Contents

Contributors / xi
Editors / ix
Preface / xvii

SECTION I

ISOLATION AND SCREENING FOR SECONDARY METABOLITES AND ENZYMES / 1

VOLUME EDITOR: J. E. DAVIES
SECTION EDITOR: A. T. BULL

Isolation

1. New Approaches to Microbial Isolation / 3

SLAVA S. EPSTEIN, KIM LEWIS, DOMINICA NICHOLS, AND EKATERINA GAVRISH

2. Selective Isolation of Actinobacteria / 13

MICHAEL GOODFELLOW

Identity / Dereplication

3. Taxonomic Characterization of Prokaryotic Microorganisms / 28

GIOVANNA E. FELIS, SANDRA TORRIANI, JOHAN E. T. VAN HYLCKAMA Vlieg, AND AHARON OREN

Screening

4. Enzymes from Extreme Environments / 43

DON A. COWAN, BRONWYN M. KIRBY, TRACY L. MEIRING, MANUEL FERRER, MARIA-EUGENIA GUAZZARONI, OLGA V. GOLYSHINA, AND PETER N. GOLYSHIN

5. Cell-Based Screening Methods for Anti-Infective Compounds / 62

STEFANO DONADIO AND MARGHERITA SOSIO

6. Metabolomics for the Discovery of Novel Compounds / 73

JENS C. FRISVAD

7. Methods To Access Silent Biosynthetic Pathways / 78

ROBERT H. CICHEWICZ, JON C. HENRIKSON, XIAORU WANG, AND KATIE M. BRANSCUM

SECTION II

FERMENTATION AND CELL CULTURE / 97

VOLUME EDITOR: A. L. DEMAIN
SECTION EDITOR: P. MASUREKAR

8. Miniaturization of Fermentations / 99

WOUTER A. DUETZ, MATTHEW CHASE, AND GERALD BILLS

9. Solid-Phase Fermentation: Aerobic and Anaerobic / 117

RAMUNAS BIGELIS

10. Bacterial Cultivation for Production of Proteins and Other Biological Products / 132

JOSEPH SHILOACH AND URSULA RINAS

11. Heterologous Protein Expression in Yeasts and Filamentous Fungi / 145

NINGYAN ZHANG AND ZHIQIANG AN

12. Mammalian Cell Culture for Biopharmaceutical Production / 157

JINYOU ZHANG

13. Manufacture of Mammalian Cell Biopharmaceuticals / 179

JINYOU ZHANG

14. Plant Cell Culture / 196

NANCY L. PAIVA

15. Insect Cell Culture / 212

SPIROS N. AGATHOS

SECTION III

GENETICS, STRAIN IMPROVEMENT, AND RECOMBINANT PROTEINS / 223

VOLUME EDITOR: R. H. BALTZ

SECTION EDITOR: C. D. REEVES

16. Genetic Engineering of *Corynebacteria* / 225

MASATO IKEDA AND SEIKI TAKENO

17. Genetic Manipulation of *Clostridium* / 238

MARITE BRADSHAW AND ERIC A. JOHNSON

18. Genetic Manipulation of *Myxobacteria* / 262

WESLEY P. BLACK, BRYAN JULIEN, EDUARDO RODRIGUEZ, AND ZHAOMIN YANG

19. Strain Improvement of *Escherichia coli* To Enhance Recombinant Protein Production / 273

MICHAEL E. PYNE, KARAN S. SUKHIJA, AND C. PERRY CHOU

20. Genetic Engineering Tools for *Saccharomyces cerevisiae* / 287

VERENA SIEWERS, UFFE H. MORTENSEN, AND JENS NIELSEN

21. Protein Expression in Nonconventional Yeasts / 302

THOMAS W. JEFFRIES AND JAMES M. CREGG

22. Genetics, Genetic Manipulation, and Approaches to Strain Improvement of Filamentous Fungi / 318

VERA MEYER, ARTHUR E. J. RAM, AND PETER J. PUNT

23. Genetic Manipulations of Mammalian Cells for Protein Expression / 330

ANNE KANTARDJIEFF, WEI-SHOU HU, GARGI SETH, AND R. SCOTT McIVOR

SECTION IV

GENETIC ENGINEERING OF SECONDARY METABOLITE SYNTHESIS / 345

VOLUME EDITOR: R. H. BALTZ

SECTION EDITOR: L. KATZ

24. Glycosylation of Secondary Metabolites To Produce Novel Compounds / 347

ANDREAS BECHTHOLD AND KATHARINA PROBST

25. Metabolic Engineering of *Escherichia coli* for the Production of a Precursor to Artemisinin, an Antimalarial Drug / 364

CHRISTOPHER J. PETZOLD AND JAY D. KEASLING

26. Heterologous Production of Polyketides in *Streptomyces coelicolor* and *Escherichia coli* / 380

JAMES T. KEALEY

27. Genetic Engineering of Acidic Lipopeptide Antibiotics / 391

RICHARD H. BALTZ, KIEN T. NGUYEN, AND DYLAN C. ALEXANDER

28. Genetic Engineering To Regulate Production of Secondary Metabolites in *Streptomyces* / 411

SUSAN E. JENSEN

29. Genetic Engineering of Myxobacterial Natural Product Biosynthetic Genes / 426

BRYAN JULIEN AND EDUARDO RODRIGUEZ

SECTION V

INDUSTRIAL ENZYMES, BIOCATALYSIS, AND ENZYME EVOLUTION / 439

VOLUME EDITOR: J. E. DAVIES

SECTION EDITOR: H. ZHAO

30. Tools for Enzyme Discovery / 441

YASUHISA ASANO

31. Enzyme Engineering: Combining Computational Approaches with Directed Evolution / 453

LOUIS A. CLARK

32. Enzyme Engineering by Directed Evolution / 466

MANFRED T. REETZ

33. Industrial Applications of Enzymes as Catalysts / 480

NIKHIL U. NAIR, WENG LIN TANG,
DAWN T. ERIKSEN, AND HUIMIN ZHAO

34. Biomass-Converting Enzymes and Their Bioenergy Applications / 495

FENG XU

35. The Use of Enzymes for Non-Aqueous Organic Transformations / 509

ELTON P. HUDSON, MICHAEL J. LISZKA, AND
DOUGLAS S. CLARK

36. Enzyme Promiscuity and Evolution of New Protein Functions / 524

BERT VAN LOO AND FLORIAN HOLLFELDER

37. Enzyme Production in *Escherichia coli* / 539

DANIEL J. SAYUT, PAVAN K. R. KAMBAM,
WILLIAM G. HERRICK, AND LIANHONG SUN

38. Bioprocess Development / 549

LUTZ HILTERHAUS AND ANDREAS LIESE

SECTION VI**MICROBIAL FUELS (BIOFUELS) AND FINE CHEMICALS / 563**

VOLUME EDITOR: A. L. DEMAINE

SECTION EDITOR: L. R. LYND

39. Accessing Microbial Communities for Solutions to Biofuels Production / 565

CARL B. ABULENCIA, STEVEN M. WELLS,
KEVIN A. GRAY, MARTIN KELLER, AND
JOEL A. KREPS

40. Micro-Algal Culture as a Feedstock for Bioenergy, Chemicals, and Nutrition / 577

SUSAN T. L. HARRISON, MELINDA J. GRIFFITHS,
NICHOLAS LANGLEY, CARYN VENGADAJELUM,
AND ROBERT P. VAN HILLE

41. Metabolic Engineering Strategies for Production of Commodity and Fine Chemicals: *Escherichia coli* as a Platform Organism / 591

PATRICK C. CIRINO

42. Improving Microbial Robustness Using Systems Biology / 605

JONATHAN R. MIELENZ AND DAVID A. HOGSETT

43. Bioethanol Production from Lignocellulosics: Some Process Considerations and Procedures / 621

CHARLES A. ABBAS, WU LI BAO, KYLE E. BEERY,
PAMELA CORRINGTON, CONSUELO CRUZ, LUCAS
LOVELESS, MARTIN SPARKS, AND KELLI TREI

44. Surface Microbiology of Cellulolytic Bacteria / 634

ALEXANDRU DUMITRACHE, GIDEON M. WOLFAARDT,
AND LEE R. LYND

45. Physiological and Methodological Aspects of Cellulolytic Microbial Cultures / 644

NICOLAI S. PANIKOV AND LEE R. LYND

SECTION VII**BIOLOGICAL ENGINEERING AND SCALE-UP OF INDUSTRIAL PROCESSES / 657**

VOLUME EDITOR: A. L. DEMAINE

SECTION EDITOR: B. JUNKER

46. Raw Materials Selection and Medium Development for Industrial Fermentation Processes / 659

SAMUN K. DAHOD, RANDOLPH GREASHAM,
AND MAX KENNEDY

47. Scale-Up of Microbial Fermentation Process / 669

XIAOMING YANG

48. Cell Culture Bioreactors: Controls, Measurements, and Scale-Down Model / 676

WAN-SEOP KIM

49. Continuous Culture / 685

AN-PING ZENG AND JIBIN SUN

50. Advances in Sensor and Sampling Technologies in Fermentation and Mammalian Cell Culture / 700

ADEYMA Y. ARROYO

51. Bioreactor Automation / 719

DAVID HOPKINS, MELISSA ST. AMAND,
AND JACK PRIOR

52. Purification and Characterization of Proteins / 731

ULRICH STRYCH AND RICHARD C. WILLSON

Author Index / 743**Subject Index / 745**

Preface

Industrial microorganisms have contributed enormously to the pharmaceutical, food, beverage, and chemical industries in the past, and are rapidly advancing in the production of renewable energy; they have been central in the development of an ever-expanding field of biotechnology.

It is hard to imagine what life would be like without the fruits of industrial microbes. Some aspects of industrial microbiology have not changed much over the years. The production of fine wines has been refined and perfected, and there is probably not much yet to be learned by studying the molecular biology of the specific yeast cultivars. Chemical mutagens still work just as they did when the first volume of *Manual of Industrial Microbiology and Biotechnology* (MIMB) was published in 1986, and they still provide powerful empirical approaches for strain improvement. However, most of the methodologies that can be applied to industrial microbes and biotechnology have advanced dramatically, even since the second volume of MIMB was published in 1998. It is because of these advances that it is now important to provide the scientific community, including academic and industrial scientists and science administrators, an updated and totally new 3rd edition of MIMB.

Many of the chapters in the first two editions continue to be relevant resources for important methods, and these have not been replicated in this edition. Rather, the 3rd edition has focused on advancements that have brought us to the current state of the art and science in 2010. As such, it contains a totally new section VI devoted to “Microbial Fuels (Biofuels) and Fine Chemicals,” and a much heavier emphasis on mammalian cell culture methods. Genomic and other “omic” approaches are widely applied in the biological sciences, and these methodologies are incorporated

in many chapters of the current edition. Methods to enhance the capacity of microbes for use in bioremediation are becoming ever more critical to the maintenance of a clean environment.

Microbes continue to yield novel secondary metabolites and novel enzymes, and the current status of this field is covered in section I. Industrial strain improvement remains a very productive approach to improve the economics of microbial processes, and section III covers methods applicable to corynebacteria, *Clostridium* species, myxobacteria, *Escherichia coli*, *Saccharomyces cerevisiae*, other yeasts and filamentous fungi, and mammalian cells. Even wine yeasts can be improved! Combinatorial biosynthetic and focused genetic engineering methodologies directed at the production of novel secondary metabolites have advanced substantially in recent years, and section IV covers approaches to engineer glycosylation, polypeptide assembly, and nonribosomal peptide assembly in *Streptomyces*, myxobacteria, and *E. coli* among others. Microbial enzymes continue to be important industrial catalysts which are amenable to directed evolution and refinement, and these subjects are covered in section V. Finally, fermentation and cell culture methods and biological engineering and scale-up methodologies continue to be key elements in industrial microbiology and biotechnology, and are updated in sections II and VII.

We sincerely hope that the current edition will be of use to researchers, administrators, and students throughout the world.

ISOLATION AND SCREENING FOR SECONDARY METABOLITES

THE OPENING SECTION OF THE 2ND EDITION OF THE *MANUAL OF Industrial Microbiology and Biotechnology* (MIMB2) described the initial stages of establishing an industrial microbiological process: culture isolation and preservation, screening, small-scale fermentation, and process optimization. Much of what was recommended in those discussions remains valid and relevant for developing modern industrial processes; what the contributors to the present Third Edition (MIMB3) provide is new vision and options with which to approach such objectives. The current rapid pace of scientific discovery and technological innovation is such that completely novel options have become available to the industrial microbiologist in the quest for new products and processes since the last edition was prepared. Arguably the most dramatic event changing the face of search and discovery has been the accelerating move from a culture-based to a genomics-based strategy. This is set, not least, against the background of a failure of combinatorial chemistry to deliver exploitable drug leads. The challenge, therefore, rests on the evolutionary power of natural biological processes to fulfill the requirement for new drugs and other products of this increasingly biotechnology-dependent age.

The contributions in this section focus broadly on two themes, namely, some central issues pertaining globally to industrial microbiology (isolation and characterization of organisms), and the routes to biodiscovery. Although each chapter addresses specific questions and provides appropriate intellectual and practical support for their resolution, a number of recurring themes can be found in the advice offered by authors having different professional backgrounds and interests. Examples include the increasing dependence on integrated skills in order to develop successful screening protocols or uncover and exploit silent biosynthetic pathways (SBPs), and the strong desirability of using efficient dereplication procedures at the chemical, organism, and genomic levels so as to avoid unnecessary and cost-ineffective redundancy during the early stages of process or product development.

A recurrent source of embarrassment for microbiologists is the fact that only a minute proportion of the estimated numbers of, in particular, bacteria have been isolated and maintained in the laboratory. Slava Epstein and his colleagues in chapter 1 tackle this dilemma head-on and argue that because such a major part of microbial diversity remains “missing” it hampers progress in basic and applied microbiology: cultures enable the comprehensive study of whole organisms and the elucidation of complete genomes. These authors have developed techniques with which to target microorganisms in their natural habitats such that they are grown *in situ* and subsequently isolated and domesticated under laboratory conditions. All-importantly, the approach recognizes the impact of naturally occurring growth conditions

and microbial interactions in enabling cultivation in ways that attempts at *in vitro* cultivation rarely achieve. In the following chapter, Michael Goodfellow presents methods for selectively isolating members of one particular group of bacteria—the actinobacteria. Although these organisms are viewed traditionally as typical members of soil and freshwater ecosystems, their distribution in the biosphere now is known to be among the widest of all bacteria, and they remain a prime choice in the search for novel industrially important natural products and biocatalysts. Goodfellow shows that intelligent manipulation of standard media components and incubation conditions, often guided by ecological and taxonomic database information and allied to the probing of poorly studied and neglected habitats, continues to yield isolates of new species and genera having biotechnological value. In this context, the isolation of members of deep lineage actinobacteria remains as a timely challenge.

Two essential tasks need to be undertaken following the isolation of an organism(s) that possesses the required properties: culture curation (described in MIMB2) and taxonomic characterization. All too often, the latter exercise is ignored or treated superficially, but as Giovanna Felis and her coauthors opine in chapter 3, such characterization is essential for organism identification, rigorous scientific communication, securing intellectual property rights, and establishing taxonomic road maps to genes and products. The importance of a polyphasic taxonomic approach is reiterated in this chapter, and “how-to” details are provided with regard to prokaryotes (similar strategies being entirely apt to eukaryotic microorganisms). Felis et al. also consider the likely impact of whole-genome sequencing on taxonomy, which, given the speed and affordable cost of genome sequencing, might be seen as the “ultimate source” for taxonomic characterization. However, they rightly caution that phenotypic analysis remains valid in order to complete the organism’s characterization, to provide a more precise idea of how it interacts with its environment, and to give clues to its industrially exploitable biological activities.

Turning to the question of biodiscovery, the *sine qua non* is to design search methods that avoid, or at least minimize, rediscovery of known entities. To this end it is desirable to isolate new organisms, explore new ecological niches, design new screens, and apply new methods for detecting natural products. These elements of the discovery process are clearly revealed in chapter 4 by Don Cowan and colleagues, who focus on obtaining biocatalysts

from extreme environments, the so-called extremozymes. An important part of this contribution is devoted to the sampling of extreme environments and extracting DNA from such extreme samples. There follow detailed protocols for producing metagenomic libraries, host-vector systems for use with extremophiles and the expression of extremozymes, and activity screens. In chapter 5, Stefano Donadio and Margherita Sosio describe cell-based assays in screening for anti-infective compounds and argue the case for these screens *vis-à-vis* cell-free systems. They guide the reader along the critical path from target identification and validation to assay development and assay implementation, and introduce a range of options that include reporter, anti-sense, and reversion assays. Important recommendations are made with regard to screening algorithms and the evaluation of target “hits.”

The final chapters in section I examine two rapidly evolving components of the search and discovery toolbox, namely, detecting the metabolic products of expressed genes (metabolomics) and probing genomes for the potential to synthesize new products (genome mining of SBPs). Metabolomics is discussed by Jens Frisvad, who at the outset reminds us that the metabolome is a snapshot of an organism’s metabolic capacity under a specific set of growth conditions, and that its definition is crucially dependent on the analytical techniques used for metabolite detection. Thus, maximizing expression and detecting compounds again emphasize the necessity of an integrated skills platform. Frisvad demonstrates the steps in metabolome analysis with reference to microfungi, but the protocols are pertinent to all microorganisms. Finally, strategies for accessing microbial secondary metabolites from SBPs are presented in detail in chapter 7, by Robert Cichewicz and his coworkers. While acknowledging the value of culture condition manipulation as a means of triggering SBPs, these authors show that a new suite of genomic-driven, mechanism-based, and hybrid approaches is providing an unprecedented opportunity for identifying SBPs. Such approaches include genome scanning, heterologous and *in situ* expression of SBP genes, and chemical epigenetic and genoisotopic methods. Yet again, the integration of microbiological and chemical techniques is a key element in the successful application of these techniques. Especially helpful features of this chapter include an analysis of the major strengths and weaknesses of the various methodological approaches, and case studies that guide the reader on such points.

New Approaches to Microbial Isolation

EKATERINA GAVRISH

1

1.1. INTRODUCTION

It has been known for over a century that most microorganisms do not grow under standard laboratory conditions (2, 7, 20, 32, 34–36, 39). At first, this appeared to be a cell number phenomenon: cells in the sample grossly outnumbered the number of colonies they produced on artificial media. The introduction of the rRNA approach to the study of microbial diversity (25) revealed that it was also a species diversity phenomenon: the number of microbial species in nature proved much larger than the richness of established culture collections (10, 12, 14, 16, 18, 22, 29, 33). In 1985, a term was coined to describe these observations: the Great Plate Count Anomaly (30).

Metagenomics approaches promised to provide access to the uncultivated species while bypassing the problem of uncultivability (11, 17). Many of these promises have been fulfilled, resulting in remarkable findings (4). The application of these and high-throughput sequencing approaches also showed that the microbial diversity in nature is so staggering that even the largest metagenomic efforts still sample only a small fraction of the metagenomes of microbial communities (18). Metagenomics libraries are dominated by gene sequences with unknown functions, and this limits the knowledge gained from the community genome. In practical application, metagenomic approaches have not yet produced a robust pipeline of bioactive compounds from uncultivated species. Microbial culture thus remains a basic necessity for the study of microbes in nature, and a prerequisite for drug discovery from natural sources. However, over a hundred years after its discovery, the anomaly remains unresolved, and more than half of microbial divisions are still without a single cultivable representative (27, 28). The fact that the major part of microbial diversity remains “missing” hampers progress in both basic and applied microbiology, and is widely recognized as one of the most important challenges facing microbiology today (19, 37).

This state of affairs set the stage for a recent resurgence of cultivation efforts (3, 5, 6, 8, 9, 13, 15, 21, 24, 26, 31, 38; D. Nichols, N. Cahoon, E. M. Trakhtenberg, L. Pham, A. Mehta, A. Belanger, T. Kanigan, K. Lewis, and S. S. Epstein, submitted for publication). Informing these efforts was the principal lesson from the past: traditional manipulation of the standard media components likely brings only incremental success. Significant departures from conventional techniques were clearly in order, and indeed, the

new technologies substantially diverged from the cultivation tradition by adopting single-cell and high-throughput strategies (8, 27, 39; Nichols et al., submitted), better mimicking the natural milieu (3, 6, 13, 31) and increasing the length of incubation and lowering the concentration of nutrients (9). Our research group contributed to the effort by developing three cultivation methodologies (15, 21; Nichols et al., submitted). Their gist is to replace the *in vitro* cultivation by growing microorganisms *in situ*, and thus provide target microorganisms with their natural growth conditions, followed by domestication of the isolates for growth under laboratory conditions. This chapter describes the principle of these methods, details their application and the initial results of this application, and summarizes the lessons learned.

1.2. METHOD 1: DIFFUSION CHAMBER

1.2.1. Principle of the Method

Designing this method to cultivate environmental microorganisms, we considered that natural environments by definition provide the necessary growth conditions to the microorganisms inhabiting these environments. No matter how transient such conditions may be for any given species, they do occur, and the species grows. It follows that by placing a sample of environmental cells into a diffusion chamber, and incubating this chamber in the natural environment of these cells, we could ensure that at least some of them would be supplied by the required growth factors via diffusion. If so, such cells should grow inside the diffusion chamber just as their kin cells would outside the diffusion chamber. The key element of this strategy is incubation of the diffusion chamber *in situ*, which allows diffusion to occur while preventing cells from migrating in and out of the chamber. Reducing this idea to practice, we tested a number of different membranes and different ways to construct the chamber, and designed a simple device (21) described below.

1.2.2. Diffusion Chamber Design

We construct the diffusion chambers (Fig. 1A) using stainless steel washers (70 mm outside diameter, 33 mm interior diameter, 3 mm thickness; Bruce Watkins Supply, Inc., Wilmington, NC) and 0.03- μ m-pore-size membranes

FIGURE 1 Design and application of diffusion chamber (A) and microbial trap (B). Explanations in the text.

(Osmonics, Inc., Westborough, MA). After a membrane is glued to one side of the washer using Silicone Glue II (General Electric, Waterford, NY), the half-assembled chamber is kept in a laminar flow hood until bonding is complete. Meanwhile, we prepare the inoculum by mixing environmental cells with warm (and still liquid) agar (0.7 to 1.5% final concentration). Note that the agar does not have to be supplemented with nutrients, as they are supposed to diffuse into the chamber during *in situ* incubation. However, when targeting specific microorganisms, their selection may be enhanced by relevant supplements, for example, with cellulose when species capable of cellulose degradation are of interest.

The diffusion chamber accommodates approximately 3 ml of the cell/agar mix; in a typical experiment this inoculum contains between 10^4 and 10^5 cells. Our experience with soil and aquatic environments shows that such inocula usually produce a number of colonies that is optimal for observations and subculturing. Once the 3-ml inoculum is administered into the chamber by pipetting, it fills the space formed by the bottom membrane and the opening in the washer. We then seal the chamber by

gluing the second membrane on the upper surface of the washer and wait for the glue to bond in a laminar flow hood. It is critical to provide extra moisture to the chamber during this drying period and we accomplish this by placing the drying chambers on moist paper. This second membrane sandwiches the microbe sample/agar mixture within the chamber between two membranes, and prepares the chamber for incubation.

The chamber can be incubated in two different ways. The first is to simply return the chamber to the place of the cells' origin. This is convenient for environments that are both close to the home laboratory and experience little recreational use. Often this approach is impractical because one or both of these conditions are not met. In these cases, the chamber can be incubated in a simulated natural environment, such as a block of freshly collected aquatic sediment or soil kept in an aquarium at ambient temperature. In our experience, this mimics the natural environment well for 2 to 4 weeks after the sample collection. As the sample ages, it exhibits signs of a shift to a new community represented by few abundant species. This results in an impoverished collection of species

grown inside the diffusion chamber, dominated by strains of uncertain environmental relevance. We note that this observation is strictly qualitative, and we have not examined the phenomenon in detail.

The length of incubation largely depends on the nature of the target environment, and could be best determined empirically. Applying the method to boreal aquatic environments and soils, we typically incubate the chambers for 3 to 4 weeks if the ambient temperature is between 10 and 20°C, and for 2 to 3 weeks at higher temperatures. When the method is applied to samples from human microbiome or sewage treatment facilities, incubations under 1 week appear sufficient to obtain microbial growth adequate for observation and subculturing.

After incubation, the diffusion chambers are retrieved and opened by cutting off the upper membrane with a sterile razor blade run along the interior diameter of the washer. Direct examination of the grown material, e.g., under a dissecting microscope, is not an efficient way to quantify growth, because most of the colonies formed during incubation are of microscopic size (Fig. 2A). In addition, the translucent nature of the bottom membrane interferes with such observation. Instead, we subsample the agar material by taking randomly distributed, measured cores using Pasteur pipettes as coring devices. As a rule, cores 1 to 30 μl in volume, depending on the density of growth, are sufficient for further examination and colony counting. Placed between a glass slide and coverslip, the flattened cores are examined

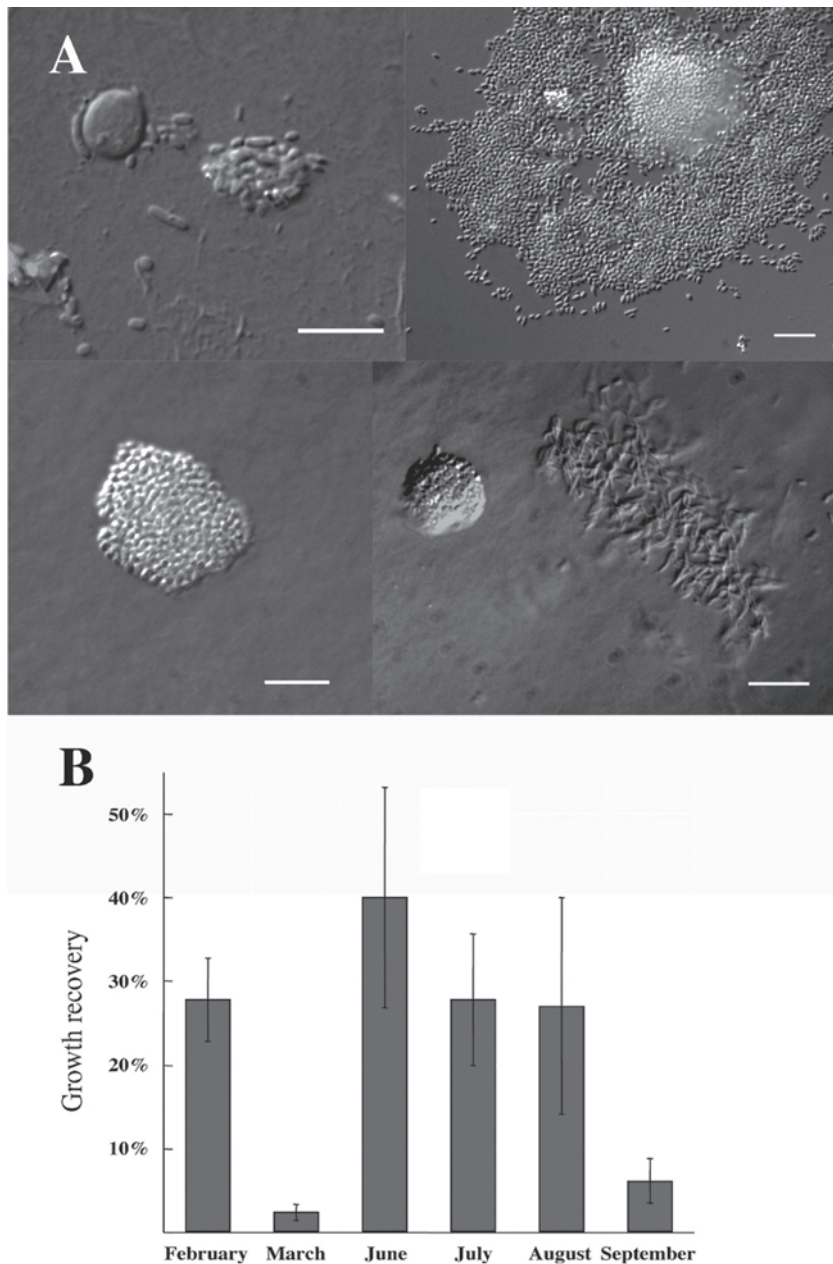

FIGURE 2 (A) Microcolonies of marine microorganisms grown inside a diffusion chamber incubated in simulated natural environment. Bars, 5 μm . (B) Growth recovery of environmental cells in diffusion chambers plotted as percentage of inoculated cells forming colonies.

in their entirety at 400 to 1,000× magnification under a compound microscope equipped for differential interference contrast (DIC), the latter being crucial for colony visualization. In a typical application, we record between 1 to 5 and several hundred microcolonies per replicate. The counts are then used to estimate the total number of colonies grown in the chamber, and these estimates are compared with the total number of cells inoculated to calculate percentage of recovery.

Subsampling grown colonies for subculturing represents one of the more time- and effort-consuming aspects of the overall protocol. If the colonies are rare in the diffusion chamber agar, they may be difficult to locate. However, increasing their number by inoculating more cells leads to a new difficulty: frequent failure to sample cells from one—and only one—colony. The next round of growth thus results in a mixed culture, necessitating additional purification efforts. One recommended way to pick up colonies from the diffusion chamber-grown material is to place a sample of this material under a compound microscope, verify the target colony under high magnification (e.g., using a dry 40× objective with a long working distance), and then sample this colony using tungsten wires (75- μ m shaft, <1 μ m at tip; FHC, Inc., Bowdoinham, ME). This material is then syringe mixed in a small volume of sterile water (seawater in marine application) and inoculated into a new diffusion chamber. If this produces a mixed culture, a series of chamber-to-chamber transfers may be necessary to achieve purity. Purity is confirmed by a combination of light microscopy at high magnification, scanning electron microscopy, and analyses of PCR-amplified 16S rRNA gene fragments.

1.2.3. Diffusion Chamber Applications

We have applied the method across a variety of different environments to quantify microbial growth inside the chambers, and assessed what part of grown species could be domesticated (subcultured under conventional laboratory conditions).

1.2.3.1. Marine Sediments Application

In this application, we grew microorganisms inhabiting a sandy tidal flat in Massachusetts Bay, close to one of our home laboratories at the Marine Science Station of Northeastern University, Nahant, MA (21). Microorganisms from the uppermost layer of these sediments were detached from sediment grains by vortexing 1-g sediment samples in 5 ml of autoclaved seawater for 5 min. The heaviest sediment particles in the supernatant were allowed to settle, and subsamples of the supernatant were mixed with 2.5 ml of warm (40°C) agar supplemented with 0.01% technical grade casein (Sigma-Aldrich, St. Louis, MO). The cells/agar mix was inoculated into the diffusion chambers as described above. Some chambers received agar but not cells; these served as a contamination control. Inoculated growth chambers were incubated in an aquarium containing freshly collected intertidal sediments and recirculating natural seawater. After 1 to 3 weeks of incubation, the chambers were opened and microbial colonies were examined, counted, and subcultured as described above. This experiment was repeated 13 times over a period of 7 months; its main results are given in Fig. 2B. The number of cells forming colonies in diffusion chambers averaged approximately 22%, exceeding hundredfold what could be achieved using standard petri dishes. This strongly indicated that the diffusion chamber-based approach to microbial cultivation

likely provides access to some of the previously uncultivated species. Indeed, in this and follow-up research (5, 24) we isolated numerous species that did not grow in petri dishes inoculated with environmental samples, but could be grown and maintained in the diffusion chambers.

Cultivation of novel species inside diffusion chambers is a welcome development, but their properties and abilities could be fully studied and utilized only if they could be adapted for growth *in vitro*. We therefore examined whether repetitive cultivation in a series of generations of diffusion chambers facilitated domestication of the grown strains, and discovered a positive correlation between the number of cultivation rounds *in situ* and the probability of obtaining a variant capable of growth *in vitro* (24). Of the 23 strains tested, approximately a quarter acquired the ability to grow on standard media after just one round, and this proportion steadily grew to 70% after four cultivation rounds (24). The nature of the domestication process remains unclear, but the empirical observations suggest that rounds of *in situ* cultivation adapt a significant number of otherwise “uncultivable” strains to growth under conventional conditions of standard petri dishes. This important observation was confirmed in follow-up studies conducted in different environments (see below).

