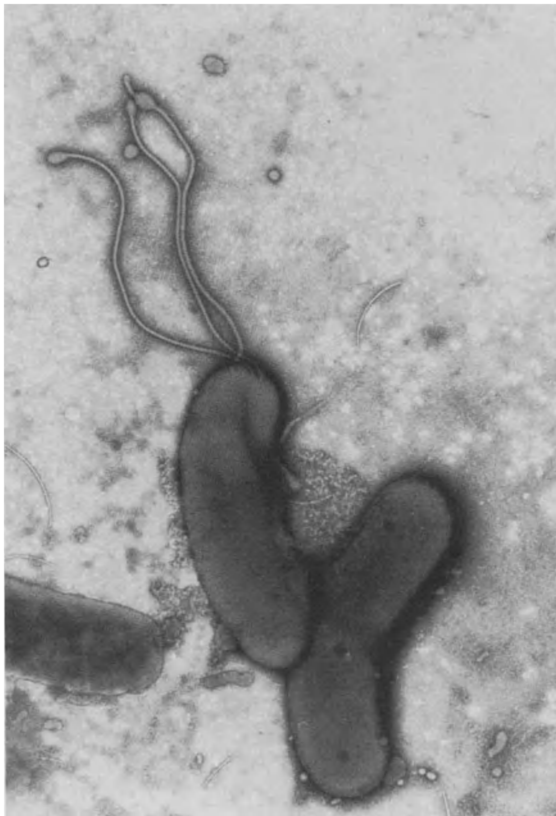

Fig. 2. Electron micrograph of *Helicobacter pylori*. Magnification 17,000 ×. Diameter of cells is approximately 0.5 μm. (Courtesy of Alan Curry and Dennis M. Jones.)

The organism requires a humid atmosphere for growth on agar. Addition of serum to liquid and solid media enhances growth. (Buck et al., 1987).

Colonies appear after 2–7 days of incubation and are 1–2 mm in diameter, opaque, convex, entire, and nonpigmented. Coccoid forms appear after exposure to room air.

H. pylori is catalase positive and strongly urease positive. It does not hydrolyze hippurate nor does it produce H_2S in TSI agar. There is no growth in the presence of 1% glycine or 3% NaCl, nitrate is not reduced, and hippurate is not hydrolyzed. Strains are susceptible to cephalothin but variable in their resistance to nalidixic acid (Dent and McNulty, 1988; Fox et al., 1989). Their strong urease activity differentiates them from members of the genus *Campylobacter* (Hazell et al., 1987). Although some strains of *C. nitrofigilis* demonstrate urease activity, it is not of the same potency as that of *H. pylori*.

H. mustelae is similar in microscopic and colonial appearance. However, several differences in biochemical and susceptibility profiles have been noted. *H. mustelae* is capable of growth at 42°C and does reduce nitrates. It has lateral as well as polar flagella, and is resistant to cephalothin but susceptible to nalidixic acid. It also has strong urease activity (Fox et al., 1989).

Diagnostic Methods

Microscopic Methods of Analysis

The motility of *Campylobacter* species is best observed by suspending the organisms in broth and examining the cells by phase contrast or darkfield microscopy. The wavelength and amplitude of the spiral forms can be measured from photographs of organisms taken under phase contrast microscopy (Karmali et al., 1981). To demonstrate a change from curved rods to coccal forms, organisms are incubated microaerobically for 48 h at 37 or 42°C, then incubated aerobically at room temperature for an additional 48 h. A Gram stain is prepared at this time and examined for a predominance of coccal forms (Karmali et al., 1981). Use of 0.1% aqueous basic fuchsin as the counterstain enhances the detection of campylobacters in Gram stains.

Biochemical Methods

A variety of methods have been used to determine the biochemical and growth characteristics of *Campylobacter* and *Helicobacter* species. Listed here are the methods that we feel are

most reproducible and that can be applied to the majority of these organisms.

Detection of cytochrome oxidase is made by rubbing a colony onto filter paper moistened with a freshly prepared solution of 0.5% tetramethyl-*p*-phenylenediamine dihydrochloride; development of a purple color within 10 s is positive. Catalase production is detected by suspending the organism in a drop of water on a glass slide and adding a drop of 3.0% hydrogen peroxide to the suspension. A more sensitive test for catalase is to add several drops of 3.0% hydrogen peroxide to cells grown on an agar slant containing a medium without blood, such as Brucella agar or TSI agar. In either case, rapid formation of bubbles is considered a positive reaction while delayed appearance of a few bubbles is a weakly positive reaction.

Biochemical tests should be performed on colonies that are no more than 48-h old (72 h for slowly growing organisms). For detection of glucose utilization, H_2S production, urease activity, nitrate reduction, and hippurate hydrolysis, media should be inoculated directly with growth from an agar plate. However, direct inoculation of colonies into tests for tolerance to various substrates may yield falsely positive results. To standardize the inoculum size for these tests, organisms should be suspended in Brucella or Mueller Hinton broth to the density of a 1.0 MacFarland standard. Several drops of this suspension are added to the test medium (Gebhart et al., 1985). Alternately, several drops from the growth at the top of semi-solid Brucella broth can be used (Roop et al., 1984). All tests should be incubated until a positive reaction or significant growth is observed, or up to seven days if the test is negative.

Various basal media have been used for biochemical and tolerance tests. Brucella albimi broth with 0.16% agar (Roop et al., 1984) or fluid thioglycolate medium with 0.1% agar (Gebhart et al., 1983) are reliable and easily prepared. To obtain adequate growth of fastidious campylobacters, such as *C. cinaedi* and *C. fennelliae,* the agar concentration of the semi-solid medium should be increased to 0.3% (Fennell et al., 1984). Use of semi-solid medium permits aerobic incubation and enhances the ability to detect growth by localizing the organisms below the surface of the medium. Other tests may be performed on solid media using bases such as Brucella agar, Mueller Hinton agar, or Yeast Extract Nutrient agar composed of Oxoid BA base No. 2, and 0.1% yeast extract (Benjamin et al., 1983). When performing any tolerance test, a tube or plate containing only basal media must be included as a positive control.

Production of acid from glucose is determined in a semi-solid medium containing 1% glucose and 0.002% phenol red, pH 7.3. Tubes are tightly capped and incubated aerobically. Appearance of a yellow color is a positive result and an indication that the organism is not a campylobacter, since campylobacters neither ferment nor oxidize sugars.

Nitrate reduction is determined in a semi-solid medium supplemented with 0.2% potassium nitrate. When visible growth is present, equal volumes (10 drops) of nitrate reagent A (8 g of sulfanilic acid in 1 liter of 5 N acetic acid) and reagent B (6 ml of *N, N*-dimethyl-l-naphthylamine in 1 liter of 5 N acetic acid) are added. Development of a red color indicates presence of nitrate reductase. If no color develops, zinc dust is added to the medium. Development of a red color after the addition of zinc confirms that nitrate is still present in the medium and that the organism cannot reduce nitrate. Absence of a red color after the addition of zinc indicates that nitrate was reduced to nitrite which was then reduced to nitrogen gas, indicating that the organism has both nitrate and nitrite reductases.

Nitrite reduction is detected in a semi-solid medium containing 0.05% potassium nitrite. When there is visible growth, reagents A and B are added to the medium as for the nitrate test. Absence of a red color is positive for nitrite reduction, while development of a red color is a negative test result.

Production of hydrogen sulfide (H_2S) may be measured by several methods including a TSI agar slant, suspending a strip of lead acetate over a semi-solid medium containing 0.02% cysteine hydrochloride (Vêron and Chatelain 1973), or using a medium containing ferrous sulfate, sodium metabisulfite, and sodium pyruvate as described by Skirrow and Benjamin (1980a). Although the TSI method is not the most sensitive method, we feel that it is the most reproducible of the tests and is the one we recommend. Blackening of the medium is a positive reaction. The medium should be fresh with water of syneresis present at the junction of the butt and slant.

Urease production is detected on Christensen's base urea agar prepared as a slant. Development of a pink color is indicative of a positive test.

To determine glycine tolerance, a semi-solid medium is supplemented with 1.0% glycine. A similar procedure is used for bile tolerance except that the medium is supplemented with oxgall to a final concentration of 1.0%. For salt tolerance, NaCl is added to a semi-solid medium to a final concentration of 3.5%. Tolerance

of 1.5% NaCl can be determined by adding salt to yeast extract nutrient agar plates.

Tolerance of 2,3,5 TTC (Leaper and Owen, 1981; Luechtefeld and Wang, 1982) is determined by incorporation of TTC into Brucella or Mueller Hinton agar to a final concentration of either 0.04%. 0.1%, or 1.0%. If organisms can grow in the presence of TTC, they will reduce the colorless dye to red tetrazolium salts. A standard concentration of TTC has not been established.

The ability of an organism to grow anaerobically in the presence of 0.1% TMAO is determined by a modification of the method described by Benjamin et al. (1983), in which the TMAO is prepared in yeast-extract nutrient broth as listed below.

TMAO Test Broth

Bacto-peptone	1%
Bacto-tryptone	1%
Yeast extract	0.1%
Trimethylamine-*N*-oxide	0.1%
NaCl	0.5%
Agar	0.2%

The medium, made in distilled water, is placed into screw-capped tubes and autoclaved just prior to use. After cooling, the medium is inoculated with a suspension of organisms and the tube is tightly capped. Incubation is at 37°C for 7 days. Growth occurring at the bottom of the tube, which is oxygen free, is indicative of anaerobic growth, a positive test result, while growth only at the surface is microaerobic growth and is a negative test result. (Roop et al., 1984).

Anaerobic growth in the presence of fumarate is assessed by inoculating a suspension of organisms onto Brucella agar supplemented with 0.3% ammonium fumarate. In a similar fashion, 0.2% sodium formate can be added to Brucella agar to determine the ability of this supplement to act as an electron donor. In each case, growth must be compared to that achieved on unsupplemented Brucella agar (Roop et al., 1985a).

Determining the ability of an isolate to grow at 25 and 42°C may be tested in a semi-solid medium or on agar plates. Temperatures must be strictly controlled for this test to be of value. Some investigators recommend 43°C rather than 42°C to identify truly thermophilic organisms. A control test incubated at 37°C, using the same medium and same amount of inoculum, should always be included for comparison.

The rapid method of Hwang and Ederer (1975) is used to detect the ability of strains to hydrolyze hippurate. Cells from an agar plate culture are emulsified in 0.4 ml of 1% aqueous sodium hippurate. After 2 h of incubation at 37°C, 0.2 ml of ninhydrin reagent (3.5% ninhydrin solution in a 1:1 mixture of acetone and butanol) is added and the test is incubated for an additional 10 min. Development of a deep purple color in the ninhydrin layer is a positive reaction. Positive and negative controls must be run simultaneously.

Molecular Methods for Differentiating Campylobacters

Several techniques using either nucleic acid hybridization methods or polyacrylamide gel electrophoresis of proteins have been applied to the identification of *Campylobacter* species isolated in pure culture.

Totten et al. (1985) used whole cell chromosomal DNA extracts from a series of campylobacter isolates in DNA-DNA hybridization reactions to differentiate among strains of *C. cinaedi* and *C. fennelliae* as well as to distinguish hippurate-negative *C. jejuni* isolates from *C. coli* and *C. laridis* (Totten et al., 1987). This spot hybridization method was relatively simple to perform and proved to be very effective for identifying these organisms.

More recently, Romaniuk and Trust (1987) and Moureau et al. (1989) have used restriction-fragment-length-polymorphism analysis of the genes encoding rRNA in campylobacter to differentiate among isolates of various species. Moureau et al. (1989) were able to accurately discriminate among isolates of *C. jejuni, C. coli, C. laridis, C. fetus,* and *"C. upsaliensis"* using a 23-base probe. Similarly, Chevrier et al. (1989), Ezaki et al. (1988), and Ng L.-K. et al. (1987) used several DNA probes to differentiate among species of *Campylobacter,* while Korolik et al. (1988) and Picken et al. (1987) developed probes that were specific for *C. jejuni.*

Hanna et al. (1983) were able to distinguish aerotolerant species of campylobacter from other *Campylobacter* species using polyacrylamide gel electrophoresis patterns. Similarly, Ferguson and Lambe (1984) were able to discriminate between species of campylobacters using soluble protein extracts of campylobacters examined on polyacrylamide gels. Tanner (1986) also used protein profiles to distinguish *C. concisus* from other gingival organisms.

Strain Typing Methods for Campylobacters

Differentiating among strains of campylobacters has been accomplished by several techniques including biotyping (Bolton et al., 1984; Hébert et al., 1982; Lior, 1984; Skirrow and Benjamin, 1980b); serotyping (Lior et al., 1982; Penner and Hennessy, 1980; Hébert et al., 1983); bacteriophage typing (Grajewski et al., 1985); auxotyping (Tenover et al., 1985a; Ten-

over and Patton, 1987); plasmid analysis (Bopp et al., 1985; Bradbury et al., 1983; Tenover et al., 1984); and restriction endonuclease analysis of chromosomal DNA (Bradbury et al., 1984; Collins and Ross, 1984; Kakoyiannis et al., 1984; Owen et. al., 1985).

Antimicrobial Susceptibility Testing in Campylobacter Species

There are several methods available for determining the antimicrobial susceptibility of *Campylobacter* species. The most common methods employed are disk diffusion and agar dilution methods. Of these, the agar dilution test is most accurate and should be considered the method of choice. However, disk diffusion testing often is used in clinical laboratories to determine an organism's susceptibility to cephalothin and nalidixic acid, two markers commonly used in identification schemes. A review of the literature shows that more than 12 combinations of temperature, atmosphere, and length of incubation have been used in an attempt to accurately predict the susceptibility of campylobacters to various agents, yet, the optimum conditions remain unclear. We recommend testing at 37°C for 48 h in a microaerobic environment achieved either through the use of evacuation/replacement, gas-generating envelopes in anaerobe jars, or biobags with microaerobic gas generators. Candle jars are to be avoided since they do not produce optimum microaerobic conditions.

Agar Dilution Method

Mueller-Hinton agar or Brucella agar produce equivalent results when used for susceptibility testing of campylobacters in our laboratory. Other investigators have noted similar results (Wang et al., 1984). The inoculum should be adjusted to deliver 10^6 colony-forming units to the plate. This can be achieved by making a suspension of organisms in saline equivalent to a 1.0 McFarland standard, and diluting the suspension 1:20 in saline before inoculating the agar medium. Plates should be examined at 48 h for all thermophilic campylobacters, although the more fastidious campylobacters may require additional incubation.

Disk Diffusion Method

The inoculum for disk diffusion testing is prepared as for agar dilution. An attempt should be made to read zone sizes after 24 h of incubation. The major disadvantage to this method is the lack of interpretive criteria for zone diameters. Van Hoof et al. (1984) have stated that the National Committee on Clinical Laboratory Standards can be followed for most antibiotics, yet we have found a relatively poor correlation between MICs and zone sizes, particularly for erythromycin.

One suggestion is to use zone/no zone interpretations for susceptibility and resistance. This is particularly helpful for interpreting cephalothin and nalidixic acid zones for the purpose of species identification. For other antimicrobials, particularly those to be used therapeutically, agar dilution testing is recommended if facilities are available.

DNA Probes

DNA probes have been used to detect both tetracycline and kanamycin-resistance genes in *Campylobacter* species (Lambert et al., 1985; Tenover and Elvrum, 1988; Courvalin and Taylor, 1988). Probes, however, only indicate the presence of a resistance determinant or portions of a determinant but do not indicate the phenotype of the organism. Thus, non-functional resistance genes may produce positive hybridization test results that would be interpreted to mean that the organism was resistant to an antimicrobial agent when, in fact, it was susceptible. Probes have primarily been used for epidemiological studies of antimicrobial resistance in campylobacters.

Mechanisms of Antimicrobial Resistance in Campylobacters

A review of the mechanisms of antimicrobial resistance in the thermophilic campylobacters has been presented by Taylor and Courvalin (1988). Of note are the presence in several species of campylobacter of two resistance determinants that probably originated in Gram-positive organisms. The first is the *aphA*-3 kanamycin resistance determinant, first reported in a strain of *C. coli* by Lambert et al. (1985), and sequenced by Trieu-Cuot et al. (1985), and the second is the *tet*O gene, whose DNA sequence was first reported by Sougakoff et al. (1987). Both genes can be carried on transmissible plasmids (Kotarski et al., 1986; Sagara et al., 1987; Taylor et al., 1981; Tenover et al., 1983; Tenover et al., 1985b), as can a new kanamycin resistance gene that may be endemic to *Campylobacter* species, the *aphA*-7 gene (Tenover et al., 1989). Resistance to quinolones, β-lactams, chloramphenicol, macrolide-lincosamide-streptogramin (MLS)-type drugs, streptomycin, spectinomycin, and other aminoglycosides have all been reported in campylobacters (Taylor and Courvalin, 1988).

Isolation

Collection and Transport of Fecal Samples

A fresh fecal sample that is rapidly transported to the laboratory is the optimum specimen for the isolation of enteric campylobacters from animals or humans. Fecal samples that cannot be processed quickly, and all rectal swab specimens, should be transported to the laboratory in alkaline peptone water, pH 8.5, containing 0.05% sodium thioglycolate and 0.025% L-cystine, or, in modified Cary-Blair medium with the agar concentration reduced to 1.6% (Wang et al., 1983). Transport media should be kept cold after inoculation because campylobacters survive longer at 4°C than at ambient temperature (Blaser et al., 1980a).

Collection and Transport of Other Specimens from Animals

Tissue samples or animal carcasses for culture should be kept moist and cool and transported to the laboratory immediately for culture. Air should be excluded as much as possible (Lander and Gill, 1985). For small tissue samples, a transport medium, such as modified Cary-Blair, or cold physiologic saline is recommended.

The lavage and aspiration method of Lander (1983) is recommended for the recovery of campylobacters from the vaginal mucus of cows. *C. fetus* subsp. *venerealis* is best recovered from bulls by collecting material from the prepuce and preputial sac by lavage. Alternately, material can be collected from the mucosal folds and placed in Clark's transport medium (Clark and Dufty, 1978) for transport to the laboratory.

Clark's Transport and Enrichment Medium (Clark and Dufty, 1978)

Fresh bovine serum to which is added

5-Fluorouracil	300 μg/ml
Polymyxin B	100 units/ml
Brilliant green	50 μg/ml
Nalidixic acid	3 μg/ml
Cycloheximide	100 μg/ml

Ten milliliter aliquots of serum containing antibiotics and inhibitors are placed in 30-ml bottles, closed with rubber stoppers, and placed in a boiling water bath for 2 min or until the serum solidifies. The medium is cooled and dispersed with a glass rod. After introducing a microaerobic gas mixture into the bottles (2.5% O_2, 10% CO_2, and 87.5% N_2), they are stored at 4°C for 1 week, after which time they are available for use for up to 4 weeks. Samples containing as few as 100 organisms remain viable in this transport media for up to 48 h. Once in the laboratory, the material can be filtered and applied to either selective or non-selective media, however, the media should not contain cephalothin or polymyxin B (Jones et al., 1985). Incubation of media should be continued for 5 days at 37C and examined at regular intervals.

Filtering Methods

The first clinical samples of campylobacter were recovered using a 0.65-μm filter to remove large particles of stool (Dekeyser et al., 1972). However, the more common application of filters for the recovery of these organisms takes advantage of the highly motile nature of most campylobacters and their slender width which allows them to pass through 0.45–0.65 μm filters leaving other bacterial flora behind. When used in this manner, nonselective media can be substituted for agar plates containing antimicrobic combinations that may prove inhibitory to certain strains of campylobacter (Steele and McDermott, 1984). Steel et al. (1985) isolated a wide diversity of *Campylobacter* species from humans using this method. It should be noted, however, that low concentrations of campylobacters may be missed if the filter technique is used exclusively for stool samples (Goossens et al., 1986).

To perform the method described by Steele and McDermott (1984), fecal samples are diluted 1:10 in sterile saline containing glass beads. 10–12 drops of the suspension are placed on a 47 mm 0.45-μm filter resting on a 6% sheep blood agar plate that had been dried for 30 min. Liquid should not spread over the edge of the filter. The filter is removed and discarded after 10–30 min. and the plate is incubated under microaerobic conditions. The authors note that cellulose triacetate filters worked best in their study.

Alternate filtering techniques using 0.65-μm Sartorius filters or attaching the filters to a Swinney adapter fitted to a syringe, have been used successfully for isolation of campylobacters from animal sources (Gebhart et al., 1983; Lander and Gill, 1985). After passing the material through the filter apparatus, the filtrate is placed on selective or nonselective media. Spreading the filtered inoculum across the medium to obtain isolated colonies will facilitate recognition of multiple species of *Campylobacter*.

Selective Isolation Media

Among the 12 selective media described for the isolation of campylobacters, no single medium is satisfactory for the recovery of all *Campylobacter* species. We will describe five media formulations, each of which offers certain advantages for the isolation of these organisms. The

investigator must decide which species are of interest and then choose the appropriate combination of media. We strongly recommend the use of a selective medium, plus filtration onto a nonselective medium, for maximum recovery of campylobacter isolates from samples.

Several antimicrobial agents have proven troublesome when used for isolation of campylobacters. Cephalothin, which is used in selective media at concentrations of 32 ug/ml, is inhibitory to *C. fetus* subsp. *fetus, C. fetus* subsp. *venerealis, C. jejuni* subsp. *doylei, "C. upsaliensis." C. hyointestinalis, C. cinaedi, C. fennelliae, C. mucosalis,* all subspecies of *C. sputorum, C. nitrofigilis,* and *H. pylori.* Also, strains of *C. coli* that are susceptible to cephalothin have been recovered from cattle (Brooks et al., 1986). Cefoperazone in concentrations of 15–32 μg/ml and cefazolin at concentrations of 15 μg/ml also may inhibit the majority of these organisms. Polymyxin B and colistin are inhibitory to some strains of *C. coli* (Ng et al., 1985), *"C. upsaliensis"* (Steele et al., 1985), and *C. fetus* subsp. *venerealis* (Jones et al., 1985). Rifampin inhibits the growth of *C. cinaedi* and *C. fennelliae* (Flores et al., 1985).

Skirrow's medium was one of the first to be described. It is widely used and permits the recovery of cephalothin-susceptible campylobacters. However, overgrowth by fecal flora is frequently a problem with this medium.

Skirrow's Medium (Skirrow, 1977)

Blood agar base No. 2, to which is added

Lysed horse blood	5%
Vancomycin	10 μg/ml
Trimethoprim	5 μg/ml
Polymyxin B	2.5 IU/ml

The agar is autoclaved, cooled to 50°C, and the blood and antimicrobials added aseptically. The medium is distributed in petri plates.

The medium described by Blaser et al. (1979a) and sold commercially as Campy BAP (BBL, Cockeysville, MD) is similar to that of Skirrow except that defibrinated sheep blood is used and cephalothin is incorporated to more effectively inhibit fecal flora.

Modified Campy BAP (Blaser et al., 1979a)

Brucella agar base, to which is added

Defibrinated whole sheep blood	10%
Cephalothin	32 μg/ml
Polymyxin B	2.5 IU/ml
Trimethoprim	5 μg/ml
Vancomycin	10 μg/ml
Amphotericin B	2 μg/ml

The agar is autoclaved and cooled to 50°C. Blood and antibiotic supplements are added aseptically and the medium is poured into petri plates.

Goossens et al. (1986) described a modification of Butzler's medium Virion (Goossens et al., 1983) that omits colistin and increases the concentration of cefoperazone to 30 μg/ml. This medium provides enhanced inhibition of human fecal flora.