1.2.3.2. Freshwater Sediment Application

We applied the diffusion chamber-based method to freshwater sediments to cultivate microbial species from the Turtle Pond, a small freshwater pond in Boston, MA (5). Pond sediment material was diluted in agar supplemented with Casamino Acids (0.01%), yeast extract (0.01%), and hot water extract from the sediment (0.1%), in various combinations, and inoculated into diffusion chambers. These were incubated on top of a freshly collected block of sediment kept under a layer of aerated extant water in an aquarium. After 4 weeks of incubation, the chambers were opened, the material was homogenized by passing the material through a syringe equipped with a gauge 25 needle and diluted with sterile, filtered pond water, and part of the material was incubated in the next generation of diffusion chambers. The remaining material was used to prepare standard pour plates supplemented with diluted (10% of manufacturer recommended) Luria-Bertani broth (LB; BD, Franklin Lakes, NJ). Reincubation in new diffusion chambers was performed once again, to a total of three rounds of *in situ* cultivation, each time with parallel subculturing in standard petri dishes. In this way, we could assess if new species would appear by repetitive incubations of the chambers, and what species from thus grown diversity could be grown *in vitro*. Indeed, 70% of the 438 strains isolated came from the diffusion chamber-reared material, and several strains unique to this approach only appeared after two or more rounds of cultivation *in situ*; notably, these represented rarely cultivated phyla *Verrucomicrobia* and *Acidobacteria*. Overlap between species composition grown in standard petri dishes inoculated with pond material directly versus petri dishes inoculated with cells first grown in diffusion chambers was minimal (7%). This confirmed a similar observation made in a different environment (24) that one or more rounds of growth inside diffusion chambers leads to domestication of novel microbial species that are difficult to grow otherwise.

1.2.3.3. Application to Contaminated Environments

We also used this method in contaminated soils and groundwaters in several areas around the Field Research Center,

Oak Ridge National Laboratory, TN. These data are being prepared for publication, but the principal results mirror those from the above-mentioned studies of marine and freshwater environments: the diffusion chamber-based method allows for growth and domestication of novel species from contaminated soils and groundwater. It also brings into culture organisms previously known only from the rRNA gene and metagenomics surveys of the sampled areas (data not shown). This indicates that some microbial species, including the likely bioremediation players, do not grow under standard conditions unless first preincubated in the diffusion chambers deployed in situ.

1.3. METHOD 2: ICHIP

1.3.1. Principles of the Method

In a typical application, the diffusion chamber described above is inoculated with a mix of environmental cells, and so the first growth event leads to a mixed culture. This necessitates additional purification and isolation efforts, which are often substantial and limit the throughput. To resolve this bottleneck, we developed a variant of the diffusion chamber method that transforms it into a high-throughput platform for massively parallel microbial isolation. While based on the same principle (placing microorganisms into diffusion chambers for incubation *in vivo*), it differs significantly from the original chamber design described above. The key element of this new method is the Isolation Chip, or ichip for short (Fig. 3; Nichols et al., submitted), which is a combination of hundreds of miniature diffusion chambers loaded with an average of one cell per chamber. The ichip thus represents a tool helping to achieve microbial growth and isolation in a single step.

1.3.2. Ichip Design

The ichip consists of several elements: the central plate, the main function of which is to house growing microorganisms; semipermeable membranes on each side of the plate, which separate the plate from the environment; and two side panels, playing mainly a structural role (Fig. 3). The central plate and side panels have multiple matching through holes. When the central plate is dipped into a suspension of cells in molten agar (Fig. 3A), its through holes capture miniature volumes of this suspension that

solidify in the form of small agar plugs. These plugs are sealed from both each other and the outside environment by membranes pressed against the central plate by the side panels, fastened with screws (Fig. 3C). The seal transforms the assembly into an array of small diffusion chambers, each filled with agar and cells. The number of cells inside each through hole is the function of the initial dilution rate in molten agar, and thus can be controlled. When an average agar plug contains a single cell, the majority of through holes will contain individual cells (Fig. 3B). The assembled ichip is incubated in nature (or simulated natural environment) similarly to the diffusion chambers of the original design (Fig. 1A). The growth of individual cells automatically leads to pure cultures inside the through holes, minimizing isolation efforts.

The ichips currently in use in our laboratories were manufactured by HI-TECH Manufacturing (Schiller Park, IL). The plastic elements are machined from blocks of hydrophobic plastic polyoxymethylene, known as Delrin®. All the through holes are uniform in their diameter (1 mm), and are arranged in two arrays with 192 through holes per array. The size of the array is such that it can be completely covered by standard 25- or 47-mm-diameter membranes. It is also possible to use commercially available sheet membranes that could be cut to the appropriate size in advance.

Prior to assembly, we sterilize the plastic components in ethanol, dry them in a laminar flow hood, and rinse the parts in particle-free DNA grade water (Fisher Scientific, Hampton, NH). After incubation, ichips are washed vigorously in particle-free DNA grade water, and disassembled. The central plate is then examined under a compound or high-power dissecting microscope for colony count. The colonies are removed from the ichip's central plate by touching agar plugs with unwound and sterile #1 gauge paper clips for further analyses and/or subculturing (e.g., in microtiter plates).

In a series of preliminary tests, we checked whether the pressure applied by tightening the screws was sufficient to prevent cells from migrating in and out of the agar plugs. Ichips were loaded with sterile 1% agar (BD, Franklin Lakes, NJ), assembled, submerged into *Escherichia coli* K-12 culture growing in LB, and incubated for 24 h. After incubation, the content of ichips was examined for growth under a compound microscope. In parallel, ichips loaded with *E. coli* K-12 cells mixed with 1% warm LB

FIGURE 3 Ichip design. Explanations in the text.

agar were incubated for 24 h while bathed in sterile LB. The outside medium was then examined for growth. In neither case were microbial cells observed crossing the barrier established by the membranes (Nichols et al., submitted).

1.3.3. Ichip Applications

In a proof-of-concept study, we used the ichip to grow marine water column and soil microorganisms, recorded the colony count, and compared the rRNA gene diversity of ichip-grown microorganisms and their colony count with microorganisms from parallel incubations in standard petri dishes (Nichols et al., submitted). Seawater and waterlogged soil samples were obtained from the respective environments in the vicinity of the Marine Science Center of Northeastern University, Nahant, MA. Microbial cells were dislodged from soil particles by two 10-s-long sonication pulses (Sonics Vibra-Cell VC130; 3-mm stepped microtip; Sonics & Materials, Inc., Newtown, CT) and collected after larger particles settled for 60 s. Seawater samples were used without sonication. All cells were enumerated with 4',6-diamidino-2-phenylindole (DAPI) (Sigma-Aldrich, St. Louis, MO) and diluted in warm diluted (0.1% wt/vol) LB agar to a concentration of 10^3 cells/ml, with or without supplementation with 4% sea salts (Sigma-Aldrich, St. Louis, MO). In the present ichip configuration (Fig. 3), each through hole captures approximately 1.25 μ l of agar, or 500 μ l of cell/agar mix per assembly. Given the dilution, each loaded through hole contained $500/384 = 1.25$ cells (on average). To approximate the species diversity inoculated into ichips, for conventional cultivation we established miniature petri dishes with 500 μ l of the cell/agar mixes in 24-well culture plates (Corning Costar, Corning, NY). The ichips were returned to the respective environments of cells within,

incubated for 2 weeks, and disassembled. Approximately 50 agar plugs from each ichip were removed for a detailed microscopic examination and colony counting, whereas the rest served as a source of DNA for 16S rRNA gene sequence-based identification of grown species. Agar material from the conventional petri dishes was processed in an identical manner.

This study led to three important observations. First, 40 to 50% of cells incubated in ichips formed colonies, which exceeded the petri dish recovery fivefold. Second, the ichip- and petri dish-grown collections of microorganisms were dramatically different and shared only one species (*Vibrio* sp.). This lack of overlap between the two species lists was not due to undersampling, because petri dishes inoculated with seawater and soil samples did share several species, as did ichips inoculated with microorganisms from these two sources. Third, the novelty of isolates grown in ichips significantly exceeded that of petri dish-reared species (Fig. 4). Our general conclusion is that the ichip-based method enables growth of a significant fraction of microbial diversity, and produces unique microbial collections of high phylogenetic novelty; it does so in a time- and effort-efficient manner, compatible with contemporary tools for high-throughput analyses, such as microtiter plates.

We note that the flexibility of the ichip design makes it useful for a variety of applications beyond those described here. For example, a single incubation of the device currently in use (Fig. 3) affords tens of microbial cultures, and cultivation efforts can be easily scaled up via minimal changes in configuration of the ichip. Matching the position of through holes with wells of microtiter plates paired with commercially available replicators that have pins spaced to match the wells will allow massively parallel growth and isolation of hundreds of cultures per incubation, with minimal labor involved. Further modifications of the ichip may make

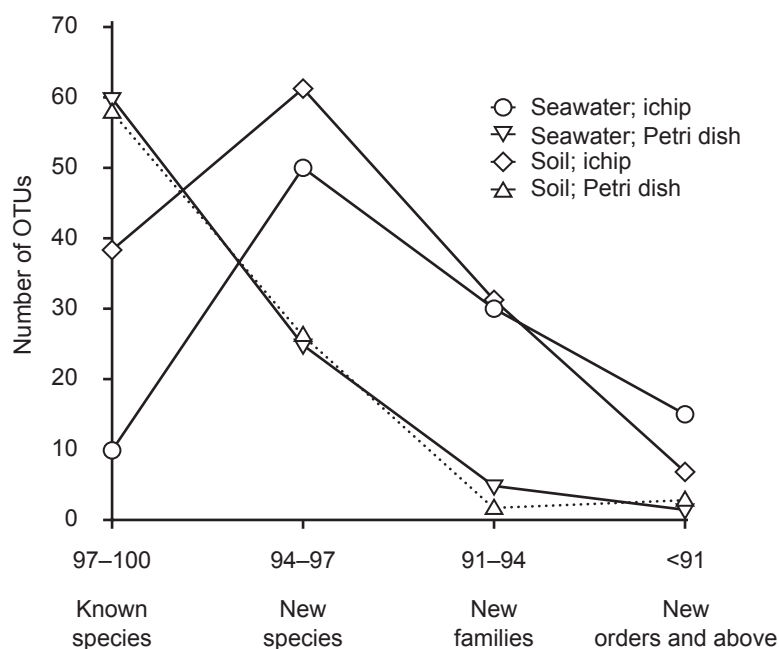

FIGURE 4 Novelty of seawater and soil microbial strains grown in ichip and petri dish. Equation of sequence novelty, in percentage of diversion from the known species, and taxonomic rank of novelty (genus, family level, etc.) is approximate. OTU, operational taxonomic unit.

it suitable to grow previously uncultivated microorganisms, not only from natural environments, but also from the human microbiome. For example, miniaturization of the ichip design opens a possibility of its incubation in the oral cavity. In this application, microorganisms from a dental plaque can be loaded into a mini-ichip (Fig. 5A and B), which is then incubated on a retainer inside the volunteer mouth (Fig. 5C). This is important because >50% of oral microflora has not been cultivated yet, and the uncultivated fraction contains species implicated in oral diseases (1, 23). Equally simple modifications can make the ichip useful to grow microorganisms from other parts of the human microbiome.

1.4. METHOD 3: MICROBIAL TRAP

1.4.1. Principles of the Method

Several types of microorganisms that are particularly important for drug discovery, microscopic fungi and actinomycetes, grow by forming filaments capable of penetrating soft substrates. Considering that actinomycetes can pass through filters with pores as small as $0.2\ \mu\text{m}$, we hypothesized that the reverse use of the diffusion chamber (Fig. 1A) could selectively enrich for these microorganisms by capitalizing on their unique abilities (trap method, Fig. 1B [15]). Visually, the trap is indistinguishable from the diffusion chamber, but

FIGURE 5 Prospective ichip to grow oral microorganisms. (A) The assembly of the device is similar to the ichip currently in use (Fig. 3): the central plate is loaded with target (dental plaque) microorganisms; two additional panels with matching through holes press the $0.03\text{-}\mu\text{m}$ -pore-size membranes against the central plate, creating multiple diffusion minichambers. (B) Relative size of the prospective ichip for oral microflora cultivation. (C) Assembled ichip is fastened in the opening of a mold of the volunteer's upper palate, to be incubated in the mouth in touch with the molar used to sample the plaque.

the main principle of its application is very different. The trap is built from similar components except the membranes have larger pores, and it is *not* inoculated with environmental cells (contrast Fig. 1A and B). Instead, the trap is incubated in the environment with sterile agar inside, with the expectation that diffusion through membranes will establish conditions inside the trap that closely mimic the natural conditions. The pore size above 0.2 μm should allow filamentous organisms active at the time of the experiment to penetrate the membranes, grow into the agar inside the trap, and establish colonies there. Though selected motile microorganisms could in principle cross the membranes and grow inside the trap as well, we hypothesized that the method should enrich for target (filamentous) organisms. These could be further purified by subculturing in diffusion chamber or petri dishes. The test study described below supported these expectations.

1.4.2. Trap Design

Traps are built using 0.2- to 0.6- μm -pore-size polycarbonate membranes, glued to the bottom of washers as in the diffusion chamber method. The trap is filled with 3 ml of sterile 1% agar or 1.2% gellan gum, with or without vitamin supplement. After the medium solidifies, the top polycarbonate membrane, with a 0.03- μm pore size, is glued to the washer, sealing the trap. After the glue dries, the traps are placed on top of the moist soil or marine sediment, ensuring that the bottom filter (with larger pores) is in good contact with the substrate. The small pore size of the upper membranes prevents contamination from the air. In aquatic application, the two membranes can be the same, with 0.2- to 0.6- μm pore sizes, allowing penetration by filamentous organisms from both sides.

1.4.3. Trap Application

We tested the trap performance (15) by incubating these devices on top of garden soil kept in large petri dishes, sealed with Parafilm to prevent evaporation. After 14 to 21 days of incubation at room temperature in the dark, the traps were opened and the slabs of solid agar or gellan

gum were removed, inverted, and placed into a sterile petri dish. The solid disks were examined for growth under a stereomicroscope at 20 to 100 \times magnification, and visible microcolonies were sampled with sterile needles. In several experiments, the agar slabs were incubated undisturbed for 5 to 7 days prior to colony sampling to allow actinomycetes to form aerial mycelia to facilitate colony picking. All sampled material was streaked on plates with agar or gellan gum medium supplemented with 0.1% Casamino Acids and 0.1% nutrient broth (BD Difco, Detroit, MI), or Actinomycete Isolation Agar (BD Difco, Detroit, MI). Because the experiment aimed to isolate actinomycetes, nystatin (50 $\mu\text{g}/\text{ml}$) and cycloheximide (100 $\mu\text{g}/\text{ml}$) were added to the media in petri dishes to prevent growth of fungi. Subcultivation was repeated to obtain pure cultures. For comparative purposes, we also prepared parallel conventional petri dishes by inoculating them with the air-dried soil material directly, followed by 2-week-long incubation in the laboratory. Similarly to subculturing trap-derived material, conventional petri dishes were established with agar or gellan gum and were supplemented with the same nutrient additives. Upon incubation and purification, 90 colonies from traps and 90 colonies from conventional petri dishes were identified by sequencing their 16S rRNA genes.

Visual inspection of traps revealed an abundance of actinobacterial colonies (Fig. 6). Traps with 0.4- to 0.6- μm -pore-size bottom membranes contained a significant number of fungal filaments, but cutting the pore size to 0.2 μm effectively excluded fungi. The majority of organisms grown in the traps proved to be actinomycetes, some of which represented rare and unusual species from the genera *Dactylosporangium*, *Catellatospora*, *Catenulispora*, *Lentzea*, and *Streptacidiphilus*. In general, gellan gum-based traps appeared to have captured more diverse assemblage of actinomycetes; conventional petri dishes produced more nonfilamentous actinobacteria. We concluded that the trap method allows for a selective capture of filamentous actinomycetes enriched for new and rare species.

1.5. CONCLUSIONS

There is a growing appreciation of microbial cultivation because microbial culture remains central not only to the study and utilization of microbial properties and capabilities, but also to the placement of molecular surveys and metagenomics data into a larger context. With the majority of microbial species remaining uncultivated, there is an urgent need to develop novel methodologies to grow previously uncultivated species from the environment and human and animal microbiomes. One way to gain access to “missing” species is to grow environmental cells in their natural habitat, capitalizing on a naturally occurring suite of growth factors. This can be accomplished by placing target cells in diffusion chambers incubated back in the cells’ habitat. We developed several variants of such diffusion chambers, each with its own set of advantages. The diffusion chamber method is a simple and inexpensive tool to grow mixes of novel environmental microorganisms. The ichip design allows for massively parallel, high-throughput isolation of novel microorganisms that may be difficult or impossible to grow by use of conventional techniques. Miniaturization of the ichip makes it suitable to grow presently uncultivated microorganisms from human microbiome. A reverse use of the diffusion chamber leads to a different type of cultivation (trap method), which selectively enriches for new and rare filamentous actinomycetes. This makes the trap method particularly useful for the discovery of novel secondary metabolites.

Selective Isolation of Actinobacteria

MICHAEL GOODFELLOW

2

2.1. INTRODUCTION

The choice of biological material for exploitable biotechnology is a daunting one given the sheer scale of microbial diversity. Molecular ecological studies, for instance, show that only a tiny fraction of prokaryotic diversity in natural habitats has been cultivated (18, 20, 70, 138), an unseen majority that encompasses enormous genetic diversity for biotechnology (15, 16, 182). Nevertheless, it is encouraging that innovative selective isolation and characterization studies are providing a way of making previously uncultivated taxa available for ecological and biotechnological studies (34, 153). 16S rRNA gene sequence data provide a particularly effective way of detecting prokaryotic taxa and resolving deep-rooted phylogenetic lineages (49, 201).

Among prokaryotes, members of the suborders *Micromonosporineae*, *Pseudonocardineae*, *Streptomycineae*, and *Streptosporangineae* of the order *Actinomycetales* of the class *Actinobacteria* (Fig. 1) are currently the most prolific sources of novel secondary metabolites, notably antibiotics (11, 105, 162). *Streptomyces* strains have a unique capacity to produce bioactive compounds and remain the richest source of novel antibiotics (33, 72, 73, 162). The significance of streptomycetes in this respect is underpinned by results from whole-genome-sequencing studies which show that the whole genomes of model *Streptomyces* strains contain more than 20 naturally produced biosynthetic gene clusters (10, 81). In contrast, whole-genome sequence data show that most other prokaryotes lack the capacity to synthesize antibiotics.

There is a continued interest in screening members of the order *Actinomycetales* because they remain the richest source of novel bioactive compounds. However, it has become increasingly difficult to find commercially useful secondary metabolites from well-known actinomycetes, because this practice leads to the wasteful rediscovery of known bioactive metabolites, especially antibiotics. There is, therefore, an urgent need to isolate and characterize representatives of the many poorly studied actinobacterial taxa, and to cultivate the astonishingly rich diversity of novel actinobacteria diversity present in natural habitats (2, 36, 51, 154, 202). The principles and practices currently used to selectively isolate and recognize previously uncultivated taxa is the subject of this chapter.

2.2. SELECTIVE ISOLATION: THE GROUND RULES

Most actinobacteria are saprophytes in aquatic and terrestrial habitats, notably in self-heating plant material, soils, and freshwater and marine habitats (13, 17, 20, 46, 47, 84). It is not possible to recommend a single procedure for the selective isolation of the multiplicity of the different kinds of actinobacteria present in environmental samples given their diverse growth and incubation requirements. Consequently, innumerable approaches have been recommended for the isolation of specific actinobacterial taxa (102, 124, 183). The most selective strategies have tended to focus on the isolation of members of a particular taxonomic group or related taxonomic groups based on the biological properties of the organisms that are being sought (28, 42, 46, 179, 195). Such approaches require some prior knowledge of the growth and incubation requirements of the target organisms. Most selective isolation procedures involve the extraction of propagules from selected environmental samples, pretreatment(s) of samples, choice of selective media, incubation, and colony selection.

2.2.1. Selection of Environmental Samples

Actinobacteria mainly occur as saprophytes in diverse natural habitats, including soil, the initial focus of selective isolation studies. The numbers and kinds of actinobacteria found in soil and other substrates are greatly influenced by primary ecological factors, such as aeration, pH, temperature, salinity, and moisture and organic matter content (46, 185, 190, 193). Indeed, the success in isolating large numbers of specific actinobacterial taxa can be highly dependent on the choice of environmental samples, as illustrated by the selective isolation of acidophilic and alkaliphilic streptomycetes (4, 9, 39, 185). Similarly, self-heating materials like bagasse, composts, grains, and fodders are useful sources of thermophilic, filamentous, spore-forming actinobacteria (103, 195).

Soil remains a fruitful source of novel actinobacteria (168, 199), although it is becoming increasingly clear that un- and underexplored habitats, notably marine ecosystems, are a rich source of novel taxa that have the capacity to produce new bioactive compounds, including the discovery of first-in-the-class drug candidates (18, 33, 74). Indeed, an encouraging stream of anticancer and anti-infective compounds have been derived from marine sources, as

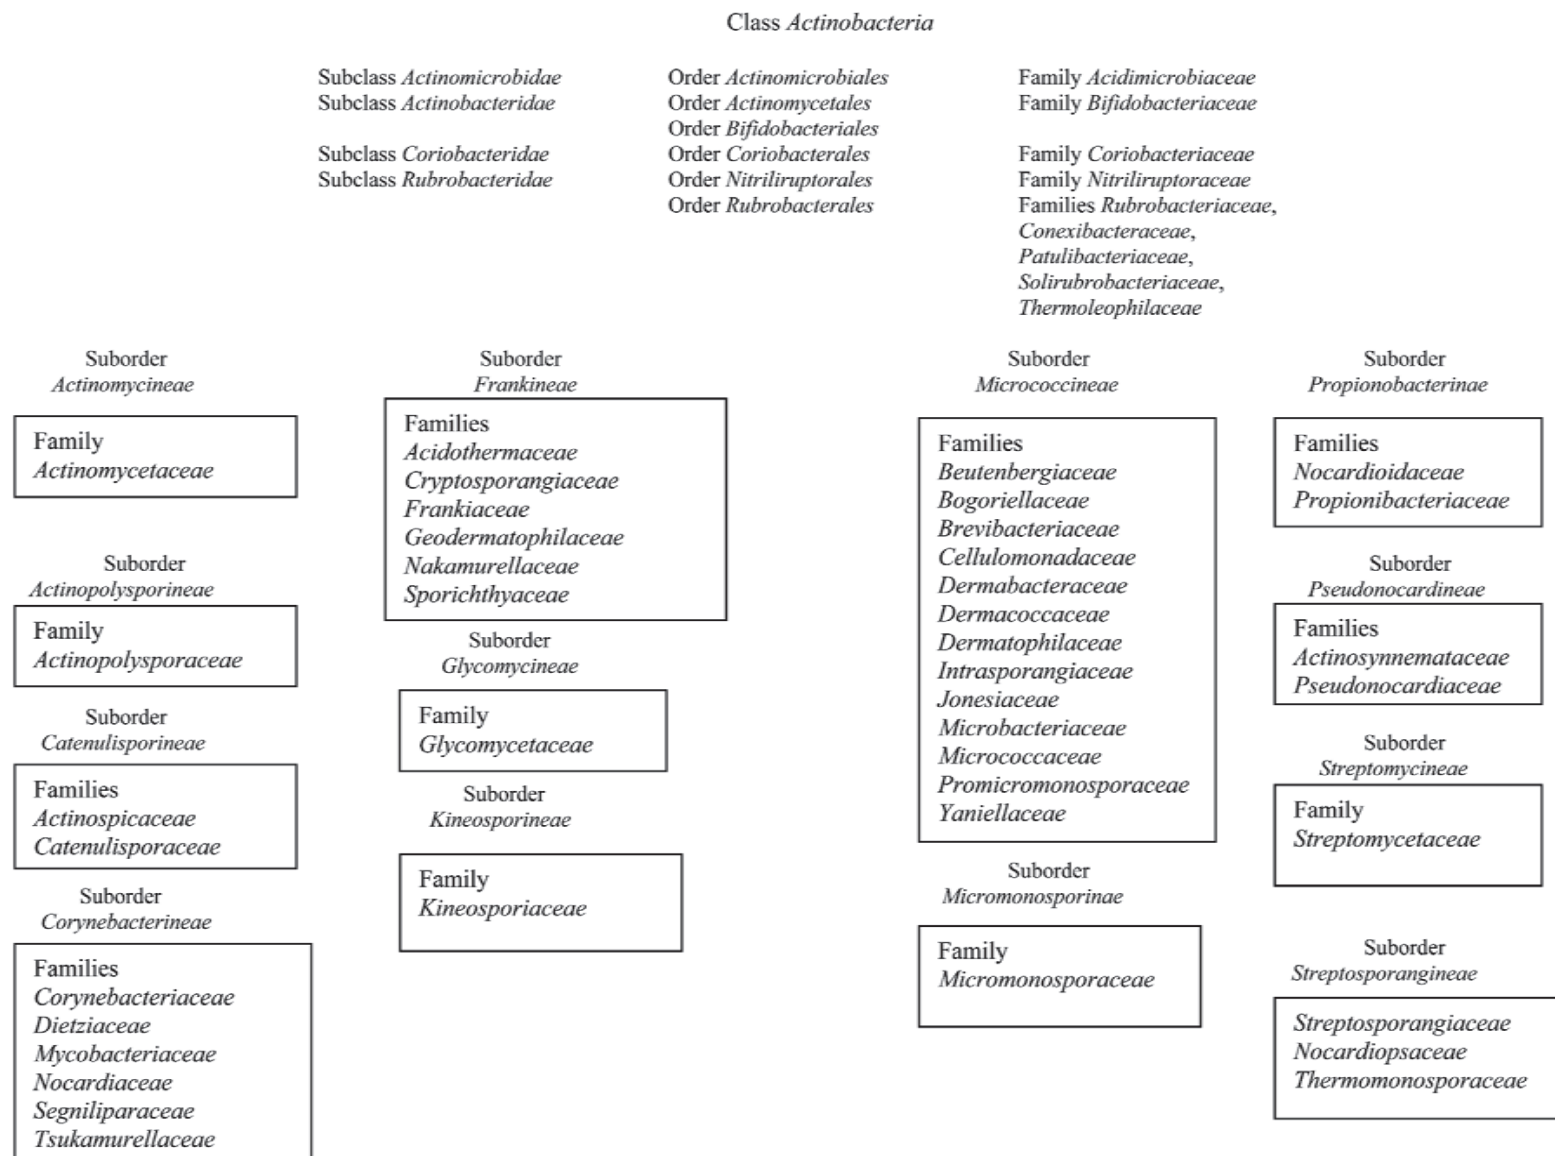

FIGURE 1 Hierarchic classification of the phylum *Actinobacteria* based on 16S rRNA gene sequences and taxon-specific 16S rDNA signature nucleotides (adapted from reference 201).

exemplified by the discovery of abyssomicin C, a potent polycyclic polyketide active against methicillin-resistant *Staphylococcus aureus* and synthesized by "*Verrucosipora maris*" (12, 151), and salinosporamide A, an anti-cancer agent produced by *Salinispora tropica* (32, 112). Novel endophytic actinobacteria are also a promising source of anticancer and antitumor agents (23, 80). Niche habitats, such as beehives (147), copper-polluted sediments (1), hyperarid soils (137), and root nodules of legumes (173, 174), are useful sources of novel actinomycetes.

2.2.2. Representative Sampling of Actinobacteria

Physicochemical interactions of bacterial propagules with particulate substrates affect their recovery from environmental samples. Traditional methods used to separate bacteria from organic matter, sediment, and soil particles, such as shaking in water or weak buffers (e.g., one-quarter strength Ringer's solution), are not effective (75). It is particularly important to thoroughly break up soil aggregates because many microorganisms, notably those showing mycelial growth, may be bound within them (54, 123, 148). Procedures used to promote the dissociation of microorganisms from particulate material include the use of chelating agents (108), buffered diluents (122), elutriation (76), and ultrasonication (148). All of these procedures address the problem of quantitative and representative sampling to varying degrees.

The dispersion and differential centrifugation (DDC) technique, a multistage procedure introduced by Hopkins et al. (75), combines several physicochemical treatments and has been found to be effective in representative sampling of bacteria, including actinomycetes, from freshwater and marine sediments, as well as from diverse soils (5, 76, 109, 119, 155). The procedure involves the use of a mild detergent (sodium cholate), Tris buffer, attenuated physical disruption (mild ultrasonication), and ionic shock (distilled water).

The DDC procedure has been shown to be much more effective in extracting propagules of streptomycetes from soil and marine sediment samples than traditional, but still widely used, reciprocal shaking techniques (5, 113, 155). Indeed some kinds of streptomycetes were only isolated by use of the DDC procedure. These observations suggest that associations between taxonomically different kinds of streptomycetes and particulate components in soil and sediments may be factors that limit representative sampling of streptomycetes, and that the DDC procedure may be effective in breaking down such associations.

2.2.3. Pretreatment of Samples

Various pretreatments can be used to select for different fractions of actinobacterial communities present in

environmental samples. In general, pretreatment regimes select for the target actinobacteria by inhibiting or eliminating unwanted microorganisms. Several physical pretreatments have been used for the isolation of actinobacteria. Actinobacterial spores are more resistant to desiccation than most bacteria; hence, simply air-drying soil/sediment samples at room temperature will eliminate most unwanted gram-negative bacteria that might otherwise overrun isolation plates (102, 118, 193). A pretreatment based on alternate drying and wetting of soil has been used to enrich for sporangia (spore vesicles)-forming actinobacteria (110). Rare spore-forming actinobacteria (e.g., *Actinomadura*, *Microtetraspora*, *Pseudonocardia*, and *Streptosporangium*) have been isolated from irradiated soil samples and soil suspensions (14, 169). Cesium chloride density gradient centrifugation has been used to isolate *Micromonospora* species from soil (89). Similarly, *Nocardia* species have been selectively isolated from soil using sucrose gradient centrifugation (200).

Resistance of actinobacterial propagules to desiccation is usually accompanied by some measure of resistance to heat. The basis of this resistance is not clear, but it is apparent that many actinobacterial spores (e.g., *Micromonospora* and *Microtetraspora*), spore vesicles (*Dactylosporangium* and *Streptosporangium*), and hyphal fragments (e.g., *Rhodococcus*) are more resistant to heat than gram-negative cells. Actinobacteria are more sensitive to wet than to dry heat; hence, much lower temperatures are used to isolate these organisms from suspensions of environmental samples.

Nocardia asteroides strains have been isolated from soil following pretreatment of 10^{-1} suspensions at 55°C for 6 min (141); modifications of this procedure were used to isolate novel nocardiae from soil, water, and deteriorating natural rubber rings (111). The same mild pretreatment regime was used to isolate *Rhodococcus coprophilus* strains from aquatic and terrestrial habitats (152). More stringent heat pretreatment regimes select for actinobacteria that produce more heat-resistant spores, such as those formed by *Micromonospora*, *Microbispora*, and *Microtetraspora* strains (130–132). A number of additional heat pretreatment regimes are shown in Table 1. Heat pretreatment protocols usually lead to a decrease in the ratio of bacteria to actinomycetes on isolation plates, although actinobacterial counts may also be reduced (193).

A simple and effective technique for the selective isolation of filamentous actinobacteria on soil dilution plates was introduced by Hirsch and Christensen (71). This procedure involves the spread of soil or soil suspensions over the surface of membrane filters placed on the surface of agar plates. The plates are incubated for several days to allow actinobacterial hyphae to grow through pores on the filters and grow on the agar surfaces below. In contrast,

TABLE 1 Selective heat pretreatments for the isolation of actinobacteria

Pretreatment	Targets	Reference(s)
Air-dried soil heated at 120°C for 1 h	<i>Microbispora</i> and <i>Streptosporangium</i> spp.	128, 129
Air-dried soil heated at 100°C for 15 min	<i>Actinomadura</i> spp.	7
Water or soil suspensions heated at 45°C or 50°C for 10 min	<i>Streptomyces</i> spp.	28
Water or soil suspensions heated at 60°C for 30 min	<i>Micromonospora</i> spp.	28
Air-dried soil heated at 120°C for 1 h	<i>Dactylosporangium</i> and <i>Streptosporangium</i> spp.	59
Air-dried soil heated at 28°C for 1 wk	<i>Herbidospora cretea</i>	93
Soil suspension heated at 110°C for 1 h	<i>Microtetraspora glauca</i>	61

nonfilamentous bacteria are confined to the surface of the membrane. The filters are removed after this initial growth phase and plates incubated further to allow the growth of actinobacteria (see also chapter 1, this volume).

Another ingenious pretreatment method involves the addition of a cocktail of polyvalent phage to soil suspensions to reduce the growth of unwanted bacteria, notably aerobic, endospore-forming bacteria and neutrophilic streptomycetes, thereby raising the probability of isolating members of rare or novel actinobacterial genera (97, 99, 196). This approach has been especially useful for the isolation of rare filamentous actinobacteria, such as *Amycolatopsis*, *Catellatospora*, *Couchiplanes*, *Kibdelosporangium*, *Thermomonospora*, and *Thermobifida* strains, from diverse environmental samples (96, 98). An impressive phage library is now available for such isolation experiments (96).

Chemical pretreatments of mixed inocula are used to isolate specific actinobacterial taxa, notably members of the genera classified in the family *Streptosporangiaceae* (57, 59, 65, 68). The selective chemical procedures introduced by Hayakawa and his colleagues are based on the differential ability of actinobacterial spores to withstand treatment with chemical germicides such as benzethonium chloride, chlorhexidine gluconate, and phenol (55). Treatment with these agents for 30 min at 30°C kills vegetative cells of aerobic, endospore-forming bacilli and pseudomonads.

The simultaneous use of more than one chemical germicide can further enhance selectivity, as exemplified by the use of chlorheximide gluconate and phenol for the isolation of *Microbispora* strains (65). Sodium dodecyl sulfate and yeast extract broth inhibit the growth of unwanted bacteria and enhance the germination of actinobacterial spores (125). Mycobacteria are routinely isolated from clinical and environmental samples by treating them with dilute acids or alkali with or without quaternary ammonium compounds, followed by neutralization, and decontaminated material is inoculated to agar or inspissated egg medium supplemented with malachite green (178). Sodium hypochloride and osmium tetroxide are routinely used to decontaminate root surfaces/root nodules before isolating endophytic actinobacteria, including *Frankia* (22, 175). Other effective chemical pretreatment procedures are shown in Table 2.

Low numbers of actinobacteria in environmental samples can be concentrated, then plated out onto nutrient or selective media to facilitate their isolation. Actinobacterial propagules in freshwater and seawater can be concentrated by filtration through membrane filters, which are then placed over agar surfaces to promote growth of constituent strains (21, 136). Similarly, actinobacterial spores can be separated from bacteria and fungal propagules by centrifuging soil suspensions for 20 min at 3,000 rpm before

seeding isolation media with supernatants containing the actinobacterial spores (150). Differential centrifugation has also been used to separate *Frankia* bacteroids from root nodule homogenates (8, 149) and to selectively isolate motile actinobacteria from soil and plant litter (64).

Nutrient amendment and baiting techniques are used to increase the populations of specific fractions of actinobacterial communities in environmental samples to facilitate their isolation on nutrient and selective media. Soil amendments with substrates such as chitin and keratin were first used by Jensen (82, 83) to boost the numbers of streptomycetes. This approach has fallen into neglect to some extent, but does provide an effective way of enhancing specific components of actinobacterial communities in soil (125, 192).

Actinobacteria with a motile spore phase in their life cycle have been isolated from environmental samples baited with natural substrates, such as hair and pollen grains, ever since the pioneering studies on actinoplanetes by Couch (24–27). The method is based on the ability of zoospores to migrate and colonize baits floated on the surfaces of soil suspended in distilled water in petri dishes. Following incubation for 1 to 2 weeks, the baits are removed and used to inoculate growth media to isolate the organisms. This procedure is still widely used for the isolation of actinobacteria, such as members of the genera *Actinokineospora*, *Actinoplanes*, *Actinosynnema*, *Catenuloplanes*, *Cryptosporangium*, *Dactylosporangium*, *Geodermatophilus*, *Kineospora*, *Pilimelia*, *Sporichthya*, and *Spirillospora* (35, 64, 67, 134, 171).

Motile actinobacteria can also be isolated by taking advantage of their ability to show chemotactic responses (55). Palleroni (143) found that actinoplanete zoospores present in soil suspensions migrated into glass capillaries containing potassium chloride within about 40 min and could then be isolated on nutrient agar plates seeded with contents of the capillaries. An improved chemotactic method based on the use of γ -collidine as chemoattractant was used to isolate *Actinoplanes* and *Dactylosporangium* species from various soils (68). Similarly, vanillin has been used as a chemoattractant for the isolation of members of the genera *Catenuloplanes* (56) and *Virgosporangium* (165).

An interesting departure from the dilution plate procedure involves the isolation of spore-forming actinobacteria from self-heating plant material. The latter is placed either in a wind tunnel (48, 103) or in a simple sedimentation chamber (104) and the resultant spore cloud passed through filters with progressively smaller pores onto plates of agar media held in an Andersen sampler (3). This method has been used to selectively isolate spore-forming taxa from composts and overheated cereal grains, including carboxydrotrophic streptomycetes (31), saccharopolysporae (41), and thermomonosporae (116).

TABLE 2 Chemical pretreatments for the selective isolation of actinobacteria

2.2.4. Choice of Selective Media

Innumerable media have been recommended for the isolation of actinobacteria, in general, and for selected families, genera, and species, in particular. Most of the “general” or “nonselective” media were formulated empirically, notably without reference to either the nutritional or tolerance preferences of the target organisms. Some recommended isolation media are nutritionally poor because many actinobacteria have a tendency to survive and grow, albeit poorly, on nutrients scavenged from tap water or even purified agar. However, most selective media have high carbon-to-nitrogen ratios because they contain complex carbon and nitrogen sources (e.g., casein, humic acid, starch, and xylan) that favor the growth of actinobacteria over the generality of bacteria that grow better on media with low carbon-to-nitrogen ratios and are usually unable to metabolize high-molecular-weight, resistant organic polymers.

Nonselective media, such as colloidal chitin-mineral salts and starch-casein-nitrate agars (78, 100, 107), are now known to select for a relatively narrow range of *Streptomyces* species (177, 188) and do not support the growth of actinomycetes with different growth requirements (29, 188). These media are still widely used even though their value is mainly restricted to detecting the presence of streptomycetes in extreme environments (137, 144). However, starch-casein-nitrate agar adjusted to pH 4.5 or 10.5 has been used to good effect in the isolation of acidophilic and alkaliphilic streptomycetes, respectively (4, 9, 39, 91, 185), and when prepared with seawater can be used to recover streptomycetes from marine habitats (40, 74). The presence of seawater can be crucial for the selective isolation of marine actinomycetes (15, 84), notably for indigenous marine taxa such as *Salinispora* (85, 112, 120).

Antimicrobial agents, notably antibiotics, provide an effective means of increasing the selectivity of isolation media. It is standard practice to control or eliminate fungal contaminants by using antifungal antibiotics, such as actidione, nystatin, and pimarinic (48, 145, 184). Similarly, penicillin G and polymyxin B have been used to select filamentous actinobacteria from competing soil-inhabiting bacteria (128, 184), as have nalidixic acid and trimethoprim (66). Antibacterial antibiotics are widely used for the selective isolation for specific actinomycete taxa, as exemplified in Table 3.

2.2.5. Incubation

Gaseous regimes, temperature, and incubation times also contribute to selectivity. Incubation at 25 to 30°C favors

mesophilic actinobacteria, whereas their thermophilic counterparts require higher temperatures. Members of commonly isolated genera, such as *Micromonospora*, *Nocardia*, and *Streptomyces*, may be selected from isolation plates after 14 days. In contrast, thermophilic actinomycetes, such as *Pseudonocardia thermophila* and *Saccharopolyspora rectivirgula*, only require incubation for 2 to 3 days at 45 to 50°C; plates incubated at these temperatures should be incubated within polythene bags or moist chambers to prevent desiccation. However, incubation times of up to 5 weeks may be required to isolate some genera, such as those classified in the family *Streptosporangiaceae*. Nonomura and Ohara, for instance, incubated plates at 30°C for a month to selectively isolate *Microbispora* and *Microtetraspora* strains (133). Prolonged incubation was also one of the factors that contributed to the initial isolation of the slow-growing, mutualistic symbiont *Frankia* (106).

Relatively little attention has been paid to the selective isolation of anaerobic, barophilic, halophilic, or psychrophilic actinobacteria from a biotechnological perspective. However, large numbers of diverse, facultatively autotrophic actinobacteria have been isolated by use of gaseous C₁ compounds, including carbon monoxide (31, 135). Some of these isolates were formally described as new *Streptomyces* species (92).

2.2.6. Selection of Colonies

Selection of colonies remains the most time-consuming and subjective stage in the isolation procedure. Colonies on isolation plates can be selected randomly or with some degree of choice. Random selection of colonies is especially laborious if it is performed manually in the absence of automated systems backed up by image analysis. When selective isolation media are used, the target organism(s) can often be provisionally identified either on the basis of colony morphology or by the examination of colonies for distinctive features, such as the presence of spore vesicles and the nature of spore chains, using a long working distance objective. However, the ability to accurately identify spore-forming actinomycetes directly on primary isolation plates requires considerable taxonomic prowess and experience. Chromogenic or fluorogenic substrates, which indicate the synthesis of taxon-specific enzymes, coupled with the use of highly specific isolation media might help in the rapid recognition of particular taxa.

It is not usually possible to distinguish between species of the same actinobacterial genus on selective isolation plates. In such instances, the selection of large numbers

TABLE 3 Antibiotics used in the selective isolation of actinobacterial taxa

Antibiotic(s)	Target genera	Reference
Bruneomycin and streptomycin	<i>Actinomadura</i>	146
Gentamicin	<i>Actinomadura</i> and <i>Streptosporangium</i>	157
Josamycin, kanamycin, and nalidixic acid	<i>A. viridis</i>	60
Kanamycin, nalidixic acid, and ofloxacin	<i>Microtetraspora</i>	61
Fradiomycin, kanamycin, nalidixic acid, and trimethoprim	<i>Actinokineospora</i>	142
Leucomycin and nalidixic acid	<i>Streptosporangium</i>	59
Nalidixic acid and penicillin	<i>Saccharothrix</i>	157
Nalidixic acid and tunicamycin	<i>Micromonospora</i>	125
Neomycin sulfate	<i>Amycolatopsis</i>	168
Novobiocin and streptomycin	<i>Glycomyces</i>	101

of colonies is laborious and can lead to serious duplication of strains and hence effort, especially in low-throughput screening systems. However, this problem can be overcome by grouping isolates based on pigmentation characters and molecular fingerprinting patterns (4, 168). Surface spread plates, dried thoroughly before or after inoculation, provide a satisfactory way of recognizing and enumerating filamentous actinobacteria, including streptomycetes (176).

2.3. RATIONAL DESIGN OF SELECTIVE ISOLATION MEDIA

Selective isolation media can be formulated in an objective way by using information held in taxonomic databases (42, 188). One of the early successes of this approach was the development of a medium selective for members of the genus *Nocardia* (111, 139–141). The discovery that diagnostic sensitivity agar supplemented with tetracyclines was selective for *Nocardia* species was based on information held in an antibiotic sensitivity database (43). A logical extension of this work was the visual scanning of phenotypic databases to highlight antibiotics that might form the basis of selective isolation media (Table 4). The number of verticillate streptomycetes (formerly members of the genus *Streptoverticillium*), for example, was increased by reducing the number of competing neutrophilic streptomycetes by supplementing isolation media with neomycin and oxytetracycline (52); verticillate streptomycetes were known to be resistant and other neutrophilic streptomycetes were sensitive to these antibiotics (187, 191). The addition of lysozyme to this medium further increased its selectivity (53).

Phenotypic databases generated in numerical taxonomic studies are ideal resources for the formulation of novel selective isolation media because they are rich in data on

the antibiotic, nutritional, and physiological properties of members of numerically defined clusters (42, 188). Such databases are available for several industrially significant actinobacterial taxa, including the genera *Actinomadura* (6, 172), *Gordonia* (45), *Nocardia* (140), *Rhodococcus* (45), *Streptomyces* (88, 114, 186, 187, 189), and *Thermomonospora* (117), and for members of the family *Pseudonocardiaceae* (180). Several computer-generated selective media have been designed for the isolation of specific fractions of the actinobacterial community from natural habitats (Table 4).

The most extensive studies on computer-based selective media formulations have been performed by Stan Williams and his colleagues (177, 188, 194). They used combinations of amino acids and carbohydrates, with or without antibacterial antibiotics, to favor the isolation of uncommon streptomycetes known to be a promising source of new antibiotics or to discourage the growth of *Streptomyces albidoflavus*, which is ubiquitous in terrestrial habitats. The selective agents were chosen after examining a neutrophilic streptomycete database (189) by use of the DIACHAR program (158), which selects for the most diagnostic characters of individual numerically defined clusters. The highest scores obtained by using this procedure are given by properties that are either all positive or all negative for strains in one cluster when compared with all of the associated numerically defined taxa (177).

The most widely used selective isolation formulation arising from the pioneering studies of Williams and his colleagues is raffinose-histidine agar (177). This medium was designed to reduce the growth of *S. albidoflavus* and related strains, as the latter grow poorly on raffinose and histidine as sole carbon and nitrogen sources, in favor of the isolation of rare and novel streptomycetes. Raffinose-histidine agar has been shown to be effective in the selective isolation of

TABLE 4 Selective media based on information mined from phenotypic databases generated in numerical taxonomic studies

^aIsolation plate incubated at 30 and 50°C.

Streptomyces cyaneus, *Streptomyces platensis*, and *Streptomyces rochei* and related taxa from a sand dune soil; *Streptomyces chromofuscus*, *S. cyaneus*, and *S. rochei* and similar organisms from a rose bed soil; *S. chromofuscus*, *S. cyaneus*, and *Streptomyces diastaticus* and related species from a grassland soil (177); and for the isolation of two novel species, *S. aureus* and *Streptomyces sanglieri*, from a hay meadow soil (5, 115). These studies show that the analysis of the growth requirements of different streptomycete taxa using the DIACHAR program provides an objective strategy for designing novel selective isolation media.

The approaches to the selective isolation of streptomycetes outlined above have been refined by Duangmal et al. (30), who found that a number of antibiotics, sole-carbon, and sole-nitrogen compounds favored the growth of members of the *Streptomyces violaceoruber* 16S rRNA gene clade; the putative selective agents had been highlighted following the application of the DIACHAR program (158) to a neutrophilic streptomycetes database modified from the one devised by Williams et al. (186). Various combinations of the putative selective agents were added to a basal mineral salts medium and the resultant agar plates were inoculated with spore suspensions prepared from members of the *S. violaceoruber* gene clade and representative *Streptomyces* species. All of the *S. violaceoruber* clade strains formed characteristic red-pigmented colonies when the basal medium was supplemented with dextran, L-histidine, sodium chloride, penicillin G, and rifampicin; the sodium chloride and rifampicin were added to the selective agents chosen using output from the DIACHAR program, because they are considered to enhance the growth of soil streptomycetes at appropriate concentrations (177, 188). None of the remaining strains were able to grow on this medium, apart from *Streptomyces rugersensis* subspecies *castelasensis* NRRL B-1567^T.

A similar approach to the one described above was used to formulate media designed to select isolate members of the genus *Amycolatopsis* from soil samples (168). The absence of an effective selective isolation procedure had limited the biotechnological exploitation of members of this taxon, a potentially rich source of new secondary metabolites, notably antibiotics (77, 166, 197). Three of 20 putatively selective agar media, namely SM1 (Stevenson's basal medium supplemented with D-sorbitol and neomycin sulfate), SM2 (Stevenson's basal medium supplemented with D-melezitose and neomycin sulfate), and SM3 (Gauze's medium no. 2 supplemented with nalidixic acid and novobiocin), supported the growth of all of the representatives of the genus *Amycolatopsis*. These strains formed abundant crusty colonies covered with white aerial hyphae on the SM1 and SM2 agar plates, and leathery colonies covered by white to yellow aerial hyphae on the corresponding SM3 plates. Colonies presumptively assigned to the genus *Amycolatopsis* based on these properties were seen on all three putative selective media after incubation with soil suspensions and incubation at 28°C for 3 weeks. Representatives of strains taken from the selective isolation plates were shown to be related to *Amycolatopsis mediterranea* and *Amycolatopsis orientalis* using 16S rRNA gene sequence data, although many others formed distinct phyletic lines in the *Amycolatopsis* gene tree. Members of two of these novel phyletic branches were subsequently described as new species, that is, *Amycolatopsis australiensis* (167) and *Amycolatopsis regifaucium* (166). Additional putatively novel *Amycolatopsis* species have been isolated from Atacama Desert soil by using the selective isolation and characterization strategy introduced by Tan et al. (168).

It is good practice to evaluate, and if necessary, to modify computer-generated media formulations by altering the combinations of selective agents to increase the recovery of target actinobacteria from environmental samples. Vickers and her colleagues identified streptomycetes growing on a range of objectively defined isolation media with use of a computer-assisted identification procedure (189) and found that it was possible to achieve increased yields of some species, although not with all of the soils. Some species were found in greater or lesser numbers than could be anticipated from information held in the streptomycete database. Such results are not altogether surprising because the surfaces of isolation plates can be sites of intensive competition between the different kinds of bacteria found in mixed inocula. The outcome of such struggles for survival will be influenced not only by the selectivity of isolation media, but also by the mix of species in the inoculum that are able to grow on it. This unpredictability can be turned to good effect when selective pressures allow the growth of novel actinobacteria that are present in environmental samples and of interest to biotechnologists (42).

Huck et al. (79) used stepwise discriminant analysis to highlight the most useful selective substrates that could be used to formulate media able to enhance the recovery of antibiotic-producing actinobacteria from soil. Initially a range of soil actinobacteria and eubacteria were examined for their ability to produce antibacterial antibiotics and for their growth responses to a range of nutritional and physiological tests. Characters that were selective for actinobacteria relative to eubacteria included growth on proline and humic acid as sole sources of both carbon and nitrogen, growth on nitrate as a nitrogen source, and growth at pH 7.7 to 8.0. Similarly, antibiotic- and non-antibiotic-producing actinobacteria were distinguished by the ability of the former to grow on proline and humic acid as sole carbon and nitrogen sources and to grow on asparagine as a nitrogen source, and by their growth in the presence of vitamins. Several simple isolation media that contained selective substrates identified by stepwise discriminant analysis were found to increase the proportion of actinobacteria isolated from soil samples. In addition, a considerable increase was found in the percentage of isolates able to produce antibiotics.

2.4. RECOGNITION OF TARGET AND NOVEL TAXA

Until recently, relatively little effort was made to evaluate the effectiveness of procedures recommended for the isolation of specific fractions of actinobacterial communities present in natural habitats. The failure to establish whether or not target organisms had been isolated not only limited the value of such procedures, but also meant that members of potentially novel taxa went undetected. Consequently, the selection of strains for screening programs owed more to custom and practice than to scientific rigor. This problem was partly historical because the need to characterize and identify representative strains growing on isolation plates had rarely been seen as a relevant task for those involved in search and discovery programs, although it also reflected the dearth of simple and accurate procedures for the classification and identification of commercially significant actinomycetes. This situation is now dramatically different because powerful taxonomic tools are available for these purposes (see chapter 4, this volume).

The assignment of unknown actinobacteria to either formally described or novel taxa is essentially a two-stage process. Reliable criteria are needed to allocate isolates to

genera and families prior to the selection of diagnostic tests for identification of new or established species. Assignment of isolates at or above the generic level can readily be achieved by comparing their 16S rRNA gene sequences with corresponding sequences retrieved from GenBank (for details, see chapter 4, this volume) and by evaluating the resultant data in light of complementary chemotaxonomic and morphological information. Similarly, assignment to established or new species can be realized by using an appropriate combination of phenotypic tests. The effectiveness of such a polyphasic approach is apparent from the steady increase in the number of actinobacterial genera, as witnessed by descriptions of the novel genera *Glacibacter* (90), *Gordonibacter* (198), *Iami* (95), *Haloglycomyces* (50), *Marinoactinospira* (170), *Ferrimicrobium* (87), *Ferrithrix* (87), and *Paraeggerthella* (198).

It is not usually possible to identify colonies growing on isolation plates unless a particular taxon is sought, as in the case of *Amycolatopsis* and *Nocardia* strains growing on SM1 and diagnostic sensitivity agar supplemented with tetracyclines, respectively (139–141, 168), or painstaking examination of individual colonies for key morphological markers is undertaken (74). However, it is often possible to group colonies with similar, distinctive growth forms and pigmentation following random transfer of individual colonies to appropriate media. Streptomycetes, for instance, can be grouped based on aerial spore mass, colony reverse

and diffusible pigment colors on oatmeal agar, and the formation of melanin pigments on peptone-yeast extract-iron agar; isolates taken to represent such taxa key out either to formally described or to novel *Streptomyces* species based on computer-assisted identification (5, 40, 115, 194), Curie-point mass spectrometry (5), and polyphasic taxonomic procedures (115). Excellent congruence has been found between the assignment of alkaliphilic streptomycetes to color and molecular fingerprint groups (4). The identity of representative isolates can also be achieved by using other molecular systematic procedures, notably by the use of taxon-specific 16S rRNA oligonucleotide primers (94, 121, 168).

2.5. INTEGRATED SELECTIVE ISOLATION PROCEDURES

It is apparent from the examples shown in Table 5 that the isolation of specific actinobacterial taxa can be achieved by combining suitable pretreatment methods with appropriate selective media. The selective isolation of some genera in the family *Streptosporangiaceae*, for instance, can be achieved by dry-heat treatment of air-dried soil samples and dilution plate culture with several selective media (62, 63, 126–130, 181). To this end, soil samples are initially dried at room temperature for a week to promote sporulation of the indigenous sporoactinomycetes. The samples

TABLE 5 Integrated procedures for the selective isolation of actinobacterial taxa

Substrate	Pretreatment	Medium ^a	Target	Reference(s)
Beach and dune sand	10 ⁻¹ suspensions heated at 55°C for 6 min	Starch-casein + cycloheximide	Alkaliphilic streptomycetes	4
Composite arid soils	10 ⁻¹ suspensions of air-dried soil heated at 50°C for 6 min	Dextran-histidine-sodium chloride mineral salts agar + nystatin, penicillin G, and rifampicin	<i>S. violaceoruber</i> clade	30
Composite arid soils	Air-dried soil	SM1-SM3 agars + cycloheximide, nystatin, and antibacterial antibiotics	<i>Amycolatopsis</i> spp.	168
Marine sediments	Wet sediment heated at 55°C for 6 min	M2-M5 agars + cycloheximide and rifampicin	<i>Salinispora</i> spp.	112, 120
Mushroom compost	Dilution in air using a sedimentation chamber and Andersen sampler	Half-strength TSA + casein hydrolysate and kanamycin (50°C)	<i>T. chromogena</i>	116
Soil	CaCO ₃ enrichment, rehydration, and centrifugation	HV agar + fradiomycin, kanamycin, nalidixic acid, and trimethoprim	<i>Actinokineospora</i> spp.	142
Soil	Chloramine-T	HV agar	<i>Herbidospora</i> , <i>Microbispora</i> , <i>Microtetraspera</i> , <i>Nonomuraea</i> , and <i>Streptosporangium</i> spp.	57

Soil	Suspension of air-dried soil treated with phenol (1.5%, wt/vol) at 30°C for 10 min	HV agar + chlortetracycline, cycloheximide, and nalidixic acid	<i>Nocardia</i> spp.	200

^aHV agar, humic acid-vitamin agar; TSA, trypticase soy agar.

are then sieved, gently ground in a mortar, and heated in a hot-air oven at 100 to 120°C. The numbers of bacteria and streptomycetes in soil samples are greatly reduced by this process, leading to the enhanced recovery of *Microbispora*, *Microtetrastora*, *Nonomuraea*, and *Streptosporangium* strains on media such as arginine-vitamin, chitin-V, and humic acid-vitamin (HV) agars. These media are usually supplemented with antifungal antibiotics and sometimes with penicillin and polymyxin to further increase their selectivity. Inoculated plates are incubated at 30°C for 4 to 6 weeks and colonies examined for the presence of spore vesicles by using a light microscope fitted with a long working distance objective. Thermophilic species of the genera *Microbispora* and *Streptosporangium* can be recovered by incubating the isolation plates at 50°C for 2 to 3 weeks.

A combination of heat and chemical pretreatments have proved to be highly selective for the isolation of several genera, notably *Microbispora* (59, 65, 66), and for species such as *Actinomadura viridis* (60). The improved method for the selective isolation of *Microbispora* spp. involved making a suspension of heat-pretreated, air-dried soil in phenol (1.5%) and chlorhexidine gluconate (0.03%) prior to dilution and plating onto HV agar supplemented with nalidixic acid. The dry-heat pretreatment regime led to a sharp reduction in the nonfilamentous bacterial community and a significant fall in the number of *Streptomyces* spp. without a reduction in the *Microbispora* component. Indeed, over 90% of colonies growing on isolation plates seeded with treated suspensions of various field soils proved to be *Microbispora* strains. Similarly, heat pretreatments (110 or 120°C) together with the use of benzethonium chloride (0.05 or 0.01%) proved to be highly selective for the isolation of *Dactylosporangium*, *Microtetrastora*, and *Streptosporangium* strains on HV agar supplemented with antibacterial antibiotics (59, 66). Innovative developments from such approaches have proved to be highly selective for the isolation of some members of the family *Streptosporangiaceae* that form motile spores, notably for *Planobispora* and *Planomonospora* (163, 164).

The genus-specific isolation procedures outlined above, while effective, have provided relatively little information on taxonomic diversity of the target organisms growing on isolation plates. This omission has been addressed in more recent studies as representative isolates taken from isolation plates have been characterized by using a combination of genotypic and phenotypic procedures (30, 168). Tan et al. (168) assigned 175 isolates shown to belong to the genus *Amycolatopsis* to 18 multimembered and 20 single-membered color groups based on their ability to form pigments on Bennett's agar supplemented with mannitol and soybean flour. Representatives of the color groups formed distinct phyletic lines in the *Amycolatopsis* gene tree, showing that the genus *Amycolatopsis* is grossly underspeciated and, hence, forms an attractive target for search and discovery programs.

2.6. CONCLUDING REMARKS

The isolation and characterization of specific actinobacterial taxa are procedures of vital importance in actinobacterial biology, the more so in light of culture-independent surveys that show that the taxonomic diversity of actinobacteria is very much greater than previously recognized (36, 159, 160, 202). It is especially important to design effective procedures for the selective isolation of commercially significant actinobacterial taxa to obtain high-quality biological material for biotechnological purposes (18, 20).

Improved selective isolation and characterization procedures show that actinobacterial taxa once considered rare are both common and widely distributed in natural habitats, as exemplified by studies on acidophilic actinomycetes (39, 91, 185), alkaliphilic streptomycetes (4, 9), and motile actinomycetes (56, 67, 163, 164). Reliable procedures are available for the selective isolation of members of specific taxa, such as the genera *Actinomadura* (7, 172), *Actinoplanes* (62, 67), *Amycolatopsis* (168), *Gordonia* (45), *Nocardia* (111, 139, 141), and *Rhodococcus* (152) and for individual species like *A. viridis* (60), *Catenuloplanes japonicus* (56), *S. violaceoruber* (30), and *Thermomonospora chromogena* (116). The availability of rapid and reliable taxonomic tools, such as the use of genus-specific probes as selective amplification primers, offers a practical way of detecting target actinobacteria taken from isolation plates (121, 168).

The application of reliable selective isolation and characterization procedures to surveys of the cultivable actinobacteria in poorly studied and neglected habitats is yielding a steady flow of novel taxa (19, 74, 137). In this context the marine environment is proving to be an especially rich source of novel taxa, members of which have the capacity to produce new anticancer and antimicrobial products, such as salinosporamide A from *S. tropica* (32) and abyssomicin C from "*V. maris*" (12, 151). Integrated selective isolation strategies can be expected to yield additional novel, commercially significant taxa, especially if neglected but effective physicochemical procedures like the dispersion and differential centrifugation technique (75) are used. Other approaches that require care and patience, such as the use of long incubation times (37) and dilution-to-extinction culturing (161), can also be expected to yield dividends.

It can be argued that conventional manipulation of standard media components is only likely to bring incremental success (see chapter 1, this volume). This may well be so; but, nevertheless, more certainly does not mean less as witnessed by the addition of the genera *Salinispora* and *Verrucosipora* to the family *Micromonosporaceae* (112, 113). Indeed, there is a compelling need to develop integrated procedures for the selective isolation of a host of well-known taxa of potential biotechnological value, not least the genera *Actinopolyspora*, *Herbidispora*, *Lechevalieria*, *Pseudonocardia*, and *Saccharopolyspora*. The detection of members of such taxa in natural habitats by the use of culture-independent methods can be used to guide the development and application of selective isolation strategies along the lines used by Maldonado et al. (113).

There is, however, an even greater need to focus on the selective isolation of understudied actinobacterial taxa, such as members of the families *Conexibacteriaceae*, *Coriobacteriaceae*, and *Rubrobacteriaceae*, which form deep branches in the 16S rRNA actinobacterial gene tree (201). It seems likely that the successful isolation of such taxa will require a profound understanding of the physicochemical-biological features of their habitats to unravel their ecophysiology and thereby help inform isolation strategies. The impressive ecophysiological studies performed by Seviour and his colleagues on actinobacteria in activated sludge systems is a model of what needs to be done in this respect (156). Other innovative approaches, such as the use of in situ procedures, are also relevant in this respect (see chapter 1, this volume).

It can be anticipated that the pace of technological change, notably in biosystematics, genomics, and metagenomics, will have a profound impact on approaches to

selective isolation, characterization, and selection of strains for future screening programs. These aspects are beyond the scope of the present article, although they are touched upon in some recent broadly based reviews on aspects of search and discovery of novel natural products (18, 20).

Taxonomic Characterization of Prokaryotic Microorganisms

GIOVANNA E. FELIS, SANDRA TORRIANI,
JOHAN E. T. VAN HYLCKAMA Vlieg, AND AHARON OREN

3

3.1. INTRODUCTION

Prokaryote microorganisms constitute a major part of the genetic diversity of our planet and they play a pivotal role in the biochemical processes of the biosphere. In addition, they find application in a broad array of industrial and biotechnological applications (18, 108, 156). In the search for new industrial strains and catalysts, prospecting of natural diversity has greatly intensified over the last decades. Improved cultivation techniques and newly emerging (meta)genomic tools have provided access to sources of microbial diversity that were previously uncovered.

The interest of biotechnologists in what microorganisms can do is not always accompanied by a serious investigation on who they are. Identification of the isolates is of primary importance, not only for the exchange of scientific knowledge, but also in an applied context, because names are crucial for regulations in biotechnology and biosafety. A survey of species names associated with published genome sequences has, in several cases, revealed incorrect, out-of-date, or incomplete strain names (44). This suggests that reductionism brought about by molecular biology (159) and the interests of single research groups could significantly affect the coherence of names, with negative consequences on accessibility of microbiological data.

Taxonomy provides the framework for correct identification of prokaryotic strains. The aim of this chapter is to present microbiologists in biotechnology and molecular biology with the basic conceptual framework and the currently accepted procedures for characterization and consistent naming of newly isolated prokaryotic strains.

3.2. THE CONCEPTS OF PROKARYOTE TAXONOMY

3.2.1. What Is Taxonomy

Taxonomy is the systematic study of biological diversity, aimed at arranging organisms in an ordered scheme. The scheme is hierarchical, and attempts to reflect the evolutionary relationships among organisms. Classification, identification, and nomenclature are three separate, but interrelated subdisciplines of taxonomy. Classification is the process of clustering organisms into taxonomic groups (taxa) on the basis of similarities or relationships. Nomenclature is the assignment of names to taxonomic groups

according to internationally accepted rules (for prokaryotes, the International Code of Nomenclature of Bacteria) (84). These rules are very clear to avoid misunderstandings. Finally, identification is the process of determining whether a new isolate belongs to one of the established and named taxa (80, 136). An isolate that cannot be assigned to a known taxon should be described and classified as a new taxon (species, genus, etc.). Therefore, classification precedes identification, since it would be impossible to assign new isolates to a taxon without prior arrangements of individuals into groups (113, 126).

Prokaryote taxonomy is a highly dynamic science. There is no official classification of prokaryotes, and classification schemes change in accordance with the development of new techniques and approaches. The sections below present an overview of the current concepts for characterization and identification of isolates and their practical application.