Modified Butzler's Medium Virion (Goossens et al., 1986)

Columbia Blood agar base (Oxoid), to which is added

Defibrinated sheep blood	5–7%
Cefoperazone	30 μg/ml
Rifampicin	10 μg/ml
Amphotericin B	2 μg/ml

The agar is autoclaved and cooled to 50°C. The antibiotic supplements and the sheep blood are added aseptically and the medium poured into petri plates.

An antimicrobial formulation similar to that of modified Butzler's medium Virion that incorporates activated charcoal into the medium in place of blood was described by Karmali et al, (1986). Charcoal was first recommended as an additive to campylobacter selective media by Bolton and Coates (1983). Charcoal effectively enhances the growth of campylobacters when added to enriched media and in some parts of the world, may be less expensive and easier to obtain than sterile animal blood.

Blood-free Medium for Isolating Campylobacters from Feces (Karmali et al., 1986)

Columbia agar base, to which is added

Activated charcoal	4 mg/ml
Hematin	0.032 mg/ml
Sodium pyruvate	0.1 mg/ml
Cefoperazone	32 μg/ml
Vancomycin	20 μg/ml
Cycloheximide	100 μg/ml

The agar and charcoal are autoclaved and cooled to 50°C. The remaining ingredients are added aseptically and the medium is dispensed into petri plates.

Finally, a novel semi-solid medium that takes advantage of the motility of campylobacters to separate them from other organisms present in stool has been described (Goossens et al., 1989). The medium is inexpensive to prepare and the cultures are easy to interpret.

Semi-solid Medium (Goossens et al., 1989)

Mueller Hinton broth, to which is added

Agar	0.4%
Cefoperazone	30 μg/ml
Trimethoprim	50 μg/ml

The broth and agar are combined, autoclaved and cooled to 50°C. The antimicrobials are added aseptically to the medium and poured into 5-cm plates and stored in the dark until used. To inoculate, a loopful of stool is placed at the periphery of the plate. Solid stools are first emulsified in saline. Plates are then incubated in a microaerobic environment. Campylobacters are recognized on the medium by characteristic swarming away from the point of inoculation.

Recovery of *C. hyointestinalis* and *C. mucosalis* from Swine

Gebhart et al. (1983) noted that combination of a filter technique and a selective medium containing trimethoprim-sulfamethoxazole was important for eliminating contamination with *Proteus* species when sampling intestinal tissues of swine with proliferative ileitis. While the 0.65-μm filter resulted in little contamination, it also decreased the number of colonies present on the medium by 40%. On the other hand, trimethoprim-sulfamethoxazole inhibited several of the *C. mucosalis* strains. Thus, a combination of 0.8-μm filters and a selective medium and 0.65-μm filters with a nonselective medium yielded the largest numbers of isolates.

Recovery of *H. pylori* and *H. mustelae*

Biopsies of the antral portion of the stomach or other areas demonstrating gastritis should be sampled via endoscopy and the tissue transported to the laboratory immediately in sterile saline at room temperature. The specimen should be inoculated onto fresh chocolate agar, Skirrow's medium modified by the addition of amphotericin B (5 μg/ml) and substitution of cefsulodin (5 μg/ml) for polymyxin B (Dent et al., 1988), or GC medium base containing either 1.0% soluble starch or 0.2% charcoal (Buck et al., 1987). Since *H. pylori* requires an extremely humid environment for growth on agar, paper towels saturated with sterile water should be placed in the jar with the media. Incubation is at 37°C under microaerobic conditions for up to 7 days.

Recovery of *C. cryaerophila* and *C. nitrofigilis*

Methods for the recovery of these organisms can be found in Neill et al. (1980) and McClung and Patriquin (1980), respectively. Because of the intricacies of the isolation techniques, they are not detailed here.

Enrichment Broths

In general, fecal samples from humans and animals do not require an enrichment broth step if the samples are processed rapidly by the laboratory (Chan et al., 1985; Bolton and Robertson, 1982). However, specimens that have been delayed in transit and specimens that may contain low numbers of organisms, such as those from patients receiving antimicrobial therapy, may benefit from enrichment (Martin et al., 1983). Environmental, milk, and food samples are usually enriched before plating due to the small number of organisms present (Heiseck, 1985). Enrichment is carried out for 24–72 h at 42°C for isolation of thermophilic campylobacters. Two commonly used enrichment broths are described below. Polymyxin B may be omitted from either one for greater recovery of nonthermophilic campylobacters. Most enrichment broths have not been evaluated for recovery of campylobacters other than *C. jejuni* subsp. *jejuni.*

Doyle and Roman Enrichment Broth (Doyle and Roman, 1982)

Brucella broth containing:

Lysed horse blood	7%
Sodium succinate	0.3%
Cysteine hydrochloride	0.01%
Vancomycin	15 μg/ml
Trimethoprim	5 μg/ml
Polymyxin B	20 IU/ml
Cycloheximide	50 μg/ml

Lovetts Enrichment Broth (Lovett et al., 1983)

Brucella broth containing:

Ferrous sulfate	0.025%
Sodium metabisulfate	0.025%
Sodium pyruvate	0.025%
Vancomycin	15 μg/ml
Trimethoprim	7.5 μg/ml
Polymyxin B	5.0 IU/ml

Recovery of *Campylobacter* Species from Milk

To recover campylobacters from milk using the method of Lovett et al. (1983), centrifuge 40 g of raw milk at 34,000 × g for 20 min and discard fat and aqueous layers. Suspend the pellet in 100 ml of Lovett's enrichment broth. Incubate in a microaerobic environment for 24 h at 42°C and filter through 0.65-μm filter. Culture the filter and the filtrate on Skirrow's agar.

Recovery of Campylobacters from Water Samples

For low-turbidity water, Blaser and Cody (1986) recommend filtering 500 cc of water through a 0.45-μm filter and placing the filter face down on a selective medium. For high-turbidity water, the sample should be pre-filtered through

5.0 and 0.6-μm membranes before passing the sample through the 0.45-μm filter. After 6 h of incubation at 42°C, the filter is removed from the plate and a loop is used to streak the inoculum area for isolation of colonies. The plate is then incubated for an additional 24–48 h. It should be noted that as many as 90% of the campylobacters could be retained by the 0.6-μm filter. Thus, low-turbidity waters should not be pre-filtered. An alternate method of processing water samples for recovery of campylobacters has been described by El-Sherbeeny et al. (1985).

Incubation Temperature

The incubation temperature chosen for culture media will have a significant impact on the recovery of campylobacters in the laboratory. With the exception of *C. cryaerophila,* all *Campylobacter* species will grow well on primary isolation at 37°C. Cultures for recovery of *C. cryaerophila* should be incubated at 30°C. However, 42°C is the optimal incubation temperature for the recovery of the thermophilic species *C. jejuni* subsp. *jejuni, C. coli,* and *C. laridis.* If a filter technique is used, the plates should be incubated at 37°C.

Providing Microaerobic Growth Conditions

There are several ways to achieve microaerobic conditions optimal for the propagation of campylobacters. The first, and most expensive, is to use an incubator with an appropriate gas mixture supplied by replaceable tanks. While optimal, this is an option that few clinical laboratories can afford.

For the clinical laboratory, the most convenient option is an anaerobe jar containing a commercially prepared gas-generating envelope. One of two types of gas-generating envelopes can be used. The first is an envelope designed to produce a microaerobic atmosphere of O_2, CO_2, and N_2, and the second is a gas-generating envelope designed to produce an anaerobic atmosphere, which, in the absence of the palladium catalyst causes the hydrogen content of the jar to increase. Increased hydrogen is important for the growth of *C. concisus* and *C. mucosalis* and also enhances the growth of several other *Campylobacter* species. It should be noted, however, that the latter option is discouraged by the manufacturers of the anaerobic gas-generating envelopes since the accumulation of hydrogen within the jar is potentially explosive (Simmons, 1977).

Commercially prepared pouches or plastic bags that contain a small gas generator capable of providing a microaerobic environment for one to two plates are also available and popular in clinical laboratories. These pouches are an effective and convenient means of growing campylobacters, particularly if the laboratory receives relatively few requests to isolate these organisms or has inadequate incubator space to accomodate jars.

Another method of providing a microaerobic atmosphere is evacuation/replacement of the gas in anaerobe jars with a mixture of 10% CO_2, 10% H_2, and 80% N_2. After two cycles of evacuation/replacement, a microaerobic environment, enriched with hydrogen, will be achieved (Gebhart et al., 1983). While this is the most cost-effective method, it is also the most tedious.

A simple and inexpensive method of providing microaerobic conditions uses the Fortner principle in which an agar plate streaked with a rapidly growing facultative anaerobe is included in a sealable pouch with the agar plates used to isolate campylobacters (Karmali and Fleming, 1979). The growth of the facultative organism reduces the oxygen content in the atmosphere surrounding the plates permitting the growth of any campylobacters present.

The final method is use of a candle jar, which provides an atmosphere of approximately 17% O_2 (Luechtefeld et al., 1982). However, we do not recommend the use of the candle jar for primary isolation of campylobacters unless no other system is available since it is less effective than the other methods mentioned for the primary isolation of campylobacters (Luechtefeld et al., 1982). However, it should be noted that the aerotolerance of many campylobacter strains can be increased by adding ferrous sulfate, ferrous metabisulfite, and sodium pyruvate to the isolation medium (George et al., 1978).

Storage and Transport Medium

Sending pure cultures of campylobacter isolates between laboratories often has proven to be a challenge. However, the semi-solid Brucella agar medium described by Wang et al. (1980) has proven effective for transporting a variety of *Campylobacter* species even over periods of up to 3 weeks. The recipe is listed below.

Wang's Transport Medium

Brucella broth, to which is added

Difco agar	0.5%
Defibrinated sheep blood	10.0%

Autoclave the basal medium plus the agar, cool to 50°C, and add the sheep blood. Dispense the medium in 0.5-ml aliquots into small vials. Inoculate the medium with several colonies of a pure culture of campylobacter and incubate the vials with the caps very loose for 24 h at

37°C in a microaerobic atmosphere. After incubation, close the caps and wrap with parafilm before shipping. Campylobacters can be frozen at −70°C for extended periods of time in a 50:50 mixture of trypticase soybroth and heat inactivated fetal calf or horse serum.

Genetic Methods of Detecting Campylobacters

DNA probes consisting of nick-translated whole cell chromosomal DNA specific for *C. jejuni* have been described, but they have not proven useful for detecting this organism directly in clinical samples (Echeverria et al., 1985; Tompkins and Krajden, 1986).

Romaniuk and Trust (1989) have developed oligonucleotide probes directed against rRNA targets that detect either *C. jejuni* and *C. laridis,* or these organisms plus *C. coli.* However, the limits of detection for these probes even when used for culture confirmation was 10^6 colony-forming units. Other DNA probes for the culture confirmation of *Campylobacter* species have been described (Chevrier et al., 1989; Ezaki et al., 1988; Korolik et al., 1988; Picken et al., 1987; Taylor et al., 1989).

Other Diagnostic Methods

Direct microscopic detection of campylobacters using darkfield or phase microscopy (Paisley et al., 1982), as well as immunofluorescent methods (Hodge et al., 1986; Price et al., 1984), have been described in the literature. However, the relatively low sensitivity of these methods have precluded their widespread usage in laboratories.

Serologic tests and immunofluorescent antibody tests are not recommended for the detection of most campylobacter infections in humans or animals. Although serology has been used to monitor herd immunity, tests for *C. fetus* subsp. *venerealis* in individual animals as a diagnostic tool is not recommended (Garcia et al., 1983). The one exception to this rule may be detection of antibodies to *H. pylori* in humans, where serologic tests may well be the current definitive test method. (Perez-Perez et al., 1988).

Finally, a ^{13}C-urea breath test has been described for detection of *H. pylori* in humans. In this test, the patient ingests a solution containing ^{13}C-labeled urea. The release of ^{13}C-labeled CO_2 in the patient's breath, as measured by mass spectrometry, indicates the hydrolysis of the labeled urea by the potent urease of *H. pylori.* While not widely used, the test appears to have merit (Graham et al., 1987).

Applications

Survival

Most studies on the survival of campylobacters in the environment have been undertaken with isolates of *C. jejuni.* These studies have demonstrated that these organisms survive from weeks to months at cold temperatures (4°C) but decrease in numbers relatively quickly at 25°C and even faster at 37°C (Blaser et al., 1980a). *C. jejuni* survived for 3 weeks in feces and milk held at 4°C, 4 weeks in water, and up to 5 weeks in urine. *C. jejuni* also survived in solutions with a pH as low as 3.6. Thus, campylobacters introduced into the environment by humans or animals may serve as a source of infection for weeks to months (Blaser et al., 1980b).

Transmission of campylobacters in water, raw milk, and meat have been reported (Blaser et al., 1979b, 1980b). With regards to control of such transmission cycles, Blaser et al. (1986b) have shown that campylobacters are killed by usual concentrations of chlorine in treated water, while Waterman (1982) has demonstrated that campylobacters are killed by pasteurization methods. In addition, Doyle and Roman have shown that *C. jejuni,* when heated in red meat, has a D value (time for 90% killing) at 60°C of less than 20 s and thus, is readily susceptible to inactivation by heat.

In contrast to its long survival in liquids and feces at low temperatures, *C. jejuni* is susceptible to drying and undergoes significant reduction in numbers when dried. Survival can be enhanced, however, at relative humidities of $<$ 14% at 4°C (Doyle and Roman, 1982). *C. jejuni* has a pH optimum of 6.5 to 7.5, although it will grow over a range of pH 5.5 to 8.0 (Blaser et al., 1980a; Doyle and Roman, 1982). Under stressful conditions, *C. jejuni* assumes a coccoid shape and can remain viable although often nonculturable in aquatic environments (Rollins and Colwell, 1986).

Vaccines

Vaccination remains a key factor in the control of campylobacteriosis in cattle (Bryner et al., 1979, 1988; Clark, 1971; Vasquez et al., 1983). Unvaccinated herds are subject to outbreaks of infertility due to *C. fetus* subsp. *venerealis* causing major economic loss (Bryner et al., 1979, 1988). The importance of booster immunizations has been emphasized for cattle (Berg and Firehammer, 1978). There are at least 10 vaccines currently licensed in the United States for immunizing cattle against *Campylobacter fetus* subsp. *venerealis* (Bryner et al., 1979). Of the

eight that have been evaluated in an animal model, usually the pregnant guinea pig, three resulted in good to very good protection while the remaining five gave minimal to no protection. There are, to date, no vaccines or candidate vaccines suitable for use in humans to protect them against any form of campylobacteriosis.

Methods of Genetic Manipulation of Campylobacters

Campylobacters have not been found to undergo DNA mediated transformation. However, both a shuttle vector (Labigne-Roussel et al., 1987) and a method for introduction of DNA by electroporation (Miller et al., 1988) have been described. Although early studies described the use of transducing bacteriophage for transmitting genetic information between strains of *C. fetus* (Chang and Ogg, 1971), such techniques are not currently used.

Acknowledgments

We are deeply grateful to Dr. Connie Gebhart for her comments regarding *Campylobacter* infections in animals, and to Larry Carlson for his help in preparing the tables for the manuscript.

The Genus *Wolinella*

ANNE TANNER and BRUCE J. PASTER

Introduction

The genus *Wolinella* was proposed (as was the genus *Campylobacter*) for certain species originally classified in the genus *Vibrio* and was placed in the family Bacteroidaceae (Krieg and Holt, 1984). *Wolinella* was named for Dr. Meyer Wolin, an American bacteriologist who first described a microorganism (*Vibrio succinogenes*) with a metabolism that characterizes this genus. Bacteria of the genus *Wolinella* are Gram-negative rods that may be straight, curved, or helical. They are motile by means of a single polar flagellum. They are anaerobic and can utilize hydrogen gas or formate as electron donor with fumarate or nitrate as electron acceptor. Under these conditions, fumarate can also serve as a sole carbon source (Bronder et al., 1982). *Wolinella* species do not oxidize or ferment carbohydrates, but peptides stimulate growth (Gillespie and Holt, 1987). The GC content of their DNA ranges from 42 to 48 mol% whereas the GC content of *Campylobacter* ranges from 28 to 38 mol%.

Except for their GC content, bacteria of the genus *Wolinella* are physiologically, morphologically, and phylogenetically similar to *Campylobacter* species. The phylogeny of *Wolinella* and related genera was examined by analyzing 16S rRNA sequences (Paster and Dewhirst, 1988). These studies demonstrated that the three *Wolinella* species fall into two distinct, but related, subgroups (Fig. 1). One subgroup contained *W. succinogenes, Helicobacter pylori, H. mustelae,* and *Flexispira rappini.* The other subgroup comprised a tight cluster consisting of *Wolinella recta, W. curva,* most species of *Campylobacter,* and two formate-and fumarate-requiring ("misclassified") *Bacteroides, B. gracilis* and *B. ureolyticus* (Fig. 1). *Wolinella recta* and *W. curva* were more closely related to the *Campylobacter* cluster at an average homology of 95% than to *W. succinogenes,* the type species of *Wolinella* (average homology level of 88%). Thus, despite the large differences in GC content of the DNA, it was suggested that *W. recta* and *W. curva* should be considered as members of the genus *Campylobacter* (Paster and Dewhirst, 1988). However, results obtained from other experimental methods will most likely be necessary to resolve the taxonomic status of *Wolinella.*

The overall phylogenetic position of *Wolinella* relative to other Gram-negative bacteria determined from 16S rRNA sequencing (Fig. 2) indicated that the genus *Wolinella* does not belong in the family Bacteroidaceae, to which it is currently assigned. Based on certain unique oligonucleotide signatures in the 16S rRNA sequences, it has been suggested that *Wolinella* is distantly related to members of the proteobacteria group, such as *Escherichia coli* and *Proteus vulgaris* (Stackebrandt et al., 1987; Lau et al., 1987). It is also possible that *Wolinella* and related bacteria are sufficiently different to form a separate phylogenetic grouping or phylum (Romaniuk et al., 1987).

The type strain of *W. succinogenes* is ATCC 29543^T (FDC 602W): *W. recta* ATCC 33238^T (FDC 371): and *W. curva* ATCC 35224^T (VPI 9584). (FDC = Forsyth Dental Center, Boston, MA, USA; VPI = Virginia Polytechnic Institute, Blacksburg, VA, USA.)

Habitats

Bacteria of the genus *Wolinella* do not appear to be free living and have been cultured from the bovine rumen and from human clinical sites.

Wolinella succinogenes

W. succinogenes was originally isolated from bovine rumen fluid (Wolin et al., 1961). One strain (IB4) was isolated from sewage by Yoshinari (Tanner et al., 1984). Nonoral, human clinical isolates that were originally classified as species of *W. succinogenes* are most likely strains of *W. curva,* based upon DNA-DNA ho-

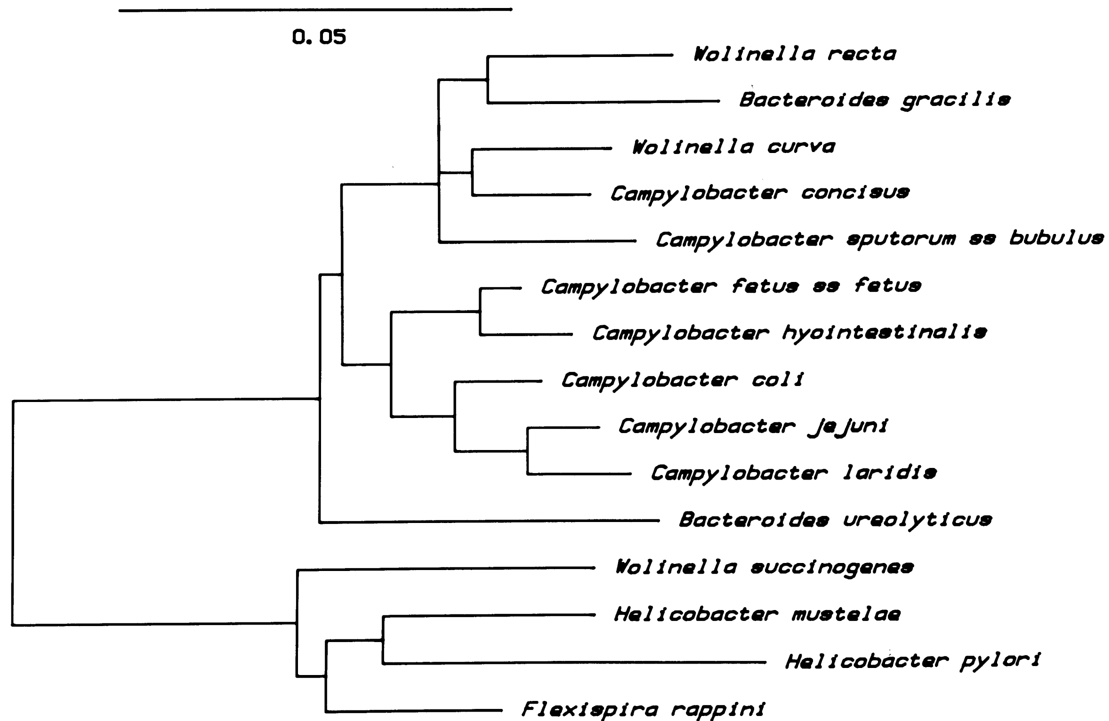

Fig. 1. Phylogenetic tree for *Wolinella* and its closest relatives. Data are based on nearly complete rRNA sequences (B. J. Paster and F. E. Dewhirst, unpublished observations). The scale bar represents the difference in nucleotide sequence determined by taking the sum of all branch lengths in connecting two species. Vertical distance has no meaning.

mologies and serological reactions (Tanner et al., 1984).

Wolinella recta

The primary ecological niche for *W. recta* appears to be subgingival sites (below the gum margin) of the human oral cavity. Isolates described as "vibrio-corroders," dry spreaders, *Campylobacter (Vibrio) sputorum, V. succinogenes, or Bacteroides corrodens* from oral and clinical sites (Smibert and Holdeman, 1976), as well as many of the small motile rods seen on darkfield examination of dental plaque samples, probably are *W. recta. W. recta* has also been isolated from an actinomycotic chest wall mass (Speigel and Telford, 1984).

W. recta may be pathogenic for humans. *W. recta* has been associated (as an anaerobic vibrio) with deep periodontal pockets (Tanner et al., 1979), with gingival (gum) inflammation (Van Palenstein Helderman and Rosman, 1976; Moore et al., 1987), with actively progressing periodontal diseases (Dzink et al., 1988), and with intractable (progressing despite treatment) periodontal lesions (Haffajee et al., 1988). *W. recta* was also isolated from painful human dental root canal (endodontic) lesions (Sundqvist, 1976; Tanner et al., 1984).

Wolinella curva

W. curva has been isolated from various human clinical sites, including subgingival sites, dental root canal (endodontic) lesions, an alveolar abscess, and septicemia (Tanner et al., 1984; Moore et al., 1987). The pathogenicity of this species is unknown as very few strains have been isolated.

Other *Wolinella* species

Additional unnamed strains of *Wolinella* have been isolated from human subgingival sites (Moore et al., 1987). Strains of *Wolinella*-like bacteria were found to colonize periodontal pockets of patients with inflammatory bowel disease. It was suggested that these strains may play a role in the pathogenesis of the disease (Van Dyke et al., 1986). Isolates resembling *Wolinella* but which decomposed hydrogen peroxide were isolated from subgingival sites by Takamori et al. (1982).