3.2.2. The Species Concept for Prokaryotes

The basic unit of classification and nomenclature of all living organisms, prokaryotes included, is the species. Species are grouped in genera, genera in families, families in orders, orders in classes, and classes in phyla or divisions. Species are categories based on the observations of recurrent patterns within the diversity of living organisms. Those patterns are different for plants, animals, and microorganisms, and arise in different taxonomic schemes, because, while all taxonomies are based on the category species, no universal species concept exists, and prokaryote systematics still lacks a firm theoretical basis (120).

The species concept for prokaryotes is a long-debated issue; its in-depth discussion is outside the scope of this chapter, but it has been discussed and reviewed in many publications (e.g., 1, 2, 15, 25, 26, 52, 68, 82, 121, 135, 153). The most accepted concept, considered to be pragmatic and useful for species definition, is the so-called phylogenetic species concept: a monophyletic and genomically coherent cluster of individual organisms (strains) that show a high degree of overall similarity in many independent characteristics, and is diagnosable by one or more discriminative phenotypic properties (121). It is therefore recommended that a distinct genospecies (i.e., a species discernible only by nucleic acid comparisons) that cannot be differentiated from another genospecies on the basis of any known phenotypic

property should not be named as a new species until some phenotypic differentiating property is found.

The development of a natural species concept is more difficult for prokaryotes than for higher organisms, where the biological species concept proposed by Ernst Mayr (99) is widely accepted. Periodic technological improvements in molecular biology and the availability of new types of data (e.g., genomic data) progressively allow a deeper understanding of prokaryote population biology, and have affected the definition of a natural species concept for prokaryotes. They allow the delineation of bacterial diversity at higher resolution, but these types of data and analysis have not been completely elaborated and incorporated in the taxonomic framework to devise a novel classification scheme that could be applied to all microorganisms (120).

Based on the experience of the past 25 years a pragmatic definition of the prokaryote species has emerged, based on the recommendations published in 1987 by a committee of experts (155) and updated a few years ago (133). The species concept is based on a “polyphasic” approach, which includes description of diagnostic phenotypic features combined with genomic properties. Many of the phenotypic and chemotaxonomic characters used individually as diagnostic properties are insufficient to delineate the species, but together they provide sufficient descriptive information to allow the definition of a species. The most widely used genomic property included in descriptions of new species, often (and not always rightfully) used to delineate species, is the sequence of the small-subunit rRNA gene (16S rRNA for prokaryotes), and many classification schemes are based on this.

3.2.3. The Definition of Species and of Higher Taxonomic Ranks

The gold-standard technique for species delineation is total DNA relatedness: a species is conventionally defined as a group of strains sharing at least 70% total genome DNA-DNA similarity and having less than $5^{\circ}\text{C } \Delta T_m$ (the difference in the melting temperature between the homologous and the heterologous hybrids formed under standard conditions, indicating the thermal stability of DNA duplexes) (132, 134). These values should not be taken as absolute limits for circumscribing the species; the concept allows more relaxed DNA-DNA similarity frontiers, and an internal genomic heterogeneity is permitted (121). The delineation value of 70%, as introduced around 1987, is artificial, but has proven satisfactory in most cases. DNA relatedness values between 30 and 70% indicate a moderate degree of relationship, often parallel to the extent of the genus. At the level of genera or higher taxa, the resolving power of DNA-DNA similarity assays is limited. There are cases of species and even genera that share more than 70% DNA-DNA similarity. For example, the enteric bacterial genera *Escherichia* and *Shigella* share more than 85% similarity. However, for pragmatic reasons, the separation into two genera is maintained. Despite the great advances made in recent years in genomic analysis and the development of other modern approaches to characterization of prokaryote isolates, DNA-DNA hybridization combined with a thorough phenotypic characterization is still the best criterion for species delineation (133).

Compared with the species concept in the plant and the animal world, the bacterial species concept is exceptionally broad. When applying the “70% DNA-DNA similarity” criterion to delineate species of higher eukaryotes, the number of recognized species would decrease dramatically, because,

for example, humans would belong to the same species as chimpanzees (98.4% DNA-DNA relatedness), gorillas (97.7%), orangutans (96.5%), and even lemurs (78%).

The technique to determine DNA-DNA relatedness is laborious and can be used only to define relatedness between pairs of strains. Therefore the first step in characterization is usually determination of the almost complete 16S rRNA gene sequence (at least 1,300 nucleotides, sequenced on both strands after cloning, to guarantee sequence reliability and no influence of sequence heterogeneity among different operons). Empirical correlations have been observed between DNA-DNA hybridization values and 16S rRNA gene sequence similarity; as a general indication, if two strains share less than 97–98% 16S rRNA gene sequence identity, they share less than 70% DNA-DNA relatedness, and they thus should belong to different species (2, 63, 121). There is good congruence between DNA-DNA relatedness and genome sequence-derived parameters, such as the average nucleotide identity of common genes and the percentage of conserved DNA (57). Many species are further divided into subspecies, which are based on the observation of minor but consistent phenotypic variations within the species or on genetically determined clusters of strains within the species (136), although phenotypic differences are usually considered more reliable (149). Other infraspecific clusters can be recognized for practical reasons, such as pathovar, phagovar, etc., but those have no standing in official nomenclature. Given that there is no proper concept of the prokaryotic species, the guidelines for the delineation of higher taxa (genera, families, orders, classes, etc.) are even less clear. The genus may be defined as “a collection of species with many characters in common,” but how many and what kind of characters should be in common for species to be classified in a single genus is largely a matter of personal judgment (131).

There is a general consensus that the classification of species into higher taxonomic levels should reflect phylogenetic relationships. Sequence analysis of small-subunit rRNA (16S rRNA in prokaryotes) has provided much insight in the phylogenetic relationships among microorganisms (87, 88, 157, 158). A DNA-DNA similarity level of less than 70% (the operative delineation of a species), in general, corresponds to less than 97% 16S rRNA sequence identity. In general, species classified in a single genus share at least 93 to 95% identity in their 16S rRNA gene sequence. However, at the species level, the 16S rRNA-based methods lack the necessary resolving power, and in these instances DNA-DNA reassociation experiments are still required.

3.2.4. Type Strains and Culture Collections of Prokaryotes

The terms “strain” and “isolate” refer to the descendants of a single isolation in pure culture. They are usually made up of a succession of cultures derived from an initial single colony. Identification of unknown isolates should use type strains of species with validly published names for comparison.

For each species (or subspecies) a type strain has been designated that is the name bearer of that species and is the reference specimen for the name. The type strain, which is permanently linked to the species name, represents the connecting point between the existing biodiversity and the conventional, artificial scheme of classification. Similarly to the type strain for a species, type genera are indicated for families and for orders, and type orders are indicated for classes.

When describing a novel species, a type strain has to be indicated and included in the subsequent taxonomic studies. One of the conditions of valid publication of a name of a new species is that the strain must be deposited by the authors in at least two public culture collections located in different countries (e.g., the American Type Culture Collection [ATCC], the Deutsche Sammlung von Mikroorganismen und Zellkulturen [DSMZ], the Japan Collection of Microorganisms [JCM], etc.) so that subcultures will be available to any interested scientist for further study. A comprehensive list of such culture collections is found in www.bacterio.cict.fr/collections.html. Culture collections generally preserve bacterial strains either in dry, lyophilized form, to be revived by wetting and suspension in suitable growth medium, or frozen in liquid nitrogen. These culture collections ensure the availability of type strains for scientific studies without restrictions (144).

3.2.5. How Many Species Have Been Described?

The number of species of prokaryotes with names validly published under the rules of the Bacteriological Code is surprisingly small compared with the numbers of plant and animal species that have been described, which are in the order of hundreds of thousands or even millions. The number of validly published names of different prokaryote species on November 3, 2009 was approximately 8,226, classified in 1,732 genera, 253 families, 116 orders, and 70 classes (see <http://www.bacterio.cict.fr/number.html>). This number is updated monthly after the publication of each new issue of the *International Journal of Systematic and Evolutionary Microbiology*, the only journal in which names of new prokaryote taxa can be validly published (see section 3.3.2 below).

Experimental data based mainly on sequencing of 16S rRNA genes retrieved directly from the natural environment without prior cultivation suggest existence of at least two orders of magnitude more species. Today it is generally accepted that less than 1% of the prokaryote species that inhabit our planet have been named (37, 108).

Description of a new species should ideally be based on a comparative study of a large number of independent isolates to define the degree of variation of certain properties within the boundaries of the species. In practice, however, over 90% of the new species descriptions published in recent years have been based on single isolates. Unfortunately, such species descriptions can lead to improper phenotypic circumscription of taxa, making the identification of new isolates as members of a taxon problematic. From time to time formal proposals have been made to the International Committee for Systematics of Prokaryotes/International Committee for Systematic Bacteriology (ICSP; see section 3.3.1) to define a minimum number of isolates necessary for description of a new species (21, 43). Such proposals have never been formally approved or fully implemented. If they had, the names of many prokaryotes described as new species in recent years could not have been validly published because it had not been feasible to obtain more isolates.

3.2.6. Bacteria and Archaea—the Two Domains of Prokaryotes

The Linnaean hierarchical scheme has been applied to the bacterial world from the beginning of classification attempts, but only in the past 30 years has the availability of sequencing techniques for nucleic acids led to the establishment of an evolutionary framework for prokaryotes (159). A comprehensive picture of the phylogenetic diversity of prokaryotic microorganisms has recently been presented (161).

Phylogenetic analysis based on rRNAs has been the first successfully applied method to investigate evolutionary relationships among prokaryotic organisms (157). This has led to the description of two domains or kingdoms for the prokaryotes (160). The Archaea (formerly known as Archaeobacteria) and the Bacteria (formerly called Eubacteria), despite both being prokaryotes, differ in many characteristics such as the structure of the cell wall, the nature of the membrane phospholipids, the properties of the protein-synthesizing system, sensitivity to different antibiotics, RNA metabolism, etc. It is intriguing to observe that several components of archaeal informational processes (e.g., primases, helicases, and polymerases) are more similar to eukaryotic than to their bacterial homologues, if such homologues exist (60). On the other hand, Archaea and Bacteria resemble each other in size and organization of chromosomes, polycistronic transcription, and presence of Shine-Dalgarno sequences for gene transcription. “To sum up, Archaea look like organisms that use eukaryotic-like proteins in a bacterial like context” (60).

The recognition of Archaea as a third domain of life has been questioned (62), with the suggestion that both the Archaea and the gram-positive bacteria should be described as monoderm prokaryotes (surrounded by a single membrane), while all true gram-negative bacteria, containing both an inner cytoplasmic membrane and an outer membrane, should be classified as diderm prokaryotes. However, genomic data have confirmed the coherence of the three domains as distinct groups (60).

Archaea and Bacteria are widespread in different environments. Archaea are not uniquely extremophiles as originally thought, but occur in the open sea, in soil, and in other “conventional” environments as well (60).

For matters concerning nomenclature, Archaea and Bacteria are both prokaryotes and their nomenclature follows the same rules fixed in the International Code of Nomenclature of Prokaryotes. The conceptual framework outlined below for the taxonomic characterization of prokaryotes applies to both groups. However, the types of phenotypic tests performed during the taxonomic characterization of isolates may differ, because, for example, determination of the chemical structure of peptidoglycan is relevant for Bacteria only. Likewise, due to the different types of lipids present in the cytoplasmic membranes, different tests should be applied in the characterization of the lipids of Bacteria and of Archaea.

3.3. PROKARYOTE NOMENCLATURE

Nomenclature is the assignment of names to the taxonomic groups defined during classification. The rules of nomenclature of prokaryotes are laid down in the International Code of Nomenclature of Bacteria (the Bacteriological Code) (see section 3.3.2).

An entirely new start was made in prokaryote nomenclature in 1980 with the publication of the “Approved Lists of Bacterial Names” (127). Rule 24a of the Bacteriological Code (see below) states: “Priority of publication dates from 1 January 1980. On that date all names published prior to 1 January 1980 and included in the Approved Lists of Bacterial Names of the ICSB are treated for all nomenclatural purposes as though they had been validly published for the first time on that date.” With the publication of the Approved Lists, which encompassed approximately 2,500 species names (127, 128), all earlier published names lost their validity. Central registration and indexing of new names

validly published after January 1, 1980, according to the rules of the International Code of Nomenclature of Prokaryotes (84; see below) ensured that the number of validly named species, genera, families, and orders of prokaryotes is known at any time (130).

The nomenclature of prokaryotes is subject to changes, and there are many examples of species that have been renamed, moved to other existing genera, or reclassified in newly established genera in accordance with new insights. For example, when based on an increased understanding of the phylogenetic relationships within the aerobic gram-positive endospore-forming bacteria it became desirable to split the genus *Bacillus* into a number of genera, the species formerly known as *Bacillus polymyxa* and *Bacillus stearothermophilus* were renamed *Paenibacillus polymyxa* and *Geobacillus stearothermophilus*, respectively. From the moment these new names were validly published, they obtained status in the nomenclature of prokaryotes.

Practical guidelines for the naming of new taxa of prokaryotes have been given by Trüper (147, 148).

3.3.1. The International Committee for Systematics of Prokaryotes

The body that oversees the nomenclature of prokaryotes is the International Committee for Systematics of Prokaryotes (ICSP) (before 2000, the International Committee of Systematic Bacteriology). This committee is a constituent part of the International Union of Microbiological Societies (IUMS). The committee meets once every 3 years to discuss nomenclatural problems that have arisen in different groups of prokaryotes and to propose changes and amendments to the rules of the Bacteriological Code.

The ICSP has established several subcommittees. One important subcommittee is the Judicial Commission, which deals with problematic cases in bacterial nomenclature and renders judicial decisions in instances of controversy about the validity of a name, identity of type strains, and cases of emerging problems with the interpretation of the rules of the Bacteriological Code. It may propose amendments to the Code and consider exceptions that may be needed to certain rules. Specific subcommittees exist that deal with the systematics and nomenclature of specific groups: “Genera *Agrobacterium* and *Rhizobium*,” “*Bacillus* and related organisms,” “*Bifidobacterium*, *Lactobacillus* and related organisms,” “*Campylobacter* and related bacteria,” “*Clostridia* and *Clostridium*-like organisms,” “*Flavobacterium*- and *Cytophaga*-like bacteria,” “Gram-negative anaerobic rods,” “Family *Halobacteriaceae*,” “Family *Halomonadaceae*,” “Genus *Leptospira*,” “Genus *Listeria*,” “Methanogens,” “Suborder *Micrococineae*,” “Families *Micromonosporaceae*, *Streptosporangiaceae* and *Thermomonosporaceae*,” “Class *Mollicutes*,” “Genus *Mycobacterium*,” “*Nocardia* and related organisms,” “Family *Pasteurellaceae*,” “Photosynthetic prokaryotes,” “*Pseudomonas*, *Xanthomonas* and related organisms,” “Suborder *Pseudonocardineae*,” “Staphylococci and streptococci,” “Family *Streptomycetaceae*,” and “Family *Vibrionaceae*.”

The minutes of the meetings of the ICSP, the Judicial Commission, and the taxonomic subcommittees are published in the *International Journal of Systematic and Evolutionary Microbiology*. Information on the ICSP, its current officers, and its subcommittees can be found at <http://www.the-icsp.org>.

3.3.2. The International Code of Nomenclature of Prokaryotes

The first Code of Nomenclature for prokaryotes was published in 1948 as “The International Code of Nomenclature

of Bacteria and Viruses.” The current version of the International Code of Bacterial Nomenclature (the Bacteriological Code) was approved at the Ninth International Congress of Microbiology, Moscow, 1966, revised in 1990 (84), and amended at the meetings of the ICSP (see section 3.3.1). The Bacteriological Code presents the formal framework according to which prokaryotes are named and according to which existing names can be changed or rejected. It covers the rules for the naming of species (and subspecies), genera, families, orders, and classes of prokaryotes. No provisions are made by the Code for the naming of the higher taxa: phylum and kingdom.

The Code contains general considerations, principles, rules, and recommendations referring to ranking and naming of taxa, nomenclatural types and their designation, priority and publication of names, citation of authors and names, changes in names of taxa as a result of transference, union, or change in rank, rules about illegitimate names and epithets, replacement, rejection, and conservation of names and epithets. When taxonomic re-evaluations are performed and changes in names occur, the existence of rules and the availability of lists of names allow the association of new name characteristics linked with older ones, avoiding loss of information. There are also appendices that clarify different aspects of nomenclature. An online version of the Code is available at <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=icnb.TOC&depth=2>.

The Code was renamed in 2000 as the International Code of Nomenclature of Prokaryotes, and the current version will soon be published in book form as well as electronically.

It must be stressed that prokaryote nomenclature is thus governed by internationally approved rules and regulations, but that there is no “official classification of prokaryotes.” General Consideration 4 of the Code states: “Rules of nomenclature do not govern the delimitation of taxa nor determine their relations. The rules are primarily for assessing the correctness of the names applied to defined taxa; they also prescribe the procedures for creating and proposing new names.” The Code deals with all prokaryotes: the nomenclatures of the Archaea and the Bacteria are governed by the same rules.

3.3.3. Effective and Valid Publication of Names of Prokaryotes

Since the publication of the Approved Lists (127, 128), the only framework in which new names of taxa can be published to obtain standing in the nomenclature of prokaryotes (“valid publication” according to Rules 27 to 32 of the Code) is the *International Journal of Systematic Bacteriology* (before 2000), now the *International Journal of Systematic and Evolutionary Microbiology*.

One way to achieve valid publication of the new name of species, genera, etc. is by publication of the description of the new taxa in that journal, while meeting the different criteria as determined by the Code. For new species a nomenclatural type has to be designated, which is the name bearer of that species and is the reference specimen for the name. As already mentioned (see section 3.2.3), when a new species is described, the type strain must be made available to the scientific community through deposit in at least two publicly accessible culture collections. For an example of the desired format of a description of a new species, see reference 72.

Descriptions of new taxa and publication of new names are also possible in other journals. This is known as “effective

publication" of the names (Rule 25 of the Code). Names thus published can only obtain standing in the nomenclature when they are included in the "Validation Lists" (lists of new names and new combinations previously effectively, but not validly, published) that appear periodically in the *International Journal of Systematic and Evolutionary Microbiology*. Authors of papers in which names have been effectively published and who wish to validate the names must submit copies of the original publication, together with proof that all criteria for valid publication have been met, such as deposition of the type strain in two culture collections, availability of the type strain without restrictions to the scientific community, etc. The request for validation of the name is then handled by one of the associate editors of the journal together with the list editor. The name becomes validly published when it is featured in a Validation List (145).

The *International Journal of Systematic and Evolutionary Microbiology* also publishes articles that address taxonomy, phylogeny, and evolution of prokaryotes (as well as of fungi and other groups of eukaryotic protists). In addition, it contains the minutes of the meetings of the ICSP, its Judicial Commission, and its taxonomic subcommittees.

3.4. CHARACTERIZATION OF PROKARYOTES—CURRENT PRACTICE AND PROCEDURES

Characterization of isolates of prokaryotes and description of new species is based on a "polyphasic approach," because it uses a combination of a variety of different genotypic and phenotypic properties (54, 151). The more properties are included in the descriptions, the more robust and stable the resulting classification will be. Different properties have different resolving power; some are species specific, while others are valuable to discriminate genera, families, and orders. The properties tested generally include morphological characters (cell shape and size, the Gram reaction, cell inclusions, presence and nature of the surface layers, including extracellular capsules), information on motility (presence of flagella, their number and the way they are inserted into the cell, gliding movement), the mode of nutrition (assimilatory metabolism) and energy generation (dissimilatory metabolism), the cells' relationship to molecular oxygen, temperature, pH, tolerance toward and requirement for salt, and many others. Miniaturized tests such as the BIOLOG® and the API system are often very useful. Additional tests of value toward the identification of the isolate may be its sensitivity toward different antibiotics, as well as immunological properties. Genotypic information includes 16S rRNA gene sequence information, which is a very valuable tool for rapidly placing any isolate within the current classification scheme, at least down to the family and genus level. For final identification of the species, DNA-DNA hybridization tests are the ultimate tool to decide whether two isolates should be classified in the same species. More specific tests such as serotyping or phage typing may be necessary for certain groups of microorganisms to obtain a reliable identification.

For several groups of prokaryotes, the taxonomic subcommittees of the ICSP have established recommended minimal standards for the description of new isolates. Groups of prokaryotes for which such minimal standards have been published are the methanogenic Archaea (11), the class *Mollicutes* (16), root- and stem-nodulating bacteria (59), anoxygenic phototrophic bacteria (67), the order

Halobacteriales (109), the families *Halomonadaceae* (3), *Flavobacteriaceae* (7), *Pasteurellaceae* (21), and *Campylobacteraceae* (150), and the genera *Moraxella* and *Acinetobacter* (12), *Brucella* (30), *Helicobacter* (33), *Staphylococcus* (50), and *Mycobacterium* (85).

A prerequisite for characterization and identification of prokaryotes is the isolation in pure culture. This means that appropriate growth media have to be set up and balanced in terms of the physical and chemical parameters such as macro- and microelements to be supplied, other growth factors (e.g., vitamins), pH, osmolarity, and temperature chosen for isolation and propagation. An in-depth discussion on the procedures for isolation of microorganisms was given by Overmann (110).

When dealing with multiple isolates from the same niche, a dereplication step is convenient to roughly determine the diversity of the sample and focus on representative members of the collection, to save time and effort. On the other hand, the more strains included in a study, the better the circumscription. Considering that a massive isolation procedure for the selection of strains potentially interesting for an industrial application could result in the isolation of hundreds of isolates, the first thing to do is to assess how many different strains are present, before their identity can be ascertained (Fig. 1). Many techniques could be used successfully for the discrimination of strains below species level: genetic fingerprinting methods (e.g., pulsed-field gel electrophoresis, restriction fragment length polymorphism, randomly amplified polymorphic DNA, and ribotyping) or phenotype-based fingerprints (such as sodium dodecyl sulfate-polyacrylamide gel electrophoresis of proteins). Some of those techniques are extremely sensitive, but they are also time- and labor-consuming; therefore, the adoption of automated techniques is really helpful. Clearly, techniques useful for dereplication also have taxonomic value, because of the discrimination they can provide; therefore short protocols are reported in the sections below. Typically, techniques chosen for dereplication provide the scientist with a complex pattern of bands (a fingerprint) characteristic of each isolate. Several software packages are available, either commercial or freely available (see below), for primary data analysis and clustering isolates according to similarity.

Description of a species should ideally be based on a comparative study of a large number of isolates to define also the degree of variation of certain properties within the defined boundaries of the species. In practice, however, most new species descriptions published in recent years have been based on the study of single isolates.

3.4.1. Genotypic Characterization

Genotype-based methods used in the characterization of prokaryotes include the sequencing of single genes (16S rRNA, 23S rRNA, the intergenic transcribed spacer [ITS] between these two genes, different housekeeping genes) and molecular fingerprinting techniques, as well as methods that provide information on the entire genome: the determination of the mol% guanine + cytosine, DNA-DNA hybridization to compare genomes, and in some cases even complete genome sequencing. Many prokaryotes contain plasmids, and these plasmids often contain genes of interest for biotechnological purposes. Therefore, characterization and analysis of plasmid DNA may provide important information.

Different DNA isolation procedures exist, aimed at obtaining as pure and undegraded DNA as possible. The

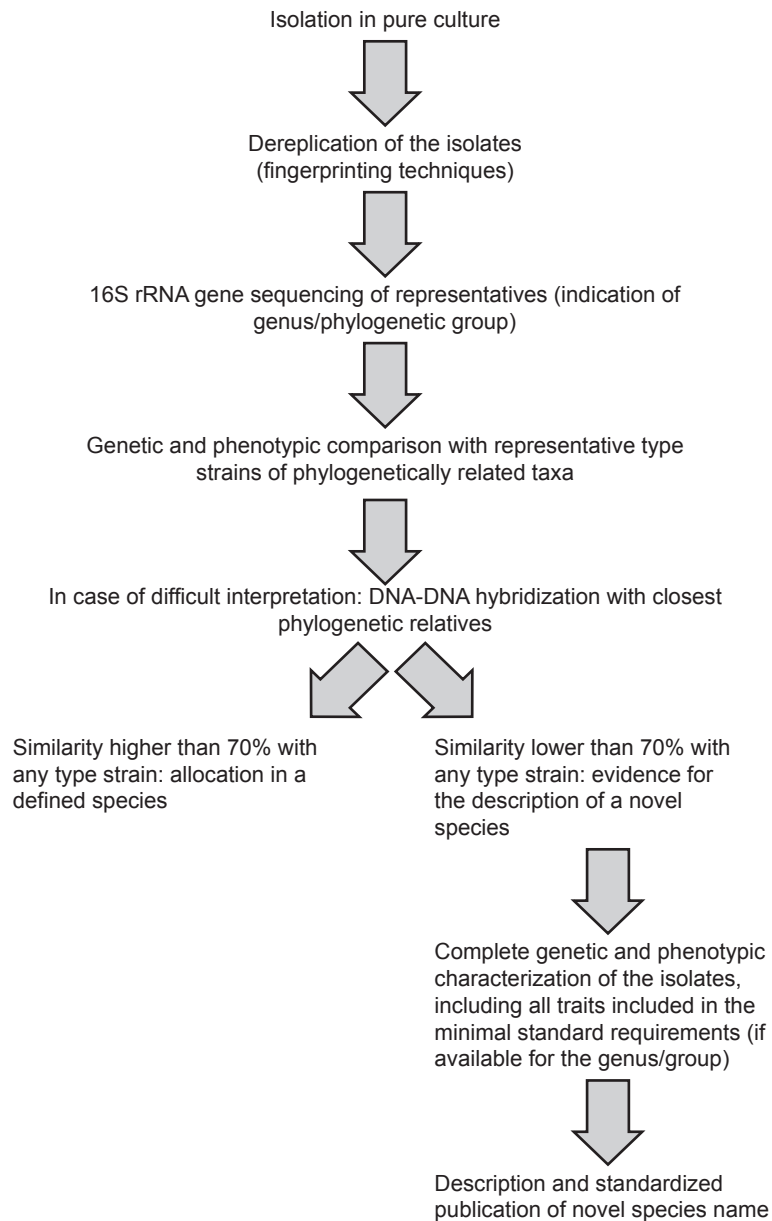

FIGURE 1 Flow sheet showing the different stages in the taxonomic characterization of new isolates of prokaryotes.

protocol proposed by Marmur (96) is still widely used in different modifications: it involves lysis of the cells by enzymatic and/or mechanical means, inactivation of nucleases, separation of the nucleic acids from proteins, and use of organic solvents such as chloroform and isoamyl alcohol to separate the DNA from other cellular components. Precipitation with ethanol or isopropyl alcohol concludes the isolation procedure. Commercial kits are available for general-purpose DNA extractions that enable efficient isolation of DNA for PCR and other applications.

3.4.1.1. rRNA-Based Methods

For sequencing the 16S rRNA gene (83), universal primers have been designed that amplify the gene in all

known prokaryotes, Archaea as well as Bacteria (4) and are reported in Table 1. In cases where the approximate phylogenetic affiliation of the organism is known, more specific primers aimed at the taxonomic group can be used. Cloning of amplicons before sequencing should be performed, because different ribosomal operons could be characterized by sequence heterogeneity, and therefore sequencing of mixed populations could generate chimeras and mistakes. There are many cases in which one organism harbors multiple copies of the 16S rRNA gene that may differ in sequence by approximately 5% (105).

After almost complete sequences (>1,400 nucleotides) have been obtained, comparison with database information

allows a tentative identification of the strain. Tools available for sequence comparison include the classical Blast in GenBank, the RDP-II database (91), the EzTaxon tool (23), and the most recent updates of ARB (89) and SILVA (114). This first comparison in general allows identification of a genus to which the strain may belong. Then, a refined phylogenetic analysis can be performed that includes all related species. The data set should also include sequences from a few unrelated species to obtain a more complete picture and to better evaluate the branching pattern (134). Sequences have to be aligned before the phylogenetic tree can be reconstructed and statistically evaluated (5). Careful data selection and optimal alignment of the sequences, including removal of ambiguous positions, are prerequisites for reliable phylogenetic conclusions. Many programs are available for alignment (142, 143), and different approaches can be applied for phylogenetic analysis, such as distance, maximum parsimony, and maximum likelihood methods of phylogeny (88); finally, verification of the statistical support of branching patterns can be obtained by bootstrap analysis (46). Available software for phylogenetic analysis include PHYLIP (47), MEGA (81, 141), and ARB software (89). Different programs allow tree inference with different methods and models (e.g., references 45, 46, 70, 73, and 123).

If the isolate under study shares less than 97 to 98% sequence identity with any known species, it might well represent a novel species. However, 16S rRNA sequence identity is not sufficient to guarantee species identity (49). Where 16S rRNA gene sequence values are above 97%, other methods such as DNA-DNA hybridization or sequence comparison of genes with a greater resolution should be used to test the affiliation of the isolate with a known species. If the sequence under study shows very low similarity with related taxa, it might represent a novel genus. Sequence variation between members of a genus may range from small (for instance, above 97% for *Micrococcus*), to moderate (92% for *Streptococcus*), to significant (approximately 79% for *Spirochaeta*) (134).

The 16S rRNA gene is most widely used as a phylogenetic marker for the prokaryotes. In some cases, the 23S rRNA gene of the large ribosome subunit is included in phylogenetic analyses as well. In many taxonomic studies the ITS region separating the 16S and the 23S rRNA genes is used, because this region is much more variable than the rRNA molecules themselves, and therefore comparison of ITS sequences can detect differences at a much higher resolution than 16S rRNA sequence comparisons.

3.4.1.2. Other Genes as Taxonomic Markers

Multilocus sequence typing (MLST) or multilocus sequence analysis (MLSA) are powerful tools to obtain taxonomic information on the species level and the interspecies variability (52, 92). The method was first developed to characterize bacterial pathogens. Sequences are determined of an internal portion (usually 450 to 700 bp) of a small number (most often seven) of housekeeping genes. Examples of genes used for this purpose are GMP synthase, methionine aminopeptidase, pyruvate formate lyase, inorganic pyrophosphatase, pyruvate kinase, RNA polymerase beta subunit, superoxide dismutase, elongation factor Tu, *recA*, and ATPase subunit genes (9, 38). Comparisons of protein sequence-based phylogenies have by and large confirmed the general structure of the 16S rRNA gene phylogenetic tree. There is a growing database available of gene sequences relevant to multilocus sequence analysis (see www.eMLSA.net). For each housekeeping gene, different sequences are assigned as distinct alleles. A dendrogram generated from the matrix of pairwise differences between the allelic profiles will display the relatedness of isolates (34, 39).

3.4.1.3. Molecular Fingerprinting Techniques

When large numbers of strains are to be compared, individual sequencing of the 16S rRNA genes of all isolates is often not feasible. Molecular fingerprinting techniques can then be used. Such methods are also useful for typing at the infraspecific level, i.e., to subdivide species into more homogeneous groups that could represent subspecies. These techniques, which include DNA- and protein-based methods, can be used also for dereplication of isolates. The choice of the most suitable technique depends on the taxon analyzed; therefore, it is difficult to give general information on the rationale to be applied for selection. Most fingerprinting techniques use PCR-based methods (151, 152). The methods differ according to the primers used, e.g., oligonucleotides of approximately 20 bases in arbitrarily primed PCR, or oligonucleotides of approximately 10 bases in randomly amplified polymorphic DNA assays (RAPD-PCR). Primers complementary to repetitive elements dispersed throughout the genomes or to tRNA gene regions could result in the production of patterns of amplification useful for discrimination (BOX- and ERIC-PCR) (151).

The discriminatory power of given primer sequences depends on the taxon investigated, e.g., arbitrary primers with a given GC content will give different results on the basis of the genome GC content of the microorganism under study, because the probability of finding a certain sequence in the genome is higher if the GC content of the genome and the primer are similar.

PCR-based DNA-typing methods can be combined with restriction enzyme analysis in the so-called amplified-rDNA restriction analysis method (ARDRA) (151): 16S or 23S rRNA genes can be amplified and then digested with restriction enzymes and compared. The results are often species specific. AFLP is also a combination of PCR and restriction enzyme methodologies: its basic principle is a restriction analysis followed by PCR-mediated amplification to select particular DNA fragments from the pool of restriction fragments. PCR-restriction fragment length polymorphism–single-strand conformational polymorphism (PCR-RFLP-SSCP; PRS) was also used successfully to analyze large numbers of strains, and it shows good congruence with chemometric fingerprinting (13, 14).