Isolation

Isolation of *W. succinogenes*

W. succinogenes was first isolated by enrichment culture from the bovine rumen and clas-

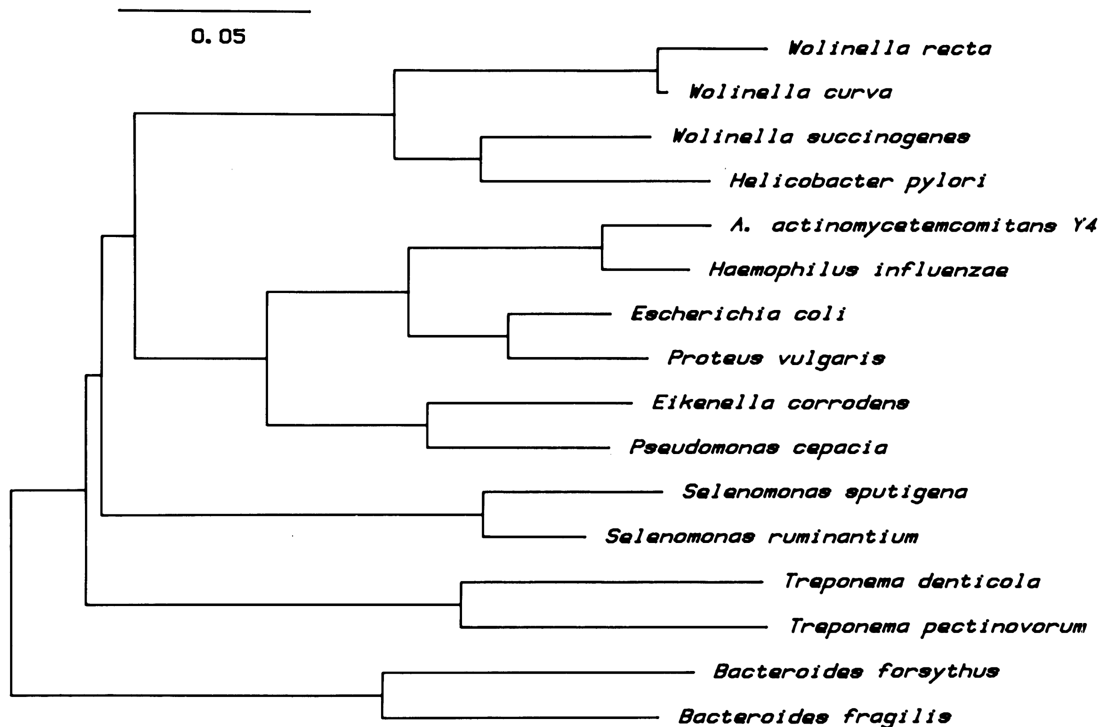

Fig. 2. Phylogenetic tree for species of *Wolinella* demonstrating their overall relationship to other Gram-negative bacteria. The scale bar represents the difference in nucleotide sequence as determined by taking the sum of all branch lengths connecting two species. The genus designation for *A. actinomycetemcomitans* is *Actinobacillus;* Y4 indicates strain FDC Y4 of *A. actinomycetemcomitans* serogroup B.

sified as *Vibrio succinogenes* (Wolin et al., 1961). An inoculum of bovine rumen fluid was serially transferred in an anaerobic methanogenic medium containing formate, sulfide, and inorganic salts. A highly motile vibrio was observed, and subsequently isolated by enrichment in a broth medium containing formate and fumarate. Wolin et al. (1961) recommended using a similar procedure to that first used to isolate additional strains.

Isolation of *W. recta, W. curva* and Other (Unnamed) *Wolinella* species

W. recta and *W. curva* were isolated from human clinical sites when anaerobic techniques were used for sample handling and culture, and specimens were inoculated and grown on enriched media that contained blood, or formate and fumarate (Tanner et al., 1979; Moore et al., 1987; Dzink et al., 1988; Haffajee et al., 1988). An example of isolation procedures used for human subgingival oral sites is as follows. Samples may be removed with a curette or scaler, and placed in a prereduced anaerobically sterilized (PRAS) salt solution. Samples should be dispersed under anaerobic conditions by vortexing, with or without glass beads, or by short periods of sonication at low power levels. Prolonged, powerful sonication techniques disrupt *Wolinella* cells (Olsen and Socransky, 1981).

Dispersed samples should be diluted under anaerobic conditions, and then plated on agar media containing formate and fumarate, with or without sheep blood. Several different basal media including trypticase soy and mycoplasma broth base (BBL) allow isolation of *Wolinella* species. The recipe for one medium (Tanner, 1987) that supports good growth of *Wolinella* species is shown below.

Medium for Isolation and Agar Cultivation of *Wolinella* Species

Brain heart infusion agar	52.0 g
Yeast extract	10.0 g
Sodium formate	2.0 g
Fumaric acid or sodium fumarate	3.0 g
Hemin stock solution (see below)	10.0 ml
Distilled water	950.0 ml
Defibrinated sheep blood	40.0 ml

Hemin Stock Solution:

Hemin	0.05 g
Potassium phosphate dibasic	1.74 g
Distilled water	100.0 ml

Boil the ingredients in a flask to dissolve the hemin. Store at room temperature and protect from light.

Combine the medium components with the exception of the sheep blood. Adjust the pH to 7.0 and sterilize by autoclaving. When the liquid has cooled, add the blood, and pour plates.

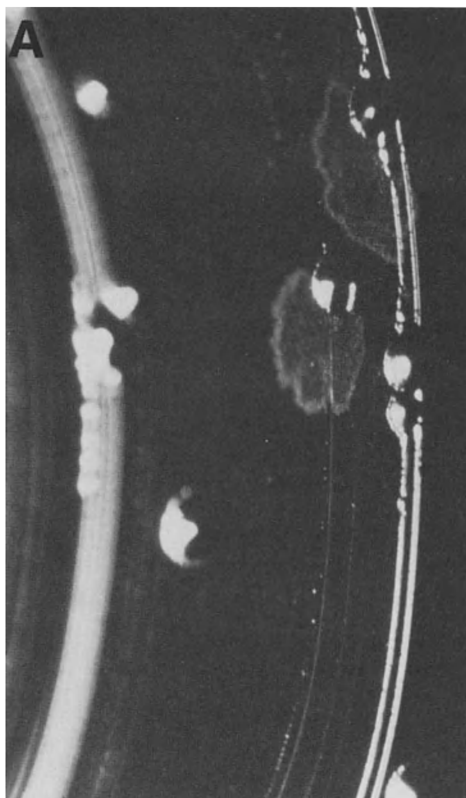
Optimal recovery of oral anaerobic and facultatively anaerobic species is achieved under an anaerobic atmosphere containing hydrogen, for example, 10% H_2, 10% CO_2, 80% N_2.

Wolinella species may be recognized by their colonial morphology (Fig. 3), which varies depending on medium composition. On certain blood agar plates, colonies may spread over the agar surface (dry spreaders), be highly translucent, and have the appearance of droplets of water (Fig. 3A). There may be small convex colonies in addition to the spreading-pitting variant (Fig. 3A). On other media, the same species may pit or corrode the agar surface (Fig. 3B). On media supplemented with formate and fumarate, colonies are larger, convex, and frequently have yellow or pink speckles. No hemolysis has been observed on blood agar.

The following selective medium for *W. recta* and *Bacteroides gracilis* (Hammond and Malonee, 1988) is a modification of the previous medium, replacing blood with sources of sulfate. *W. recta* and *B. gracilis* produce excessive hydrogen sulfide and form small, black colonies on primary isolation. Upon subculture, however, colonies may not turn black on this agar medium.

Selective (Agar) Medium for Isolation of *Wolinella recta* and *Bacteroides gracilis*

Brain heart infusion agar	52.0 g
Sodium formate	2.0 g
Fumaric acid or sodium fumarate	3.0 g
Yeast extract	10.0 g
Sodium thiosulfate	0.3 g
Ferrous sulfate	0.2 g
Hemin stock solution (see below)	10.0 ml
Distilled water	980.0 ml
Menadione stock solution (see below)	10.0 ml
Vancomycin stock solution (see below)	1.0 ml



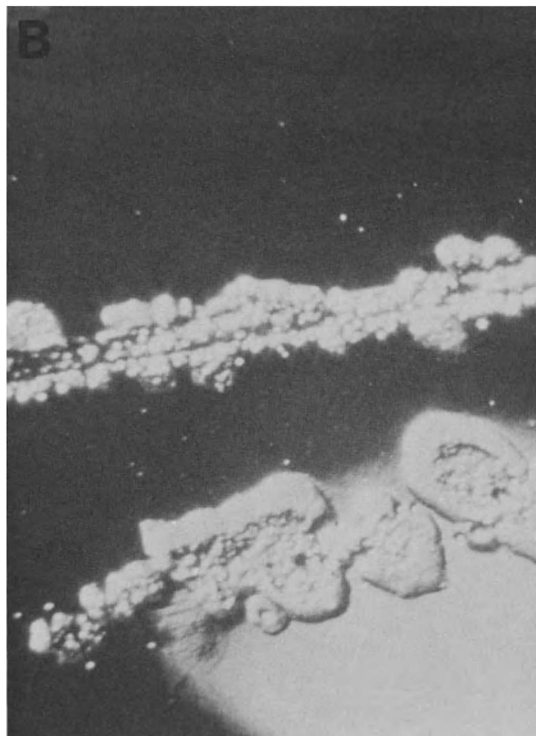


Fig. 3. Colonial morphology of *Wolinella recta*. (A) Agar-spreading (dry-spreading, water drop) colonies and small convex colonial variants of *W. recta*. On blood agar plates unsupplemented with formate and fumarate, the small convex variant is usually 1 mm in diameter, whereas the spreading variant may be up to 5 mm in diameter. (B) Agar-corroding colonies of *W. recta*. This colonial variant is produced from the agar-spreading variant if cells are plated on certain media, including many "home-made" media, as compared to commercially prepared media. Agar-corroding colonies are usually less than 5 mm in diameter.

Hemin stock solution, see recipe for previous agar medium.

Menadione stock solution (100 ml):

Menadione	0.005 g
Ethanol	1.0 g
Distilled water	99.0 ml

Dissolve the menadione in ethanol. Add the water and filter sterilize. Aliquots may be frozen.

Vancomycin stock solution (5 mg/l):

Vancomycin	5.0 mg
Distilled water	4.0 ml

Dissolve the vancomycin in the water in a test tube. Filter sterilize the solution. Aliquots may be frozen.

Combine the ingredients above except the menadione and vancomycin solutions. Adjust the pH to 7.0 and sterilize by autoclaving. When the medium has cooled, add the filter-sterilized menadione and vancomycin solutions, and pour the plates.

Broth Cultivation of *Wolinella* Species

Several broth media have been described for culturing *Wolinella succinogenes*. Wolin et al. (1961) used a medium containing: $(NH_4)_2SO_4$, 0.1%; K_2HPO_4, 0.5%; fumaric acid, 0.3%; sodium formate, 0.3%; yeast extract (Difco), 0.1%; $MgCl_2 \cdot 6H_2O$, 0.02%; and $FeSO_4$, 0.001%; pH 7.0 to 7.2. An improved medium was described by Kafkewitz (1975) consisting of 0.4% yeast extract, 100 mM ammonium formate, 120 mM sodium fumarate, and 0.05% sodium thioglycollate, pH 7.3. When freshly prepared, this broth medium, incubated aerobically, supported growth of several reference strains of *Wolinella,* including representatives of the three named species (Tanner et al., 1984).

In an attempt to improve growth of oral agar-corroding species and species stimulated by formate and fumarate, optical densities of cells of *Wolinella* species was compared following culture in multiple media bases in different combinations with different organic acids and reducing agents (Tanner, 1987). These studies were performed mainly in wells of microtiter plates. Excellent growth of *W. succinogenes* was achieved in yeast extract, 10–15 g/liter; sodium formate, 2 g/liter; sodium fumarate, 3 g/liter; and sodium thioglycollate, 0.5 g/liter. In these studies, the increased concentrations of yeast extract compared to that of the media described by Wolin et al. (1961) and by Kafkewitz (1975) resulted in higher yields of cells. While this medium supported growth of *W. recta* and *W. curva,* cell yields were never as high as with *W. succinogenes.* Maximal growth of *W. recta* and *W. curva* was achieved by the addition of yeast extract at 5 g/liter to complex media including brain heart infusion (BBL), Todd-Hewitt broth (BBL), or mycoplasma broth base (BBL). *W. curva* was stimulated by the inclusion of L-cysteine, 0.5 g/liter, and sodium bicarbonate, 1 g/liter, whereas *W. recta* appeared to prefer sodium thioglycollate, 0.5 g/liter, as a reducing agent.

Gillespie and Holt (1987) studied the growth in broth of the type strain of *W. recta.* Their studies indicated that ammonium formate could substitute for sodium formate and that hemin was not required for growth of *W. recta.* Maximal growth of *W. recta* was achieved in mycoplasma broth base supplemented with 25 mM formate and 75 mM fumarate.

Preservation of Cultures

Wolinella species may be preserved by lyophilization using a dense suspension of cells in broth containing 5% serum and 1% glucose. Cells may also be stored frozen either in liquid nitrogen, or in ultra-low-temperature freezers (−80°C) by suspending young colonies in a broth containing 5% dimethyl sulfoxide prior to slow freezing and storage.

Identification

Wolinella species have been difficult to differentiate from each other and historically were all grouped together as *Vibrio succinogenes* or *Bacteroides corrodens.* However, accurate species identification has become quite feasible using protein profiles from polyacrylamide gel electrophoresis, indirect immunofluoresence, or hybridization with species-specific DNA probes.

Morphology

All species of *Wolinella* are nonsporeforming, Gram-negative rods that are motile by means of a single polar flagellum. Cells are 0.4 μm in diameter and 0.9–4.0 μm long, and each species appears to have a different predominant cell shape with rounded or tapered ends (Table 1; Figs. 4 and 5). *W. succinogenes* cells from a log phase broth culture may appear helical or curved. *W. curva* cells are frequently curved, whereas *W. recta* cells are predominantly straight. Cells of *W. recta* possess a distinctive cell wall surface layer (S-layer) characterized by a hexagonal arrangement of subunits that are in close contact with the outer membrane (Fig. 5; Lai et al., 1981; Kerosuo et al., 1989). S-layers present on archaebacteria and other eubacteria are composed of crystalline protein or glycoprotein (Sleytr and Messner, 1983). Colonial

(C) *W. succinogenes,* strain ATCC 29543 (FDC 602W): a short curved rod with a typical Gram-negative cell wall surface and a single polar flagellum. Bars = 0.5 μm.

morphology (Fig. 3) for *Wolinella* species was described under isolation procedures.

Biochemical Characteristics

Characteristics common to *Wolinella* species are listed in Table 2. *Wolinella* strains grow at 37°C, demonstrate oxidase activity, and produce hydrogen sulfide, but are asaccharolytic and are negative in many routine biochemical tests including enzyme substrate tests (Table 2). Because of their reducing metabolism, *Wolinella* species all reduce benzyl viologen (−421 mV). Growth in broth media of *W. recta* is accompanied by an increase in pH to a maximum of 8.0 (Gillespie and Holt, 1987). While strains

The cell periphery has a well-defined inner membrane, lacks a distinct peptidoglycan layer, and has bullet-shaped subunits covering the outer membrane. Within the cell there is a nuclear region (N) and small electron-dense cytoplasmic inclusions (C). Bar = 0.2 μm. (B) *W. recta*. Section of cell wall illustrating its ultrastructure. The inner membrane (IM), the outer membrane (OM), and the regularly arranged bullet-shaped subunits (BSU) at the cell surface are visible. Bar = 0.1 μm. (C) *W. curva:* a curved-to-helical rod showing the flagellar insertion (F), a nuclear region (N), and small electron-dense cytoplasmic inclusions (C). The ultrastructure of *W. curva* is similar to that of *Campylobacter concisus*. Bar = 0.2 μm. (D) *W. succinogenes:* a curved rod showing the flagellar insertion (F), nuclear region (N), and small electron-dense cytoplasmic inclusions (C). Bar = 0.2 μm.

do not grow on agar surfaces incubated in air, they may grow in an atmosphere containing 5% oxygen (microaerophilic). Characteristics that differ among *Wolinella* species, *Bacteroides gracilis,* and *Campylobacter concisus* are listed in Table 1. *Wolinella recta* is considerably more sensitive to many inhibitory agents, including antibiotics, than is *W. succinogenes, W. curva, B. gracilis,* or *C. concisus.*

Species Differentiation

Determination of *Wolinella* species requires differentiation from other nonfermentative species that either corrode agar or demonstrate a formate- and fumarate-utilizing metabolism (Table 3). *Eikenella corrodens* may be distinguished by its growth on agar surfaces in air with 10% carbon dioxide; growth in the presence of 4 μg/ml clindamycin; lack of active cell motility; lack of growth in media supplemented with formate and fumarate without nitrate; and the presence of lysine and ornithine decarboxylases (Table 3). The other species listed in Table 3 differ physiologically from *E. corrodens.* The formate-and fumarate requiring species proved difficult to differentiate using the characteristics of source of isolation, presence or absence of motility, unreactivity of strains (e.g., of *W. recta* to inhibitors), cell morphology, and urease activity (Tables 1 and 3; Tanner et al., 1987). However, *Wolinella* species can be differentiated using serology, polyacrylamide gel electrophoresis, and DNA probes.

SEROLOGY. All *Wolinella* species are serologically distinct based on agglutination tests (Badger and Tanner, 1981), ELISA (Tanner et al., 1984), and indirect immunofluoresence (Werner-Felmayer et al., 1988; Lai et al., 1989). Different serotypes have been described for *W. recta* using polyclonal antibodies (Badger and Tanner, 1981) and indirect immunofluoresence utilizing different monoclonal antibodies to *W. recta* (Werner-Felmayer et al., 1988). Fluorescently labeled polyclonal antibodies have been

Table 2. Characteristics common to all *Wolinella* species.[a]

Common positive characteristics:	Gram-negative rods; actively motile by a single polar flagellum; 0.4 μm in diameter and 0.9–4.0 μm in length; growth in broth supplemented with formate and fumarate; growth in anaerobic and microaerophilic (5% O_2) atmospheres; reduction of nitrate, nitrite, neutral red, and benzyl viologen; oxidase and benzidine positive; production of hydrogen sulfide, hydrogen, carbon dioxide, and succinate; growth in the presence of Evans blue (0.05 g/liter), malachite green (0.02 mg/liter), brilliant green (0.0125 g/liter), and kanamycin (1, 2, or 4 μg/ml); arginine aminopeptidase positive in API An-Ident tests; GC content, 42–47 mol%.
Common negative characteristics:	No growth in unsupplemented broth media or in media supplemented with only 0.2% nitrate; no growth on agar surfaces in air, or in air containing 10% CO_2; no spores formed; not haemolytic; no reduction in pH when incubated in formate- and fumarate-supplemented media with 1% adonitol, 1% amygdalin, 1% arabinose, 1% dextran, 1% dulcitol, 1% fructose, 1% galactose, 1% glucose, 1% glycerol, 1% glycogen, 1% inositol, 1% inulin, 1% lactose, 1% maltose, 1% mannitol, 1% mannose, 1% melezitose, 1% melibiose, 1% raffinose, 1% rhamnose, 1% ribose, 1% salicin, 1% sorbitol, 1% sucrose, 1% trehalose, 1% xylose, 0.25% esculin, or 0.5% starch; catalase negative; lysine, ornithine, and arginine not decarboxylated; starch, dextran, esculin, casein, DNA, and gelatin not hydrolyzed; hydrogen peroxide, urease, lethicinase, lipase, indole, ammonia, and acetylmethylcarbinol not produced; nitrous oxide, methane, formate, acetate, propionate, isobutyrate, butyrate, isovalerate, valerate, caproate, lactate, and pyruvate not detected; gas not formed under an agar layer over a broth culture; no growth in the presence of NaCl (20 or 40 g/liter) or penicillin (64 μg/ml); negative or weak reactions in API ZYM and API An-Ident tests, except for arginine aminopeptidase.

[a]These characteristics are shared by *B. gracilis, C. concisus,* and *C. sputorum,* except: *B. gracilis* has no flagellum and is not actively motile; *Campylobacter* species have a lower GC content.
Data from Tanner et al., 1981, 1984, 1985.

Table 3. Differentiation of *Wolinella* species from other asaccharolytic agar-corroding, and formate- and fumarate-requiring species.

Characteristic	*Eikenella corrodens*	*Bacteroides ureolyticus*	*B. gracilis*	*Campylobacter sputorum*	*C. concisus*	*Wolinella* species

Urease	–	+	–	–	–	–
GC content, mol%	50–58	28	42–47	30–34	34–38	42–47

used to identify *W. recta* from dental plaque samples (Lai et al., 1989).

USE OF GEL ELECTROPHORESIS. Sonicated whole cell preparations of the formate and fumarate-utilizing species were run on SDS-polyacrylamide gels. Each species demonstrated a different protein profile when gels were stained with a conventional silver stain (Fig. 6). *W. recta* was most easily distinguished from these other species by the presence of yellow-stained bands (in contrast to typical black bands) at an approximate molecular weight of 25 kDa Tanner, 1986).

DNA PROBES. *W. recta* can be identified from pure cultures and in dental plaque samples using either whole genomic DNA probes (Gunaratnam et al., 1990) or short oligonucleotide probes (Dix et al., 1990; B. J. Paster and F. E. Dewhirst, unpublished observations). Whole genomic probes (Gunaratnam et al., 1990) were prepared and labeled with a nonradioactive label as described by Smith et al., (1989). Colonies of strains to be identified were "lifted" onto nylon filter membranes, and the DNA was extracted and fixed to the solid support. Positive hybridization reactions were visualized by a nonradioactive color reaction.

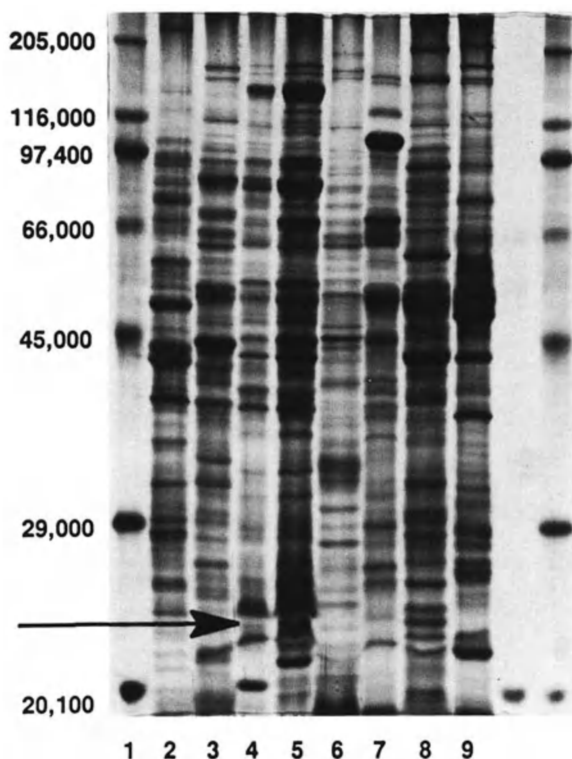

Fig. 6. Silver-stained SDS-polyacrylamide gel of sonicated whole cells of species with a formate and fumarate metabolism. The running and stacking gels contained 14% and 4% acrylamide respectively. The current was run at 15 mA per 0.75 mm thick gel. The arrow indicates the level of yellow-staining bands of *Wolinella recta* isolates in lanes 4 and 5. Lane 1, high-molecular-weight standard mixture; lane 2, *W. succinogenes* ATCC 29543ᵀ, lane 3, *W. curva* ATCC 35244ᵀ; lanes 4 and 5, *W. recta* strains ATCC 33238ᵀ and FDC 267; lane 6, *Campylobacter concisus* ATCC 33237ᵀ; lane 7, *C. sputorum* ATCC 35980ᵀ (VPI S-17); lane 8, *Bacteroides gracilis* ATCC 33236ᵀ; and lane 9, *B. ureolyticus* VPI 7815.

Short DNA oligonucleotide probes (20–24 bases) were designed by comparing 16S rRNA sequences to determine those regions of the molecule that were unique to any given species. Complementary DNA to that region was synthesized, and the probe was labeled with a radioisotope. Probes specific for the RNA of the three *Wolinella* species have been developed, but they have not yet been tested directly on clinical samples (B. Paster and F. Dewhirst, unpublished observations).

Physiological Properties

Wolinella species have generated the interest of several investigators because of their unusual, previously unrecognized, formate- and fumarate-requiring metabolism. Most of the physiological studies have been performed on strains of either *W. succinogenes* or *W. curva.*

Wolinella species can utilize formate or hydrogen gas as an energy source with formate being oxidized to CO_2. *W. succinogenes* can also use hydrogen sulfide as an energy source (Macy et al., 1986). The oxidation of the electron donors can be coupled with any of several electron acceptors, including fumarate and nitrate. Succinate is produced when cells are grown on fumarate, which can also serve as the sole carbon source (Bronder et al., 1982). Fumarate can be replaced by L-malate, L-aspartate, or L-asparagine for *W. succinogenes* and *W. curva* (Wolin et al., 1961; Kafkewitz, 1975).

Oxidation of formate or hydrogen may also be coupled with reduction of nitrate or nitrite, or for *W. succinogenes,* with nitrous oxide or sulfur (Wolin et al., 1961; Yoshinari, 1980; Schröder et al., 1988). Nitrate or nitrite is reduced to ammonia, but not to nitrogen gas (Bokranz et al., 1983). However, nitrous oxide can be reduced to nitrogen via nitrous oxide reductase (Teraguchi and Hollocher, 1989). Sulfur is reduced to hydrogen sulfide via sulfur reductase (Schröder et al., 1988). *W. recta* can grow with oxygen as the sole electron acceptor in continuous culture if the oxygen concentration is maintained below 2–5 μM (Ohta and Gottschal, 1988).

A growth requirement for succinate was described for *W. succinogenes* when nitrate replaced fumarate as the electron acceptor (Niederman and Wolin, 1972), but not nitrous oxide (Yoshinari, 1980). Added succinate was not needed in the presence of substances that could be converted to succinate, including malate, fumarate, and L-asparagine. The succinate requirement could not be replaced by oxaloacetate, pyruvate, bicarbonate, acetate, propionate, butyrate, L-glutamate, D-aspartate, or δ-aminolevulinic acid (Niederman and Wolin, 1972). L-aspartate and L-asparagine could substitute for fumarate, malate, and nitrate as electron acceptors when *W. succinogenes* was grown in the presence of formate.

The electron transport chain is comprised of formate dehydrogenase and fumarate reductase, which are linked by a menaquinone. Formate dehydrogenase was isolated from *W. succinogenes* as a dimer of two identical subunits of molecular weight equal to 110,000, containing a cytochrome *b* that mediated electron transfer to menaquinone (Kröger et al., 1979). Fumarate reductase was isolated in two forms, one of which contained a cytochrome *b* that mediated electron transfer from menaquinone to fumarate reductase (Unden et al., 1980). The reactive sites of formate dehydrogenase appear

to face the outside, while those of fumarate reductase face the inside of the cytoplasmic membrane (Kröger et al., 1980).

Two nitrite reductases (mol. wt: of 63,000) were characterized from *W. succinogenes,* one isolated from the cytoplasm and the other associated with the cytoplasmic membrane (Schröder et al., 1985). In these studies, it was suggested that a hemeC protein with a molecular weight of 22,000 was a form of cytochrome *C.* A cytochrome *C*-containing nitrous oxide reductase (a dimer of mol. wt. 162,000) was also isolated and purified from *W. succinogenes* (Teraguchi and Hollocher, 1989). Sulfur reductase, isolated as sulfur dehydrogenase, is involved in the sulfur respiration of *W. succinogenes* (Schröder et al., 1988). When growth is driven by the reduction of sulfur, a menaquinone is apparently not involved in the phosphorylative electron transport chain.

L-Asparaginase has been isolated from *W. succinogenes* (Kafkewitz and Goodman, 1974) and from strains currently recognized as *W. curva.* (Albanese and Kafkewitz, 1978; Abouchowski et al., 1979; Radcliffe et al., 1979). This enzyme inhibited growth of an in vitro culture of human pancreatic carcinoma cells (Wu et al., 1978) and was thus of interest for its potential antitumor activity.

Genetic information

The G C content of the DNA of *Wolinella* species ranges from 42–46 mol% (Tm). DNA-DNA hybridization studies demonstrated that the currently recognized species were distinct from each other (Tanner et al., 1981, 1984). The phylogeny of *Wolinella* species and related bacteria has been determined by 16S rRNA sequence analysis and was described in the introduction. Two structural genes coding for subunits of the enzyme fumarate reductase from *W. succinogenes* were cloned and expressed in *Escherichia coli* (Lauterbach et al., 1987). No genetic transfer among the species has been observed.

Acknowledgments

We would like to thank Drs. C.-H. Lai, and M. A. Listgarten for the electron photomicrographs. This manuscript was prepared with support from research grants form the National Institutes of Health, National Institute of Dental Research Grants DE-03488, DE-02847, and DE-08303.

CHAPTER 191

Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta*

ERCOLE CANALE-PAROLA

The genus *Spirochaeta* includes anaerobic and facultatively anaerobic spirochetes that are indigenous to aquatic environments such as the mud and water of ponds and marshes. These spirochetes occur in nature as free-living forms, that is, their existence does not depend on physical associations with other organisms (Canale-Parola, 1984b).

Spirochaeta cells are helically shaped (Figs. 1–12) and possess the typical ultrastructural features of spirochetes (Fig. 13) (Canale-Parola, 1984a). The outermost structure of the cells is an "outer membrane," or "outer sheath," which encloses the coiled cell body ("protoplasmic cylinder") consisting of the cytoplasm, the nuclear region, and the peptidoglycan-cytoplasmic membrane complex (Fig. 13). Organelles ultrastructurally similar to bacterial flagella are located in the area between the outer membrane and the protoplasmic cylinder (Fig. 13). These organelles are essential components of the motility apparatus of spirochetes (Paster and Canale-Parola, 1980) and are usually called "periplasmic flagella." Other names that have been used to designate these motility organelles are "periplasmic fibrils," "axial fibrils," "axial filaments," and "endoflagella." One end of each periplasmic flagellum is inserted near a pole of the protoplasmic cylinder, whereas the other end is not inserted (Fig. 13A). Individual periplasmic flagella extend for most of the length of *Spirochaeta* cells, so that those inserted near opposite ends overlap in the central region of the organism (Fig. 13A). In contrast to flagella of other bacteria, the periplasmic flagella of spirochetes are permanently wound around the cell body and are entirely endocellular (Fig. 13B). Thus, the motility mechanism of spirochetes is different from that of other bacteria, which have flagella that function in direct contact with the external environment and are not wound around the cell body.

With one exception, all the known *Spirochaeta* species (Table 1) have two periplasmic flagella per cell, one flagellum being inserted near each cell pole. The exception is the large spirochete *S. plicatilis* (Table 1), which has as many as 18–20 periplasmic flagella inserted near each end of the protoplasmic cylinder (Blakemore and Canale-Parola, 1973).

Seven species of *Spirochaeta* are presently known (Table 1; Figs. 1–12). One of these, *S. plicatilis,* has not been grown in pure culture, but its ultrastructure and some of its ecological characteristics have been described (Blakemore and Canale-Parola, 1973). Four species—*S. stenostrepta, S. litoralis, S. zuelzerae,* and *S. isovalerica*—are obligate anaerobes. Two other species—*S. aurantia* and *S. halophila*—are facultative anaerobes and characteristically produce carotenoid pigments when growing aerobically (see below).

S. stenostrepta, S. zuelzerae, and *S. aurantia* are freshwater species, whereas *S. litoralis* and *S. isovalerica* are marine species (Table 1) and require Na^+ concentrations ranging from 200 to 300 mM for optimal growth (Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). *S. halophila* was isolated from a high-salinity pond and grows optimally when 750 mM NaCl, 200 mM $MgSO_4$, and 10 mM $CaCl_2$ are present in the medium (Greenberg and Canale-Parola, 1976).

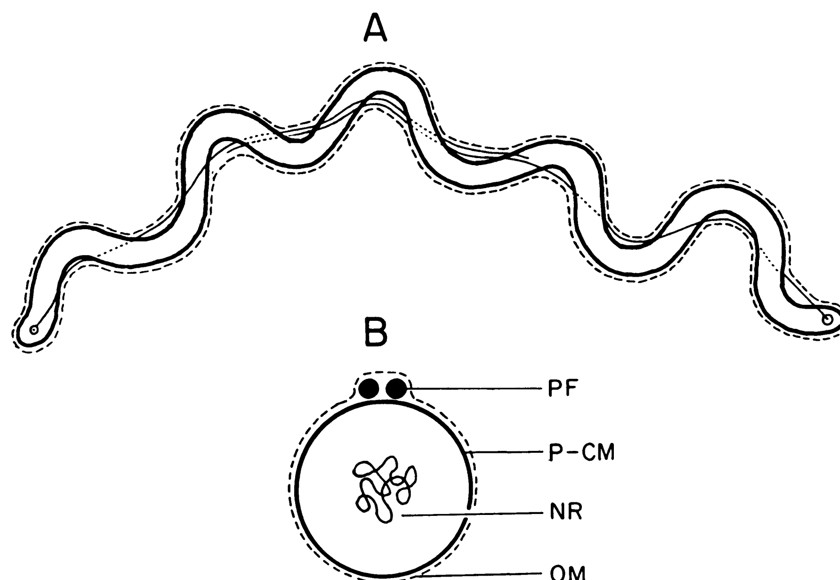

Fig. 13. (A) Schematic representation of a *Spirochaeta* cell. The outermost broken line indicates the outer membrane (outer sheath). The protoplasmic cylinder is represented by the area delimited by the solid line adjacent to the outermost broken line. The cell has two periplasmic flagella indicated by the solid-dotted thin lines wound around the protoplasmic cylinder. The insertion points of the periplasmic flagella are represented by the small circles near the ends of the cell. (B) Schematic representation of a cross section through a *Spirochaeta* cell. PF, periplasmic flagella; P—CM, peptidoglycan-cytoplasmic membrane complex; NR, nuclear region; OM, outer membrane (outer sheath).

Two subspecies of *S. aurantia* are known (Table 1). One of these (subsp. *stricta*) is characterized by significantly narrower coils than the other (subsp. *aurantia*), and its DNA possesses a slightly lower GC content (Breznak and Canale-Parola, 1975; Canale-Parola, 1984b).

Fracek and Stolz (1985) described a strain of anaerobic marine spirochetes isolated from sulfide-rich mud, and concluded that it represented a new species, which they named *Spirochaeta bajacaliforniensis.* The strain is essentially identical to *S. litoralis* with respect to physiological characteristics and GC content of the DNA but differs from the latter spirochete in some minor morphological features. Further work, possibly involving nucleic acid homology studies, is needed to determine whether Fracek and Stolz's isolate is a strain of *S. litoralis* or is, in fact, a new species of *Spirochaeta.*

Ribosomal RNA oligonucleotide cataloging studies have shown that *Spirochaeta* species and most *Treponema* species tested fall within a large cluster which is subdivided into two subclusters (Paster et al., 1984). The smaller of these subclusters includes *S. isovalerica, S. litoralis, S. aurantia,* and *S. halophila.* The larger subcluster consists of *S. stenostrepta, S. zuelzerae,* and all *Treponema* species that were tested except *T. hyodysenteriae.*

Habitats

Species of *Spirochaeta* occur, grow, and persist as free-living organisms in a variety of aquatic environments, such as the water, sediments, and muds of ponds, marshes, lakes, rivers, and oceans. Numerous strains of *Spirochaeta* have been isolated from various freshwater environments (Canale-Parola, 1984b) and from marine muds collected in Pacific and Atlantic coastal regions (Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). *Spirochaeta* cells are present in salt marshes at densities ranging from 10^4 to 10^6 per gram (wet weight) of the top 1 cm of sediment (Weber and Greenberg, 1981). Selective isolation procedures did not yield spirochetes from deep-sea sediments and water from the Sargasso Sea (3,630 m) and the Puerto Rico Trench (8,140 m) (Harwood et al., 1982). These results indicate that although anaerobic and facultatively anaerobic free-living spirochetes are common in marine coastal environments, they are not widely distributed in deep-sea regions. However, Harwood and coworkers (1982) isolated an obligately anaerobic spirochete from a sample collected near a deep-sea (2,550 m) hydrothermal vent at the Galapagos Rift ocean floor spreading center, and they observed bacteria with morphologies typical of spirochetes in surface scrapings from

mussels present near a vent. The occurrence of spirochetes in this deep-sea region may be ascribed to the environmental conditions characteristic of the vent area, which are favorable to the growth of various bacteria.

Halophilic forms (*S. halophila*) with optimum growth temperatures between 35 and 40°C have been isolated from a high-salinity pond located on the Sinai shore of the Gulf of Aqaba (Greenberg and Canale-Parola, 1976). Obligately anaerobic thermophilic spirochetes isolated from New Zealand thermal springs grow optimally at 45 to 50°C (Patel et al., 1985). Other *Spirochaeta* species behave like mesophiles with regard to growth temperatures (Canale-Parola, 1984b).

All species of *Spirochaeta* that have been cultivated are saccharolytic, and they usually lack the ability to utilize compounds other than carbohydrates as oxidizable substrates for growth. Various pentoses, hexoses, and disaccharides, as well as starch, are used as carbon and energy sources (Canale-Parola, 1984b; Greenberg and Canale-Parola, 1976). Even though free-living spirochetes are commonly observed in natural anaerobic environments in which plant material that contains cellulose and pectin is biodegraded (Canale-Parola, 1978; Harwood and Canale-Parola, 1984), none of the *Spirochaeta* species has been reported to ferment these polysaccharides. It may be inferred that in their habitats, which frequently are rich in decaying plant material, *Spirochaeta* species ferment soluble sugars released into the environment by the enzymatic activities of microorganisms that depolymerize plant polysaccharides. Both facultatively and obligately anaerobic species of *Spirochaeta* grow abundantly when the energy source available to them is cellobiose, a major product of cellulose depolymerization, which is produced by the extracellular cellulase systems of some microorganisms (Breznak and Canale-Parola, 1969, 1975; Greenberg and Canale-Parola, 1976; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970a, 1970b). Furthermore, free-living spirochetes, such as *S. aurantia,* exhibit a strong tactic response toward very low cellobiose concentrations (Greenberg and Canale-Parola, 1977a), and possess regulatory systems that enable them to enhance their chemotactic responses when attractants that serve as energy sources are present at very low concentrations in the environment (Terracciano and Canale-Parola, 1984). Inasmuch as cellobiose levels in environments in which cellulose is degraded are likely to be quite low (Smith et al., 1973), a strong tactic response to very low concentrations of cellobiose may confer an important selective advantage on the spirochetes with respect to other cellobiose-utilizing microorganisms.

In addition to their ability to regulate their chemosensory apparatus in response to low substrate concentrations, some species of *Spirochaeta* have developed other strategies to survive in environments lacking or nearly depleted of energy sources. One of these survival strategies has been studied in *S. isovalerica,* a saccharolytic anaerobe that does not utilize amino acids as fermentable substrates for growth, but catabolizes small amounts of L-leucine, L-isoleucine, and L-valine with the formation of isovalerate, 2-methylbutyrate, and isobutyrate, respectively, as end products (Harwood and

Table 1. Characteristics of the seven species of the genus *Spirochaeta*.

Species[a]	Size[b] (μm)	Relationship to O_2[c]	Optimum growth temperatures (°C)	Habitat	GC content of DNA (mol%)[d]
1. *S. stenostrepta*	0.2–0.3 × 15–45	OA	30–37	Freshwater	60.2

[f]Observed in mud from a brackish marsh (Blakemore and Canale-Parola, 1973).

Canale-Parola, 1981a, 1983, 1984). Although these amino acids are not used by *S. isovalerica* as fermentable substrates for growth, their fermentation serves to generate ATP, which is utilized by the spirochetes as a source of maintenance energy. This process allows cells to survive during periods of growth substrate starvation (Harwood and Canale-Parola, 1981a, 1981b, 1982). Other starvation-survival strategies utilized by *Spirochaeta* species may involve ATP generation through metabolism of endogenous RNA (Canale-Parola and Kidder, 1982; Harwood and Canale-Parola, 1984) or metabolism of intracellular polyglucose storage granules (Kropinski et al., 1988).

The large spirochete *S. plicatilis* has been observed within masses of *Beggiatoa* trichomes in samples of black, sulfide-rich marsh mud covered with a layer of marsh water (Blakemore and Canale-Parola, 1973). In this study, the spirochetes were seen to swim freely among the tangled *Beggiatoa* trichomes, and "crept" on or otherwise moved in contact with the surface of the trichomes. The close association with *Beggiatoa* suggested a chemotactic response by the large spirochete toward metabolites produced by the sulfur bacteria. As the level of sulfide generated by biological activities in the mud became low, gradual lysis of the *Beggiatoa* trichomes was observed. This lytic process coincided with a dramatic increase in the number of large spirochetes (Blakemore and Canale-Parola, 1973). Possibly, substances released by the lysing *Beggiatoa* were used as growth substrates for *S. plicatilis.*

Physiology

Motility and Chemotaxis

Three main types of motion are observed in species of *Spirochaeta:* 1) translational motion; 2) rotation of the cell around its longitudinal axis; and 3) flexing motion (Canale-Parola, 1978). In addition to swimming freely in liquid environments, some *Spirochaeta* are able to "creep" or "crawl" on solid surfaces, a movement resembling that of the gliding bacteria (Blakemore and Canale-Parola, 1973). Species of *Spirochaeta* retain their translational motion in environments of relatively high viscosity, e.g., 500 centipoise (Greenberg and Canale-Parola, 1977b). In comparison, flagellated bacteria such as *Escherichia coli, Pseudomonas aeruginosa,* and *Aquaspirillum serpens* are immobilized at viscosities of or above 60 centipoise (Greenberg and Canale-Parola, 1977c).

The motility of a strain of *Spirochaeta aurantia* in liquid environments has been described as follows (Greenberg and Canale-Parola, 1977a; Greenberg et al., 1985): The spirochete usually swims in nearly straight lines (runs) and appears to spin about its longitudinal axis as it progresses through the liquid. From time to time the cell reverses swimming direction, the anterior end of the cell becoming the posterior end. Occasionally, the spirochete stops running, flexes, and then resumes its translational motion. However, upon resuming its translational motion, the spirochete usually alters the direction of its movement, and the previously leading cell end may or may not become the trailing cell end. Thus, *S. aurantia* performs three kinds of behavior (runs, flexes, and reversals), in contrast to *Escherichia coli* which performs two kinds (runs and tumbles). During runs, *S. aurantia* cells have an average linear speed of approximately 16 μm/s (Fosnaugh and Greenberg, 1988). Flexes last from a fraction of a second to several seconds. The average frequency of reversals in cell populations is approximately 0.31 reversals/5 s (Fosnaugh and Greenberg, 1988).

A model that interprets the motile behavior of *S. aurantia* has been proposed (Berg, 1976; Greenberg et al., 1985). According to this model, the two periplasmic flagella of *S. aurantia* rotate, each driven by a motor at the insertion end. Rotation of the flagella in one direction (looking at the cell head on; see Fig. 13B) causes the periplasmic cylinder and the outer membrane to move in directions opposite to each other. Due to its helical shape, the cell rotates about its longitudinal axis and moves along it. Runs occur when the flagellar motor at one cell end rotates clockwise (CW) while the motor at the other cell end rotates counterclockwise (CCW). When both motors switch direction of rotation at the same time, a reversal takes place. A flex is generated during asynchronous switching, i.e., when only one motor switches direction so that both motors are rotating CW or CCW. Asynchronous switching causes the cell ends to twist in opposition to each other, and a flex occurs.

S. aurantia exhibits chemotaxis toward D-glucose, D-xylose, cellobiose, and various other sugars, but not toward amino acids (Greenberg and Canale-Parola, 1977a). Many of the chemoattractants also serve as carbon and energy sources for growth of *S. aurantia.* In the presence of very low concentrations of an attractant that serves as a carbon and energy source, growing cells of *S. aurantia* specifically enhance their chemotactic response toward the attractant and are able to sense concentrations of the attractant much lower than those sensed by cells growing in the presence of excess attractant (Terracciano

and Canale-Parola, 1984). Most likely, the ability to regulate its chemosensory system provides *S. aurantia* with competitive advantages in natural environments deficient in nutrients.

Fosnaugh and Greenberg (1988) carried out an analysis of the motility and chemotaxis behavior of *S. aurantia.* They observed that a population of *S. aurantia* cells spent, on the average, 66% of the time swimming smoothly (runs), 33% of the time flexing, and 1% of the time in reversals. After addition of an attractant (D-xylose, 10 mM final concentration) there was an increase in smooth swimming, a decrease in flexing, and a complete suppression of reversals. From 1.5 to 2 min after addition of the attractant, the population resumed its unmodified behavior. On the basis of their observations and of the above-mentioned motility model for *S. aurantia,* Fosnaugh and Greenberg (1988) postulated that a mechanism for communication between the two flagellar motors is present in this spirochete, and that a motor-switch-synchronizing device is also operating.

Fermentation Products and ATP-Yielding Pathways

Under anaerobic conditions, all species of *Spirochaeta* that have been cultured (Table 1), except *S. zuelzerae,* ferment carbohydrates with formation of acetate, ethanol, CO_2, and H_2 as major end products (Canale-Parola, 1984b; Harwood and Canale-Parola, 1983). *S. zuelzerae* primarily produces acetate, lactate, CO_2, H_2 and a relatively small amount of succinate from carbohydrates (Canale-Parola, 1977, 1984b; Veldkamp, 1960).

S. isovalerica (Table 1), in addition to fermenting carbohydrates, ferments L-leucine, L-isoleucine, and L-valine—forming isovaleric, 2-methylbutyric, and isobutyric acids, respectively, as end products (Harwood and Canale-Parola, 1983). However, *S. isovalerica* requires a fermentable carbohydrate for growth. When *S. isovalerica* is grown in medium containing both glucose and the three above-mentioned amino acids, only a relatively small fraction of the total amount of available amino acids is fermented (Harwood and Canale-Parola, 1981a, 1981b). Under these growth conditions, the ATP derived from amino acid catabolism is estimated to be 4 to 5% of the total ATP formed. Fermentation of the amino acids in the absence of glucose does not support measurable growth of *S. isovalerica,* but serves to generate ATP which is utilized as a source of maintenance energy by the spirochete when fermentable carbohydrates are not available (Harwood and Canale-Parola, 1981b, 1983). In addition to the branched-chain fatty acids, amino acid catabolism by *S. isovalerica* yields small quantities of isobutanol and isoamyl alcohol (Harwood and Canale-Parola, 1981a, 1983).

All *Spirochaeta* species whose metabolic pathways have been studied (species 1, 2, 4, 5, and 6 in Table 1) catabolize glucose to pyruvate via the Embden-Meyerhof pathway (Canale-Parola, 1984b; Harwood and Canale-Parola, 1983). Anaerobic metabolism of pyruvate yields acetyl CoA, CO_2, and H_2 via a clostridial-type clastic reaction (Canale-Parola, 1977; Greenberg and Canale-Parola, 1976). Acetate is formed from acetyl CoA in reactions catalyzed by phosphotransacetylase and acetate kinase. A double reduction involving aldehyde and alcohol dehydrogenases is responsible for ethanol production from acetyl CoA (Canale-Parola, 1977).

When growing aerobically, the two facultatively aerobic species (*S. aurantia* and *S. halophila*) oxidize glucose incompletely, with formation of CO_2 and acetate as major end products. Aerobically, both oxidative phosphorylation and substrate-level phosphorylation are utilized by the two species to generate ATP (Breznak and Canale-Parola, 1972b; Greenberg and Canale-Parola, 1976). The tricarboxylic acid cycle is either absent or plays a minor catabolic role in these two species.