The ribotyping method consists of a restriction enzyme digestion of genomic DNA, which is afterward transferred

to a membrane and hybridized with a labeled probe targeting rRNA. This DNA-typing technique has also been reported for dereplication (118).

Pulsed-field gel electrophoresis is a powerful and discriminatory technique, based on enzymatic digestion of chromosomal DNA with a rare cutter enzyme and migration of the bands in a variably oriented electric field. This allows the separation of large fragments of DNA and the generation of highly discriminative strain-specific fingerprints. However, the technique is labor- and time-consuming and requires a sophisticated instrument.

A phenotype-targeting fingerprinting technique is standardized sodium dodecyl sulfate-polyacrylamide gel electrophoresis of whole-cell proteins, which can be used effectively for dereplication because it has discriminative information at or below the species level (69, 112, 151).

3.4.1.4. DNA-DNA Hybridization and G+C Content Analyses

When collected data are not sufficient to clearly determine identification, DNA-DNA hybridization should be performed, as a hybridization value of 70% was proposed as the boundary for the delineation of prokaryote species (61, 155). If a new isolate shows a high degree of similarity to more than one species, DNA-DNA hybridization experiments should be performed with all relevant type strains to ensure that there is enough dissimilarity to warrant classification of the strain(s) as a new taxon. A number of techniques are available; most of these have been validated and show comparable results (32, 41, 57, 58, 66, 120).

Most laboratories do not routinely perform DNA-DNA hybridization assays. The protocol includes labeling of the DNA (in general, with radioisotopes), shearing, and denaturing the sheared DNA, after which the labeled denatured DNA is mixed with excess of unlabeled DNA from the second organism. The mixture is then cooled and allowed to reanneal under carefully controlled conditions. Duplex DNA is separated from any unhybridized DNA remaining, and the amount of bound DNA is quantified. A control experiment with homologous DNA is included and its results of the heterologous DNA binding are normalized with respect to the homologous control. Nonradioactive methods have also been introduced. The procedure is time-consuming and allows for pairwise comparisons only, making comparisons of large numbers of strains cumbersome.

Another analysis performed historically is the determination of genome G+C base content. The G+C base ratio varies from approximately 20 to 80% in the prokaryote world. While an identical G+C content of two species does not prove the existence of any relationship, a difference of 5 mol% or more shows that the isolates cannot be closely related. Techniques for the experimental determination of the G+C percentage include thermal denaturation profiles, centrifugation methods that assess the buoyant density of the DNA, and high-performance liquid chromatography methods that determine the amount of each nucleotide after hydrolysis of the DNA (20, 55, 94, 95, 97, 101, 102, 111, 139, 140). Whatever method is used, different types of reference DNA of known G+C content should be included in the tests for calibration, and information about the method used should be provided.

3.4.2. Phenotypic Characterization

Phenotypic properties important in prokaryote taxonomy comprise morphological, physiological, and biochemical features (10, 107, 129, 131, 151). Phenotypic physiological

and biochemical tests should be carried out under standardized conditions. Type strains of the most closely related taxa should be tested at the same time for comparison, and known positive and negative controls should always be included.

3.4.2.1. Morphological Properties

Morphological characteristics commonly used in the taxonomic characterization of prokaryotes include:

- Cell shape and size, with use of phase-contrast microscopy, transmission electron microscopy, and other microscopy techniques.
- Gram-staining behavior, providing information on the structure of the cell wall of the Bacteria. For halophilic prokaryotes, a special modification of the fixation protocol used is necessary (35).
- Other staining methods are used to identify other cellular components, such as acid-fast staining, used to detect the presence of mycolic acids in the cell wall (106).
- Presence of extracellular capsular material. Extracellular polymers can often be visualized by suspending cells in a solution of India ink and observing wet mounts under the microscope.
- Colony morphology and size when grown on solid surfaces.
- Pigmentation.
- Formation, location, and shape of endospores.
- Presence of intracellular structures such as gas vesicles, intracellular membranes, granules of storage materials such as poly(β -hydroxyalkanoates), elemental sulfur, and others.
- Motility (swimming, gliding), and presence and location of flagella.

3.4.2.2. Physiological Properties

Physiological traits commonly tested for prokaryotes are given below. Not all tests are equally relevant for all groups of organisms. For example, tests for the consumption of different organic compounds are irrelevant for chemoautotrophic sulfur bacteria; for such specialized groups special tests should be added such as the range of sulfur compounds used as electron donor. Fermentation products should be determined for obligate or facultative anaerobes that grow in the absence of an external electron acceptor, etc. Among the most relevant and generally recorded characteristics are:

- The temperature range and optimum for growth.
- The pH range and pH optimum for growth.
- The influence of salt concentration on growth rate.
- The relation to oxygen: obligate aerobic, facultative anaerobic, obligate anaerobic.
- The use of electron acceptors other than oxygen for respiration, e.g., anaerobic respiration with nitrate as electron acceptor (denitrification) or reduction of sulfate and other oxidized sulfur compounds.
- The ability to grow heterotrophically, phototrophically, and chemoautotrophically.
- For chemoautotrophs, the range of inorganic electron donors and energy sources used.
- The range of organic compounds used as carbon and energy source by aerobic heterotrophs. Miniaturized standardized tests such as those provided by the BIOLOG[®] system are often helpful. The latter consists of microtiter

plates with wells that contain potential growth substrates and a redox indicator. Utilization of the carbon source causes a color change of the indicator, enabling the simultaneous determination of the utilization of a large number of substrates within a short time. The procedure can also be easily automatized.

- For fermentative prokaryotes: the nature of the fermentation products made and their ratio.
- Different enzymatic tests (oxidase, catalase, dissimilatory nitrate reduction, and others) (65). In addition, commercially available test kits (e.g., the API system for identification of enteric bacteria, which consists of miniaturized test tubes with different media and reagents) are helpful to routinely test isolates under standardized conditions.
- Excretion of extracellular enzymes such as amylases, proteases, and lipases.
- Susceptibility to different antibiotics and other antibacterial compounds.

3.4.2.3. Chemotaxonomic Properties

Chemical properties of prokaryotic cells useful in polyphasic taxonomy studies include the composition of the cell wall, membrane lipids, respiratory quinones, polyamines, and others. Not all chemical tests should be performed on all prokaryotes. Determination of the detailed structure of the amino acid bridges in peptidoglycan is important only for certain groups of gram-positive Bacteria that possess a peptidoglycan cell wall and for which variations in peptidoglycan structure have been documented. For Archaea, which lack peptidoglycan, different chemical assays can yield information on the structure of the wall (glycoproteins, pseudomurein, etc.) (75). Analysis of teichoic acids is important only for gram-positive Bacteria, and mycolic acids are present only in mycobacteria and relatives. Likewise, fatty acid profiles are not relevant for the Archaea, which lack ester-type lipids that yield fatty acids on hydrolysis. Here, special methods are needed to obtain information on the presence of a lipid bilayer with 20- and/or 25-carbon isoprenoid branched chains (71) or, alternatively, a lipid monolayer membrane in which two glycerol moieties are linked by 40-carbon isoprenoid (biphytanyl) chains, providing a highly stable membrane with covalent bonds spanning over its whole width. The list below, therefore, provides general information only, and the nature of the tests to be performed depends to a large extent on the group to which the organisms to be studied belong.

Among the properties often tested are:

- The type of peptidoglycan, and especially the nature of the peptides linking the polysaccharide chains. The discriminatory power of the structure of peptidoglycan is apparently restricted to gram-positive bacteria, whereas no variation has been reported among *Proteobacteria* and *Bacteroidetes*. The simplest analysis is the determination of the characteristic diamino acid (lysine or diaminopimelic acid) in the cross-linking peptide, and more complex tests for a complete structure elucidation are available as well (74, 124, 125).
- Teichoic acids, which are polyols consisting predominantly of glycerol, ribitol, and mannitol, and are covalently linked to the peptidoglycan through phosphodiester bonds, can be useful for characterization of gram-positive Bacteria, and can be extracted, purified, and analyzed by gas-liquid chromatography (151).

- Polar lipids, both for Bacteria and Archaea, can be extracted with organic solvents, separated by one- or two-dimensional thin-layer chromatography, and detected by different spray reagents, including reagents that specifically stain phospholipids, glycolipids, amino lipids, etc. (74, 146).
- Fatty acid profiles (for Bacteria only) are made by acid methanolysis of the lipids, followed by gas chromatographic separation of the fatty acid methyl esters and detection and identification by mass spectrometry. For such studies, growth conditions must be strictly standardized, because factors such as temperature and age of the culture may have a strong influence on the fatty acid pattern (74).
- The structure of the outer membrane of gram-negative Bacteria shows considerable variation in the nature of the sugar present in lipid A and in the fatty acids in the lipopolysaccharide (104).
- The presence and length of the carbon chain of the mycolic acids that occur in certain members of the high-GC gram-positive Bacteria (19, 56).
- The presence and types of respiratory quinones. Respiratory lipoquinones are widely distributed in both anaerobic and aerobic organisms within the Bacteria and Archaea. These can be divided into two structural classes: naphthoquinones and benzoquinones (which include ubiquinones, rhodoquinones, and plastoquinones). A third class includes the benzothiophene derivatives, such as *Sulfolobus* quinone and *Caldariella* quinone, which are probably restricted to members of the order *Sulfolobales*. The side-chain lengths recorded to date range from 6 to 15 isoprenoid units, and different variations in the structure of the quinones and the degree of saturation of the side chain have been reported for specific groups of prokaryotes. Different techniques of thin-layer chromatography, high-performance liquid chromatography, mass spectrometry, and nuclear magnetic resonance should be combined to fully characterize the respiratory quinones present (27, 28, 103, 138).
- Many prokaryotes are colored by carotenoids, flexirubins, (bacterio)chlorophyll, pyocyanin, and other pigments. Extraction of pigments in suitable solvents and spectrophotometric characterization add much important information that can be used in polyphasic taxonomic characterization (67).
- The types of polyamines present in the cells is another chemotaxonomically relevant property.

3.5. CONCLUDING REMARKS: WHOLE-GENOME SEQUENCING IN PROKARYOTE TAXONOMY

The availability of the methodology to determine complete genome sequences of prokaryotes has initiated discussions on changing the rules and concepts used in delineating species in the near future. Several papers have already been published on the impact of genomics in taxonomy (e.g., references 53 and 76–79). A full genome sequence provides a view of the genetic information in a microbe at the highest possible resolution. It can therefore be considered the “ultimate source” of molecular information for taxonomic and phylogenetic studies. In addition, whole genomic sequences contain the information required for all of the molecular tools currently applied for genotyping; therefore, these data can easily be correlated

to existing data sets in this field. Classical Sanger sequencing is a time-consuming and costly process and does not allow the throughput needed for most taxonomic studies. Yet, it has proven a valuable source of information for phylogenetic studies at the species, genera, and higher levels for microbes that are of key importance to industrial microbiology (24, 93).

The emergence of a new generation of sequencing technologies is rapidly changing this notion. It addresses the two major limitations of Sanger sequencing because it provides a dramatic increase in throughput at a much lower cost (90). The costs of sequencing per base pair has already decreased by a factor of 1,000 or more, and, as a result, it is anticipated that very soon a full genome sequence will be obtained via commercial providers for a few hundred to a thousand euros or dollars. These costs may become even lower if low-coverage sequence data are sufficient, as may be the case for taxonomic studies. These costs are comparable or even lower than the costs of many of the molecular and biochemical typing techniques described above.

Therefore, it can be anticipated that publication of the complete genome sequence of the type strain will soon become obligatory for the description of a new species. However, the impact that this could have on the general taxonomic scheme is less trivial. First, genome sequencing provides a framework of the potentialities of the organism, but the phenotypic analysis necessarily completes the characterization of the organism and can give a more precise idea on how the organism itself interacts with the environment. Moreover, a careful analysis will be needed to determine new cutoffs and methodologies for comparison of taxa. Approaches based on whole-genome sequences could successfully integrate previous “traditional” knowledge, only if bioinformatics pipelines become available to rapidly extract the information relevant for taxonomic and phylogenetic purposes (119), and only if methods for comparison are evaluated and carefully chosen, because more than 20 methods to compare genomes are currently available (8). Therefore, there still is considerable uncertainty regarding how complete genome sequence data could best be evaluated in a taxonomic framework.

APPENDIX: IMPORTANT RESOURCES OF INFORMATION RELEVANT TO PROKARYOTE TAXONOMY

Information on taxonomy of prokaryotes can be found in many sources: handbooks, review articles, public databases, and other sources of information available online. A selection of those sources follows here.

- The International Committee for Systematics of Prokaryotes (ICSP) and its taxonomic subcommittees (www.the-icsp.org).
- The International Code of Nomenclature of Bacteria (the Bacterial Code), 1990 version (84). Available at: <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=icnb.TOC&depth=2>. An updated version entitled International Code of Nomenclature of Prokaryotes is in preparation.
- The *International Journal of Systematic and Evolutionary Microbiology* (<http://ijs.sgmjournals.org/>), the official journal of the ICSP, and the only journal where names of new taxa of prokaryotes can be validly published.
- *Bergey's Manual of Systematic Bacteriology*, the major handbook with descriptions of prokaryote species and higher taxa, that provides a systematic framework for

their classification (<http://www.taxonomicoutline.org>). (Note that this classification has no official status.) *Bergey's Manual of Systematic Bacteriology* and its predecessor, *Bergey's Manual of Determinative Bacteriology*, have served microbiologists since 1923. Eight editions of *Bergey's Manual of Determinative Bacteriology* were published between 1923 and 1974. The first edition of *Bergey's Manual of Systematic Bacteriology* was published in four volumes between 1984 and 1990. The first volumes of the five-volume second edition appeared in 2001 and 2005 (51), and the third volume is due to be published in 2009.

- *The Prokaryotes*, a comprehensive seven-volume handbook on the biology of Bacteria and Archaea, now in its third edition (36).
- The list of prokaryotic names with standing in nomenclature, compiled by Dr. Jean Euzéby of the University of Toulouse, France (www.bacterio.cict.fr) (40). This website contains a wealth of information on prokaryote nomenclature, and it is updated monthly with the publication of the latest issue of the *International Journal of Systematic and Evolutionary Microbiology*.
- For information on culture collections from which type strains of prokaryotes and other isolates can be obtained, see the web pages of the World Federation for Culture Collections (<http://www.wfcc.info/datacenter.html>). A list of culture collections that maintain cultures of prokaryotes can also be found at www.bacterio.cict.fr/collections.html.
- Some public culture collections maintain websites that, in addition to the strain catalogs and technical details about depositing and ordering strains, provide information about the history and the nomenclature of the strains, recipes for media in which the isolates can be grown, and more. The sites of the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ, Braunschweig, Germany; www.dsmz.de) and the American Type Culture Collection (ATCC, Manassas, VA; www.atcc.org) are especially recommended.
- Sequence information on 16S rRNA genes can be retrieved from the GenBank (<http://www.ncbi.nlm.nih.gov>) and results can be easily formatted to visualize the phylogenetic placement of the newly obtained sequence with respect to the closest relatives. The European database EMBL (<http://www.ebi.ac.uk>) and the Japanese DDBJ (<http://www.ddbj.nig.ac.jp>) share sequences with GenBank on a daily basis.
- The Ribosomal Database Project (<http://rdp.cme.msu.edu/>) is a database devoted to storage and analysis of ribosomal sequences. Other databases related to the ribosomal operon sequences and numbers are the 5S rRNA database (<http://biobases.ibch.poznan.pl/5SData/>) and the RRNDB, on the rRNA operon numbers in different prokaryotes (<http://ribosome.mmg.msu.edu/rrndb/index.php>) (86).
- A very promising resource is the SILVA rRNA database project, a "comprehensive on-line resource for quality checked and aligned ribosomal RNA sequence data" (<http://www.arb-silva.de/>) (161).
- For comparison of 16S rRNA gene sequences with the type strains of prokaryotes with validly published names, the EzTaxon tool has been developed (<http://147.47.212.35:8080>) (23).
- Multilocus sequence typing data can be found at www.eMLSA.net (9) and at <http://pubmlst.org>.

- For complete prokaryote genome sequences online, <http://www.genomesonline.org> and <http://www.jcvi.org> provide a wealth of information.

4.1. INTRODUCTION

Environmental samples are colonized by complex microbial communities whose composition and functions may differ significantly. Some organisms are overrepresented in a sample, whereas others can be found at concentrations below 10 cells per g of soil (106). However, at present, we simply do not know the extent of the functional diversity that microbes encompass: a classical theoretical analysis estimates that the prokaryotic population on Earth is approximately 10^{30} bacteria, a few orders of magnitude higher than the number of stars in the known universe (estimated 10^{22} to 10^{24}), with most microbes being members of complex communities (106). Any individual survey to study such diversity is limited because of our relatively poor ability to grow most microorganisms under standard laboratory conditions (53). This problem is exacerbated in the case of organisms living in habitats with extreme conditions (e.g., low or high temperatures, low and high pH, high pressure, and high salinity), the so-called extremophiles that operate under conditions generally considered to be hostile to life. These environments often contain very few microbes. Even though the genetic diversity of such environments may in some cases be low, it may nevertheless be particularly interesting, warranting the special effort required to access it. To do so, along with traditional cultivation methods, a wide range of approaches collectively described as “metagenomics” have been developed to study communities through the analysis of their genetic material without culturing individual organisms (40, 41). Metagenomics is analogous to genomics with the difference that it does not deal with the single genome from a clone or microbe cultured or characterized in the laboratory, but rather with that from the entire microbial community present in an environmental sample, the so-called community genome. Metagenomics represents a strategic concept that includes investigations at three major interconnected levels (sample processing, DNA sequencing, and functional analysis), with an ultimate goal of obtaining a comprehensive view of the functioning of the microbial world.

One of the major problems associated with metagenomic analysis is that the total DNA extracted from environmental samples in many cases may not contain an even representation of the population genome, meaning that rare organisms would contribute less to the overall DNA diversity, with the library being dominated by the most abundant organisms (32, 33). It is thus of great priority to adapt

sample and DNA extraction methods and cloning strategies for normalization of the sample, because the relative abundance of representatives of a certain group of microbes is not necessarily linked to the importance of that group in the community functioning: common organisms may not necessarily play a critical role in a community despite their numbers, and organisms that comprise only 0.1% of the total population (e.g., nitrogen fixers) can be of pivotal importance (106). To date, much of the research has been focused on the sequence-centered analysis of community DNA. This analysis has a great throughput in data production and can access much greater genomic information of microbial communities, but sequence-based functional reconstruction and predictions of whole-community metabolic processes is reminiscent of crystal ball gazing: most of the genes have no clear function; and there is no support through functional verification, albeit this method can suggest some candidates/targets for expression and further characterization. Since new technologies allow dramatic expansion of sequencing data production, the current development of new analytical approaches and techniques will help to make more sense of these data and provide a holistic insight into the global ecosystem functioning (26). Nevertheless, in contrast to this sequence-centered metagenomics, another function-based, or activity-based approach currently shows better options to link specific microbes to specific ecological functions (12, 58, 105).

Below we provide a view of technical issues to illustrate the potential of getting appropriate sample material to create representative gene libraries as the first step for analysis of community genomes. We also provide an extensive description of tools and protocols for DNA extraction and cloning, as well as of host/vector expression systems developed for specific groups of microorganisms, with a special focus on extremophiles.

4.2. SAMPLING PROTOCOLS

Little of the technology relevant to environmental sampling of extremophilic habitats is unique to these organisms, and where specialized methods are required, they are normally the obvious consequences of the properties of the specific group of organisms and their favored habitats. Nevertheless, general protocols used in “normal” environmental sampling should be equally valid when sampling extreme habitats. In

particular, sampling protocols that take account of potential problems such as microheterogeneous distribution should be used. The use of such protocols is critical where sampling is for the purpose of comparative microbial ecology or where representative metagenomic coverage is required. Although there is no standardized sampling protocol, and most field biologists will adapt procedures to the requirements of their sampling program, the physical characteristics of their sampling site, and the technology available to them, the following protocol can be used as a guideline for sampling where issues of microheterogeneity are potentially important.

For open soils and the margins of aquatic systems:

- Lay out a 50-m transect line, marked at the center point (to increase coverage, a second 50-m line may be laid out at right angles, intersecting at the midpoint).
- Establish 1-m² quadrants at the center and the ends of the transects (to increase coverage, quadrants may also be sited at the 10-m points).
- Sample an appropriate volume (using sterile procedure as appropriate) at four points (typically the corners) of each quadrant.
- Label and identify each sample separately.
- Subsequently, recover and mix approximately 50% of each of the four samples from each quadrant into a fifth sample.

The purpose of this approach is to pre-prepare samples for subsequent analysis of homogeneous (or otherwise) microbial distribution. This would typically be done by denaturing gradient gel electrophoresis or automated ribosomal interspacer sequence analysis (ARISA). The results of this analysis can be used as a guide for subsequent separation (or mixing) of the samples.

There is no standard technology for recovery and retention of samples. However, sampling devices and sample containers should be compatible with the physical and chemical properties of the sample, and compatible with the requirements of postsampling transport and storage. Sterile 50-ml plastic Greiner® tubes and wide-mouth Nalgene® containers (for volumes of >100 ml) are ideal for liquid samples, while WhirlPak® bags conserve both weight and space for collection of solid/dry samples.

4.2.1. Rules for Sampling Extreme Environments

In general, the more detailed and sophisticated the microenvironmental data obtained, the better! Parameters such as temperature, pH, percentage of relative humidity, salinity, dO₂, redox state, moisture content, light, local geology, weather (cloud, precipitation, wind speed), and so on, may be critical or irrelevant. Date and time of sampling together with accurate Global Positioning System coordinates should be recorded. Further, as a general rule, good sterile technique should be used in any sampling protocol, the objective being to minimize contamination of both the sample and the sampling site. Avoiding cross-contamination between multiple sites may be important. Sampling tools (metal or wooden spatulas, trowels, etc.) can be presterilized in tinfoil and opened on-site, or (for larger tools where one-off use is not feasible) can be cleaned and sterilized between samples by using sterilizing wipes. The following are issues for consideration in the sampling of various specific extreme environments.

4.2.1.1. Thermophilic Samples

In hydrothermal systems, the solid phase (sinter surfaces, sand and gravel deposits, sediments, etc.) typically have

much higher cell loads than the aqueous phase (99). Given that even a gloved hand cannot be immersed for more than fractions of a second in thermal waters of above approximately 60°C, a sampling device is essential for recovering sediment material. The simplest effective device is a pair of tongs, preferably long-handled, with which a wide-mouthed plastic bottle can be grasped and manipulated. More sophisticated devices can be engineered—a 500-ml aluminium or titanium collection vessel with a threaded detachable handle is practical for both transport and sampling.

For recovery of liquid samples, handheld suction devices (“turkey basters”) are adequate for recovering small volumes, but they are readily blocked by particulates. Microbial cell yields from bulk liquids may be no more than 10⁴ to 10⁵ ml⁻¹, so filtration may be preferable for recovery of larger volumes of biomass. A handheld suction device (such as the Nalgene Mityvac®), used in conjunction with a plastic Buchner flask and a Millipore® filtration unit (for 7-cm diameter 0.2-µm filters), is a slow but effective method for scaling up the recovery of biomass from bulk liquids. Filters will block when fully coated with cellular material: after filtration of a few hundred milliliters (for very high biomass fluids such as algal blooms) or quite a few liters for low biomass (e.g., hydrothermal) fluids. Once blinded, filters can be transferred with sterile tweezers to sealable plastic bags, tubes of growth media, or nucleic acid-stabilizing solutions.

To the authors’ knowledge, there is no strong evidence that the survival of thermophilic species in environmental samples is improved by maintaining samples at the *in vivo* temperature during transport from site to laboratory. If it is deemed essential to maintain sample temperatures, volumes of a few liters can be transported in Thermos® flasks with good temperature retention over 24 to 36 h.

In thermal environments of above approximately 75°C, most microbial species are facultative or obligate anaerobes. The maintenance of cell viability for this group of organisms thus critically depends on the retention of anaerobic status. The minimum necessary action is to ensure that sample containers are “brim-full”—i.e., that air is effectively excluded. Note also that some plastics are highly permeable to oxygen! Ideally, where anaerobic status is important, addition of a sterile sodium sulfide solution (e.g., sodium sulfide nonahydrate ACS reagent; Sigma-Aldrich, St. Louis, MO) after collection, together with a drop of the redox indicator resazurin (e.g., 0.1% solution prepared in distilled water), will result in the maintenance of anaerobic conditions, and allow the researcher to visually confirm that status.

4.2.1.2. Psychrophilic Samples

True psychrophiles are highly sensitive to elevated temperatures and may be inactivated by temperatures as low as 30°C (87). All cold-active microorganisms probably maintain some level of metabolic activity at temperatures well below 0°C. For these reasons, temperature control is particularly important in the handling of samples from psychrophilic environments. Ideally, field samples collected in psychrophilic environments (mountain, polar, etc.) should be stored at or just below 0°C for as short a time as possible before transfer to colder storage—domestic freezer temperature (−12 to −18°C) at least. Even at these temperatures, it is likely that many psychrophiles maintain some metabolic activity, and ideally, 70°C storage, in particular for longer-term maintenance of samples, is preferable. However, note that freeze-thaw cycling is extremely damaging to both viable cells and polynucleotides, and large samples should be subfractionated before long-term storage.

4.2.1.3. Halophilic Samples

High-salt environments frequently carry very high biomass loads. This usually facilitates the recovery of biomass, in particular in the filtration of water samples (see above).

The cytoplasm of extremely halophilic organisms is generally hyperosmotic, and cells will lyse very rapidly if exposed to a low-ionic-strength environment. Consequently, buffers or media used to stabilize filters should be adjusted (or pre-prepared) to the approximate salt concentration of the sampling site.

4.2.1.4. Acidophilic Samples

Field researchers report that samples recovered from acidophilic sites, in particular high-temperature (thermoacidophilic) sites, show rapid loss of viable biomass and degradation of high-molecular-weight DNA. This is believed to be the result of acidification of cellular cytoplasm under conditions where the organisms are metabolically inactive, and the resulting accelerated acid hydrolysis of ester, amide, and phosphodiester bonds. Some field researchers prefer to neutralize acidophilic samples at the time of recovery; typically by addition of sterile Na_2CO_3 , NaOH , or CaCO_3 , and the judicious use of pH paper. Others, concerned by the possible impact of large shifts in pH and ionic strength on cell viability, do nothing. To the authors' knowledge, this problem has been neither rigorously investigated nor satisfactorily resolved.

4.2.1.5. "Normal" Superficial Sea- and Freshwater Samples

Immediately after collection, samples (approximately 2 to 20 liters) are filtered onto a 500-kDa NMWL (nominal molecular weight limit or membrane cutoff in kilodaltons) ultrafiltration disc (Biomax polyethersulfone; Millipore). After this, the filters are cut into strips (1 cm \times 2 mm) and used directly for DNA extraction (see the protocols described below). Alternatively, in the case of large sample amounts (e.g., 100 to 200 liters) a tangential flow filtration device can be used, such as Pellicon TFF 0.1 μm (Millipore), to separate solid particles and picoeukaryotic organisms (2 to 4 μm). Part of the overconcentrated product (retentate solution; e.g., 10 ml) can be used for the enrichment of cells with a desired supplement (e.g., minimal medium supplemented with petroleum, to enrich for microbes able to metabolize it) or this retentate solution can be filtered onto a 500-kDa pore size with the Amicon® system (Millipore), and the filter cut into strips and used directly for DNA extraction.

4.2.1.6. Soil Samples

Soil or sediment samples (1 to 5 g) are resuspended in 5 to 40 ml (depending on the sample properties) of Tris-EDTA (TE) buffer, pH 8.0, and mixed by inverting the tube 10 to 15 times. The samples are mixed with moderate shaking, to release cells from the solid matrix, and centrifuged at a low speed (approximately 200 to 400 \times g for 1 to 5 min) to eliminate bulky soil particles. The supernatant is transferred to a fresh sterile tube and is centrifuged at 6,000 \times g for 15 to 30 min at 4°C. The supernatant is discarded and the pellet is retained for DNA extraction. In some cases, for example, dealing with the samples containing particulate materials (soils, sediments), a Nycodenz® extraction technique is highly recommended. During the physical separation of the bacterial fraction with use of a Nycodenz® cushion, a whitish band of microbial biomass is obtained at the interface between the Nycodenz® and the aqueous layer by using a high-speed density gradient.

This method has been used successfully to isolate DNA from freshwater, compost, rhizosphere-associated soils, as well as from pristine- and contaminated sediments. The procedure is outlined below.

- Prepare sample suspension: to 15 g of sample, add disruption buffer (35 ml total volume: 0.2 M NaCl, 50 mM Tris-HCl, pH 8.0) and mix (preferably overnight with orbital shaking).
- Centrifuge at a low speed (approximately 200 to 400 \times g for 1 to 5 min) to eliminate large soil particles and then use supernatant for biomass separation via Nycodenz®.
- Transfer 25 ml of the soil homogenate to an ultracentrifuge tube and carefully pipette 9 to 11 ml of Nycodenz® (0.8 to 1.3 g ml⁻¹) to form a layer below the homogenate.
- Centrifuge at 10,000 \times g for 20 to 40 min at 4°C.
- A faint, whitish band containing bacterial cells is resolved at the interface between the Nycodenz® and the aqueous layer. Transfer this band into a sterile tube. Note that some soils, in particular clay soils, contain small particles that do not separate from the microbial biomass, forming a layer mixed on the Nycodenz® surface.
- Add approximately 35 ml of phosphate-buffered saline, and pellet the cells by centrifugation at 10,000 \times g for 20 min. Discard the supernatant and resuspend the cell pellet in 0.5 to 2.0 ml of TE buffer, pH 8.0.

4.3. DNA EXTRACTION

4.3.1. Wet-Lab Techniques for DNA Extraction

Two major extraction protocols may be used: (i) phenol extraction, where the gentle hydrophobicity of phenol makes it a good solvent for DNA extraction, and (ii) the use of commercial kits (in this case, it is highly recommended to separate cells from the matrix to allow efficient DNA recovery yields). The protocols are as follows.

Isolation of High-Quality DNA by the Phenol/Chloroform Method Followed by DNA Cleaning

The following procedure is recommended when a large quantity of humic acids is present in the soil samples and for Nycodenz®-separated biomass to minimize the volume of solvents required for large-scale soils.

1. To the solution obtained as above (cell pellet in TE buffer), add 25 μl of lysozyme solution (10% wt/vol, prepared before use), and incubate for 2 h at 37°C (1,500 rpm).
2. Add 6 μl of RNase solution (1% wt/vol) free of DNase, and incubate for approximately 30 min at 37°C.
3. Add 8 μl of solution of proteinase K (1% wt/vol) and 60 μl of sodium dodecyl sulfate solution (10% wt/vol) and incubate 30 min at 50°C, until it becomes clear and viscous.
4. Add 100 μl of 5 M NaCl and mix gently by inverting the tube four to six times.
5. Add 80 μl of a cetyltrimethylammonium bromide solution prewarmed at 65°C (10% wt/vol in 0.7 M NaCl), mix gently by inverting the tube four to six times, and incubate 10 min at 65°C.
6. The final volume should be approximately 748 μl .
7. Add 750 μl of CHCl_3 /isoamyl alcohol (24:1), mix gently by inverting the tube four to six times, then centrifuge for 3 min at 12,000 \times g and quickly transfer the upper aqueous phase into a new 2-ml Eppendorf tube.