Rubredoxin was detected in cell extracts of the obligate anaerobes *S. stenostrepta* and *S. litoralis,* and of the facultative anaerobe *S. aurantia* (Breznak and Canale-Parola, 1972a; Hespell and Canale-Parola, 1973; Johnson and Canale-Parola, 1973). Rubredoxin was isolated from extracts of both aerobically and anaerobically grown cells of *S. aurantia.* Ferredoxin was present in cell extracts of anaerobically grown *S. aurantia,* but was not found in aerobically grown cells of this bacterium (Johnson and Canale-Parola, 1973).

Isolation

Selective Procedures

Anaerobic and facultatively anaerobic spirochetes are readily isolated from natural environments by means of selective procedures, and usually grow abundantly in ordinary laboratory media. Anaerobic growth yields of the isolates range from 2×10^8 to approximately 10^{10} cells/ml, but commonly are 6×10^8 to 8×10^8 cells/ml (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970a,b). Cell popula-

tion doubling times in anaerobic cultures vary from 2.2 to 8.5 h, depending on the species and the growth conditions. Aerobically grown cultures yield from 0.7×10^9 to 1.2×10^9 spirochetes/ml, with doubling times of 2 to 4 h (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976).

A procedure in which the antibiotic rifampin (rifampicin) serves as selective agent is quite effective for the isolation of free-living spirochetes (genus *Spirochaeta*) from natural environments (Harwood et al., 1982; Patel et al., 1985; Stanton and Canale-Parola, 1979; Weber and Greenberg, 1981). This procedure, which is described below, is based on the observation that spirochetes in general are naturally resistant to rifampin (Leschine and Canale-Parola, 1986; Stanton and Canale-Parola, 1979). Thus, spirochetes such as *S. stenostrepta* and *S. aurantia* grow in the presence of as much as 100 to 200 μg of rifampin per ml of medium (Leschine and Canale-Parola, 1986), whereas the growth of many other bacteria is inhibited. The resistance of spirochetes to rifampin is probably due to the low affinity of their RNA polymerase for the antibiotic (Allan et al., 1986; Leschine and Canale-Parola, 1986).

Other enrichment procedures used in the isolation of *Spirochaeta* species are based either on one or both of the following selective factors: 1) the ability of spirochetes to pass through filters that retain most other bacteria; and 2) the migratory movement of spirochetes through agar media (Canale-Parola, 1973, 1984b). These selective procedures enrich for species of *Spirochaeta* measuring less than 0.5 μm in diameter (Table 1).

In the enrichment-by-filtration procedure, which is described in detail below, separation of *Spirochaeta* species from most of the microorganisms present in mud or water is achieved by techniques involving filtration through cellulose ester filter discs (e.g., Millipore filters) having an average pore diameter of 0.3 or 0.45 μm. Spirochetes pass through these filter discs because of their relatively small cell diameter (Table 1), and probably also because their motility apparatus enables them to swim freely in liquids as well as to move in contact with solid surfaces.

The enrichment-by-migration procedure uses the ability of spirochetes to move through agar gels or media containing as much as 1 to 2% (wt/vol) agar. This movement or migration occurs primarily within the agar gel, i.e., below the surface of the agar medium. In contrast, flagellated bacteria usually cannot carry out translational movement through gels or media containing agar at the above-mentioned concentrations, although several exceptions have been reported (Greenberg and Canale-Parola, 1977c). Apparently the cell coiling of spirochetes is important for their translational motion through agar gels, inasmuch as this type of movement is impaired in mutant spirochetes lacking the cell-coiling characteristic of the parental strain (Greenberg and Canale-Parola, 1977b).

Migration of spirochetes through agar media results from the unique motility mechanism of these bacteria (Canale-Parola 1977, 1978), as well as from chemotaxis toward the energy and carbon source (Breznak and Canale-Parola, 1975; Greenberg and Canale-Parola, 1977a). The role of chemotaxis in the migration of saccharolytic spirochetes through agar media has been studied (Breznak and Canale-Parola, 1975). When these spirochetes are inoculated in the center of glucose-containing agar medium plates, they grow using this sugar as their energy source. Utilization of the sugar by the spirochetes gives rise to a glucose concentration gradient that moves away from the center of the plate as more of this carbohydrate is metabolized by the spirochetes. Since the spirochetes exhibit chemotaxis toward glucose and are able to move through the agar gel, they migrate into the areas of higher glucose concentration within the gradient. Thus, the spirochetal population follows the outward movement of the gradient and migrates toward the periphery of the plate. This behavior results in the formation of a growth "veil" or "ring" of spirochetes for which glucose serves both as the energy source for growth and as the chemoattractant (Breznak and Canale-Parola, 1975; Canale-Parola, 1973). The veil or ring increases continuously in diameter during incubation and may reach the outer edge of the plate. The migration rate of the spirochetal population is greatest in agar media containing low substrate concentrations (e.g., 0.02% glucose). In these media the substrate becomes rapidly depleted in the region where spirochetes are growing, and the spirochetal population moves toward the outer zone of higher substrate concentrations at a relatively fast rate (Breznak and Canale-Parola, 1975).

In procedures for the isolation of *Spirochaeta* species from natural environments, the chemotactic behavior and the ability of these bacteria to move through agar gels have important selective functions. In a typical isolation procedure, a small, shallow cylindrical hole is made through the surface of an agar medium containing a low concentration of carbohydrate. Rifampin may be included in the medium as an additional selective agent for spirochetes. The medium may be in a petri dish or a small bottle.

A tiny drop of pond water, or of any other material in which spirochetes have been observed, is placed within the hole. The chemotactic, saccharolytic spirochetes in the inoculum multiply and form a growth veil that extends outwardly through the agar medium. Thus, the spirochetes in the veil move away from contaminants, which remain mainly in the vicinity of the inoculation site. Spirochetal cells from the outermost edge of the veil are used to obtain pure cultures by conventional methods, such as streaking on agar medium plates. Isolation procedures involving chemotaxis and movement through agar gels are described below.

Selective isolation techniques have not been developed for the large *Spirochaeta* species, such as *S. plicatilis.*

Enrichment by Migration

When spirochetes are vastly outnumbered by other bacteria in the inoculum, it is advisable to begin the isolation procedure with an enrichment-by-migration step (the principle has been discussed above). A suitable medium (EBM agar medium) for this enrichment has the following composition in g/100 ml distilled water: yeast extract (Difco), 0.1; Trypticase (BBL Microbiology Systems), 0.1; L-cysteine, HC1, 0.05; resazurin, 10^{-4}; agar (Difco), 1. For the enrichment and isolation of marine spirochetes, a mixture of sea water (70 ml) and distilled water (30 ml) is used instead of plain distilled water. The pH of the medium is adjusted to 7.2. After autoclaving, cellobiose is added as a sterile solution to a final concentration of 0.01 g/ 100 ml medium. Rifampin (filter-sterilized solution) may be used as a selective agent (0.5 mg per 100 ml of medium).

The medium is prereduced (Hungate, 1969) and is dispensed into narrow-necked 60 ml glass bottles. During this step and the steps that follow, the medium is maintained in an anaerobic atmosphere by delivering a stream of 0_2-free N_2 into the bottles. The bottles containing the medium are sealed with neoprene rubber stoppers and are placed in a press to hold the stoppers in place during autoclaving. The sterilized medium is allowed to cool to approximately 50°C, and cellobiose and, if desired, rifampin are added. The complete medium is solidified at a 45° angle, so that bottle slants are obtained. Then, a small (5 mm diam., 6 mm depth), cylindrical well is melted halfway down each slant by heating the tip of a thin metal rod and touching the agar with it. Alternatively, the well can be made by aspirating some of the agar medium with a sterile Pasteur pipette connected to a vacuum apparatus. All further manipulations are made either while maintaining an N_2 atmosphere within the bottles (Hungate, 1969) or with the bottles placed within an anaerobic chamber and the rubber stoppers replaced by cotton stoppers.

Before inoculation, any liquid that oozed from the agar medium is removed by suction from the well and the lower part of each slant. The bottle slants are inoculated by carefully placing a small volume of inoculum (e.g., mud) into the well, and are incubated at 30°C. In successful enrichments, the spirochetes form a characteristic, semitransparent growth veil that extends down into the agar medium and diffuses out toward the periphery of the slant, away from contaminating organisms growing in and near the well. The veil usually is visible after 4 to 7 days of incubation. Cells from the edges of the growth veil are used to obtain pure cultures of the spirochetes by means of a procedure involving serial dilutions in a rifampin-containing medium (see below).

Isolation in Rifampin-containing Media

Serial dilutions in melted, rifampin-containing agar medium can be used to isolate spirochetes from materials in which they are present in relatively large numbers (e.g., directly from mud or from the outer edges of growth veils in the bottle slants mentioned above). The spirochete-containing inoculum is serially diluted in tubes of melted (45°C), prereduced RIM medium. This medium is identical to the EBM agar medium described above except that the final concentration of cellobiose is 0.2% (wt/vol), rifampin (0.5 mg/100 ml of medium) is added, and the agar (Bacto, Difco) concentration is 0.8 g/ 100 ml of medium. The medium is dispensed and sealed in anaerobic culture tubes containing an N_2 atmosphere (Hungate, 1969).

Spirochete colonies in the RIM agar medium deeps are recognizable inasmuch as they are spherical and because, as a result of cell migration through the agar medium, they appear as "transparent bubbles," "veil-like growth with a dense center," or "cotton ball-like" (Paster and Canale-Parola, 1982; Stanton and Canale-Parola, 1979; Weber and Greenberg, 1981). To obtain pure cultures, the serial dilution step is repeated at least twice, using cells from spirochete colonies that developed in the RIM agar medium dilution deeps.

Procedures involving serial dilutions in rifampin-containing agar media have been used by Weber and Greenberg (1981) and by Patel et al. (1985) to isolate spirochetes from salt marsh sediments and hot springs, respectively.

Selective Enrichment by Filtration

A filtration technique has been used in the isolation of *Spirochaeta stenostrepta* (Canale-Parola et al., 1967; Canale-Parola et al. 1968), *S. litoralis* (Hespell and Canale-Parola, 1970b), and the facultatively anaerobic *S. halophila* (Greenberg and Canale-Parola, 1976). In all cases, the source of the spirochetes was black mud that had the characteristic smell of H_2S. *S. stenostrepta* was isolated from a mud sample collected from a fresh-water pond, *S. litoralis* from marine mud, and *S. halophila* from the mud of Solar Lake, a high-salinity pond located on the Sinai shore of the Gulf of Aqaba.

Medium for Isolating *Spirochaeta stenostrepta*

Distilled water	875 ml
Glucose	5.0 g
Peptone	2.0 g
Yeast extract	0.3 g
Vitamin B_{12}	10^{-5} g
Phosphate solution	15 ml
Salts solution	100 ml
Sulfide solution	10 ml

The phosphate solution is prepared by dissolving 30 g of KH_2PO_4 and 70 g of K_2HPO_4 in 1,000 ml of distilled water.

To prepare the salts solution, 0.2 g of ethylenediamine tetraacetic acid are added to 800 ml of distilled water and dissolved by heating. The pH of the resulting solution is adjusted to 7.0 with 2.5% KOH. Then the following additions are made: $MgSO_4 \cdot 7H_2O$, 2.0 g; $CaCl_2 \cdot 2H_2O$, 0.75 g; $FeSO_4 \cdot 7H_2O$, 0.1 g; trace elements solution (below), 5.0 ml. Finally, the volume of the salts solution is adjusted to 1,000 ml with distilled water.

The sulfide solution (2 g $Na_2S \cdot 9H_2O$/100 ml distilled water) is autoclaved separately and added shortly before inoculation to the sterile medium cooled to 30–35°C.

After sterilization by autoclaving, a precipitate is present in the medium, but it disappears as the medium cools. The final pH of the complete medium is 6.9–7.0.

Trace elements solution: A separate solution of each salt listed below, in the amount indicated, is prepared in distilled water. Heating may be required to dissolve some of the salts. The pH of the Na_2MoO_4 and $NaVO_3$ solutions is adjusted to a value below 7. The KI solution is added to the $AlCl_3$ solution and mixed by stirring. Then the other solutions are added, one at a time, to this mixture, with stirring, in the order in which they are listed below.

1. $AlCl_3 \cdot 6H_2O$	0.50 g
2. KI	0.25 g
3. KBr	0.25 g
4. LiCl	0.25 g
5. $MnCl_2 \cdot 4H_2O$	3.50 g
6. H_3BO_3	5.50 g
7. $ZnCl_2$	0.50 g
8. $CuCl_2 \cdot 2H_2O$	0.50 g
9. $NiCl_2 \cdot 6H_2O$	0.50 g
10. $CoCl_2 \cdot 6H_2O$	0.50 g
11. $SnCl_2 \cdot 2H_2O$	0.15 g
12. $BaCl_2 \cdot 2H_2O$	0.15 g
13. $Na_2MoO_4 \cdot 2H_2O$	0.25 g
14. $NaVO_3$	0.05 g

The volume of the final mixture is adjusted to 1,800 ml by adding distilled water, and the pH is adjusted to a value between 3 and 4 with HCl. A yellow precipitate, present at first, is replaced by a fine, white precipitate after a few days. The solution should be mixed thoroughly immediately before it is used and may be stored at room temperature. This trace element solution is a modification of a solution described by Pfennig (1965).

Isolation of *Spirochaeta stenostrepta* (Canale-Parola et al., 1967)

Black mud, from which a strong odor of H_2S could be detected, was suspended in aqueous 0.02% $Na_2S \cdot 9H_2O$. The slurry was filtered through Whatman No. 40 filter paper, and the filtrate was subjected to filtration through sterile cellulose ester filter discs (Millipore, pore diameter 0.45 μm). One ml aliquots of the resulting filtrate were added aseptically to 60-ml glass stoppered bottles, half filled with sterile isolation medium. The bottles were then completely filled with medium, stoppered without trapping air bubbles, and incubated at 30°C (each bottle was covered with a sterile 50-ml beaker). After 5 to 7 days of incubation, the microbial population in many of the bottles consisted predominantly of thin spirochetes. Pure cultures were obtained by use of dilution shake cultures (the medium was covered with sterile paraffin) or by plating serial dilutions and incubating the plates in the absence of O_2 (Bray dishes). The isolation medium solidified with 1.5% agar was used. Spirochetal colonies appeared after 5 to 6 days. After isolation the organisms were also grown in Florence flasks filled with a medium (GYPT) containing (g/100 ml distilled water): glucose, 0.5; yeast extract and peptone, 0.2 each; sodium thioglycolate, 0.05. The pH of this medium was adjusted to 7.0–7.3 before sterilization. The spirochetes were maintained in paraffin-layered stab cultures of medium GYPT containing 1.5% agar, at 5°C and transferred monthly.

Subsurface colonies of *S. stenostrepta* in agar media are white, spherical, and characteristically fluffy in appearance.

S. litoralis and *S. halophila* were isolated by a procedure similar to that used for *S. stenostrepta,* except that different isolation media were used and the incubation temperatures were 22–23°C for *S. litoralis* and 37°C for *S. halophila* (Hespell and Canale-Parola, 1970b; Greenberg and Canale-Parola, 1976). Furthermore, 1 volume of the mud used as the source of *S. litoralis* was suspended in 5 volumes of isolation medium before filtration through filter paper.

Isolation of *Spirochaeta litoralis* (Hespell and Canale-Parola, 1970b)

The isolation medium for the marine spirochete included (g/100 ml distilled water): tryptone (Difco), 0.3; yeast extract (Difco), 0.05; and NaCl, 2.0. To this mix-

ture 2 ml of M potassium phosphate buffer (pH 7.4) and 0.2 ml of a salt solution (see below) were added. The pH of the medium was adjusted to 7.3 with KOH before sterilization. Immediately before inoculation the medium was supplemented with 2 ml of a sterile glucose solution (25 g per 100 ml distilled water) and with 0.5 ml of a sterile $Na_2S \cdot 9H_2O$ solution (10 g per 100 ml distilled water). The final pH of the medium ranged from 7.4 to 7.5.

The salts solution contained (g/75 ml distilled water): tetrasodium ethylenediamine tetraacetate, 1; $CaCl_2 \cdot 2H_2O$, 3.75; $MgCl_2 \cdot 6H_2O$, 12.5; $FeSO_4 \cdot 7H_2O$, 0.5.

To 75 ml of this salt mixture, 25 ml of a trace elements solution (see Medium for Isolating *Spirochaeta stenostrepta*) was added.

After cloning, *S. litoralis* was grown routinely in the isolation medium. Subsurface colonies of *S. litoralis* in agar media are white to cream-colored, and resemble those of *S. stenostrepta* in appearance.

Maintenance procedures: Broth cultures of *S. litoralis* in test tubes remained viable for three days at 30°C. Agar stabs grown at 30°C and then kept either at 5 or 30°C were no longer viable after approximately one week, whether they were layered with paraffin or not. Viable cells were not recovered from lyophilized preparations.

S. litoralis was satisfactorily maintained by using "depression" cultures (Canale-Parola and Wolfe, 1960) prepared by using 1-liter Erlenmeyer flasks each containing 800 ml of isolation medium to which 2 g of agar per 100 ml were added. These cultures, when incubated for 2 days at room temperature and then at 15°C, remained viable for at least three months.

Isolation of *Spirochaeta halophila* (Greenberg and Canale-Parola, 1976)

The isolation medium contained 0.2 g of peptone (Difco) and 0.4 g of yeast extract (BBL) per 97 ml of an inorganic salt solution which had the following composition: $CaCl_2$, 0.04 M; NaCl, 0.85 M; and $MgSO_4$, 0.2 M. In preparing the salt solution, salts were added in the order in which they are listed, to avoid formation of a precipitate. The dihydrate form of $CaCl_2$ and the heptahydrate form of $MgSO_4$ were used. After adjusting the pH to 7.5 with KOH the medium was sterilized by autoclaving. The volume of the medium was brought to 100 ml by adding separately sterilized solutions of glucose and sodium sulfide to final concentrations of 0.5% and 0.05%, respectively.

S. halophila was grown routinely at 37°C in ISM broth (Greenberg and Canale-Parola, 1975), which differed from the isolation medium because maltose replaced glucose, the sodium sulfide was omitted, and the composition of the salt solution was changed (to $CaCl_2$, 0.01 M; NaCl 0.75 M; $MgSO_4$, 0.2 M). Furthermore, BBL yeast extract was replaced by Difco yeast extract which supported higher growth yields of our isolate. *S. halophila* was maintained by storing ISM agar (ISM broth containing 0.75 g agar per 100 ml) plate cultures at 5°C. The cultures were transferred monthly.

Colonies of *S. halophila* are pigmented when growing aerobically but lack pigmentation under anaerobic growth conditions. Colonies grown in air on ISM agar plates were red and appeared circular when viewed from above. A portion of each colony grew above the surface of the medium, and part of the colony extended into the agar. Areas of diffuse growth were present at the periphery of the colonies. Generally, colonies measured 2–6 mm in diameter after 5 days at 35°C but were smaller or larger depending on the number of colonies on the plate and the length of incubation. Cells streaked on ISM agar plates, and grown anaerobically in Bray dishes formed colonies which developed below the surface of the agar medium and were white, spherical, and diffuse.

Cultivation of most of the anaerobic species of *Spirochaeta* described here (Table 1; species 1, 2, 3) and does not require the use of stringent anaerobic procedures (e.g., the Hungate technique). Reducing agents, such as sodium thioglycolate or L-cysteine, are commonly added to the growth media, and other conventional techniques for the growth of anaerobes are used, as discussed elsewhere (Canale-Parola, 1973).

Enrichment by Filtration and Migration

Many strains of *Spirochaeta aurantia* have been isolated by means of a selective technique that combines filtration of the inoculum through a cellulose ester filter disk with migration of the spirochetes in agar media (Breznak and Canale-Parola, 1969; Canale-Parola, 1973; Breznak and Canale-Parola, 1975).

Isolation of *Spirochaeta aurantia* by Filtration and Migration

	Medium HE	Medium PEP
Distilled water	50 ml	100 ml
Peptone	0.1 g	0.5 g
Yeast extract	0.1 g	0.05 g
K_2HPO_4	–	0.01 g
Hay extract	50 ml	–
Agar	1 g	1 g

The pH of medium HE is adjusted to 6.5 before sterilization. To prepare the hay extract, 0.5 g of dried barn hay are boiled in 100 ml of distilled water for 10 min. The boiled mixture is filtered using Whatman No. 40 filter paper. The filtrate is the hay extract.

The inoculum, consisting either of pond or marsh water, or of a water-mud slurry, was prefiltered through Whatman No. 40 filter paper to remove large particles. Then, the enrichment cultures were prepared by depositing one or two drops of the filtrate near the center of each of a number of sterile cellulose ester filter disks (47-mm disk diameter, 0.3- or 0.45-μm pore diameter, Millipore) previously placed on the surface of isolation medium plates. One filter disk had been placed on each plate, approximately in the center. The cultures were incubated at 30°C for 12–24 h to allow spirochetes in the inoculum to move through the filter disk onto the surface of the medium. Then the filter disks were removed aseptically from the plates, and incubation of the plate cultures was continued. Spirochetes that had passed through the filter disks grew and migrated

through the agar medium, forming semitransparent growth veils that diffused toward the edge of the plates. Spirochetal growth veils usually developed in 5–10 days. Generally, 10–20% of the plate enrichments were successful (i.e., yielded growth veils) when spirochetes were present in the inoculum as determined by light microscopy. Analyses showed (Breznak and Canale-Parola, 1975) that the total carbohydrate content of a batch of isolation medium HE was 40 mg/100 ml and the glucose content 5 mg/100 ml. Medium PEP contained 6 mg total carbohydrate, and less than 1 mg glucose per 100 ml. As discussed previously, low carbohydrate concentrations, such as those in isolation media HE and PEP, are used to enhance the rate of spreading of the spirochetal growth veil through the agar medium.

It should be noted that bacteria other than spirochetes may form subsurface, spreading growth veils in the enrichment plates. Most common among these veil-forming bacteria are *Aquaspirillum (Spirillum) gracile* (Canale-Parola et al., 1966) and *Serpens flexibilis* (Hespell, 1977). *Serpens flexibilis* cells are flexible, Gram-negative rods that have bipolar as well as lateral flagella.

Pure cultures of *S. aurantia* are obtained by streaking cells from the outer edge of the growth veil onto isolation medium plates or growth medium plates.

A suitable growth medium for *S. aurantia* contains (g/99 ml distilled water): glucose, 0.2; yeast extract, 0.2; Trypticase (BBL), 0.5. The pH is adjusted to 7.5 before sterilization. When desired, agar (1 g) is added. After autoclaving and allowing the medium to cool, 1 ml of sterile 1 M potassium phosphate buffer (pH 7) is added.

Growth of some *S. aurantia* strains is either partially or totally inhibited in media containing agar (Difco) concentrations higher than 1% (wt/vol). Thus, viable cell counts usually are higher when performed using plates of media containing 0.75 or 1% agar than when the cells are grown in media including agar at higher concentrations. *S. aurantia* cells grown in media containing agar at concentrations higher than 1% frequently are aberrant in morphology. Many usually long, poorly coiled, filamentous cells are present, as well as an abundance of spherical bodies (Breznak and Canale-Parola, 1975).

Surface, aerobic colonies of *S. aurantia* in growth medium (agar, 1%) are light orange to orange, round or nearly round, with slightly irregular edges, and measure 1–4 mm in diameter after 4–7 days at 30°C. The colonies grow mostly within the agar medium, just under the surface, but many have a slightly raised central portion. One strain (Vinzent strain) was found to produce both this type of colony and a "pinpoint" type of colony, measuring approximately 0.5 mm in diameter and growing primarily on the surface of the agar medium (Breznak and Canale-Parola, 1975).

Surface, anaerobic colonies of *S. aurantia* (growth medium, 1% agar) are similar in morphology to the aerobic ones, but are not pigmented. Subsurface anaerobic colonies are white and spherical.

S. aurantia may be maintained on slants of growth medium at 5°C. These stock cultures are transferred monthly.

Maintenance

Maintenance procedures suitable for individual *Spirochaeta* species have been described above. It should be added that cells of all *Spirochaeta* species that have been cultured can be preserved in a viable condition for several years by maintaining them at the temperature of liquid nitrogen. Conventional methods are used to prepare liquid nitrogen stock cultures of spirochetes (Canale-Parola, 1973).

Identification

Free-living, anaerobic and facultatively anaerobic, helical bacteria which possess the ultrastructural features typical of spirochetes (e.g., periplasmic flagella and outer sheath) are classified in the genus *Spirochaeta.*

Differentiation among the obligately anaerobic species (Table 1, species 1–4) may be based in part on determinations of carbohydrate fermentation end products. *S. stenostrepta, S. litoralis,* and *S. isovalerica* form acetate, ethanol, CO_2, and H_2 as major products of glucose fermentation, whereas *S. zuelzerae* produces acetate, lactate, CO_2, H_2, and small amounts of succinate (Canale-Parola, 1984b). In addition, *S. isovalerica* forms small amounts of isovalerate, 2-methylbutyrate, and isobutyrate as fermentation end products when growing in media containing L-leucine, L-isoleucine, and L-valine, as well as a fermentable carbohydrate (see "Physiology," this chapter) (Harwood and Canale-Parola, 1983). *S. stenostrepta* and *S. zuelzerae* are freshwater forms, whereas *S. litoralis* and *S. isovalerica* were isolated from seawater environments and have salt requirements typical of marine bacteria (Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). Further characterization of the obligate anaerobes should take into account interspecific differences in GC content of the DNA and in cell size (Table 1).

Salt requirements constitute an important basis of distinction between the facultative anaerobes *S. aurantia* and *S. halophila* (Table 1, species 5 and 6). The latter species is halophilic and has an absolute requirement for relatively high concentrations of Na^+, Cl^-, Ca^{++}, and Mg^{++} (see above), whereas *S. aurantia* strains have been isolated only from freshwater environments and do not exhibit special salt requirements.

As mentioned previously, *S. halophila* and *S. aurantia* produce pigments when growing aerobically. In both species the pigments are carotenoids. The major pigment of *S. halophila* (strain RS1) is 4-keto-1′,2′-dihydro-1′-hydroxytorulene, whereas *S. aurantia* (strain J1) produces mainly 1′, 2′-dihydro-1′-hydroxytorulene (Greenberg and Canale-Parola, 1975). Nonpigmented mutants of *S. halophila* (Greenberg and Canale-Parola, 1976) and of *S. aurantia* (B. J.

Paster and E. Canale-Parola, unpublished data) have been isolated.

Cells of *S. aurantia* subspecies *stricta* are more tightly coiled than those of *S. aurantia* subspecies *aurantia* (Table 1, footnote[e]).

Criteria used for the identification of *S. plicatilis* (Table 1, species 7) are its large size (Table 1) and its characteristic morphology and motility (Blakemore and Canale-Parola, 1973).

CHAPTER 192

The Genus *Treponema*

JAMES N. MILLER, ROBERT M. SMIBERT, and STEVEN J. NORRIS

Introduction and Habitats

The genus *Treponema* is composed of both pathogenic and nonpathogenic species indigenous to humans and animals. They are helical, tightly coiled, motile spirochetes ranging from 5–20μm in length and 0.1–0.4μm in diameter and are best observed by dark-field microscopy. The organisms stain poorly with the usual aniline dyes; however, those that are capable of aniline-dye uptake are Gram-negative. Staining can best be accomplished by the use of silver impregnation or immunofluorescent methods. A general review of the spirochetes is given in Chapter 191.

The truly pathogenic members of the genus are specific for their natural hosts. The four morphologically identical human pathogens and the diseases they cause are: *Treponema pallidum* subsp. *pallidum* (syphilis), *T. pallidum* subsp. *pertenue* (yaws), *T. pallidum* subsp. *endemicum* (nonvenereal endemic syphilis), and *T. carateum* (pinta). The 100% DNA homology between *T. pallidum* subsp. *pallidum* and *pertenue* provides the basis for subspeciation of these two organisms (Miao and Fieldsteel, 1980). *T. pallidum* subsp. *endemicum* was created because it is considered a variant of *T. pallidum* (Smibert, 1984). *T. paraluiscuniculi* (venereal rabbit spirochetosis) and *T. hyodysenteriae* (swine dysentery) are the only treponemes that have been established unequivocally as animal pathogens (Bayon, 1913; Glock and Harris, 1972; Harris et al., 1972a; Hunter and Ross, 1972; Taylor and Alexander, 1971; Todd et al., 1970; Vallejo, 1969). The isolation of *T. hyodysenteriae* from wild rodents suggests a role for these animals as reservoir hosts in the epidemiology of the disease (Joens and Kinyon, 1982).

The only pathogenic treponeme that has been cultured in vitro in or on artificial media is *T. hyodysenteriae* (Harris et al., 1972a, 1972b). Limited multiplication of *T. pallidum* subsp. *pallidum* has been accomplished in a tissue culture monolayer system (Fieldsteel et al., 1981).

Selected differential characteristics of the pathogenic treponemes are shown in Table 1.

Well-defined, cultivable species of treponemes have been found in the oral cavity, intestinal tract, and/or genitalia of chimpanzees, pigs, and dogs, as well as in the rumen of cattle (Bryant, 1952; Cwyk and Canale-Parola, 1979; Hanson, 1970; Harris et al., 1972b; Holdeman et al., 1977; Kinyon and Harris, 1979; Leach et al., 1973; Paster and Canale-Parola, 1982; Paster and Canale-Parola, 1985; Pindak et al., 1965; Smibert and Claterbaugh, 1972; Socransky et al., 1969; Stanton and Canale-Parola, 1979, 1980; Wojciechowicz and Ziolecki, 1979; Ziolecki, 1979; Ziolecki and Wojciechowicz, 1980; Zymet, 1969). In addition, spirochetes resembling treponemes have been observed in the intestinal tract of horses, mice, rats, guinea pigs, opossums, insects, and termites, and in the tissues of brine shrimp (Breznak, 1973; Lee and Philips, 1978; McLeod et al., 1977; Osborn and Bain, 1961; Savage et al., 1971; Turek and Meyer, 1979; Tyson, 1974). Despite the fact that many of these anaerobic and putative microaerophilic host-associated treponemes have been cultured in vitro and subsequently characterized, microscopic studies of animal and human tissues, exudates, and normal flora suggest that these are other species that have not as yet been isolated. Whether these spirochetes, alone or in combination with other organisms, can be implicated as the cause of oral, genital, or gastrointestinal disease remain uncertain; as a result, they should be considered to be nonpathogens.

In humans, as in animals, treponemes are found as part of the normal oral, intestinal, and genital flora (Hanson and Cannefax, 1964; Harland and Lee, 1967; Lee et al., 1971; Parr, 1923; Rosebury, 1962; Ruane et al., 1989; Shera, 1962; Takeuchi et al., 1974). Again, their association with disease remains speculative, and they are considered as nonpathogens. In the oral cavity, they are more prominent in persons with periodontal disease and gingivitis than in people with a healthy gingiva (Addy et al., 1983;

Armitage et al., 1982; Listgarten and Hellden, 1978; Mikx et al., 1986; Moore et al., 1982, 1983, 1984, 1985, 1987; Offenbacker and Van Dyke, 1985; Simonson et al., 1988). Treponemes and treponeme-like organisms have been isolated from fecal and rectal samples obtained from patients with mild to severe intestinal illness, including homosexual males with and without AIDS (Coene et al., 1989; Jones et al., 1986; Sanna et al., 1982, 1984; Tompkins et al., 1981, 1986; Willen et al., 1985). On the basis of DNA DNA homology studies, some of the treponemes isolated from homosexual men with AIDS appear to be *T. hyodysenteriae* (Coene et al., 1989; Wergifosse and Coene, 1989). The distribution in nature of the known cultivable species and some key unnamed isolates is shown in Table 2.

Additional information on the evolution and biology of treponemes and their distribution in nature can be found in the following reviews (Breznak, 1973; Canale-Parola, 1977, 1978; Harwood, 1984; Holt, 1978; Johnson, 1977; Sell and Norris, 1983; Smibert, 1973, 1976a, 1985).

Morphology and Structure-Function Relationships

Selected General Characteristics

Treponemes, like all spirochetes, (see Chapter 191) are composed of an outer membrane (OM) that delimits the outer cellular surface of the organisms and an inner membrane (IM) that encloses the protoplasmic cylinder (Canale-Parola, 1977; Holt, 1978; Hovind-Hougen, 1976, 1983; Kinyon and Harris, 1979; Johnson et al., 1973; Walker et al., 1989). Unlike the flagella of members of other bacterial genera, spirochetal flagellar organelles lie entirely within the periplasmic space between the IM and OM and are commonly referred to as periplasmic flagella (PF) (Canale-Parole, 1978; Holt, 1978; Hovind-Hougen, 1976; Kinyon and Harris, 1979); older names for PF are endoflagella and axial filaments. The PF attach at either pole of the organism through basal hook structures and wrap around the helical protoplasmic cylinder (Canale-Parola, 1977; Holt, 1978; Hovind-Hougen, 1976). The number of PF and the wavelength of the helix differ among members of this diverse group of organisms. *T. pallidum* and several other treponemes have been shown to possess cytoplasmic fibrils, thin filaments which run the length of the organism just under the cytoplasmic membrane (Hovind-Hougen, 1983). Fig. 1 depicts the ultrastructure of the human pathogen type species, *T. pallidum* subsp. *pallidum.*

Outer Membrane Structure

The outer membrane (OM) of *T. hyodysenteriae* and other cultivable members of the genus *Treponema* appears similar to those of Gram-negative bacteria in structure and chemical makeup (Chatfield et al., 1988; Hovind-Hougen, 1976; E. M. Walker, unpublished observations; Walker et al., 1989; Wannemuehler et al., 1988). However, the lipid-bilayered OM of *T. pallidum* subsp. *pallidum* and *pertenue* differs significantly from these organisms in its strikingly low integral-membrane protein content (Radolf et al., 1989; Walker, unpublished observations; Walker et al., 1989) and its absence of lipopolysaccharide (LPS) (Penn et al., 1985b; Radolf and Norgard, 1988). It is conceivable that the

low particle density of the OM of *T. pallidum* subsp. *pallidum* and *pertenue* represents a significant strategy on the part of the organisms for evading the host immune response (Walker, unpublished observations; Walker et al., 1989). The inability to demonstrate LPS in the OM of these *T. pallidum* subspecies does not preclude the possibility that the morphology of the treponemal rare outer membrane protein (TROMP) molecule(s) is determined by lipid-protein interaction (Walker et al., 1989). Studies addressing the integral-membrane protein content and the presence or absence of LPS among the other human treponemal pathogens and the rabbit pathogen *T. paraluiscuniculi* have not been reported.

Subsurface Structures

Treponemal subsurface structures may be defined as those molecules that lie beneath the OM. The most prominent structures are the PF, which mediate the striking translational and axial motility common to all spirochetes (Bromley and Charon, 1979; Goldstein and Charon, 1988; Limberger and Charon, 1986a; Paster and Canale-Parola, 1980). Members of the genus *Treponema* contain two to nine PF inserted into each end of the cell (Smibert, 1984). Intact treponemal PF are composed of multiple polypeptide subunits (Bailey et al., 1987; Blanco et al., 1986, 1988; Cockayne et al., 1987; Hardy et al., 1975; Limberger and Charon, 1986a, 1986b; Norris et al., 1988; Penn et al., 1985a; Radolf et al., 1986; Sand-Petersen et al., 1981). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis has shown that *T. pallidum* subsp. *pallidum* PF is composed of at least four polypeptides with molecular weights of 37, 34.5, 33, and 31 kDa, while the PF of *T. phagedenis* biotypes reiter and kazan 5 are made up of four polypeptides with similar molecular weights (Blanco et al., 1986; Limberger and Charon, 1986a; Norris et al., 1988; Radolf et al., 1986; Sand-Petersen et al., 1981). On the basis of antigenic structure and *N*-terminal amino acid sequence studies, Norris et al. (1988) have divided the flagellar polypeptides of *T. pallidum* and *T. phagedenis* into two classes. The 37-kDa polypeptide of the single sheath or outer surface of these organisms (Blanco et al., 1986; Cockayne et al., 1987; Limberger and Charon, 1986a; Norris et al., 1988; Radolf et al., 1986) has been designated class A; the three proteins related to the core structure of the filament (Cockayne et al., 1987; Penn et al., 1985a), have been designated as class B. The class B proteins of *T. pallidum* subsp. *pallidum* share significant *N*-terminal amino acid sequence homology and antigenic cross-reactivity (Blanco et al., 1986, 1988; Norris et al., 1988) and are encoded by three highly homologous yet distinct structural genes (Champion et al., 1990; Pallesen and Hindersson, 1989). In contrast, the 37-kDa sheath protein of *T. pallidum* subsp. *pallidum* does not possess *N*-terminal amino acid sequence homology with the core proteins (Blanco et al., 1988; Isaacs et al., 1989;

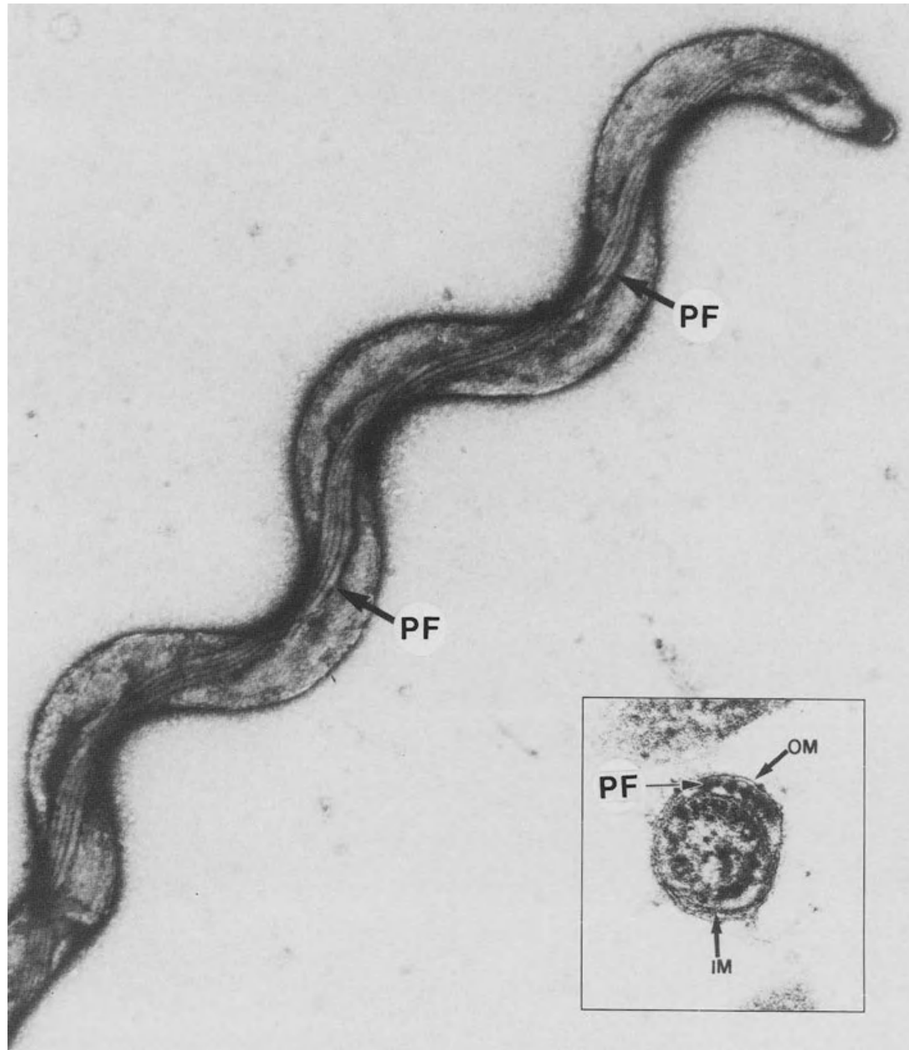

Fig. 1. Transmission electron micrograph of whole-mounted *Treponema pallidum* subspecies *pallidum* negatively stained with uranyl acetate. Photograph and permission to use by E. M. Walker.

Norris et al., 1988). The PF of *T. pallidum* subsp. *pallidum* and *T. phagedenis* share considerable antigenic and structural homology (Bharier and Allis, 1974; Blanco et al., 1986, 1988; Hardy et al., 1975; Norris et al., 1988; Penn et al., 1985a; Radolf et al., 1986; Sand-Peterson et al., 1981). Indeed, the PF of *T. pallidum* subsp. *pallidum* may represent a key virulence factor as well as a secondary target for the protective immune response that develops during the course of syphilitic infection. Evidence to support this hypothesis is provided by 1) the presence in normal human serum of complement-dependent treponemicial antibodies to shared PF epitopes (Blanco et al., 1986); 2) the existence of pathogen-unique epitopes on the surface of the *T. pallidum* subsp. *pallidum* Class A and Class B polypeptides (Blanco et al., 1988; Norris et al. 1988); 3) the altered course of disease in response to *T. pallidum* subsp. *pallidum* challenge following vaccination of rabbits with *T. pallidum* subsp. *pallidum* PF (Champion, C. I., Miller, J. N., Lovett, M. A., Blanco, D. R., unpublished observations); and 4) the potential role of motility as a factor that enables the organism to disseminate by invading the tight junctions between endothelial cells (Thomas et al., 1988).

Their unique properties may also be relevant to treponemal vaccine development and to the construction of immunologically specific and sensitive serodiagnostic assays. The cloning and

sequencing of the *T. pallidum* subsp. *pallidum* PF structural genes that encode for the class A and Class B proteins (Champion et al., 1990; Isaacs et al., 1989; Pallesen and Hindersson, 1989) and the ability to express the two genes that encode for the 34.5-and 31-kDa class B polypeptides in *Escherichia coli* (Champion et al., 1990), permit novel approaches to these problems.

The PF of *T. hyodysenteriae* are composed of 37-, 34-, and 32-kDa polypeptides (Miller et al., 1988). Furthermore, it has been shown that the epitopes residing on the 33-kDa PF polypeptide of *T. phagedenis* biotype kazan 5 are found on each of these three proteins. The protection of mice against *T. hyodysenteriae* challenge by vaccination with a crude, cloned PF antigen has been reported (Boyden et al., 1989).

In addition to the proteins that make up the PF subunit structures, several antigenic polypeptides from *T. pallidum* subsp. *pallidum* and *pertenue,* ranging in molecular weights from 12 to 190 kDa, have been identified by immunoprecipitation (Alderete and Baseman, 1981; Baseman and Hayes, 1980; Moskophidis and Muller, 1984), cross-over immunoelectrophoresis (Pedersen et al., 1981; Penn and Rhodes, 1982), and SDS-PAGE-Western blot analysis (Baker-Zander et al., 1985; Fehniger et al., 1984; Hanff et al., 1983, 1982; Lukehart et al., 1982; Thornburg and Baseman, 1983; van Eijk and van Embden, 1982). Characterization of *T. pallidum* subsp. *pallidum* by two-dimensional electrophoresis has revealed at least 78 antigenic polypeptides (Norris and Sell, 1984; Norris et al., 1987). Phase partitioning with the nonionic detergent Triton X-114 has identified seven to eight *T. pallidum* subsp. *pallidum* antigenic polypeptides in the hydrophobic phase with molecular weights of 14 to 57 kDa (Cunningham et al., 1988; Radolf et al., 1988). Recent evidence indicates that the majority of these antigens are, in fact, proteolipids, which may anchor to the cytoplasmic membrane or OM by means of their covalently attached fatty acids (Chamberlain et al., 1989a, 1989b; Swancutt et al., 1990). Three of these proteolipids, the pathogen-specific 47-, 34-, and 15-kDa antigens (Radolf and Norgard, 1988), stimulate immobilizing antibody (47 and 34 kDa), treponemicidal antibody (47 kDa), and lymphocyte proliferative responses (15 kDa) (Baker-Zander et al., 1988; Jones et al., 1984; Robertson et al., 1982). As with the PF of *T. pallidum* subsp. *pallidum,* the role of these proteolipids antigens—as virulence factors, target molecules for the protective immune response in syphilitic infection, as well as their vaccinogenic capabilities—is speculative. However, their pathogen specificity points to the possibility for development of serodiagnostic antigens of high immunological specificity and sensitivity. The cloning, expression, and sequencing of the genes that encode for the 47-, 34-, and 15-kDa antigens (Chamberlain et al., 1988; Hsu et al., 1989; Norgard et al, 1986; Purcell et al., 1989; Swancutt et al., 1986; Swancutt et al., 1989) and other proteins should provide the armamentaria for more detailed and accurate structure-function analysis as well as for the development of more accurate serodiagnostic assays.

Recently, Masuda and Kawata (1989) have isolated and characterized the cytoplasmic fibrils of *T. phagedenis* and other treponemes. The cytoplasmic fibrils are comprised of a single, major, 80-kDa polypeptide; a similar protein is present in *T. pallidum* subspecies and may represent the cytoplasmic fibril subunit in these organisms. The function of the cytoplasmic fibrils is unknown. They may, however, be involved in motility in some way, inasmuch as they run parallel to the endoflagella.

The major 60-kDa polypeptide of *T. pallidum* subsp. *pallidum* has been shown to be the subunit of a multimeric protein homologous to the *groEL* chaperonin protein of *E. coli* (Houston et al., 1990). These chaperonins are found in all prokaryotes and eukaryotes and apparently are involved in protein folding and assembly. Similar proteins exist in the other treponemes.

Isolation, Identification, and Characterization

Human Treponemal Pathogens

METHODS OF ISOLATION AND CULTIVATION. *T. pallidum* subsp. *pallidum* is the only human treponemal pathogen that has been grown in vitro (Fieldsteel et al., 1981). However, continuous in vitro culture has not been achieved, thus precluding the use of this procedure for isolation and identification. Isolation of *T. pallidum* subsp. *pallidum, pertenue,* and *endemicum,* along with the rabbit pathogen *T. paraluiscuniculi,* is conducted for the purpose of experimental investigation; infectious tissue or exudates are inoculated into adult male rabbits by either the intratesticular or intradermal routes. *T. carateum* is isolated by the intradermal inoculation of chimpanzees (see Table 1 for animal susceptibility to cutaneous lesions). Detailed procedures for the preparation of suspensions and methods of inoculation, and accepted criteria for determining infectivity, and identification by dark-field microscopy have been described by Turner and Hollander (1957) and Miller (1971). The development of lesions in these animals characteristic for each

species and subspecies of *Treponema* (Turner and Hollander, 1957; Miller, 1971) as well as the pattern of lesion development in human disease (see Table 1 and Miller, 1987) are useful criteria for identification. Several isolates of *T. pallidum* subspecies continue to be propagated by intratesticular passage in rabbits. The Nichols strain of *T. pallidum* subsp. *pallidum* has been passaged continuously by this route since 1912. It has been studied more extensively than any other isolate and is the strain used in the preparation of treponemal antigens for immunologically specific serodiagnostic assays.