8. Add 700 μl of phenol/chloroform/isoamyl alcohol (25:24:1); mix gently by inverting the tube four to six times. Centrifuge for 3 min at $12,000 \times g$, and quickly transfer the upper aqueous phase to a new 2-ml Eppendorf tube.
9. Add 650 μl of chloroform/isoamyl alcohol (24:1) and mix gently by inverting the tube four to six times. Centrifuge for 3 min at $14,000 \times g$, and quickly transfer the upper aqueous phase to a new 1.5-ml Eppendorf tube.
10. Finally, add 0.6 volumes of isopropyl alcohol and mix gently by inverting the tube four to six times. Place the tubes on ice for 10 min, followed by centrifugation for 30 min in a benchtop centrifuge at maximal speed ($>12,000 \times g$). The supernatant can be removed by gentle suction with a vacuum pump.
11. Add 500 μl of ethanol (70% vol/vol) to the DNA pellet, centrifuge in a microcentrifuge at the maximal speed ($>12,000$ relative centrifugal force), and using a gentle suction with a vacuum pump remove the supernatant.
12. Quickly transfer the tube into the Speed-Vac and dry for approximately 5 min without heating.
13. Resuspend the DNA pellet in 500 μl of TE buffer, pH 8.0 (typically, at room temperature, overnight).
14. If the quality of DNA from the previous step is good enough (of satisfactory size, as can be judged with agarose gel electrophoresis) and does not contain inhibitors (as can be judged by the enzymatic endonuclease digestion of a small DNA aliquot and its subsequent gel electrophoresis), then proceed directly to the digestion and cloning step. If not, an ultrapure DNA protocol should be applied. DNA Clean & Concentrator® (Zymo Research Corp., Orange, CA) has been shown to yield a high-purity DNA. By using this product one could purify DNA by using a single-buffer system that allows efficient and selective DNA adsorption onto a matrix. Here, it is important to use at least 200 μg of DNA since the recovery of DNA is, in most samples, lower than 40%.

Important note: in case high-molecular-weight DNA is needed, avoid pipetting samples, because this may shear the DNA.

Isolation of High-Quality DNA by Commercial Kits

Commercial kits such as UltraClean MegaPrep (MoBio Laboratories, Inc., Carlsbad, CA) and GNOME® DNA Extraction Kit (BIO101) may be used for isolation of metagenomic DNA from eukaryotic or prokaryotic cells and tissues in less than 2 h with no organic extractions. Preliminary separation of cellular biomass from soil homogenate via Nycodenz® gradient is recommended to achieve maximal DNA recovery per gram of soil. DNA purification kits from other manufacturers presumably work equally well, but they have not been tested in our laboratory. The GNOME® DNA kit uses RNase Mix to eliminate RNA immediately after lysis, and Protease Mix to rapidly degrade cellular proteins. This is followed by a proprietary “salting out” technique that precludes the need for phenol, chloroform, or other organic extractions. Preparation of metagenomic DNA using this kit is described below.

1. Immediately after collection, samples are either stored in 95% ethanol at 4°C or are shock-frozen in liquid nitrogen, followed by storage at -80°C . Alternatively, 10 g of soil is directly homogenized with 40 ml of a 0.2 M NaCl, 50 mM Tris-HCl, pH 8.0, buffer, mixed (overnight, 4°C , orbital shaking), and then

centrifuged at low speed (approximately 200 to $500 \times g$ for 1 to 5 min) to eliminate large soil particles. Cells (plus small particles) are separated by centrifugation at high speed ($9,000 \times g$ for 15 min). Freshwater samples (>600 ml) are subjected to cell separation either by centrifugation ($9,000 \times g$ for 15 min) or filtration through a 0.20- μm filter (the filter is removed and used directly). DNA is isolated from these samples after steps 2 to 10. To each 0.1 g of cells (from pellets obtained by centrifugation, or cells separated by filtration), add 1.85 ml of Cell Suspension Solution (use a 15-ml clear-plastic tube for efficient mixing). Mix until the solution appears homogeneous.

2. Add 50 μl of RNase Mix and mix thoroughly. Add 100 ml of Cell Lysis/Denaturing Solution and mix well.
3. Incubate at 55°C for 15 min.
4. Add 25 μl of Protease Mix and mix thoroughly.
5. Incubate at 55°C for 30 to 120 min (the longer time will result in minimal protein carryover and will also allow for substantial reduction in residual protease activity).
6. Add 500 μl of “Salt-Out” Mixture and mix gently, yet thoroughly. Divide sample into 1.5-ml tubes. Refrigerate at 4°C for 10 min.
7. Spin for 10 min at maximum speed in a microcentrifuge (at least $10,000 \times g$). Carefully collect the supernatant, avoiding the pellet. If a precipitate remains in the supernatant, spin again until it is clear. Pool the supernatants in a 15-ml (or larger) clear-plastic tube.
8. To this supernatant, add 2 ml of TE buffer and mix. Then add 8 ml of 100% ethanol. If spooling the DNA, add the ethanol slowly and spool the DNA at the interphase with a clean glass rod. If centrifuging the DNA, add the ethanol and gently mix the solution by inverting the tube.
9. Spin for 15 min at $1,000$ to $1,500 \times g$. Eliminate the excess ethanol by blotting or air drying the DNA.
10. Dissolve the genomic DNA in TE (10 mM Tris, pH 7.5, 1 mM EDTA).

4.3.2. DNA Extraction from Extreme Samples

Many of the methods that are used routinely to extract genomic DNA from mesophiles can be used to extract DNA from extremophiles. However, from the authors' experience, extracting good-quality, high-molecular-weight DNA from halophilic organisms can be problematic, due to the high salt concentration of the culture medium necessary for the growth of obligate halophiles. In our laboratory, the method of Yu et al. (109) has been adapted successfully to extract genomic DNA from high-salt soil samples or halophilic bacterial cultures. The method involves direct cell lysis of soil or cell pellets embedded in agarose plugs, with the agarose plugs being cast in 96-well microtiter plates. Yu and coworkers used pulsed-field gel electrophoresis followed by dialysis to remove soil contaminants and cellular debris. However, our laboratory has replaced the pulsed-field gel electrophoresis with electrophoresis in low-melt agarose. Relatively pure, high-molecular-weight DNA can be obtained by this method, which can be used directly for downstream applications, including cloning into fosmids.

1. One gram of soil/200 μl of cell pellet is mixed with 1 ml of suspension buffer (10 mM Tris-HCl, 1 M NaCl, 50 mM EDTA) and 1 ml of 1% low-melting-point agarose. Keep at 37°C to prevent the agarose from solidifying.
2. Several (at least five per sample) 100- μl aliquots of the slurry are pipetted into a mold (we use a 96-well microtiter plate) and placed at 4°C to solidify. Soil that has a lot of plant litter or compost is not well suited to this

method, because the agarose plugs are not firm and tend to break apart during the extraction process.

3. For each sample, place three plugs in a 2-ml Eppendorf tube and add 1.5 ml of lysis buffer (50 mM Tris-HCl, 100 mM EDTA, 100 mM NaCl, 0.2% [wt/vol] sodium deoxycholate, 0.5% [wt/vol] 20 cetyl ether, 0.5% [wt/vol] lauroylsarcosine sodium salt, and 5 mg/ml lysozyme). Place tubes at 37°C for 24 h with gentle agitation (50 rpm).
4. Remove the lysis buffer and add 1.5 ml of digestion buffer (100 mM Tris-HCl, 500 mM EDTA, 100 mM sodium phosphate, 1.5 M NaCl, 1.5 mg/ml proteinase K, and 0.5% [wt/vol] sodium dodecyl sulfate). Place tubes at 50°C for 24 h with gentle agitation.
5. Collect the plugs and wash in 50 volumes of wash buffer (10 mM Tris-HCl, pH 8, 100 mM EDTA) and then several times with ice-cold 0.5× TBE buffer.
6. Secure the washed plugs with molten agarose to the teeth of an electrophoresis comb and allow to solidify. Pour molten 0.7% low-melt agarose carefully around the plugs and allow the gel to solidify. The gel is electrophoresed for 18 h at 35 V. The gel is then stained, viewed under UV (360 nm). DNA of the desired size is excised from the gel, destained, and stored at -20°C.
7. Remove agarose by agarase digestion with standard methods and purify the DNA by ethanol precipitation.

4.4. CONSTRUCTION OF METAGENOMIC LIBRARIES

Two distinct strategies are taken in metagenomics, according to the primary goal. First, large-insert libraries (cosmid, fosmid, or bacterial artificial chromosomes) are constructed for archiving and sequence homology screening purposes, to capture the largest amount of the available genetic resources available in the sample and archive it for further studies/interrogation. Second, small-insert expression libraries, especially those made in lambda phage vectors, are constructed for activity screening. The small size of the cloned fragments means that most genes present in the appropriate orientation will be under the influence of the extremely strong vector expression signals, and thus have a good chance of being expressed and detected by activity screens (32, 35). Although these two strategies may differ in some technical aspect, both are increasingly used together because of their complementarity. Activity mining often reveals novel enzymes, but the nature of the organism from which they originate can rarely be determined, nor can their genetic context, which may harbor equally or even more interesting similar or related enzymes. Primary enzyme discovery in an expression library, followed by identification of the same gene in a large-insert library and genome walking on the identified fragment, constitutes a powerful means of maximizing the discovery process and identifying the interesting new organisms that are producing such enzymes. Below we describe the methods used to construct small- and large-insert libraries.

4.4.1. Libraries in pCC1FOS Vectors

The CopyControl™ Fosmid Library Production kit (Epicentre, Madison, WI) uses a strategy based on the cloning of randomly physically sheared and end-repaired DNA with an average insert size of 40 kbp. Physical shearing of the DNA into approximately 35- to 40-kb-long fragments results in the generation of more random DNA fragments compared with those from partial endonuclease digestion of the genomic/metagenomic DNA. Genomic DNA is frequently sheared sufficiently, as a result of pipetting

during the purification process, so additional shearing is not necessary. Test the extent of shearing of the DNA by first running a small amount of it (approximately 100 ng). Run the sample on a 20-cm-long 1% agarose gel at 30 to 35 V overnight at 4°C and stain with ethidium bromide. If 10% or more of the genomic DNA migrates with the Fosmid control DNA provided with the kit (36 kb size), then one can proceed to the end-repair protocol. If the genomic DNA has a higher molecular mass than the 36-kb DNA fragment supplied with the kit, then the DNA needs to be sheared. The DNA (2.5 µg) is sheared by passing through a 200-µl small-bore pipette tip 50 to 100 times. The degree of shearing must be controlled through gel electrophoresis: if the (meta)genomic DNA migrates faster than the 36-kb fragment, then it has to be reisolated; the kit uses phage-assisted packaging and size selection of the cloned fragment, and in case the fragments are too short, it could lead to the hybrid insertions. For the end-repair protocol, take into account the following suggestions.

1. Thaw and thoroughly mix all of the following reagents before dispensing, and place on ice. Combine the following on ice: 8 µl of 10× End-Repair Buffer, 8 µl of 2.5 mM dNTP Mix, 8 µl of 10 mM ATP, 32 µl of sheared insert DNA (approximately 4.3 µg), 20 µl of sterile water, 4 µl of End-Repair Enzyme Mix, 80 µl of total reaction volume. (The end-repair reaction can be scaled up or down depending on the quantity of DNA available.)
2. Incubate at room temperature for 45 min.
3. Add gel-loading buffer and incubate at 70°C for 10 min to inactivate the End-Repair Enzyme Mix.
4. Select the size of the end-repaired DNA by low-melting-point (LMP) agarose gel electrophoresis. Run the sample on a 20-cm-long 1% agarose gel at 30 to 35 V overnight at 4°C. Do not stain the DNA with ethidium bromide, and do not expose it to UV. Use ethidium bromide-stained DNA marker lanes as a ruler to cut out the agarose region corresponding to 25- to 60-kb DNA and trim excess agarose, then proceed with the agarose gel-digesting assay using the "GELase (Epicentre) Agarose Gel-Digesting protocol" described in steps 5 to 11 below.
5. Thoroughly melt the gel slice by incubating at 70°C for 3 min for each 200 mg of gel.
6. Transfer the molten agarose immediately to 45°C and equilibrate 2 min for each 200 mg of gel.
7. Digest the agarose with 1 U of gelase for 30 min at 45°C.
8. Centrifuge the tubes in a microcentrifuge at maximum speed (15,000 × g) for 15 min at 4°C to pellet any insoluble oligosaccharides. Carefully remove the upper 90% to 95% of the supernatant, which contains the DNA, to a sterile 1.5-ml tube. Be careful to avoid the gelatinous pellet.
9. Precipitate the DNA by adding 1/10 volume of 3 M sodium acetate, pH 7.0, and 2.5 volumes of ethanol, and mix gently.
10. Wash the pellet with 70% ethanol. Gently resuspend the DNA pellet in TE buffer (approximately 200 µl).
11. Concentrate the DNA in a Microcon-100 (Millipore) concentrator membrane (100 kDa cutoff) at 4°C to a final volume of 20 to 30 µl. The DNA concentration can be approximately 100 ng/µl. This concentrated DNA will serve as the insert to ligate with the pCC1FOS vector.

The next step is the ligation of DNA fragment into the pCC1FOS fosmid vector. A single ligation reaction will produce 10^3 to 10^6 clones depending on the quality of the insert DNA. Based on this information, calculate the number of ligation reactions that you will need to perform. The ligation reaction can be scaled up as needed. A 10:1 molar ratio of pCC1FOS vector to insert DNA is optimal. If we use 0.5 μg of a 50-kb DNA insert, we need approximately 0.1 μg of vector. Combine the following reagents in the order listed and mix thoroughly after each addition: 1 μl of $10\times$ Fast-Link Ligation Buffer, 1 μl of pCC1FOS (0.5 $\mu\text{g}/\mu\text{l}$), 1 μl of 10 mM ATP, up to 6.8 μl of concentrated insert DNA (75 $\text{ng}/\mu\text{l}$), 0.2 μl of MilliQ water, 1 μl of Fast-Link DNA ligase, and 10 μl of total reaction volume.

Incubate at room temperature for 2 h and then transfer the reaction to 70°C for 10 min to inactivate the Fast-Link DNA ligase; proceed with *in vitro* packaging as follows:

1. Thaw on ice one tube of the MaxPlax Lambda Packaging Extract for every ligation reaction performed in the step above.
2. When thawed, immediately transfer 25 μl (one-half) of each package extract to a second 1.5-ml microfuge tube and place on ice.
3. Add 10 μl of the ligation reaction to each 25 μl of the thawed extracts being held on ice.
4. Mix by pipetting the solutions several times. Avoid the introduction of air bubbles. Briefly centrifuge the tubes to get all liquid to the bottom.
5. Incubate the packaging reactions at 30°C for 90 min. After the 90-min packaging reaction is complete, add the remaining 25 μl of MaxPlax Lambda Packaging Extract to each tube.
6. Incubate the reactions for an additional 90 min at 30°C.
7. At the end of the second 90-min incubation, add Phage Dilution buffer (PD buffer: 10 mM Tris-HCl, pH 8.3, 100 mM NaCl, 10 mM MgCl_2) to 1 ml of final volume in each tube and mix gently. Add 25 μl of chloroform to each. Mix gently and store at 4°C (up to a month). A viscous precipitate may form after addition of the chloroform. This precipitate will not interfere with library production. Determine the titer of the phage particles (packaged fosmid clones) and then plate the fosmid library.

The day of the packaging reactions, inoculate 50 ml of LB broth + 10 mM MgSO_4 with 5 ml of the EPI300-T1^R overnight culture. Shake at 37°C to an optical density at 600 nm ($\text{OD}_{600\text{nm}}$) of 0.8 to 1.0. Store the cells at 4°C until needed for titer determination. The cells may be stored for up to 72 h at 4°C if necessary.

Before plating the library, we recommend that the titer of packaged fosmid clones be determined. This will aid in determining the number of plates and dilutions to make to obtain a library that meets the needs of the user (first, to determine the clone densities before picking the colonies).

1. Make serial dilutions of the 1 ml of packaged phage particles into PD buffer in sterile microcentrifuge tubes. For example, use dilutions 1:10¹, 1:10², 1:10⁴, and 1:10⁵.
2. Add 10 μl of each of these dilutions, individually, to 100 μl of the prepared EPI300-T1^R host cells. Incubate each for 20 min at 37°C.
3. Spread infected EPI300-T1^R cells on an LB plate plus 12.5 $\mu\text{g}/\text{ml}$ chloramphenicol and incubate at 37°C overnight to select for the fosmid clones.

4. Count colonies and calculate the titer of the packaged clones as follows: if there were 200 colonies on the plate streaked with the 1:10⁴ dilution, then the titer in CFU/ml of this reaction would be: (# of colonies) (dilution factor) (1,000 $\mu\text{l}/\text{ml}$) / (volume of phage plated [μl]).

That is, (200 CFU) (10⁴) (1,000 $\mu\text{l}/\text{ml}$)/(10 μl) = 2×10^8 CFU/ml. Note that the surface area of a standard 90-mm petri dish corresponds to one-eighth of a standard 22.5 \times 22.5-cm square plate that is typically used.

Based on the titer of the phage particles determined previously, dilute the phage particles with PD buffer to obtain the desired number of clones and clone density on the plate. Mix the diluted phage particles with EPI300-T1^R cells prepared in the ratio of 100 μl of cells (prepared as above) for every 10 μl of diluted phage particles. Spread the infected bacteria on an LB plate plus 12.5 $\mu\text{g}/\text{ml}$ chloramphenicol and incubate at 37°C overnight to select for the fosmid clones. Subsequently these clones are plated with the help of a colony-picker robot, in 384-well plates (LB, 12.5 $\mu\text{g}/\text{ml}$ chloramphenicol and 15% of glycerol). Plates are incubated overnight without shaking at 37°C. The colony-picker robot is again used to produce copies of the 384-well plates.

4.4.2. Libraries in the Cosmid pLAFR3

Of particular interest is the mining and further reconstitution of natural-product biosynthetic pathways where large multienzyme assemblies should be functionally expressed and where the choice of a suitable heterologous host is critical (108). In this case, the generation of broader host range vectors mobilized in different gram-negative species—such as pLAFR3 vector, which is able to replicate in *Pseudomonas* strains—has been proposed (97). Strains of *Pseudomonas* are known to be ubiquitous and metabolically versatile, with a great ability to metabolize toxic organic chemicals, such as aliphatic and aromatic hydrocarbons (28). This ability, along with their genetic plasticity, makes these bacteria very attractive for cloning of DNA libraries rich in biodegradation pathways. To this end, below we provide the protocol to generate metagenomic libraries in the pLAFR3 vector, which allows the cloning of ca. 23 kbp of insert DNA and their transfer into different gram-negative expression hosts. To prepare the pLAFR3 shoulders:

1. Inoculate 200 ml of LB, tetracycline 10 $\mu\text{g}/\text{ml}$ with a single colony of *Escherichia coli* S17-3 (bearing pLAFR3 cosmid), and grow overnight with orbital shaking (250 rpm) at 30°C. Pellet cells for 10 min at 7,000 $\times g$ and isolate pLAFR3 cosmid according to the Large Construct Kit (Qiagen), treating the sample with ATP-dependent exonuclease to eliminate the chromosomal DNA of *E. coli*.
2. Take two aliquots of approximately 3 μg of pLAFR3 and cut one with HindIII (shoulder 1) and the other with EcoRI (shoulder 2) at 37°C overnight. Run small aliquots in a 0.75% agarose gel to check that the digestion worked properly, then incubate samples at 65°C for 20 min to inactivate restriction enzymes.
3. Add 3 μl of Shrimp Alkaline Phosphatase (SAP; e.g., from Biotec ASA) to dephosphorylate DNA and incubate for 1 h at 37°C. To prevent DNA shearing, avoid pipetting; just stir the tube content with a pipette tip to mix. Then incubate samples at 65°C for 20 min to inactivate SAP.
4. To remove the endonuclease buffers, mix the pLAFR3 shoulders from the above two reactions 1:1, add 400 μl of water, transfer into a Microcon-100 (Millipore) concentration device, and wash the sample via centrifugation. Concentrate to a final volume of approximately 30 to 40 μl .

5. To a volume of 37 μl of Microcon-concentrated DNA add 5 μl of 10 \times New England Biolabs Buffer 3 (NEB3), 5 μl of bovine serum albumin (BSA) 10 \times , 2 μl of MilliQ water, and 1 μl of BamHI enzyme, and digest overnight at 37°C.
6. Run small aliquots in a 0.75% agarose electrophoresis gel to ensure that the size of the fragments (22 kbp) has not been altered by digestion with BamHI.
7. Use the GeneClean Kit (BIO101) to inactivate BamHI and to concentrate the pLAFR3 shoulders.
8. Ligate the shoulders with insert DNA overnight at 4°C (see the preparation procedure of the insert DNA partially digested with Sau3AI below).
9. Perform the packaging with Gigapack XL (Stratagene, La Jolla, CA) as described by the supplier and select on LB, tetracycline 10 $\mu\text{g}/\text{ml}$, X-Gal 40 $\mu\text{g}/\text{ml}$.

To obtain DNA fragments of 25 to 50 kbp partially digested with Sau3AI it is recommended to do some trial reactions using different amounts of enzyme. Set up a series of reactions starting, for example, with 2 U of enzyme per 1 μg of DNA, 1 U/ μg , 0.5 U/ μg , 0.25 U/ μg , and 0.125 U/ μg . Incubate for 20 min at 37°C. Stop reactions by adding 65 mM EDTA (pH 8) from 0.5 M stock solution, and by heating the samples at 65°C for 15 min. Then run a 20-cm-long 1% agarose gel at 30 to 35 V overnight at 4°C and stain with ethidium bromide. Monitor the partial digestion conditions that optimally should result in a majority of the DNA migrating in the desired size range (25 to 50 kbp) in the agarose gel. To make the preparative (larger-scale) digestion, scale up the enzyme quantity, amount of DNA, and reaction volume, proportionally. Choose two different restriction conditions, as in the following example:

Reaction 1: 0.14 U/ μl - 20 μl of concentrated insert DNA (12 μg), 5 μl of buffer NEB1 10 \times , 5 μl of BSA 10 \times , 2 μl of MilliQ water, 18 μl of Sau3AI 0.4 U/ μl . Total reaction volume: 50 μl .

Reaction 2: 0.21 U/ μl - 20 μl of concentrated insert DNA (12 μg), 7 μl of buffer NEB1 10 \times , 7 μl of BSA 10 \times , 2 μl of MilliQ water, 36 μl of Sau3AI, 0.4 U/ μl . Total reaction volume: 70 μl .

Incubate 20 min at 37°C. Stop reactions by adding 1.5 μl of 0.5 M EDTA (pH 8) to each 10- μl reaction volume and heat the samples to 65°C for 15 min. Then mix both reactions and load samples on a 20-cm-long preparative (seal together the comb teeth with an adhesive band) 1% LMP agarose gel, run it at 30 to 35 V overnight at 4°C and cut and stain the slots with the DNA marker with ethidium bromide. Do not stain the part of the gel containing your DNA for cloning. Under UV light cut out the part of the gel blocks with the DNA markers in the range of ca. 20 kbp and above to use them as a marker to cut the gel part containing the DNA to be cloned. Cut out the desired gel region (25 to 40 kbp gel) and trim the excess of agarose. Then proceed to the agarose gel digestion following the GELase (Epicentre) protocol and concentrate the insert DNA on a Microcon-100 as described above.

Further, ligate overnight at 14°C partially digested DNA and pLAFR3 shoulders in a ratio 1:2 or 1:1. The ligation volume must be as low as possible, preferably up to 5 μl . If you take 100 ng of both shoulders together, then add 50 or 100 ng of the insert. Depending on the amount of DNA available, you may consider doing two separate ligation reactions (50 and 100 ng of DNA, respectively) to determine which reaction generates the best results. It

is highly recommended to run small aliquots (e.g., 1 μl) of all your samples after any manipulation, and after ligation in an agarose gel. Then, package with Gigapack XL (Stratagene, La Jolla, CA) as described in the Packaging Protocol:

1. Remove the appropriate number of packaging extracts from a -80°C freezer and place the extracts on dry ice.
2. Quickly thaw the packaging extract by holding the tube between your fingers until the contents of the tube just begin to thaw.
3. Add the experimental DNA immediately (1 to 4 μl containing 0.1 to 1.0 μg of ligated DNA) to the packaging extract.
4. Stir the tube with a pipette tip to mix well. Gentle pipetting is allowable provided that air bubbles are avoided.
5. Spin the tube quickly (for 3 to 5 s), if desired, to ensure that all contents are at the bottom of the tube.
6. Incubate the tube at room temperature (22°C) for 2 h.
7. Add 500 μl of SM buffer (50 mM Tris-HCl, pH 7.5, 0.1 M NaCl, 8.5 mM MgSO₄, and 0.01% [wt/vol] gelatin) to the tube. The gelatin in SM buffer stabilizes lambda phage particles during storage.
8. Add 20 μl of chloroform and mix the contents of the tube gently.
9. Spin the tube briefly to sediment the debris.
10. The supernatant containing the phage is ready for titrating. The supernatant may be stored at 4°C for up to 1 month.

The next step is the titration of the cosmid-packaging reaction to check the library size:

1. Streak the bacterial glycerol stock (*E. coli* DH5 α or XL1Blue) onto the LB agar plates. Incubate the plates overnight at 37°C. Do not add antibiotic to the medium in the following step. The antibiotic will bind to the bacterial cell wall and will inhibit the ability of the phage to infect the cell.
2. Inoculate 50 ml of LB, supplemented with 10 mM MgSO₄ and 0.2% (wt/vol) maltose, with a single colony.
3. Grow at 37°C, shaking for 4 to 6 h (do not grow past an OD₆₀₀ of 1.0). Alternatively, grow overnight at 30°C, shaking at 200 rpm.
4. Pellet the bacteria at 500 \times g for 10 min.
5. Gently resuspend the cells in half the original volume with sterile 10 mM MgSO₄.
6. Dilute the cells to an OD₆₀₀ of 0.5 with sterile 10 mM MgSO₄. The bacteria should be used immediately after dilution.
7. Prepare a 1:10 and a 1:50 dilution of the cosmid-packaging reaction in SM buffer.
8. Mix 25 μl of each dilution with 25 μl of the appropriate bacterial cells at an OD₆₀₀ of 0.5 in a microcentrifuge tube and incubate the tube at room temperature for 30 min.
9. Add 200 μl of LB broth to each sample and incubate for 1 h at 37°C, shaking the tube gently once every 15 min. This incubation will allow time for expression of the antibiotic resistance.
10. Spin the microcentrifuge tube for 1 min and resuspend the pellet in 50 μl of fresh LB broth.
11. Using a sterile spreader, plate the cells on LB agar plus 10 $\mu\text{g}/\text{ml}$ tetracycline and incubate at 37°C overnight to select for the fosmid clones. Incubate the plates overnight at 37°C.
12. Count colonies and calculate the titer of the packaged phage particles as described above.

Based on the titer of the phage particles, dilute the phage particles with SM buffer to obtain the desired number of clones and clone density on the plate. Mix the diluted phage particles with *E. coli* DH5 α or XL1Blue cells prepared in the ratio of 100 μ l of cells for every 10 μ l of diluted phage particles. Spread the infected bacteria on LB agar, tetracycline 10 μ g/ml, X-Gal 40 μ g/ml plates and incubate at 37°C overnight to select for the plasmid clones. These clones are subsequently picked with a colony-picker robot and transferred into 384-well plates containing liquid LB, tetracycline 10 μ g/ml, and 15% of glycerol. Plates are incubated overnight without shaking at 37°C. The colony-picker robot or the 384-pin replicators can be used to produce multiple copies of the primary library arrayed in 384-well plates.

4.4.3. Libraries in Lambda Zap® Express

Small insert expression libraries, especially those made in lambda phage vectors, are specially constructed for activity screens; however, in contrast with cosmid or fosmid vectors, the Zap Express pBK vector (Stratagene, La Jolla, CA) allows cloning of up to 15 kbp (usually, approximately 6.5- to 8.5-kbp-long DNA inserts). To obtain DNA fragments of approximately 8.5 to 9.5 kbp partially digested with Sau3AI it is recommended to conduct some trial reactions using different amounts of enzyme. Set up a series of reactions starting, for example, from 0.1 to 0.04 U of enzyme per 1 μ g of DNA:

Reaction 1: 0.04 U (0.004 U/ μ l) - 0.683 μ l of DNA (585.5 ng/ μ l), 1.0 μ l of NEB buffer \times 10, 1.0 μ l of BSA \times 10, 7.23 μ l of H₂O, 0.1 μ l of Sau3AI 0.4 U/ μ l.

Reaction 2: 0.06 U (0.006 U/ μ l) - 0.683 μ l of DNA (585.5 ng/ μ l), 1.0 μ l of NEB buffer \times 10, 1.0 μ l of BSA \times 10, 7.17 μ l of H₂O, 0.15 μ l of Sau3AI 0.4 U/ μ l.

Reaction 3: 0.1 U (0.01 U/ μ l) - 0.683 μ l of DNA (585.5 ng/ μ l), 1.0 μ l of NEB buffer \times 10, 1.0 μ l of BSA \times 10, 7.07 μ l of H₂O, 0.25 μ l of Sau3AI 0.4 U/ μ l.

Reaction 4: 0.5 U (0.05 U/ μ l) - 0.683 μ l of DNA (585.5 ng/ μ l), 1.0 μ l of NEB buffer \times 10, 1.0 μ l of BSA \times 10, 6.07 μ l of H₂O, 1.25 μ l of Sau3AI 0.4 U/ μ l.

Reaction 5: 1 U (0.1 U/ μ l) - 0.683 μ l of DNA (585.5 ng/ μ l), 1.0 μ l of NEB buffer \times 10, 1.0 μ l of BSA \times 10, 4.82 μ l of H₂O, 2.5 μ l of Sau3AI 0.4 U/ μ l.

Incubate for 20 min at 37°C. Stop reactions by adding 65 mM EDTA, pH 8, and by heating the samples at 65°C for 15 min. Then run a 20-cm-long 1% agarose gel at 30 to 35 V overnight at 4°C and stain with ethidium bromide. Use the partial digestion conditions that result in a majority of the DNA migrating in the desired size range (5 to 15 kbp). For the partial digestion of the DNA, you should scale up the Sau3AI enzyme amount for at least 2 μ g of DNA. The two best restriction conditions to be selected and scaled up are as follows:

Reaction 1: 20 μ l of DNA (11.7 μ g), 5 μ l of buffer NEB \times 10, 5 μ l of BSA \times 10, 2 μ l of H₂O MilliQ, 18 μ l of Sau3A 0.4 U/ μ l (7.2 U; 0.144 U/ μ l of reaction; 0.61 U/ μ g of DNA)

Reaction 2: 20 μ l of DNA (11.7 μ g), 7 μ l of buffer NEB \times 10, 7 μ l of BSA \times 10, 0 μ l of H₂O MilliQ, 36 μ l of Sau3A 0.4 U/ μ l (14.4 U; 0.206 U/ μ l of reaction; 1.23 U/ μ l DNA).

Incubate for 20 min at 37°C. Stop reactions by adding 65 mM EDTA, pH 8 (1.5 μ l of 0.5 M, pH 8.0 EDTA for each 10- μ l reaction volume) and heat the samples to 65°C for 15 min. Then mix both reactions and load samples on a

20-cm-long preparative 1% LMP agarose gel, run it at 30 to 35 V overnight at 4°C, and cut out and stain marker lanes with ethidium bromide. On the latter mark the desired gel region (10- to 15-kbp gel region) and cut the corresponding region from the nonstained part of the gel, and trim the excess of the agarose. Do not expose the gel slice to UV light to minimize the formation of pyrimidine dimers. Then proceed with the agarose gel digestion following the GELase (Epicentre) protocol and concentrate DNA as above.

The next step is the ligation of pBK-CMV vector predigested with BamHI (Stratagene, La Jolla, CA) with the insert DNA prepared above. Ligate overnight at 4°C Sau3AI-digested DNA and pBK-CMV, using the following ligation conditions: 1 μ l of Zap Express Vector, 0.6 μ l of T4 ligase buffer (\times 10), 4 μ l of concentrated insert, 0.6 μ l of T4 DNA ligase. The final volume should not exceed 5.0 to 5.5 μ l.

Further, the ligation reaction is packaged with Gigapack XL (Stratagene, La Jolla, CA), as described above, and titrated as follows:

1. Streak the bacterial glycerol stock (*E. coli* XL1 MRF') onto the LB agar plates and incubate overnight at 37°C. Do not add antibiotic to the medium in the next step. The antibiotic will bind to the bacterial cell wall and inhibit the ability of the phage to infect the cell.
2. Inoculate 50 ml of LB, supplemented with 10 mM MgSO₄ and 0.2% (wt/vol) maltose with a single colony.
3. Grow at 37°C with shaking for 4 to 6 h (do not grow past an OD₆₀₀ of 1.0). Alternatively, grow overnight at 30°C, shaking at 200 rpm.
4. Pellet the bacteria at 500 \times g for 10 min.
5. Gently resuspend the cells in half the original volume with sterile 10 mM MgSO₄.
6. Dilute the cells to an OD₆₀₀ of 0.5 with sterile 10 mM MgSO₄. The bacteria should be used immediately after dilution.
7. Prepare dilutions from 1:1 to 1:10⁵ of the packaging reaction in SM buffer.
8. Mix 1 μ l of each dilution with 200 μ l of the appropriate bacterial cells at an OD₆₀₀ of 0.5 in a microcentrifuge tube and incubate the tube at 37°C for 15 min, shaking the tube gently.
9. Add 500 μ l of NZY soft agar to each sample plate on NZY agar plates. Incubate the plates overnight at 37°C.
10. Count phage particles and calculate the titer of the packaged phage particles as described above.