The limited in vitro multiplication of *T. pallidum* subsp. *pallidum* in a tissue culture system was first described by Fieldsteel et al. (1981). Treponemes extracted from infected rabbit tests are inoculated into cultures of Sf1Ep rabbit epithelial cells (American Type Culture Collection, Rockville, MD, USA). The medium used is a modification of Eagle's minimal essential medium with Earl's salts containing 13.9 mM D-glucose, 0.63 mM dithiothreitol, 31.3 mM HEPES (*N*-2-hydroxyethylpiperizine-*N'*2-ethane sulfonic acid) buffer (pH 7.4), 0.126 mg/ml resazurin, and 20% fetal bovine serum or calf serum inactivated at 56°C for 30 minutes. Optimal conditions for growth consist of incubation at 33–35°C in an atmosphere containing 1.5 to 5% O_2, 5% CO_2, and the balance N_2 (Fieldsteel et al., 1982). *T. pallidum* subsp. *pallidum* attaches to the Sf1Ep cells and multiplies on the mammalian cell surface (Fieldsteel et al., 1981; Konishi et al., 1986). Under these conditions, the Nichols strain of *T. pallidum* subsp. *pallidum* can increase in numbers up to 100-fold and maintain viability and infectivity for rabbits for 12 to 15 days. Although several strains of *T. pallidum* subsp. *pallidum* multiply in this system, isolates of *T. pallidum* subsp. *pertenue* and *endemicum* fail to grow (Cox et al., 1984). Attempts to extend multiplication by subculture have thus far been unsuccessful (Norris and Edmondson, 1986a).

Little is known about the growth requirements of *T. pallidum*. Treponemal multiplication does not occur in the absence of mammalian cells; the reason for this dependence has not been determined. The requirement for serum is stringent, and the required components are associated with the protein fraction (Norris and Edmondson, 1986b). Inasmuch as only certain lots of fetal bovine or calf sera are effective in maintaining growth, serum lots must be prescreened for this activity. Human serum inactivated at 56°C for 30 min can also fulfill the serum requirement (Norris and Edmondson, 1986b). Optimal multiplication at 1.5 to 5% O_2 (Fieldsteel et al., 1982) and metabolic and survival studies (reviewed by Cox, 1983; Jenkin and Sandok, 1983; Sell and Norris, 1983) provide evidence that *T. pallidum* subsp. *pallidum* is microaerophilic. The fact that *T. pallidum* subsp. *pallidum* (Nichols) grows best at 33 to 35°C (Fieldsteel et al., 1982) mirrors its in vivo behavior, in which the infection in rabbits is enhanced in cooler regions of the body, such as the testes and exposed areas of the skin (Miller, 1971; Turner and Hollander, 1957).

IDENTIFICATION IN EXUDATES AND TISSUES. The restrictions of in vitro cultivation, together with the impracticability of animal inoculation, preclude the use of these isolation procedures in the diagnosis of treponemal disease. At present, the identification of treponemes in lesion exudates from patients with early acquired treponemal disease or early congenital syphilis is usually attempted by dark-field microscopy, in which identification is based upon the observation of characteristic morphology and motility. Unfortunately, this assay has several limitations that, in light of the similarities in clinical manifestations between treponemal and other diseases and the lack or inconclusive nature of serological reactivity, can and do cause errors in differential diagnosis. The following represent the most important limitations of dark-field microscopy:

1. *Limited criteria for T. pallidum identification:* the organisms observed must exhibit both the characteristic morphology and motility of *T. pallidum* in order to establish identification. The potential presence of host indigenous, nonpathogenic treponemes with similar characteristics in the oral cavity, genitalia, and gastrointestinal tract preclude an unequivocal identification from these sites. Indeed, dark-field examination of lesions within the oral cavity and the anal region is most often contraindicated due to the potential presence of nonpathogenic spirochetes.
2. *Necessity for rapid examination of prepared slides:* the relatively rapid loss of motility in the presence of atmospheric O_2 necessitates that slide specimens be examined within a short period of time after preparation (15–30 minutes) to ensure the observation of characteristic movement. This restriction not only reduces the chances for accurately identifying organisms in the exudate but also reduces the probability of observing the treponemes that might be present.
3. *Relatively poor sensitivity:* dark-field examination of lesion exudates from patients with early treponemal disease may be negative, despite the presence of *T. pallidum.* This lack of sensitivity is not surprising. Dark-field examination of *T. pallidum* suspensions con-

taining 10^6 organisms per ml was the equivalent of 1 organism per high dry field (HDF) when utilizing a calibrated microscope (J. Miller, unpublished observation). By extrapolation, 10^3 treponemes per ml of lesion exudate, a significant number of organisms, would present as 1 organism per 1,000 HDF and would not be detectable.

4. *Technical difficulty:* The identification of *T. pallidum* by dark-field microscopy requires the availability of a specially equipped microscope as well as considerable training, experience, and expertise. This combination is generally not available at most health care facilities. As a result, dark-field examination may not be done or may be performed incorrectly. Again, because antibody may be lacking or its presence is inconclusive, this creates a serious problem for both physicians and health care officers responsible for controlling spread of the disease.

These limitations associated with dark-field examination have been recognized since the procedure was first described, and, as might be expected, attempts have been made to develop a more efficient method. A proposed assay utilizes the principle of direct immunofluorescence and is referred to as the Direct Fluorescent Antibody Test for *T. pallidum* (DFA-TP) (Kellogg, 1970). With this procedure, lesion material or tissue sections are fixed to a microscopic slide and combined with Flourscein isothiocyanate labeled rabbit anti-*T. pallidum* immunoglobulin conjugate previously absorbed with cross-reacting nonpathogenic treponemes to render it specific for *T. pallidum.* Following a 30-min incubation period and washing, the slide is examined for the presence or absence of treponemes by fluorescence microscopy. This immunological procedure provides the opportunity to examine accurately not only smears from oral and anal lesions, but also tissue sections for the presence of treponemes. In addition, the organisms need not be motile, thus eliminating the need for immediate examination. The use of adequate controls with this assay is essential, because conjugates of poor specificity due to incomplete absorbance of cross-reacting antibodies may give misleading results.

More detailed information on the collection, submission, preparation, and examination of specimens for dark field examination and DFA-TP is contained in the excellent review by Larsen et al. (1984).

Silver impregnation methods have proved valuable in the identification of treponemes in tissues. However, their technical difficulty, poor reproducibility, and presence of artifacts resembling treponemes often make identification difficult. The modified Krajian procedure is one of many available silver impregnation methods and is described in detail by Miller (1971), along with techniques for tissue fixation, embedding, and sectioning.

A discussion of nontreponemal and treponemal tests in the serological diagnosis of treponemal infection is beyond the scope of this chapter. However, an excellent detailed presentation of the principles, procedures, interpretations of results, precautions, and potential problems associated with these serological assays is contained in the review by Larsen et al. (1984).

Treponemes Cultivable in or on Artificial Media

NUTRITIONAL AND ATMOSPHERIC REQUIREMENTS FOR GROWTH. A summary of some key nutritional and atmospheric requirements of the cultivable treponemes is given in Table 3.

Treponemes cultured in or on artificial media are strict anaerobes or microaerophiles. Growth and propagation require patience and an appreciation of their nutritional and metabolic requirements. These requirements differ for each species. Some treponemes need serum in the culture medium while others need short-chain fatty acids (Smibert, 1973, 1976a). Usually, any animal serum can be used in final concentrations ranging from 5 to 10%. All sera used in a medium must be inactivated at 60°C for 30 min. The serum provides the required long-chain fatty acids. There is very little free fatty acid in serum, and the long-chain acids are part of the neutral fats and phospholipids present. Most treponemes have a lipase that acts to liberate fatty acids. The only phospholipid in serum found to be used by five species was lysophosphatidylcholine (Trevathan et al., 1982). Two different pathways of phospholipid metabolism were proposed for two groups of the species studied. The long-chain fatty acids required by treponemes are not the same for all species studied. Van Horn and Smibert (1982) reported that *T. denticola* and *T. vincentii* require oleic acid (*cis*-18:1[9]). Elaidic acid (*trans*-18:1[9]) also supports growth but to a lesser extent than the *cis* form. No other short-or long-chain fatty acids support growth of these two species. The main component of serum containing the fatty acids that support growth is the alpha-globulin fraction. Serum albumin is also needed to "detoxify" or bind the fatty acids in order to keep their concentration at a nontoxic level (van Horn and Smibert, 1982). Johnson and Eggebraten (1971) reported that *T. phagedenis* requires a pair of fatty acids, one being saturated

Table 3. Some nutritional and atmospheric requirements of cultivable treponemes.

	Serum[a]	Volatile fatty acids[b]	Thiamine pyrophosphate[c]	Requires carbohydrate[d]	Aerated medium[e]
T. denticola	+	−	+	−	−
T. vincentii	+	−	+	−	−

T. sacchrophilum	−	+	−	+	−

[a]Inactivated animal serum.
[b]Rumen fluid or volatile fatty acid mixture.
[c]Addition of filter-sterilized TPP to medium.
[d]Needs a fermentable carbohydrate as an energy source for growth.
[e]Addition of some air (oxygen) to prereduced medium.
[f]*Brachyspira aalborgi* is included for convenience.

with at least 14 carbons and the other acid unsaturated with at least 15 carbons with one, two, or three double bonds. Elaidic acid (*trans*-18:1(9)) can be used in place of the pair of acids. Lemcke and Burrows (1980) reported that *T. hyodysenteriae* requires cholesterol for growth and that serum can be replaced by cholesterol and serum albumin. Sitosterol and cholestanol are the only sterols that can replace cholesterol. Stanton (1985) reported that the organism needs cholesterol and the phospholipid phosphatidylcholine, (Stanton, 1987; Stanton and Cornell, 1987). The sterol can be obtained from serum or red blood cell membranes. Cholesterol is converted to cholestanol, which is incorporated into the treponemal cell membrane. Thus, this organism can grow with only cholesterol and phosphatidylcholine added to the culture medium. The requirement for short-chain fatty acids can only be met by the addition of either rumen fluid or a mixture of short-chain fatty acids (Smibert, 1973, 1976a).

Socransky et al. (1969) reported the isolation of an oral treponeme that needs isobutyric acid. Smibert and Claterbaugh (1972) reported isolates from pig rectal and intestinal samples that require glucose, heme, isobutyric acid, and *n*-valeric acid. Hardy and Munro (1966) described an oral isolate that needs isobutyric acid, and Wegner and Foster (1966) reported on a rumen isolate that needs both isobutyric acid and *n*-valeric acid. Rumen fluid from cattle will supply acetic acid, propionic acid, isobutyric acid, *n*-butyric acid, isovaleric acid, and *n*-valeric acid as well as heme. A medium with rumen fluid can be autoclaved and is used in the medium at final concentration of 20 to 30%. The short-chain fatty acid requirement can also be met by an artificial rumen fluid (volatile fatty acid and heme mixture) described by Caldwell and Bryant (1966). (See also Holdeman et al., 1977, for the formula of medium 10, which contains the artificial rumen mix; and Smibert et al., 1984, for the mixture used in oral treponeme cultures.)

Artificial Rumen Fluid Mixture (Caldwell and Bryant, 1966)

Acetic acid	17 ml
Propionic acid	6 ml
n-Butyric acid	4 ml
n-Valeric acid	1 ml
Isovaleric acid	1 ml
Isobutyric acid	1 ml
DL-Methylbutyric acid	1 ml

Adjust the pH to 7.0.
Add 0.31 ml of the above to 100 ml of medium.

Heme Solution

Heme solution is prepared by combining 50 mg of heme or hemin, 1 ml of 1 N NaOH, and 100 ml distilled water. Add 1 ml to 100 ml of medium.

While rumen fluid, the above artificial rumen fluid mixture, and the heme solution can be

autoclaved, serum must be filter sterilized using a 0.2-μm-pore-size membrane filter. Both serum and rumen fluid (or fatty acid mixture and heme,) can be used together in the same medium in order to have a universal medium that can support growth of both kinds of treponemes.

Unfortunately, there are also other nutritional considerations to be considered. The serum-requiring oral treponemes require thiamine pyrophosphate for growth (Austin and Smibert, 1982), while the short-chain fatty acid-requiring oral, intestinal, and rumen treponemes need a fermentable energy source in the medium. Glucose will serve as an energy source for many strains while other carbohydrates *may* be the best energy source for others. Some organisms have a need for a unique energy source; for example, *T. pectinovorum,* an oral species, requires pectin (or glucuronic or galacturonic acid) for growth (Smibert and Burmeister, 1983); no growth occurs with other carbohydrates. Even some serum-requiring treponemes may need a fermentable energy source for growth; *T. phagedenis* needs glucose for growth in a serum-containing medium (George and Smibert, 1982a, 1982b).

Atmospheric conditions are also important factors to be considered for the growth of treponemes. Most organisms require a highly reduced medium for optimum growth, while others need either a less reduced medium or a small concentration of air in a reduced medium. As a rule of thumb, the short-chain fatty acid-requiring organisms need a highly reduced medium, while most of the serum-requiring treponemes have a lesser need for a well-reduced medium. *T. hyodysenteriae* and *T. innocens* will not grow in a highly reduced medium. For growth in roll tubes, 1 ml of air is injected into each tube. Although, *T. hyodysenteriae* will grow in a system containing 1 to 5% O_2, maximum cell yields occur when the culture is stirred in a 1% atmosphere. No growth occurs in a medium with less than 1% O_2 or with more than 5% O_2 (Stanton and Lebo, 1988). When growing these organisms on blood agar medium, it is best to use ordinary aerobic plates (not prereduced) and to incubate them in anaerobic jars using conventional anaerobic methods. The treponemes isolated from the intestinal tract of homosexual males with diarrhea (Jones et al., 1986) also require 1% O_2 for growth. Two procedures for growing most treponemes in order to attain high yields are the roll-tube and the anaerobic chamber methods (Rosebury and Reynolds, 1964); the roll tube method is the most convenient.

METHODS OF ISOLATION AND MICROSCOPIC OBSERVATION. Isolation of treponemes can be accomplished with an anaerobic chamber, anaerobic jars, or roll tubes. When either a chamber or anaerobic jar system is used for isolation, solid media in agar plates are used. When a roll-tube system is used, the isolation medium is usually liquid or semisolid. Anaerobic jars should be used properly to ensure good anaerobic conditions when isolating treponemes with strict anaerobic requirements. The cold catalyst should be changed after one or two uses and replaced with fresh catalyst. A used catalyst can be reactivated by placing the pellets in an oven at 110–130°C for several hours. The gas mixture used in anaerobic jars can be either a hydrogen-generating system, such as the GasPak (BBL) envelope, or a tank gas mixture containing H_2 and CO_2, such as 95% H_2–5% CO_2. Samples for isolation of treponemes can be used directly or diluted in anaerobic broth. They can be either fecal, rumen, genital, intestinal, intestinal mucosal scrapings, or oral plaque. All samples to be cultured for treponemes should be examined by dark-field microscopy. The number and size of the treponemes should be noted, and the data matched with the results of isolation. Subsequent observations for growth and multiplication should be conducted by dark-field microscopy.

GENERAL METHODS. The following general methods have been used to isolate treponemes from samples that contain other faster growing bacteria:

SELECTIVE MEDIA. These are media that contain antibiotics to suppress other bacteria (Leschine and Canale-Parola, 1980; Smibert et al., 1984; Songer et al., 1976; Stanton and Canale-Parola, 1979). Samples are either streaked onto agar plates or inoculated into a broth medium containing antibiotics. This method will suppress most of the oral, intestinal, or rumen flora and allow growth of the slower growing treponemes in the selective medium (Fiehn and Frandsen, 1984; Lee and Philips, 1978; Leschine and Canale-Parola, 1980; Smibert et al., 1984; Songer et al., 1976).

Selective Method of Smibert for Isolation of Oral, Genital, and Intestinal Treponemes (Smibert and Burmeister, 1983; Smibert et al., 1984)

The samples are placed in a tube with a prereduced buffer containing small glass beads, and the cells dispersed on a Vortex mixer for 5–10 seconds. Serial 10-fold dilutions are made and each dilution inoculated into tubes of prereduced Oral Treponeme Isolation (OTI) broth (see below) containing rifampin (2 μg/ml)

and polymyxin (800 U/ml). The cultures are incubated at 37°C for 1 to 2 weeks and the presence of treponemes determined weekly by dark-field microscopy.

OTI Medium of Smibert

Polypeptone (BBL)	5.0
Heart infusion broth (BBL)	5.0 g
Yeast extract	5.0 g
Pectin	0.8 g
Glucose	0.8 g
Soluble starch (Difco)	0.8 g
Sucrose	0.8 g
Maltose	0.8 g
Xylose	0.8 g
Ribose	0.8 g
Fructose	0.8 g
Sodium pyruvate	0.8 g
K_2HPO_4	2.0 g
NaCl	5.0 g
$MgSO_4$	0.1 g
L-Cysteine-HCl	0.68 g
Clarified rumen fluid	500 ml
Distilled water	500 ml

Adjust the pH to 7.0–7.2.

OTI agar medium contains 0.8% purified agar (Oxoid), while OTI broth medium contains 0.16% agar. OTI base medium is boiled, and the broth base is put into tubes containing an atmosphere of nitrogen. The tubes are rubber stoppered and autoclaved in a rack, which is then placed into a press in order to keep the stoppers in place. OTI agar base medium is autoclaved in a flask, cooled to 45°C under a stream of N_2. (See Holdeman et al., 1977, for details of preparing prereduced media.) The agar medium is poured into petri dishes, and then placed in anaerobe jars when the agar solidifies. The jars are evacuated and filled with a gas mixture of N_2, H_2, and CO_2; GasPak (BBL) envelopes may be used. The plates are held prereduced in the jars until used. Heat-inactivated serum and thiamine pyrophosphate are added to OTI medium to a final concentration of 5–10% and 0.75–1.5 mg/100ml respectively (100 ml of serum and 1 ml of an aqueous solution of thiamine pyrophosphate, 500 mg/ml). Occasionally, organisms require a filter-sterilized yeast autolysate, which is added to the medium at a final concentration of 5%. The yeast autolysate is prepared by adding 56 g of dry Bakers yeast to 200 ml of distilled water and incubating at 56°C for 4 days. The yeast cells are centrifuged and removed and the clear supernatant fluid is filter sterilized.

Selective Method of Stanton and Canale-Parola for Isolation of Rumen Treponemes (Paster and Canale-Parola, 1985; Stanton and Canale-Parola, 1979)

Rumen samples are serially diluted into agar medium tubes containing 1 μg/ml of rifampin. The gas phase of the prereduced medium is CO_2. After incubation at 39°C, typical treponemal colonies are picked with a Pasteur pipette and subcultured in broth medium. Colonies in agar tubes are described as round "cotton balls," a "veil-like" growth with denser center, and like a "transparent bubble."

Selective Rumen Fluid Cellobiose (RFC) Agar

Clarified rumen fluid	30 ml
Salt solution A	20 ml
Salt solution B	20 ml
Resazurin (0.1% solution)	0.1 ml
Distilled water	19 ml
L-Cysteine-HCl	0.1g
Noble agar (Difco)	0.7 g

Adjust the pH to 6.7–7.0.

Salt solution A contains $CaCl_2$, 0.45 g; $MgSO_4$, 0.45 g; and 1 liter distilled water. Salt solution B contains KH_2PO_4, 2.25 g; K_2HPO_4, 2.25g; NaCl, 4.5 g; $(NH_4)_2So_4$, 4.5 g; and 1 liter distilled water. The base RFC medium is boiled to reduce resazurin and dispensed into culture tubes using a gas phase of CO_2 after which the tubes are rubber stoppered and autoclaved. $NaHCO_2$ (5%) and cellobiose (10%) stock solutions are filter sterilized and pipetted into each tube. Rifampin (10 μg/ml) is added to the $NaHCO_2$ stock solution. One ml of the $NaHCO_2$ solution and 0.1 ml of the cellobiose solution is added to 8.9 ml of base medium. Final concentration of rifampin is 1 μg/ml. RFC broth is made without agar.

GM-1 and NOS Selective Method for Isolation of Oral Treponemes (Blackmore and Canale-Parola, 1976; Leschine and Canale-Parola, 1980; Weber and Canale-Parola, 1984).

Gingival samples are taken with sterile toothpicks, and the toothpicks placed into tubes containing either prereduced GM-1 or NOS medium in a N_2 atmosphere. The tubes are shaken and serially diluted into tubes of melted GM-1 or NOS agar containing 2 μg/ml of rifampin. After incubation at 37°C, colonies appearing like "cotton balls" and "transparent bubbles" are removed with a Pasteur pipette and subcultured.

GM-1 Medium

Trypticase (BBL)	0.5 g
Yeast extract	0.25g
NaCl	0.25 g
Sodium thioglycolate	0.05 g
L-Cysteine-HCl	0.1 g
Distilled water	100 ml

The medium is adjusted to a pH of 7.4, autoclaved, and then cooled rapidly to 35°C. The sample is inoculated into the medium after adding the following supplements (per 100 ml of medium): 0.2% thiamine pyrophosphate, 0.3 ml; volatile fatty acid solution, 0.5 ml; 10% sodium bicarbonate, 0.5 ml; and heat-inactivated rabbit serum, 0.3 ml. The volatile fatty acid solution consists of 0.5 ml each of isobutyric, DL-2-methylbutyric, isovaleric, and valeric acids dissolved in 100 ml of 0.1 N KOH. Rifampin is added to the medium at a final concentration of 2 ug/ml.

NOS Medium

Heart infusion broth (Difco)	1.24 g
Trypticase (BBL)	1.0 g
Yeast extract	0.25 g
Sodium thioglycolate	0.05 g
L-Cysteine-HCL	0.1 g
L-Asparagine	0.025 g

Glucose	0.2 g
Distilled water	100 ml
Noble agar (Difco)	0.7 g

The base medium is supplemented with the following: 0.2% thiamine pyrophosphate, 0.3 ml; volatile fatty acid mixture prepared as in GM-1 medium, 0.2 ml; 10% sodium bicarbonate, 2.0 ml; and heat-inactivated rabbit serum, 2.0 ml. Each of the supplements are filter sterilized and added to the prereduced base medium. Other carbohydrates such as pectin can be used in place of glucose in the NOS medium to isolate treponemes with different carbohydrate requirements. Fiehn and Frandsen (1984) reported that rifampin 2 μg/ml; polymyxin, 800 U/ml; and nalidixic acid, 75 μg/ml in GM-1 blood agar give the best recovery of oral treponemes and suppress most other kinds of oral bacteria.

Selective Method for Isolation of *T. hyodysenteriae* from Pigs with Swine Dysentery (Songer et al., 1976)

The mucosa of the large intestine of pigs is washed to remove intestinal contents. Colonic mucosal scrapings of lesions from pigs with acute swine dysentery are streaked onto selective isolation agar medium that has not been prereduced. The inoculated plates are incubated in anaerobic jars containing 80% H_2 and 20% CO_2; a GasPak envelope (BBL) can also be used. The plates are examined after 2, 4, and 6 days of incubation for areas of beta hemolysis with little or no surface growth in the hemolytic zone. The hemolytic zone is scraped with a loop, streaked onto Trypticase soy agar plates supplemented with citrated bovine blood, and incubated in an anaerobic jar at 37°C for 3–5 days.

TSA-5400 Selective Method for *T. hyodysenteriae*

Trypticase soy agar (BBL)	100 ml
Citrated bovine blood	10%
Spectinomycin (Upjohn)	400 μg/ml

The agar plates are poured under aerobic conditions and can be stored like ordinary aerobic media. Other antimicrobial agents can be used in the medium for isolation of this organism. The medium can be supplemented with polymyxin B, 200 U/ml, or spectinomycin, 200 μg/ml; vancomycin, 25 μg/ml; and colistin sulfate, 25 μg/ml (Jenkinson and Wingar, 1981; Kitai et al., 1987).

Selective Method for Isolation of Large Treponemes from Human Feces (Hovind-Hougen et al., 1982; Jones et al., 1986; Sanna et al., 1982; Tomkins et al., 1986)

Stool specimens from homosexual males with diarrhea are examined by dark-field microscopy for the presence of treponemes. Positive samples are streaked onto selective medium.

Selective Method of Jones et al. (1986)

Trypticase soy agar (BBL)	100 ml
Citrated human blood or defibrinated horse blood	5%
Spectinomycin	400 μ/ml
Polymyxin B	5 μg/ml

Plates are incubated in anaerobic jars for 5–7 days at 37°C. A haze of growth on the surface of the agar is examined for treponemes and subcultured onto fresh blood-agar selective plates; slight beta hemolysis is sometimes seen. Tomkins et al. (1986) used a similar medium containing 400 μg/ml of spectinomycin, while Sanna et al. (1982) employed Trypticase soy-7% horse blood agar supplemented with 400 μg/ml of spectinomycin and 15 μg/ml of rifampin. Houvind-Hougen et al. (1982) used Trypticase soy-10% calf blood supplemented with 40 μg/ml of spectinomycin and 5 μg/ml of Polymyxin B for the isolation of *Brachyspira aalborgi.*

Selective Method of Lee and Philips (1978) for Isolation of Putative Treponemes from the Intestines of Mice and Rats

Blood agar base no. 2 (Oxoid)	100 ml
Lysed horse blood	7%
Polymyxin B	80 μg/ml

The cecum of mice and rats is removed and a piece of tissue washed in physiological saline. The mucosal surface is scraped and inoculated onto the selective medium. Plates are incubated for 2–3 days in anaerobic jars.

MEMBRANE-FILTER METHODS. Membrane-filter methods have been described by Hardy et al. (1964); Hunter and Ross (1972); Loeche and Socransky (1962); Smibert and Burmeister (1983); Smibert et al. (1984); Smibert and Claterbaugh (1972); Socransky et al. (1969); and Taylor and Alexander (1971). They utilize the ability of treponemes to move through the pores of a membrane filter that will hold back most other bacteria. These methods are limited, therefore, to the isolation of treponemes smaller than most other bacteria. Samples are inoculated onto membrane filters that are placed on top of agar media, which may also contain antimicrobial agents that make the media selective. Motile treponemes migrate through the pores of the filter and grow in the agar medium. The unavailability of Ionagar No. 2 from Oxoid has necessitated the substitution of Purified agar from Oxoid (R. Smibert, unpublished observations).

Membrane-Filter Method of Smibert for Isolation of Intestinal and Oral Treponemes (Smibert and Burmeister, 1983; Smibert and Claterbaugh, 1972; Smibert et al., 1984)

Oral, intestinal, or rumen samples diluted 10-fold are mixed with a Vortex mixer for 1 min. Several drops of each dilution are placed onto the surface of a 45-mm diameter (0.22-μ pore size) membrane filter which is on the surface of any of the agar medium mentioned in this Chapter. A sterile O-ring, 1 inch in diameter, is first placed on the filter, and a seal of sterile 2% agar is placed around the O-ring. The O-ring prevents other bacteria from swarming or being washed off the filter and growing on the agar medium. The plates are incubated in an

anaerobic jar in a gas mixture containing 95% H_2 and 5% CO_2 at 37°C for 1–2 weeks. GasPak envelopes (BBL) or anaerobic chambers can also be used. The membrane filter is removed and a white haze of growth is seen in the depth but not on the surface of the agar. A plug of growth near the leading edge of the haze is cut out with a loop or Pasteur pipette and examined by dark-field microscopy for treponemes. A larger plug of agar is removed and placed in a tube of prereduced broth medium. The medium used for isolation of treponemes by this method contains serum, rumen fluid, or volatile fatty acid-heme solution. The rumen fluid and/or volatile fatty acid solution can be omitted from the medium if culturing only for serum-requiring organisms. Short-chain fatty acid-requiring treponemes do not require serum in the medium.

Agar plates with filter and O-ring should be prereduced by incubation in anaerobic jars prior to use. Uninoculated and inoculated plates should be kept in separate anaerobic jars under a stream of CO_2. This procedure prevents the medium from becoming oxidized and limits the plates' exposure to air.

Antibiotics such as rifampin (2μ/ml) and polymyxin B (800 U/ml) can be included in the media; other antibiotics such as nalidixic acid (75μ/ml) can also be used (Fiehn and Frandsen, 1984).

Smibert and Claterbaugh (1972) Isolation Medium

Polypeptone (BBL)	0.5 g
Yeast extract	0.5 g
Glucose	1.4 g
Soluble starch	0.5 g
Ammonium sulfate	0.5 g
L-Cysteine-HCl	0.68 g
Resazurin	1.6 mg
Bovine rumen fluid	280 ml
Distilled water	220 ml
Salt solution	500 ml
Purified agar (Oxoid)	8 g

Adjust to pH 6.5 (yields a pH of 7.2–7.5 after autoclaving).

The salt solution contains K_2HPO_4, 1 g; KH_2PO_4, 1 g; $NaHCO_3$, 10 g; NaCl, 2 g; $CoCl_2$, 0.0034 g; $NaMoO_4$, 0.0034 g; $MnSO_4$, 0.0034 g; $CaCl_2$, 0.2 g; $MgSO_4$, 0.2 g; and 1 liter distilled water.

Membrane-Filter Method of Taylor and Alexander (1971) for Isolation of Pig Intestinal Treponemes

Colon samples are diluted in prereduced peptone-yeast extract broth and centrifuged at 700× for 10 min. The supernatant fluid is filtered through a 0.65μ Millipore filter, and a few drops of the filtrate spread onto the surface of prereduced 10% horse blood agar plates. The plates are incubated in an anaerobic jar for 48 hours. Areas of complete hemolysis with no apparent surface growth are examined for treponemes by dark-field microscopy and subcultured.

Membrane-Filter Method of Hunter and Ross (1972) for Isolation of Pig Intestinal Treponemes

Pieces of large intestinal mucosa and mucosal scrapings from pigs with swine dysentery are suspended in a small volume of nutrient broth and incubated for 4 hours at 37°C. A sterile 0.22-μm or 0.65-μm membrane filter is placed on the surface of isolation agar medium. A ring of sterile petrolatum is placed around the filter and 2 drops of the broth sample are placed on the center of the filter. Plates are incubated for 5 days at 37°C and examined for the typical haze of treponeme growth in the agar.

Hunter and Ross (1972) Isolation Medium

Brain heart infusion broth	50% vol/vol
Spirolate broth (BBL)	50% vol/vol
Purified agar (Oxoid)	0.8%
Inactivated rabbit serum	10%
Mucin (1%; filter-sterilized)	2 ml/100 ml

Adjust the pH to 7.8.

Membrane-Filter Method of Hardy et al. (1964) for Isolation of Oral Treponemes

Gingival scrapings are spread over 0.45-μm or 0.3-μm membrane filters on isolation agar medium and the plates incubated for 7 days at 37°C. A hazy growth under the filter is plugged and fresh plates streaked and incubated for 14 days at 37°C.

Hardy et al. (1964) Isolation Medium

Spirolate broth (BBL)	3 parts
Brain heart infusion broth (BBL)	1 part
Sodium thioglycolate	0.1%
Inactivated rabbit serum	10%
Purified agar (Oxoid)	0.8%

Adjust the pH to 7.0–7.2.

Membrane-Filter Method of Blake (1968) for Oral Treponemes

Oral samples are inoculated onto membrane filters that are placed on the surface of agar medium. Membrane filters are cemented to Lucite plastic rings in order to prevent other bacteria from being washed off the filter and contaminating the isolation medium agar. The plates are incubated for 5–7 days at 37°C and the agar under the filter examined for treponemal haze.

Blake (1968) Isolation Medium

Tryptone (Difco)	3%
Yeast extract	0.5%
NaCl	0.25%
L-Cysteine-HCl	0.075%
Glucose	0.5%
Purified agar (Oxoid)	0.8%
Inactivated horse serum	10%

Adjust the pH to 7.4.

Membrane-Filter Method of Socransky et al. (1969) for Oral Treponemes

Samples are inoculated onto the surface of 0.22-μm pore size Millipore filters placed on the surface of the agar and the plates incubated for 2–7 days at 37°C.

Isolation Medium of Socransky et al. (1969) for *T. macrodentium*

PPLO agar (BBL)	100 ml
Glucose	1 mg/ml
Nicotinamide	400 μg/ml

Spermine tetrahydrochloride	150 μg/ml
Sodium isobutyrate	20 μg/ml
Thiamine pyrophosphate	5 μg/ml

Adjust the pH to 7.0.

Isolation Medium of Socransky et al. (1969) for *T. denticola*

Spirolate broth (BBL)	45% vol/vol
Brain heart infusion broth	45% vol/vol
Sodium thioglycolate	0.025%
Asparagine	0.025%
Tryptone (Difco)	0.025%
Purified agar (Oxoid)	0.7%
Inactivated rabbit serum	10%

Adjust the pH to 7.0.

WELL-PLATE METHODS. Many early investigators used well-plate methods to isolate treponemes from oral, genital, and fecal samples. These methods are based upon the ability of treponemes to migrate through agar and thus move away from other bacteria and colonize. The methods can be used with any of the media already described. Furthermore, antimicrobial agents can be added to make the medium selective and to reduce bacterial contamination (Hampp, 1957; Hanson, 1970; Hanson and Cannefax, 1964; Rosebury, 1962; Rosebury and Foley, 1942; Rosebury et al., 1951).

Well-Plate Method of Hanson for Oral, Fecal, and Genital Treponemes (Hanson, 1970; Hanson and Cannefax, 1964)

This method may be used to isolate treponemes or other spirochetes from the oral cavity, anus, and genitalia of the chimpanzee, monkey, dog, cat, rabbit, rat, mouse, hamster, guinea pig, gerbil, fox, raccoon, skunk, and opossum. Samples are collected with sterile swabs and held until used at 1–5°C in 3 ml of broth containing 20 U of polymyxin B. The swab is then pressed against the side of the tube to remove excess broth and debris. Isolation agar medium in 14 × 100-mm petri dishes containing a well 10 mm in diameter and 12–14 mm deep is inoculated with 0.2 ml of the holding broth. The plates are incubated at 37°C in an anaerobic jar. After 5–7 days incubation, a white haze of growth is seen 1–3 cm from the edge of the well. Agar plugs are cut from the hazy area with a Pasteur pipette and subcultured. The authors used a medium with 0.001% crystal violet for initial subculture and after several transfers omitted the dye from the medium.

Hansen (1970) Holding and Isolation Medium

Spirolate broth (BBL)	45%
Brain heart infusion broth	45%
Sodium thioglycolate	0.025%
Asparagine	0.025%
Tryptone (Difco)	0.025%
Inactivated rabbit serum	10%
Agar	0.7%–0.8%

The broth medium is the same but without the agar.

Well-Plate Method of Hampp (1957) for Oral Treponemes

Twenty ml of agar medium is placed in a sterile 30-ml beaker. A well 5 mm in diameter and 15 mm deep is cut into the agar with a sterile pipette. The beaker is covered with a sterile cup or aluminum foil. At frequent intervals, the water of syneresis is removed from the well. The sample is placed in the well being careful not to touch the lip of the well. The beakers are incubated in anaerobic jars and examined after 4–7 days at 37°C for a hazy growth in the agar several cm from the well.

Well-Plate Method of Rosebury for Oral Treponemes (Rosebury, 1962; Rosebury and Foley, 1942; Rosebury et al., 1951)

Ten ml of medium is placed into 50 × 14-mm dishes; the depth of the medium should be at least 7 mm. Prior to use, a well approximately 4 mm deep is cut in the center of the agar with a Pasteur pipette having a tip approximately 2 mm in diameter. The plate is inoculated by stabbing one side of the well obliquely about 2 mm deep. Inoculated plates are inverted and incubated in anaerobic jars at 37°C.

MISCELLANEOUS ISOLATION METHODS. Two other methods have been used for isolating treponemes. The first is used in the laboratory of one of the authors (R. Smibert) either for primary isolation or, mostly, to purify cultures of contaminating bacteria either not inhibited by antimicrobial agents in selective media or capable of moving through membrane filters because of their small size. A parabiotic chamber (Bellco Glass, Inc., Vineland, NJ, catalogue no. 1945) with rubber stoppers on each tube is fitted with a 25-mm-diameter membrane filter. The pore size of the filters may be 0.15, 0.22, 0.30, or 0.45 μm. The sterile chamber is assembled and gassed with a stream of nitrogen while both tubes of the chamber are partially filled with sterile, prereduced, antibiotic-containing broth or semisolid medium. One tube is inoculated with the sample or contaminated culture, and the chamber incubated for 2–3 days at 37°C. The treponemes migrate through the filter separating the two tubes of the chamber and grow in the broth in the other tube. The broth is examined by dark-field microscopy for treponemes. Any broth medium can be used with this method.

The second method has been used by Stanton and Canale-Parola (1979) and Paster and Canale-Parola (1985) for the isolation of rumen treponemes. Dilutions of a sample are inoculated into agar tubes composed of an agar medium containing rifampin, 1μg/ml. The fluffy, hazy colonies of treponemes are picked by stabbing through the agar into the colony with a Pasteur pipette.

Subculture Procedures

The isolation procedures described above separate treponemes from other kinds of bacteria, but not from different species of treponemes. Mixed treponemal cultures must be streaked for isolated colonies, identified to species, and, if not previously recognized, must be fully characterized prior to the conduct of further studies. Inasmuch as the greatest number of motile and viable treponemes are found at the outer edge of the hazy colony, small plugs of agar near the leading edge of the haze are transferred to broth or semisolid medium. The best methods for subculture of most treponemes are the roll-tube method using prereduced media and the anaerobic chamber method (Holdeman et al., 1977). In the roll-tube system, a gas mixture of 90% nitrogen and 10% carbon dioxide is used. Broth culture medium is usually the same as the isolation medium. Thus, any medium described in the "Isolation" section can be used for subculture. The agar is omitted or replaced with 0.16% agar if a semisolid medium is desired. When transferring cultures, it is best to use large inocula. For most treponemes, well-reduced culture media are necessary for good growth.

Treponema hyodysenteriae, T. innocens, and the large treponemes isolated from the feces of homosexual male patients with diarrhea (Jones et al., 1986) will not grow in highly reduced media such as prereduced roll-tube media. They can be subcultured by streaking ordinary aerobic (i.e., not prereduced) blood agar plates, such as Trypticase soy agar (BBL) with 5–7% blood. The plates are incubated in an anaerobic jar under anaerobic conditions for 4–5 days at 37°C. The plates have areas of complete or almost complete hemolysis. Faint growth of small clear colonies can be seen in the hemolytic area by examining the plates under oblique lighting. Cultures must be transferred once a week. Growth in broth requires the addition of 10% inactivated serum in place of blood. Kinyon and Harris (1974) described growth of *T. hyodysenteriae* in Trypticase soy broth (BBL) with fetal calf serum. Aerobic Trypticase soy broth is pipetted into culture tubes gassed with CO_2. The tubes are rubber stoppered, the rack placed in a press, and autoclaved. After cooling, 10% fetal calf serum is added to each tube. Stanton and Lebo (1988) found that *T. hyodysenteriae* does not grow under strict anaerobic or normal aerobic conditions but requires between 1 and 5% O_2 with 1% being necessary for optimal multiplication. The air space above prereduced media, such as Tryticase soy broth-serum or prereduced brain heart infusion broth with 10% inactivated bovine serum in culture tubes, is injected with 1 ml of air, after which the medium is inoculated with the culture, and the tubes are rubber stoppered and incubated. When using a VPI anaerobic inoculator, the gas flow is shut off and the tubes inoculated and restoppered. This allows sufficient air into the headspace of the culture tube to allow good growth of the organism. For mass culture in a flask of prereduced medium, air (30–40 ml/1-liter flask containing 500 ml of medium) is inoculated into the headspace of the flask with a 50- or 100-ml syringe fitted with a sterile membrance-filter holder so that approximately 1% O_2 is in the headspace. In order to obtain maximum cell yield, a stirring bar is placed into each tube or flask and the cultures stirred on a magnetic stirrer; a shaker may also be used. It is not known if the organisms are respiring or if they are able to grow only in a medium with a certain O/R potential. One of us (R. Smibert, unpublished observations) has found that *T. innocens* and the large treponemes from homosexual male patients with diarrhea also need air injected into prereduced media for growth and stirring for maximum cell yields.

Colonization

After isolation and subculture, single colonies of treponemes must be picked for further study. Obtaining single-colony, pure-culture isolates is most difficult, time consuming, and frustrating. Any medium mentioned in the isolation section of this chapter can be used to colonize treponemes. In selecting a medium, there are several considerations. First, a medium with serum will only isolate treponemes that require long-chain fatty acids. Secondly, many oral treponemes require thiamine pyrophosphate. Lastly, many oral, rumen, and intestinal treponemes require both short-chain fatty acids found in rumen fluid and a fermentable energy source. Treponemes grow into the agar medium and spread into the agar. Surface colonies are not usually seen. Thus, the agar should be softer than the usual 1.5% in order to allow the treponemes to migrate. Agar medium for colonization should contain 1.25–1.3% Bacto-agar or Noble agar. If Purified agar (Oxoid) is employed, 0.7–0.8% should be used in the medium. When prereduced agar plates are required, they should be prereduced in an anaerobic jar for several days prior to use. Two anaerobic jars are used, one containing the uninoculated prereduced media and the other to receive the plates as they are inoculated. Both anaerobic jars are gassed with a stream of O_2-free CO_2 while they are open. CO_2 is heavier than air and prevents atmos-

Table 4. Key characteristics of *Treponema* species.

(1978); 7, Kinyon and Harris (1979); 8, Smibert et al. (1984); 9, Stanton and Canale-Parola (1980); and 10, Paster and Canale-Parola (1985).

pheric O_2 from seeping into the open jars. The streaked plates are incubated upright for 1 to 2 weeks. Anaerobic chambers can also be used for colonizing treponemes. Another method used by one of the authors (R. Smibert) is prereduced agar medium in rubber stoppered 3-, 4-, or 6-ounce prescription bottles. The bottle-plates are gassed with a stream of O_2-free N_2 or a mixture of 95% N_2 and 5% CO_2, then streaked, restoppered, and incubated for 1 to 2 weeks. Pour bottle-plates can also be used. Colonies of treponemes are subsurface and become larger in diameter as the cultures grow. They may be several millimeters in diameter and appear as a white, translucent haze in the medium. Some have an irregular edge and appear like bits of cotton in the medium, while others have an entire edge that may or may not appear denser than the center of the colony. Colonies are picked with a loop or a plug is taken with a Pasteur pipette and subcultured. All cultures must be examined by dark-field microscopy to determine purity.

One of us (R. Smibert) employs the OTI medium (see "Selective Media") as a general purpose medium for isolation, maintenance of stock cultures, and as an agar medium with 0.7% Purified agar (Oxoid) for colonization of these organisms.

Christiansen (1964) colonized *T. phagedenis* and *T. refringens* in the following medium:

Medium of Christiansen

Fluid thioglycolate	100 ml
Purified agar (Oxoid)	0.7%
Inactivated rabbit serum	10%

Hardy et al. (1963) colonized *T. denticola, T. refringens, T. phagedenis,* and *T. vincentii,* using three different media. The plates are streaked and quickly put into anaerobic jars for 6–14 days.

Hardy Medium for *T. phagedenis* and Oral Treponemes

USP alternate thioglycolate broth	100 ml
Inactivated normal calf serum	10%
Purified agar (Oxoid)	0.7%

Hardy Medium for *T. refringens* and *T. phagedenis*

Trypticase (BBL)	3%
Yeast extract	0.5%
Glucose	0.5%
NaCl	0.25%
L-Cysteine -HCl	0.2%
Inactivated rabbit serum	10%
Purified agar (Oxoid)	0.7%
Adjust the pH to 7.2.	

Hardy Medium for *T. denticola* and *T. vincentii*

Thioglycolate broth	3 parts
Brain heart infusion broth	1 part
Inactivated rabbit serum	10%
Purified agar (Oxoid)	0.7%

Hanson and Cannefax (1965) colonized 48 strains representing *T. denticola, T. refringens, T. phagedenis* and *T. vincentii.* Colonies appeared in 7–8 days.

Medium of Hanson and Cannefax (1965)

Spirolate broth	45%
Brain heart infusion broth	45%
Sodium thioglycolate	0.05%
Inactivated rabbit serum	10%
Agar	2.5%

Identification and Characterization

During the last few years, several new treponemal species have been created and their identification accomplished using conventional bacteriologic methods. Many other species of treponemes are yet to be isolated, characterized, and named. The base medium for identifying and characterizing treponemes can be any medium described in this chapter. One of us (R. Smibert) uses a prereduced peptone-yeast extract-basal (PY) medium with a gas phase of either N_2 or 95% N_2 and 5% CO_2. This medium and its preparation are described in the *Anaerobe Laboratory Manual* (Holdeman et al., 1977). Carbohydrates and other compounds

used in the study of treponemes are added to the PY medium. It is supplemented with 10% inactivated serum, thiamine pyrophosphate, and either 30% rumen fluid or the artificial rumen fluid mixture.

Basal PY Medium for Treponemes (Holdeman et al., 1977):

Peptone	0.5 g
Trypticase	0.5 g
Yeast extract	1.0 g
Resazurin	0.16 mg
L-Cysteine-HCl	0.5 g
Salt solution (see below)	4.0 ml
Distilled water	100.0 ml

Salt solution:

$CaCl_2$, anhydrous	0.2 g
$MgSO_4$, anhydrous	0.2 g
K_2HPO_4	1.0 g
KH_2PO_4	1.0 g
$NaHCO_3$	10.0 g
NaCl	2.0 g
Distilled water	1 liter

All media with carbohydrates are checked for acid production after 3 to 5 days incubation. A pH of 6.0 or below is considered positive for acid formation. A carbohydrate-containing culture (preferably glucose) is kept for determining end products of fermentation by gas chromatography or high-pressure liquid chromatography. A culture must be examined for end products even if the pH is above 6.0 because some organisms metabolize amino acids and neutralize an acid pH.

Antibiotic susceptibility of these organisms can be determined by the addition of various concentrations of antibiotics to inoculated broth medium (Abramson and Smibert, 1971a, 1971b) or by the addition to the broth medium of one or more high-concentration susceptibility disks (Abramson and Smibert, 1972); after a suitable incubation period, the tubes are assayed for growth inhibition.

Key characteristics for the identification of cultivable treponemes are described in Tables 4–7. Additional information on identification of treponemes can be found in: Cwyk and Canale-Parola (1979); Holdeman et al. (1977); Kinyon and Harris (1979); Paster and Canale-Parola (1985); Smibert (1973, 1976a, 1976b, 1984, 1985); Smibert and Burmeister (1983); Smibert et al. (1984); and Stanton and Canale-Parola (1980).

Preservation of Cultures

Most cultivable treponemes are transferred to a suitable medium weekly for experimental use. However, *T. pallidum* subsp. *pallidum, pertenue,* and *endemicum* and *T. paraluiscuniculi* require propagation in the rabbit testis as a source of treponemes for the conduct of experiments. Cultures and rabbit testicular extracts of treponemes can be stored in the frozen state in liquid N_2 or in a mechanical freezer at $-70°$ to $-80°C$. For preservation over several years, sterile cryoprotective agents such as 10–15% glycerol or 3% dimethylsulfoxide (DMSO) are added to the cultures and extracts in sterile plastic cryotubes. Prior to freezing, the cryotubes containing cultivable treponemes are gassed with N_2 until the top is secured. In order to revive the cultures and extracts, they are removed from storage and thawed at room temperature. Cultivable treponemes are transferred to fresh medium and incubated at 37°C for 4–6 days. The human and rabbit pathogens are inoculated into rabbit testes for growth and multiplication.