After the titration, used to calculate the library size, the library is further amplified. Amplification can be performed both in liquid medium or agar plates. For amplification in liquid culture use the following protocol:

1. Mix 2 ml of a fresh, overnight bacterial culture (OD₆₀₀, 0.95) with approximately 10⁶ PFU of bacteriophage in a sterile culture tube.
2. Incubate for 15 min at 37°C to allow the bacteriophage particles to adsorb.
3. Add 8 ml of prewarmed LB medium (or NZY) and incubate for 6 to 12 h at 37°C with vigorous shaking until lysis occurs: the cell suspension becomes less dense.
4. After lysis has occurred, add 2 drops of chloroform and continue incubation for 15 min at 37°C.
5. Centrifuge at 4,000 \times g for 10 min at 4°C.
6. Recover the supernatant, add 1 drop of chloroform, and store at 4°C. The titer of the stock should be approximately 10¹⁰ PFU/ml, and this usually remains unchanged as long as the stock is stored at 4°C.

For the amplification in solid agar, *E. coli* XL1 MRF' cells are prepared as described above in MgSO₄ 10 mM and with an OD₆₀₀ of 0.5. Then proceed as follows:

1. Two aliquots are prepared, each of them containing approximately 5×10^4 PFU and 600 μ l of *E. coli* cells. Do not exceed 300 μ l of phage suspension per 600 μ l of cells.
2. Incubate for 15 min at 37°C with gentle shaking, after which 3 ml of NZY broth is added and further spread over NZY agar plate (22.5 \times 20 cm) prewarmed at 37°C.
3. Incubate the plates at 37°C for about 8 to 10 h, after which 8 to 10 ml of SM buffer is added. Shake the plates at 50 rpm for 10 h at 4°C.
4. Decant into a Falcon (50 ml) tube. Add additional 2 ml of SM buffer to the agar, shake the plate briefly, and decant to the same Falcon tube.
5. Add 5% (vol/vol) chloroform and incubate 15 min at 4°C.
6. Centrifuge at $500 \times g$ for 10 min at 4°C.
7. The supernatant is collected and stored: one small aliquot at 4°C for lab use and the remaining supernatant is stored at -70°C after the addition of 7% dimethyl sulfoxide (DMSO). The library is then ready to use.

4.5. HOST-VECTOR SYSTEMS FOR "COMMON" ENZYMES AND "EXTREMOZYME" EXPRESSION

The production of enzymes of industrial interest is usually accomplished through the overexpression of the corresponding genes in well-characterized bacterial or eukaryotic hosts such as *E. coli*, *Bacillus subtilis*, and *Saccharomyces cerevisiae*. Numerous sophisticated genetic tools for heterologous gene cloning and expression in these hosts are commercially available. However, the success of this approach for the production of extremozymes has been limited.

Expression in an enzymatically active form is commonly achieved only for simple monomeric or homo-oligomeric soluble extremozymes that do not require *trans*-acting factors that need to be provided by the host. Host-specific factors include transcription factors, tRNAs for rare codons, cofactors, posttranslational modification systems, proteolytic processing, chaperones, and components for multi-subunit assembly. In addition, factors such as temperature may affect the folding of enzymes into active forms. For thermophilic bacteria and archaea it is currently estimated that a large proportion (more than 40%) of the proteins encoded within the genome cannot be expressed or would be expressed in enzymatically inactive forms in common mesophilic hosts (54).

For a significant number of extremozymes large-scale production in heterologous nonextremophile hosts will therefore probably not be achievable. Similarly, the use of these hosts for activity-based screening of genomic and metagenomic libraries from extremophilic organisms limits the success rate for assessing enzymatic diversity and isolating novel extremozymes. The development of shuttle vectors with wider host ranges, such as the *E. coli*-*Actinomyces* shuttle vector (18) and a bacterial artificial chromosome shuttle vector system capable of replicating in *E. coli*, *Streptomyces lividans*, and *Pseudomonas putida* (69), should increase the probability of detecting genes encoding novel extremozymes. Expression in extremophilic hosts is however likely to prove the ultimate solution to these problems. The next section will therefore

focus on the recent development and use of genetic tools for extremophilic organisms.

4.5.1. *Thermus thermophilus* Expression Systems

The thermophilic gram-negative bacterium *T. thermophilus* has become the model of choice for the development of genetic tools for the expression of thermozymes (reviewed in reference 14). The genome sequences of the two commonly used strains, *T. thermophilus* HB8 and HB27, are available (42, 70). Well-adapted laboratory strains grow aerobically at optimum temperatures ranging from 62 to 75°C with high growth rates and good cell yields on complex medium (TB medium, 8 g/liter trypticase, 4 g/liter yeast extract, and 3 g/liter NaCl, pH 7.5) without the addition of specific amino acids or vitamins (24). *Thermus* spp. are readily accessible to genetic manipulation due to the constitutive expression of a natural competence apparatus, with high transformation efficiencies typically achieved (91). *Thermus* vector systems have been developed for the expression of homologous or heterologous genes, genomic or metagenomic libraries, and the tailoring of the biocatalytic properties of thermozymes.

Numerous cloning and expression vectors have been described for *T. thermophilus* (23, 61, 63, 71, 84). However, in most cases, these systems achieved only moderate protein overexpression levels. Moreno and coworkers (74), however, report the construction of a shuttle expression vector, pMKE2, facilitating overexpression in *T. thermophilus* to levels greater than that obtained in *E. coli* expression systems. Plasmid pMKE2 (Biotools, Madrid, Spain; <http://www.biotools.eu>) contains several restriction sites for cloning, a selection gene encoding a thermostable resistance to kanamycin under the control of a bifunctional *E. coli*-*Thermus* promoter, and replicative origins for *E. coli* and *Thermus* (75). Inserted genes are placed under the control of an inducible modified promoter from the respiratory nitrate reductase operon (*Pnar*) of HB8. Plasmids are transformed into HB27::nar, a derivative of HB27 that contains the gene cluster for nitrate respiration. This system allows for inducible expression based on the presence of nitrate and absence of oxygen. Transformed HB27::nar cells are grown aerobically in TB medium supplemented with kanamycin to an OD₅₅₀ of 0.2 to 0.3 at 60 or 70°C under mild stirring. Transcription from the *nar*p promoter is then initiated through the simultaneous addition of KNO₃ (40 mM) and induction of anoxia through incubation without shaking. Thermophilic enzymes expressed in this system include β -galactosidase (75), Mn-dependent catalase (46), DNA polymerase (76), and Omp85 (78).

A *T. thermophilus*-*E. coli* fosmid system for functional screening of genomic and metagenomic libraries from thermophiles has recently been described (3). The fosmid integration vector, pCT3FK, allows for the construction of large-insert libraries in *E. coli* and the transfer of these recombinant libraries to *T. thermophilus* for functional screening. pCT3FK (Fig. 1) is a derivative of pCC1FOS (Epicentre), with the addition of a gene encoding thermostable resistance to kanamycin and two fragments that flank the *pyrE* locus derived from the *T. thermophilus* HB27 genome. Fosmid libraries are generated by shearing the genomic DNA of interest to an average size of 40 kb, end-repairing and ligating to Eco721 linearized dephosphorylated pCT3FK. Fosmids are then prepared by use of lambda phage packaging extracts and propagated in *E. coli* EPI300 (Epicentre). Fosmid DNA is isolated using commercial DNA isolation kits and used to transform *T. thermophilus* HB27. The incorporation of the sequences flanking the

FIGURE 1 Vector map of the shuttle fosmid pCT3FK (Chl, chloramphenicol resistance; kat, thermostable kanamycin resistance) and the region of *T. thermophilus* HB27 genome containing the *pyr* genes. G3PDH, glycerol-3-phosphate dehydrogenase; hyp, hypothetical protein (3).

pyrE locus on either side of the Eco721 site in pCT3FK then guides the homologous integration of the insert into the *pyrE* locus of HB27, creating site-specific *Thermus* libraries. In a xylanase activity screen test of a *Spirochaeta thermophila* genomic library created in pCT3FK, 50% of the fosmids that conferred xylanase activity in *T. thermophilus* did not give rise to xylanase-positive *E. coli* clones (3).

Recently, new technologies for the generation and identification of thermostable mutants in *T. thermophilus*, named Massive Mutagenesis and THR, have been developed by Biométhodes (Evry, France; <http://www.biometodes.com>). THR is based on an *E. coli*-*Thermus* spp. shuttle plasmid, pNCK, developed by Chautard and coworkers (15). This plasmid contains both *Thermus* and *E. coli* origins of replication, an ampicillin resistance gene, and a gene encoding thermostable resistance to kanamycin (*kat^{tv}*). Two unique restriction enzyme sites (NcoI and NotI) inserted between the *kat^{tv}* promoter and open reading frame facilitate the cloning and expression of the gene of interest as an N-terminal fusion construct with *kat^{tv}*. The recombinant pNCK plasmid is introduced into *E. coli* and mutant libraries (representing complete diversity introduced in a combinatorial manner at each amino acid position) generated using Massive Mutagenesis technology (88). Libraries are then transformed into *T. thermophilus* by electroporation and transformants grown at high temperature on TB plates supplemented with kanamycin. Because improper folding of the N-terminal portion of a protein has a negative impact on the folding of the C terminus (in this case, the reporter Kat^{tv}), the stability of the protein of interest will influence the antibiotic resistance of transformed cells. In the presence of kanamycin and high temperature, only *Thermus* transformants encoding thermostable proteins will have increased antibiotic resistance, thus allowing direct overnight plate selection (15). Biométhodes' Massive Mutagenesis and THR technology should allow for the rapid tailoring of the thermal stability and activity of enzymes.

4.5.2. *Geobacillus* spp. Expression System

The thermophilic bacilli of the genus *Geobacillus* have emerged as having considerable potential in biotechnological applications. Strains can be cultivated under aerobic or anaerobic conditions on a wide range of growth substrates, their metabolism has been researched extensively, and they are amenable to genetic manipulation. Full genomes for *Geobacillus kaustophilus* and *Geobacillus thermodenitrificans* are available, and the genome of *Geobacillus stearothermophilus* is currently being sequenced (*Bacillus* [*Geobacillus*] *stearothermophilus* Genome Sequencing Project: <http://www.genome.ou.edu/bstearo.html>).

An improved versatile shuttle vector, pUCG18, has been developed for heterologous gene expression in thermophilic *Geobacillus* spp. (101). This vector can replicate in *E. coli* and *Geobacillus* spp., encodes ampicillin and thermostable kanamycin resistance, has multiple cloning sites, and permits LacZ blue-white screening for the selection of recombinants in *E. coli*. The vector has been used for the expression of *Zymomonas palmarum* pyruvate decarboxylase in *Geobacillus thermoglucosidarius*.

4.5.3. *Sulfolobus* spp. Expression Systems

Sulfolobus spp. belong to the class *Crenarchaeota* and are thermoacidophiles with an optimal growth temperature above 70°C (up to 82°C) and an optimum pH of 3. *Sulfolobus* strains are grown in the laboratory with relative ease. Strains can be grown to high cell density heterotrophically on organic substrates such as tryptone and a variety of sugars. During liquid cultivation in complex media, doubling times of 3 to 6 h are achieved during exponential growth. Strains can be grown on plates prepared with gellan gum (Gelzan or Gelrite; Sigma), a gelling agent that, in the presence of divalent cations, does not melt at 80°C. *Sulfolobus* can be transformed by electroporation (90). Complete genome sequences for the commonly used laboratory strains *Sulfolobus solfataricus* P2 and *Sulfolobus acidocaldarius* are available (16, 93).

A variety of virus- and plasmid-derived *Sulfolobus*-*E. coli* shuttle vectors have been developed with variable success and reproducibility (reviewed in reference 9). Of these the pA to pN shuttle vector series appears the most straightforward and promising in terms of vector size (approximately 9 kbp), unique cloning sites, lack of repetitive sequence, and stability in *E. coli*. In addition, the performance of this vector has been confirmed independently (10). The pA to pN vector series were constructed by the insertion of an *E. coli* replicon and the marker genes *pyrEF* into the *Sulfolobus* plasmid pRN1 at a number of different sites. These vectors therefore differ only in the orientation and location of these inserted genes. Transformation is achieved by electroporation of stable *S. acidocaldarius* or *S. solfataricus pyrE* mutants and selection on uracil-deficient media. Cloning of an *S. solfataricus* expression cassette encoding *lacS* and expression of this enzyme in an active form indicated that the system is suitable for gene expression.

4.5.4. *Pyrococcus abyssi* Expression System

Pyrococcus spp. are hyperthermophilic anaerobic euryarchaea that grow optimally at 100°C. Complete genome sequences for *P. abyssi*, *P. furiosus*, and *P. horikoshii* are available (17). *Pyrococcus* spp. can be grown to high cell densities and are relatively easy to handle. Transformation is achieved by use of a polyethylene glycol-mediated spheroplast method (66). An *E. coli*-*P. abyssi* shuttle vector, pYS2, was derived from the endogenous pGT5 plasmid of the *P. abyssi* strain

GE5 and includes the *pyrE* gene from *S. acidocaldarius* as a selectable auxotrophic marker. Transformation of a *pyrE* mutant *P. abyssi* strain GE9 with pYS2 restored growth on uracil to wild-type levels. Under selective conditions pYS2 was shown to be stable and maintained at high copy numbers in both *E. coli* and *P. abyssi* (66, 86).

4.5.5. *Thermococcus kodakaraensis* Expression System

Thermococcus kodakaraensis is a hyperthermophilic euryarchaeon that is naturally competent for DNA uptake. An *E. coli*-*T. kodakaraensis* shuttle vector pLC70 was recently constructed by Santangelo and coworkers (89). This vector can replicate stably and express genes in both *E. coli* and *T. kodakaraensis* (at 85°C). A selectable marker for $\Delta trpE$ complementation in *T. kodakaraensis* KW128 ($\Delta pyrF \Delta trpE::pyrF$) allows for the selection of transformants on plates in the absence of tryptophan. An additional mevinolin resistance marker allows for transformant selection in *T. kodakaraensis* without the $\Delta trpE::pyrF$ mutation. Recombinant expression of a subunit (RpoL) of the *T. kodakaraensis* RNA polymerase using this system revealed incorporation into functionally active RNA polymerase holoenzymes (89).

4.5.6. Haloarchaeal Expression Systems

Haloarchaea are adapted to high-salt environments (typically requiring molar salt concentrations for growth) and accumulate equivalent cytoplasmic concentrations of salt. For an excellent technical resource for haloarchaea, detailing methods used in growth media preparation, cultivation, transformation, and DNA extraction procedures, see *The Halo handbook* (29). Haloarchaea were the first archaea to be successfully transformed, allowing for the development of a number of genetic tools. Genetic manipulation systems include vectors, selection systems, or reporter genes used primarily for targeted gene knockout, exchange, or mutation, and the analysis of *cis*-acting factors involved in transcription and translation in archaea (e.g., see references 7, 44, and 49). Several *E. coli*-*Halobacterium* shuttle vectors have been constructed based on, for example, the endogenous plasmids pHV2 (62, 79, 85) and pHK2 (48, 49). Shuttle plasmids pMDS24, and derivatives pBAP5009 and pJAM202, all include the P2 promoter of the rRNA operon of *Halobacterium cutinubrum* for recombinant expression and ampicillin, mevinolin, or novobiocin resistance genes. These plasmids have been used successfully for the overexpression of a number of enzymes in *Halobacterium volcanii* DS70 (22, 55–57, 107).

4.5.7. Acidophiles and Alkalophiles

Native plasmids have been isolated from acidophiles (4, 94) and alkalophiles (34). To our knowledge no suitable expression or shuttle vectors have been generated, this is probably due to the large size and cryptic nature of most plasmids isolated. Increased interest in the biotechnological applications of acid- and alkaline-resistant proteins should promote the development of genetic tools for these hosts.

4.6. ENZYMES FROM EXTREMOPHILES

4.6.1. Thermophiles

Thermophiles are defined as organisms with an upper growth limit between 50°C and 70°C, that are able to grow, albeit slowly, at mesophilic temperatures (25 to 40°C). Hyperthermophiles, which include representatives from the domains *Bacteria* and *Archaea*, are defined as microorganisms

that grow fastest between 80°C and 110°C (98). Many of the enzymes produced by thermophilic organisms are thermostable (20). These enzymes are of much interest to the biotechnology industry, not only for their stability at elevated temperatures, but also because of their resistance to other denaturants. It has been well documented that some mechanisms that impart resistance to denaturation by heat also confer resistance to other denaturants such as detergents and organic solvents (19). One advantage of working with thermophilic enzymes is that, in general, they can be purified by simple heat precipitation, even when they have been expressed in a mesophilic host (27).

When performing an assay with a thermostable enzyme, one should be aware of several factors that may affect the outcome of the experiment. First, although most enzymes are relatively thermostable at the optimal growth temperature for the producing strain, some enzymes may be more or less thermostable at the optimal growth temperature, and the best temperature at which to perform the assay should be determined empirically. For some thermostable enzymes optimal thermostability may be achieved at temperatures from 10 to 20°C above or below the optimal growth temperature (19). The thermostability of an enzyme should be determined before selecting at which temperature to perform an assay (38, 72). Second, some reactants or products may become unstable at elevated temperatures and, therefore, it is not always feasible to carry out the reaction at an enzyme's thermal optimum. The loss of catalytic efficiency caused by running a reaction at a lower temperature should be balanced out with the increased stability of all the reactants. However, some substrates, including polymeric substrates such as starch, are in fact more susceptible to catalysis at high temperatures (19, 45). Finally, because many of these enzymes need to be assayed at elevated temperatures, researchers should consider the effect that temperature has on the pH of a buffer. Table 1 lists the pK_a of some commonly used biological buffers at 20, 25, and 37°C. Table 2 shows the change in pH of Trizma buffer versus temperature.

4.6.2. Psychrophiles

While we live in a world dominated by “cold” environments, where the ambient temperature is permanently below 5°C, the amount of published work on cold-adapted proteins is limited. For several decades the most commonly cited definition of a psychrophile has been any organism that has a growth optimum below 15°C, with an upper limit for growth at ~20°C (77). However, this broad classification is highly ambiguous and could be extended to include many microorganisms, plants, and invertebrates living in colder habitats. Recently, researchers have started to define true psychrophiles as any organism that permanently “thrives” at temperatures close to the freezing point of water (31). Many psychrophilic microorganisms are completely adapted to living in extremely cold environments. This is evident because, when some psychrophiles are cultured in rich medium at 4°C, they have a doubling time similar to that of *E. coli* when cultured at 37°C; however, these same psychrophilic organisms will be unable to grow at elevated temperatures (31).

Two striking adaptive features of cold-adapted proteins are their weak stability and high activity at low temperatures. Because low temperatures inhibit the rate of catalytic reactions, one of the main challenges faced by psychrophilic organisms is the need to maintain the rate of enzyme-catalyzed reactions that are essential for their survival.

TABLE 1 Useful pH range of common biological buffers (25°C, 0.1 M)^a

Buffers ^b	Useful pH range	pK _a at 20°C	pK _a at 25°C	pK _a at 37°C
Bis-Tris	5.8–7.2	n/a	6.50	6.36
CABS	10.0–11.4	n/a	10.70	n/a
CAPS	9.7–11.1	10.56	10.40	10.02
HEPES	6.8–8.2	7.55	7.48	7.31
MES	5.5–6.7	6.16	6.10	5.97

MOPSO	6.2–7.6	n/a	6.90	6.75
PIPES	6.1–7.5	6.80	6.76	6.66
TES	6.8–8.2	7.50	7.40	7.16

^aSee reference 21 for details.^bCABS, 4-[cyclohexylamino]-1-butananesulfonic acid; CAPS, *N*-cyclohexyl-3-aminopropanesulfonic acid; MES, morpholineethanesulfonic acid; MOPS, morpholinepropanesulfonic acid; MOPSO, 3-(*N*-morpholino)-2-hydroxypropanesulfonic acid; PIPES, piperazine-*N,N'*-bis(2-ethanesulfonic acid); TES, *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid.

Therefore, the activity of many cold-active, heat-labile proteins is 10-fold greater at low temperatures compared with the activity of the homologous mesophilic proteins at mesophilic temperatures. The increased activity of cold-adapted proteins is achieved by destabilizing either the active site of the enzyme or the entire protein, rendering the catalytic site more flexible (31). Two general considerations when assaying psychrophilic enzymes is that, while these heat-labile proteins may have thermal optima that are significantly lower than those of the corresponding mesophilic proteins, these thermal optima may be significantly higher than the optimal growth temperature, and may even exceed the upper growth limits, for the producing strain (86). Second, some cold-adapted proteins are inactivated at a

temperature below which the protein itself denatures (30). The thermodynamics of psychrophilic proteins is discussed in detail by Feller (30).

4.6.3. Halophiles

While many prokaryotes can survive over a wide range of salinities, true halophilic organisms require NaCl for growth. Halotolerant organisms can grow over a salt range of 0 to 1.0 M, moderate halophiles are capable of growth from 0.4 to 3.5 M salt, while an extreme halophile has a growth range from 2.0 to 5.2 M and typically displays optimal growth at >3.0 M (39). Because halophiles need to contend with high intra- and extracellular ionic concentrations, the enzymes they produce must retain functionality under conditions of low water activity.

The purification of halophilic proteins can be problematic because of their requirement for salt to maintain structural integrity. In general, halophilic proteins have acidic surfaces and the associated negative electrostatic forces may potentially provide a stabilizing force. These proteins may unfold at low salt concentrations due to the repulsive force exerted by the acidic residues. Many halophilic proteins also have a low thermal stability (95). Ion-exchange chromatography with an increasing salt gradient to elute the protein is a technique that is routinely used to purify mesophilic proteins. However, because a high salt concentration must be maintained to retain halophilic proteins in their native, active conformation, ion-exchange chromatography is not a suitable method to purify these proteins. Possible methods that can be used to purify halophilic proteins include gel filtration and hydroxylapatite chromatography using high-salt buffers, hydrophobic chromatography with a decreasing gradient of ammonium sulfate on carboxymethylcellulose or Sepharose 4B columns, and affinity chromatography (73). Electrophoresis of halophilic proteins may also be problematic because of the high electrical conductivity of the suspending solution required to maintain the protein in its native configuration (82). Structural studies of halophilic proteins may also prove to be problematic because of the difficulty in crystallizing proteins at high ion concentrations (95).

4.6.4. pH Extremes: Alkaliphiles and Acidophiles

Horikoshi (51) defined an alkaliphile as “an organism whose optimum rate of growth is observed at least two pH

TABLE 2 Trizma buffer: pH versus temperature^a

pH at 5°C	pH at 25°C	pH at 37°C
7.76	7.20	6.91
7.89	7.30	7.02
7.97	7.40	7.12
8.07	7.50	7.22
8.18	7.60	7.30
8.26	7.70	7.40
8.37	7.80	7.52
8.48	7.90	7.62

9.36	8.80	8.51
9.47	8.90	8.62
9.56	9.00	8.70

^aSee reference 21 for details.

units above neutrality.” Alkali-tolerant organisms have an optimum growth rate around neutrality but can grow or survive at $\text{pH} \geq 9$. The current consensus is that a true alkaliphile grows optimally at $\text{pH} \geq 9$, but is unable to grow or grows very slowly at $\text{pH} 6.5$ (51). Obligate alkaliphiles require alkaline conditions and sodium ions for growth, sporulation, and germination; in fact, many alkaliphiles display sodium ion-dependent nutrient uptake.

Acidophiles have a growth optimum between $\text{pH} 0$ and 5.5 and cannot grow at neutral pH . The cytoplasmic membrane of an obligate acidophile requires a high concentration of hydrogen ions to maintain membrane stability, and at neutral pH the membrane begins to dissolve and the cell lyses (68). The internal pH of acidophiles is typically between $\text{pH} 5$ and $\text{pH} 7$ (81). Serour and Antranikian (92) isolated heat- and acid-stable glucoamylases from three thermoacidophilic *Archaea* species. The enzymes displayed optimal activity at 90°C and $\text{pH} 2.0$. These authors encountered a problem in that, when they ran the concentrated supernatant on native polyacrylamide gels, they were unable to detect the proteins. They surmise that the acidophilic proteins failed to migrate into the gel under nondenaturing conditions because of the aggregation of the proteins at low pH (92). When performing an assay on acidophilic proteins the pH optima of the enzyme may not necessarily mimic that of the natural environment and one should consider the intracellular pH of the host strain, the extracellular pH , and the stability of a substrate at an acidic pH when selecting the assay conditions. The pH profile of an acidophilic protein may also shift by the addition of NaCl or CaCl_2 . The intracellular glucoamylase produced by the extreme thermoacidophilic archaeon *Thermoplasma acidophilum* displayed maximal amylolytic activity at $\text{pH} 5$. With the addition of NaCl or CaCl_2 the pH optimum of the enzyme was $\text{pH} 5.5$ (27).

4.6.5. Archaeal Enzymes

Archaea are seen by many scientists as an ideal source of thermophilic and/or acidophilic enzymes. However, the large-scale production of archaeal proteins has several disadvantages. The biomass yield from archaea may be low (less than 10 g/liter wet weight versus 5 to 30 g for many common eubacteria) (19). While a possible solution to this obstacle would be to clone the gene of interest into a suitable host, some archaeal proteins can not be expressed in eukaryotic or bacterial expression hosts. At the protein level there are a number of explanations as to why an expression host may be unable to express archaeal proteins, including the absence of appropriate cellular chaperones, some strains that possess the correct translational machinery lack the protease Lon, or the formation of inclusion bodies. Possible ways to prevent or overcome the formation of inclusion bodies include moderate heat shock, decreased temperature during expression, and use of growth media that are enriched with amino acids (25, 45, 52).

4.7. ENZYMES FROM “COMMON” AND EXTREME ENVIRONMENTS

4.7.1. Lignocellulose-Degrading Extremozymes

It has become increasingly apparent that the production of fuel from traditional, nonrenewable sources is unable to match the global population's demand for fuel. Therefore, there is an incentive to discover alternative, readily available sources. The production of biofuels from lignocellulosic biomass is an attractive option, because the processing

costs are low, large quantities of the raw materials are available, and production is environmentally benign (almost carbon neutral) (67). Most of the methods currently used to produce biofuels from lignocelluloses require enzymes that function at high temperature and under acidic conditions (30). The elevated temperatures are needed to solubilize the starch and maintain a low viscosity (27). Therefore, extremophiles are an obvious source of novel enzymes that may revolutionize the biofuels industry.

Much research has focused on thermoacidophilic species. When screening for enzymes from these organisms it is important to note that some small sugars (i.e., maltose) are not suitable substrates because the combination of low pH and high temperature may result in the occurrence of Maillard's reaction. (Maillard's reaction is a chemical reaction between the carbonyl group of reducing sugars and an amino group [92].)

4.7.1.1. Cellulose-Degrading Enzymes

Cellulases (EC 3.2.1) are enzymes that catalyze the hydrolysis of cellulose by cleaving the β -1,4-D-glycosidic linkage between glucose monomers. Examples of enzymes that degrade cellulose include β -1,4-endoglucanase, carboxymethyl cellulase, and endo-1,4-D-glucanase (25). See Table 3 for examples of lignocellulosic-degrading enzymes that have been isolated from extremophiles.

4.7.1.2. Amylases

Glucoamylases are exohydrolases that attack the substrate from the nonreducing end, producing glucose monomers with a β -anomeric configuration. Amylases have been characterized from various extremophiles. Heat- and acid-stable glucoamylases have been isolated from the thermoacidophilic archaeon species *T. acidophilum*, *Picrophilus torridus*, and *Picrophilus oshimae*. All three species grow optimally at 60°C and at a pH of ≤ 2 , and the enzymes they produce have optimal activity at 90°C and at a pH of 2.0 (92). α -Amylases have also been isolated from psychrophilic strains, including the Antarctic bacterium *Pseudoalteromonas haloplanktis* (30). Horikoshi (50) was the first to describe an alkaline-stable α -amylase from an alkaliphilic *Bacillus* species. This enzyme was most active between $\text{pH} 10$ and 10.5 , and hydrolyzed 70% of starch yielding glucose, maltose, and maltotriose (50). γ -Amylases (EC 3.2.1.3) cleave the α -1,4-glycosidic linkage at the nonreducing end of amylase and amylopectin, as well as cleaving α -1,6-glycosidic linkages. γ -Amylases are most effective in acidic environments, and many have optimal activity at $\text{pH} 3$.

4.7.1.3. Hemicellulose-Degrading Enzymes

Hemicellulose is one of the most abundant polysaccharides in nature, and unlike cellulose, which contains only glucose monomers, hemicellulose contains an array of different of sugar monomers, including galactose, glucose, mannose, and rhamnose, with xylose often being present in large quantities.

4.7.1.4. Ethanol Production from Xylose

Theoretically, thermophilic anaerobes can produce large quantities of ethanol from xylose, with yields of 0.51 g of ethanol per g of xylose being reported (96). Sommer et al. (96) investigated the potential of thermophilic anaerobic bacterial strains and anaerobic enrichment cultures (all with optimal growth occurring at 70 to 80°C) to produce ethanol from D-xylose and hemicellulose hydrolysate from wheat straw. The authors used pretreated wet, oxidized hemicelluloses (13) and detected the end products of fermentation

TABLE 3 Lignocellulosic-degrading enzymes produced by extremophiles: producing strains and assays used

^aOSX, oat-spelt xylan.

including ethanol, lactate, and acetate by high-pressure liquid chromatography (96). Conclusions drawn from this study confirmed previously published results, in that while some strains may be able to produce ethanol from pure xylose in well-defined growth media, they are unable to ferment lignocellulosic hydrolysate effectively. This is possibly due to the presence of inhibitors such as weak organic acids (including acetate) (104) or phenolic monomers generated from the degradation of lignin or sugars present in the hydrolysate (83).

4.7.1.5. Xylanases

Xylanases (EC 3.2.1.8) are produced by a range of fungi, bacteria, and yeasts. Xylanases break down β -1,4-xylan into xylose and can be used to digest hemicelluloses. Xylanases can be produced from a number of different substrates (for a comprehensive list, see reference 102). Many fungal species produce xylanases when cultured in the presence of

1% (wt/vol) xylan, *Bacillus* species on 0.5 to 5.0% wheat bran, while some actinomycete species (including thermophilic strains) have detectable activity when grown in media containing 1% oat-spelt xylan.

4.7.1.6. Lignin-Degrading Enzymes

Several bacterial and fungal species produce ligninases, with the enzymes produced by brown- and white-rot fungi being studied the most extensively. Enzymes with lignolytic activity include the redox enzymes manganese peroxidase and the copper-containing phenol oxidase, laccase, as well as lignin peroxidase and cellobiose dehydrogenase (CDH) (60).

4.7.1.7. CDH

CDHs oxidize soluble cellodextrins, lactose, and mannodextrins into their corresponding lactones via a ping-pong mechanism. The most extensively studied CDHs were isolated from the white-rot fungi *Trametes versicolor* and

Phanerochaete chrysosporium. The assay most commonly used to detect CDHs is based on the reduction of benzoquinone or dichlorophenol indophenols (DCPIPs) (43). However, Henriksson et al. (43) identified two possible sources of error with this assay that should be considered. First, some sugar oxidases, such as glucose oxidase, might show activity with the DCPIP assay, thereby generating a false-positive reaction (43). Second, many white-rot fungi produce laccases that may reoxidize all the electron acceptors available, thereby masking the CDH activity (42). Baminger et al. (6) reported that the inclusion of 4 mM NaF, prior to performing a DCPIP assay, inactivated all laccases (6).

4.7.1.8. Laccases

Thermomonospora fusca BD25, a thermophilic actinomycete, produces several extracellular lignocellulose-degrading enzymes, including endoglucanase, endoxylanase, and peroxidase (90). Studies have found that the production of these enzymes depends on the growth phase. The synthesis of endoglucanases and endoxylanases occurs during the growth phase (0 to 96 h), while the production of peroxidases is nongrowth phase associated and is likely to be produced as a secondary metabolite. (Tuncer et al. [103] reported that peroxidase production peaked within 36 h, after which it rapidly decreased [1, 65]). Tuncer and coworkers found that the production of all three enzymes was highest on growth media containing oat-spelt xylan or ball-milled wheat straw, and that the addition of straw (0.6% or 0.8% wt/vol) induced the production of all three enzymes. The authors also found that the ratio of carbon/nitrogen affected enzyme production and that a C/N ratio of 4:1 to 5.3:1 resulted in maximal enzyme production. This article also highlighted the need to grow all test strains on a range of different carbon sources, because the amount of extracellular enzymes produced varies depending on the carbon source, and it is essential to find the best medium for enzyme production (90).

4.8. ACTIVITY SCREENS

The activity-based mining of enzymes performing a particular chemical conversion seems to be a better option, in contrast to the “(meta)genome gazing” approach, to look for new proteins that do not share any homology with those that are available in the public databases (8). Numerous assays enable the detection of enzymatic activities in colonies cultured on agar or crude cell lysates by the production of a fluorophore or chromophore (see examples in reference 2). Assays on agar-plated colonies typically enable the screening of $>10^4$ variants in a matter of days, but are often limited in sensitivity. The range of assays that are applicable for crude cell lysates is obviously much wider, but their throughput is rather restricted to only 10^3 to 10^4 clones (36). These low- to medium-throughput screens have proved effective for the isolation of enzymes from natural or preenriched metagenomic libraries, some of which has been successfully applied at industrial scale (for extensive review, see reference 2). A number of examples are described below.

4.8.1. Esterase Screens

Plates are incubated for 12 h at 37°C and then are covered with a second layer containing the substrate (20 ml of buffer HEPES 50 mM, pH 7.5, 0.4% [wt/vol] agarose, 320 μ l of Fast Blue RR [Sigma] solution in dimethyl sulfoxide [80 mg/ml], and 320 μ l

of α -naphthyl acetate solution in acetone 20 mg/ml). Positive clones appear due to the formation of a brown precipitate.

4.8.2. Cellulase-Like Screens

Plates are incubated for 12 h at 37°C in appropriate solid medium containing 0.5 to 1.0% (wt/vol) of the substrate (e.g., crystalline cellulose). The plates are subsequently stained for 20 min with 0.5% Congo red. Transparent halos in Congo red are formed around the positive colonies/clones.

4.8.3. P450 Oxidoreductase Screens

Plates are incubated for 12 h at 37°C and then are covered with a second layer containing the substrate (100 ml of Tris-HCl 50 mM, pH 7.5, 0.4% agarose, 50 μ l of *p*-nitrophenoxycarboxylic acids, e.g., 12-*p*NC₁₀ in DMSO [15 mM]). Positive clones appear visible due to the formation of a yellow color.

4.8.4. Laccase-Like Screens

Laccase production by library clones is screened by plating hybrid phage-infected cells or clones on appropriate soft agar containing 50 μ M syringaldazine. Positive clones are identified by a purple halo, produced by the oxidation of syringaldazine, on agar plate.

4.8.5. Screens for Sugar-Fermenting Enzymes Able to Produce Alcohol

The presence of ethanol produced by an active clone is determined by adding a solution of 0.4% agarose made up in a sodium phosphate buffer (0.1 M, pH 8), containing 50 μ l of 0.05 M 2,6-dichlorophenolindophenol and 100 μ l of 0.15 M NAD solution. The solution must be well shaken, poured over the agar plate, and allowed to solidify. The plates are incubated at room temperature for 30 min, after which 5 to 20 ml of 0.005 M 5-methyl-phenazinium methyl sulfate is spread over each plate by flooding or spraying and allowed further incubation at 30°C for 30 min. A yellow color indicates the reaction zone on a blue background.

4.8.6. Alcohol Oxidoreductase Screens

The screening is performed on indicator plates that contain 1,2-ethanediol, 2,3-butanediol, or a mixture of 1,2-propanediol and glycerol (as test substrates, although other alcohols may be used) and a mixture of *p*-ararosaniline and bisulfite for the detection of carbonyl compounds formed by the *E. coli* clones. In brief, indicator plates are prepared by adding 8 ml of *p*-ararosaniline (2.5 mg/ml of 95% ethanol; nonautoclaved) and 100 mg of sodium bisulfite (nonsterile dry powder) to 400-ml batches of precooled (45°C) Luria agar lacking added carbohydrate. Most of the dye is immediately converted to the *leuko* form by reaction with the bisulfite to produce a rose-colored medium. Plates with colonies are then stored at room temperature, away from fumes that contain aldehydes (cigarette smoke, many plastic containers, etc.) and light, both of which promote increased background color. Upon production of carbonyls from the test substrates, an intensely red Schiff base is formed. Thus, colonies capable of carbonyl formation appear red on the indicator medium and are surrounded by a red zone, whereas colonies failing to produce carbonyl compounds remain uncolored.

4.8.7. Catechol Dioxygenase Screen

Agar plates, containing the medium that depends on the strain growth requirement (e.g., M9 supplemented with bi-phenyl crystals placed on the plate lid), are incubated for 12 h

at 37°C and then are covered with a second layer of 100 ml of Tris-HCl 50 mM, pH 7.5 buffer containing the substrate (5 µl of catechol; 0.5 mM final concentration) and 0.4% (wt/vol) agarose, and the reaction plates are incubated at 25°C. Positive clones are normally identified after incubation for 1 h for 16 h, by the development of intense yellow color.

4.8.8. Polyol Oxidase-Like Screens

Screening of enzymes able to oxidize methyl-β-D-galactopyranoside (or other polyol such as 2-butanol, to cite some) is performed in a 0.4% (wt/vol) agarose solution prepared in sodium phosphate solution (50 mM, pH 7.0) that contains substrate (300 mM), catalase (700 U; Sigma), and CuSO₄ (0.5 mM). The screening is performed at room temperature and detection of a dark-blue color indicates a positive clone.

4.9. CONCLUSIONS

This chapter presented a number of methods that have been successfully applied in the screening for enzymes from extremophilic microorganisms and their communities. Nevertheless, the mining of enzymes from extremophiles and their communities will never be a trivial business and will require a number of parallel strategies, depending on the nature of the sample to be analyzed. There is certainly a need for a standardized set of methods for performing metagenomics projects, from physical-chemical description of sampling sites and sampling procedures down to the data interpretation and integration.

Cell-Based Screening Methods for Anti-Infective Compounds

STEFANO DONADIO AND MARGHERITA SOSIO

5

5.1. INTRODUCTION

This chapter describes selected cell-based assays, and the selection of the corresponding target(s), amenable for the discovery of novel antibacterial and antifungal agents from microbial products, screened as complex mixtures resulting from partial processing of fermentation broths. We also provide a framework to view target choice and assay design in the context of the microbial diversity available for screening, highlighting the importance of designing an overall strategy for an effective drug discovery program. A related chapter present in the previous edition of this manual (18) described some aspects of microbial product screening, which will not be covered here.

5.1.1. Microbial Products in Anti-Infective Screening

Aging, immunosuppression, and invasive surgical procedures are determining an increase in the number of people at risk of contracting a bacterial infection, while currently available antibiotics are becoming less effective because antibiotic resistance is spreading among microbial pathogens. Despite the increasing medical need, the pharmaceutical industry as a whole has manifested a diminished interest in the anti-infective field, with a limited number of antibiotics in clinical development and just three new chemical classes of antibacterial and antifungal agents approved for life-threatening infections during the past four decades (3).

Despite this grim scenario, the sequenced genomes of microbial pathogens provide a multitude of targets (28), while effective assays can be designed and implemented to discover new leads by high-throughput screening (HTS). Along with these new opportunities, there is also the increasing recognition that microbial products represent one of the best sources for screening programs aimed at identifying novel antibacterial and antifungal compounds (29). However, because screening of microbial products for antibiotics has been extremely intensive and successful, with several thousands of bioactive metabolites described, effective screening strategies must be devised to increase the probability of discovering novel compounds.

In the anti-infective field, a drug discovery program based on microbial products has the ultimate goal of discovering a new, patentable chemical entity possessing desired properties, such as antimicrobial spectrum, molecular weight, solubility, and preferred route of administration.

Obviously, it would be quite difficult and prohibitively expensive to design and implement assays that can measure all the properties sought in a drug candidate at the screening stage. Therefore, HTS programs aim at identifying *hits*, compounds, or mixtures thereof possessing one or more desired properties. Hits undergo further evaluation and characterization to possibly become *leads* (Fig. 1).

The effectiveness of an HTS program lies in devising a series of assays (the *screening algorithm*) that can rapidly identify samples possessing desired properties. When screening microbial products, it must also be realized that some classes of antibiotics have been extensively investigated, either because many variants are naturally produced by different microbial strains or because they have been intensively explored by chemical derivatization. There is thus a small probability of discovering improved variants of highly explored classes through HTS. As a consequence, screening programs based on microbial products should aim at discovering either a novel class or an improved variant of a poorly explored class.

5.1.2. Strategies for Screening Programs

Most HTS programs are target based, i.e., they involve evaluating an appropriate number of samples for their ability to modulate the activity of one or more targets through use of a series of assays. Samples passing the threshold criteria defined in the screening algorithm become *hits*. In microbial product screening, hits emerging from HTS must be evaluated in two parallel paths: for their biological properties, using further tests that complement those employed in HTS; and for their potential novelty, comparing the newly identified bioactive compounds with previously discovered molecules possessing similar chemical and biological properties, a process designated *novelty evaluation* (Fig. 1). The target and assay type determine which classes of known microbial metabolites can potentially be detected. Furthermore, since most classes of microbial metabolites are restricted to particular taxa, there is also a strong influence on this frequency from the microbial strains used as a source of chemical diversity. Therefore, the selectivity and sensitivity of the assays and the microbial diversity used in screening determine the number of known chemical classes and their expected frequency (see section 5.1.4). In any case, appropriate tools must be available to rapidly recognize the expected known microbial products. It is our experience that any HTS program will usually detect additional classes of known

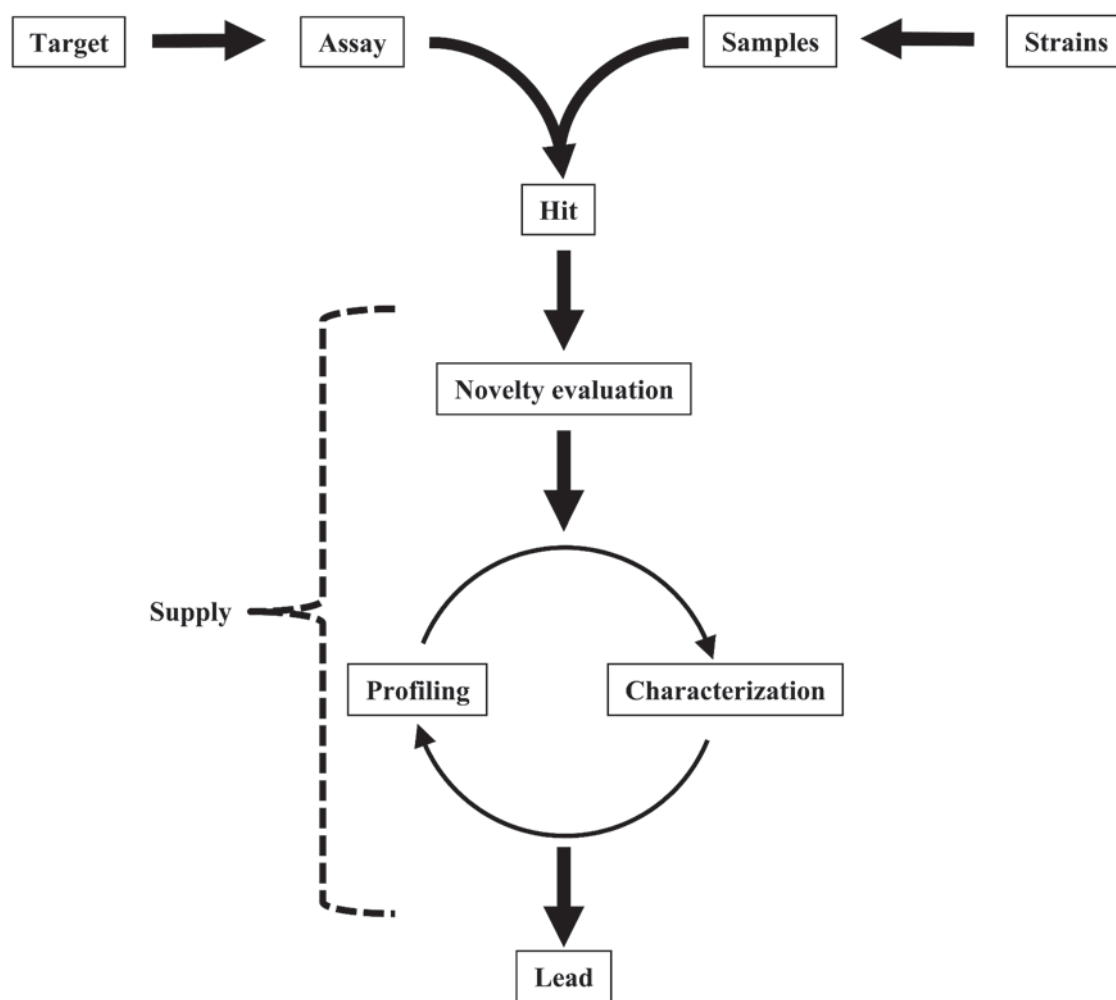

FIGURE 1 Scheme of a screening process.

metabolites, either because they represent *false positives* in the assay, or because their target was not yet known at the time of assay design.

5.1.3. Cell-Based and Cell-Free Assays

Cell-free assays directly measure the effect of a sample on the biological activity of one or more relevant targets. In general, these types of assays are more specific and sensitive than cell-based assays. Because most cell-free assays were unconceivable before the advent of recombinant DNA, they rarely were used during the golden age of antibiotic discovery and are thus more likely to discover new classes of inhibitors. However, a serious limitation of cell-free assays is that they also detect compounds that are unable to enter a microbial cell. While these types of inhibitors might be expected to offer little selective advantage to the producer strain, they are in fact relatively frequent among microbial metabolites. Furthermore, some of these inhibitors may be prohibitively hard to modify to allow them to enter a microbial cell while retaining activity and selectivity on the target. Cell-based assays, instead, do not suffer from this limitation, and progress in microbial genetics can ameliorate limitations in their sensitivity and specificity. The possible approaches and types of cell-based assays are discussed in section 5.2.

5.1.4. Novelty of the Program

A key factor for success in any HTS program based on microbial metabolites is to introduce elements of novelty. Although many details of previous screening campaigns are not known, a reasonable assumption is that easy-to-isolate strains (e.g., streptomycetes and other easily retrieved actinomycetes) were screened for antibacterial and antifungal agents by simple growth inhibition tests, prioritizing the many positives by potency, selective effect on one macromolecular synthesis, and/or lack of toxicity. Consequently, most discovered compounds are produced by relatively abundant species within the sampled genera, act on canonical targets (e.g., cell wall synthesis, transcription, and translation), and are rather potent. Thus, the novelty of a program can result from one or more of the following elements: (i) a relatively unexplored source of microbial diversity, which is expected to produce novel compounds at a higher frequency than an explored microbial group; (ii) an assay directed at canonical targets that is more sensitive than growth inhibition of commonly used test strains, allowing detection of compounds of lower potency or produced at lower levels; and (iii) an assay directed at “novel” targets, which is expected to detect compounds with a lower probability of having been pursued in the past. These

elements of novelty must be appropriately combined and evaluated to increase the probability of identifying novel compounds at a reasonable cost.

5.2. TARGETS AND ASSAYS

5.2.1. Target Identification and Validation

In general, it is accepted that an antibacterial or antifungal target must respond to three criteria: (i) it must be a cellular component essential for cell viability or required for infection and disease; (ii) it must be present and well conserved in the desired range of pathogens, where it must play a similar essential function; and (iii) it must be specific to bacteria or fungi, or at least significantly different from similar components present in humans. The first criterion is generally dichotomous (i.e., a target is either essential or not essential), while the second and third criteria, by definition, are quantitative and require a definition of similarity thresholds of the same target among different pathogens or between a microbial and a human target. Indeed, because of the existence of common protein domains and folds, virtually any target will have some relatedness to one or more human proteins. A recent example highlights that a chemical library biased for inhibitors of human targets can afford selective inhibitors of a bacterial enzyme (26), through the use of an effective screening algorithm. In any case, when using targets with related human counterparts, it is essential to have comparable assays in place to evaluate selectivity.

Current clinically used antibiotics inhibit approximately 25 to 30 distinct cellular components, while the number of essential genes in a microbial cell is about 1 order of magnitude higher, thus offering ample choice of possible targets. However, while most antibacterial targets show limited relatedness to human proteins, fungal pathogens have a limited number of essential components sufficiently different from higher eukaryotic counterparts to represent promising drug targets. Therefore, in the antifungal field target choice is limited and appropriate assays for measuring selectivity must be always considered.

As mentioned above, target validation requires experimental demonstration of its essentiality in a given set of microbial cells. This can be achieved by the inability to perform a gene knockout, by conditional antisense-RNA expression, or by other experimental demonstrations (Fig. 2). Advances in genomic technologies have allowed the systematic investigation of essential genes in many strains, including the prokaryotes

Bacillus subtilis (23), *Escherichia coli* (14), *Haemophilus influenzae* (31), *Helicobacter pylori* (21), *Salmonella enterica* (22), and *Staphylococcus aureus* (20), and the eukaryotes *Aspergillus fumigatus* (17), *Saccharomyces cerevisiae* (15), and *Candida albicans* (33). The ample literature on the topic has resulted in the availability of catalogs of essential genes for many microbial strains. Comparative genomics (Fig. 2) can be used for predicting the presence of chosen genes in desired microbial pathogens and for establishing the level of relatedness to human proteins. A key factor in choosing “esoteric” targets is to ensure their essentiality in different pathogens. Examples of genes essential in one species but not in another are known (39). We refer the reader to a previously reported discussion on the opportunity and limitations of novel targets (9).

New anti-infective agents must act on drug-resistant pathogens. Drug resistance mechanisms are often class specific and, as mentioned, current drugs affect few targets. Furthermore, most targets present multiple sites for potential inhibition. Therefore, it is extremely unlikely that a new antibiotic class will exhibit cross-resistance, either because it acts on a target not affected by currently available drugs or because it acts at a different site. This may not be the case, however, when drug efflux is the prevalent mechanism operating in multiresistant pathogens.

5.2.2. Assay Development and Validation

An identified target must be transformed into an assay concept (how inhibitors will be detected), which is strictly connected to the assay format (Fig. 2). Although this is the logical flow, a favorite assay format, which has proven effective in HTS, can often be adapted to different targets. In HTS, assays are designed to test a large number of samples (on the order of 100,000) and must be performed robotically in small volumes, to reduce labor and reagent cost. Furthermore, they must be sufficiently sensitive to allow detecting bioactive compounds present also at low concentrations, and specific for the target to avoid detecting compounds acting on other targets. Finally, the assay must be robust, i.e., reproducible and relatively unaffected by the type of samples used in screening (see below). Assays can be set up and performed in multiple ways, but the implementation of a target into a screening program requires common steps as described below and shown in the flow chart in Fig. 2.

Cell-based assays detect, by definition, compounds able to exert their action on an intact microbial cell, but they present the challenge of being made specific, i.e., responsive to inhibition of the desired target(s) only, since signal is

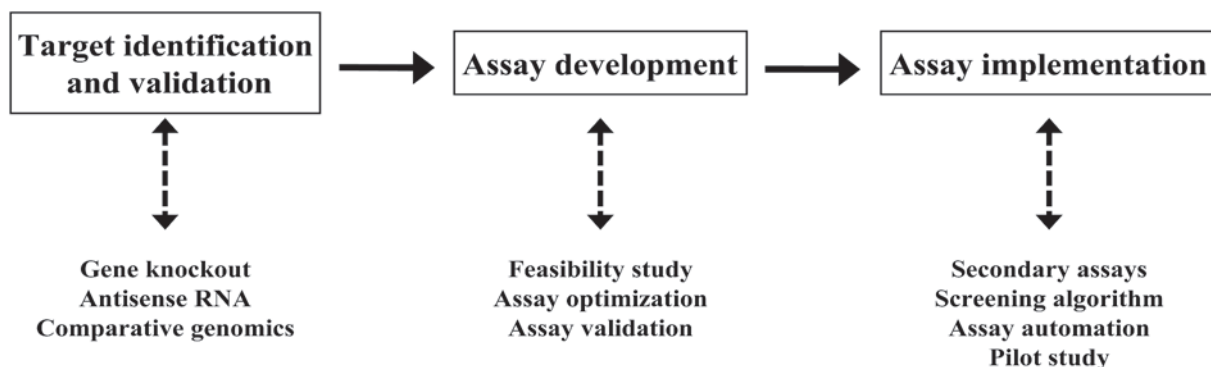

FIGURE 2 From target to screens. Main conceptual passages required (top) and the experimental steps required at each stage (bottom).

measured in the presence of all cellular targets and operating networks. A further challenge is to make cell-based assays more sensitive than simple growth inhibition assays. In the past decade, general formats have become available for cell-based assays that are amenable to multiple targets: reporter (11, 37) and antisense assays (6, 20) represent the two most notable examples. Other assay formats are also possible, and selected examples will be provided.

During assay selection, it is important to be aware of the likely positivity rate, which depends on the assay type and sensitivity, on the number of affected targets, and on the samples used. For example, an assay in which multiple targets can be inhibited (e.g., a *B. subtilis* reporter assay responding to any inhibitor of translation; 37) may have a positivity rate 2 orders of magnitude higher than an assay based on the inhibition of a single target within a gram-negative cell (see, e.g., reference 13). Therefore, the former assay may be used with a sample library obtained from *Streptomyces* strains (which at high frequency produce compounds able to inhibit *B. subtilis* growth) only in the presence of an effective screening algorithm to decrease the hit rate.

Assay development can be conceptually simplified as consisting of three phases: a *feasibility study*, assay *optimization*, and assay *validation* (Fig. 2). However, it is more an iterative than a linear process, because results obtained during a later phase may require reevaluating earlier parameters. The feasibility study includes a determination of whether the test is specific for the desired target. To do this, it is necessary to perform the test in the presence of positive (compounds acting on the target) and negative controls (compounds inhibiting the growth of the test strain but acting on different targets) to determine the threshold of sensitivity and the presence of possible false positives. For many novel targets, appropriate small-molecule inhibitors may not be available as positive controls, and one solution is to generate an inhibitor within the test strain itself by producing a peptide or nucleotide inhibitor after addition of an inducer (13). The assay should also be executable in miniaturized format and be sufficiently reproducible and simple enough for automated handling, generating a readout amenable to automated analysis. The ideal test is performed in a single well, requires only addition of reagents, and does not require separating the reaction product(s) before detection (a so-called mix-and-measure assay). Any general interference from the samples (i.e., residues from the fermentation broths or the solvent used to dissolve them) must be evaluated at this stage. Finally, the availability and stability of the assay reagents must be also taken into consideration.

The objective of the *assay optimization* phase is to ensure that the assay is more sensitive than growth inhibition of the same test strain. This usually involves varying the assay parameters (such as inoculum, incubation times, and temperatures) to establish the best signal-to-noise ratio, with use of positive and negative controls. Samples representative of the extract bank are also used, and a few samples are spiked with the positive control(s) to ensure lack of interference. Further negative controls are tested at this stage. Depending on the results obtained, secondary assays are devised at this stage, and the screening algorithm is implemented. In this respect, it is also important to consider that a primary assay, performed on the entire library, must be robust and inexpensive, while the cost of secondary assays, which are performed on a subset of samples only, can be higher.

After establishing the protocol, the assay is *validated* by executing it on a relevant number of samples (from a few hundred to a few thousand), which must be representative

of the entire collection, both in terms of producing strains and extraction methods. This step is actually a first "road test" of the assay, evaluating parameters such as performance, variability, and positivity rate, which should be within expectations. In some cases, the assay is validated directly during a *pilot study*. However, we prefer to perform assay validation manually, before spending resources in assay automation. In some cases, an assay may actually turn out to have an unexpectedly high positivity rate and require going back to the drawing board.

Once the newly developed assay has been validated, it is adapted to the available HTS instrumentation, automated, adjusted for expected throughput and personnel working hours, and implemented into a pilot study. At this stage, the screening algorithm is also definitively established, including the numerical threshold for accepting or discarding a sample. Because in microbial product screening the identity of the bioactive compound(s) present in a hit is, in most cases, unknown, an effective screening algorithm is almost as critical as the primary assay for pursuing only the most promising hits. Therefore, secondary assays are directed at recognizing known antibiotic classes, at highlighting undesirable biological properties (e.g., selectivity for the microbial target), or, more rarely, at independently confirming the activity on the selected target. Secondary assays usually involve evaluating the potency (the lowest dilution still giving a signal above threshold) of the positives on the primary assay and on selected secondary assays, to establish selectivity.

It is important to keep in mind that the screening algorithm must be designed with consideration of the complexity of the samples to be used (e.g., a single microbial extract may contain two or more classes of bioactive metabolites), and that the primary and secondary assays must have comparable windows. For example, a screening algorithm consisting of an antisense assay to detect inhibitors of a single fungal target (primary test) and of cytotoxicity against a mammalian cell line (secondary test) assumes the existence of only one bioactive substance in the samples and may be appropriate when screening prefractionated microbial extracts.

5.2.3. General Types of Cell-Based Assays

As mentioned above, reporter and antisense assays can in principle be applied to multiple targets, but they require validation to ensure that the assay is truly responsive to inhibitors of the chosen target(s), with acceptable rates of false positives and false negatives. The choice of assay format is linked to the anticipated screening strategy. Antisense assays can in principle be applied to any target, but a separate assay is required for each target. Instead, a single reporter assay can detect inhibitors of multiple targets, thus increasing the probability of discovering hits. However, a suitable reporter assay may not be available in a desired cell for the chosen target(s). Furthermore, technical implementation and troubleshooting strongly depend on the assay format, so it may be preferable to apply a favorite assay format to many different targets rather than devising different formats for each target.

Important decisions to be made at the onset are whether to identify inhibitors of a single target or of multiple targets (a cellular pathway); and the microbial strain in which to perform the assay, including the possible use of hyperpermeable strains or strains resistant to particular classes of compounds. These decisions are part of the general strategy and are intimately connected with the samples to be screened, the size of the screening effort, and, often, the idiosyncrasies of the screening team.

One important issue relates to the expected positivity rate. In a given microbial strain, an assay directed at a cellular pathway consisting of multiple targets is expected to have a positivity rate higher than an equivalent assay involving a single target. Similarly, independently of the individual cellular response, the same assay is expected to have different sensitivity according to the intrinsic permeability of the microbial cells employed. As an example, permeability generally decreases along the following list of bacterial strains: *B. subtilis*, *Enterococcus faecium*, and *E. coli*. Permeability can be modulated by employing hypersensitive strains (e.g., *E. coli* strains devoid of the major porin TolC; 27) or strains constitutively expressing promiscuous efflux pumps (e.g., *Pseudomonas aeruginosa* MexAB-OprM, *E. coli* AcrAB, and *S. aureus* NorA; 40). Employing microbial strains with defined resistance mechanisms can also affect the positivity rate. Thus, no screening assay is ideal, and each choice results in opportunities and caveats. Our general advice is to use hypersensitive strains when employing assays based on just one or a few well-defined molecular targets, while relying on strains of wild-type permeability when using assays based on multiple targets such as “pathway assays.” The use of strains expressing defined resistance markers is always an advantage, provided that there is no fitness cost associated with the resistance mechanism. In any case, the resistance markers employed should be relevant to the microbial diversity employed in screening. For example, the use of a vancomycin-resistant strain is unlikely to affect the positivity rate when screening samples derived from fungi or mycobacteria.

Finally, while it may be preferable to utilize a microbial strain representative of the pathogens of interest, difficulties in its genetic manipulation or safety issues while handling pathogens in HTS may tip the scale in favor of using a related microbial strain.

5.2.3.1. Reporter Assays

Reporter assays are conceptually based on the observation that microbial cells respond to perturbations in many cellular pathways by specific transcriptional responses (16). These perturbations can be brought about by sub-MIC concentrations of an antibiotic inhibiting a particular pathway. Hence, bacterial cells can be engineered so that the expression of a convenient reporter gene is under the control of a promoter specifically induced upon perturbation of a cellular pathway, as diagrammed in Fig. 3. Many such assays have been described, which respond to inhibition of one or more targets: DNA replication (e.g., reference 36), translation (e.g., reference 37), cell wall (e.g., reference 25), fatty acid formation (e.g., reference 11), or secretion (1). In general, the promoter(s) responding to the stimulus is determined empirically, and systematic evaluations of antibiotics within a single microbial species can identify potential promoters to drive expression of a desired reporter gene (19).

These assays can be effectively adapted to microwell format and usually provide advantages such as increased sensitivity and relatively short incubation times, since transcriptional responses are sensitive (sub-MIC) and rapid. Two important considerations must be made: one is that transcriptional responses can be species specific, and different microbial strains are likely to switch on different genes in response to the same physiological insult; the other is that the molecular mechanism through which a microbial cell senses an antibiotic-caused insult is often not known, and thus a reporter assay must be validated to understand the extent of possible false positives and false negatives (e.g., reference 7).

For example, a reporter assay for detecting antimicrobial compounds affecting DNA replication takes advantage of the ability of DNA-damaging compounds to induce SOS response genes. Thus, an *E. coli* strain bearing the highly SOS-inducible promoter of the cell division inhibitor *sulA* fused to β -galactosidase gene can be used (36). The lower limit of detection for nalidixic acid, used as positive control, is 1.25 $\mu\text{g/ml}$, or $0.25 \times \text{MIC}$. This amount is sufficient to cause an about fourfold increase in β -galactosidase activity relative to untreated cultures, while maximum signal-to-noise ratio is obtained at 10 $\mu\text{g/ml}$. The test, originally validated using six different antibiotics acting on other macromolecular synthesis (36), responds only to SOS-inducing agents. The assay can be implemented in a ΔtolC background to increase sensitivity and is readily adapted to 96-well microtiter plates. Midexponential cultures of *E. coli* *sulA::lacZ* ΔtolC grown in LB medium at 30°C are added to the wells of a 96-well microplate, containing 10 μl of 80 different samples, leaving in each plate 8 wells with 10 μl of 2.5 $\mu\text{g/ml}$ nalidixic acid and of 10% dimethyl sulfoxide as positive and negative controls, respectively. After 2 h at 30°C, the A_{600} is measured in a thermostated microplate reader. Next, 25 μl per well of B-PER II bacterial protein extraction reagent (Pierce, Rockford, IL) is added and the plate is agitated for 15 s before addition of 50 μl of ZOB buffer (36). The A_{420} is read immediately after ZOB buffer addition and after 30 min at room temperature. β -Galactosidase activity can be expressed as $\Delta A_{420}/A_{600}$. (If growth of individual wells is sufficiently reproducible, the A_{600} measure can be skipped.) Results are normalized to those of positive controls using the formula

$$I_i = 100 \times (A_i - A_c)/(A_p - A_c)$$

where I_i represents the relative β -galactosidase activity of sample i , with a ΔA_{420} of A_i , while A_c and A_p represent the average ΔA_{420} values of negative and positive controls, respectively.

5.2.3.2. Antisense Assays

Antisense assays are based on the principle that sensitivity of a microbial cell to an antibiotic is inversely related to the concentration of the target affected by that antibiotic. The level of a cellular target can be progressively diminished by increasing the expression levels of an antisense-RNA, which sequesters the target's mRNA, leading to decreased translation. When no mRNA is available for translation, the cell is no longer viable. Therefore, the trick with antisense assays is to find a level of antisense-RNA expression high enough to result in hypersensitivity to a specific inhibitor of the chosen target, but not sufficient to affect significantly the duplication time, which may render the cell hypersensitive to many different antibiotics. This is achieved by placing the antisense-RNA under the control of a promoter whose activity can be modulated by increasing levels of an exogenously added inducer.

The antisense approach has been used for the systematic identification of essential genes in microbial strains (20). In *S. aureus*, an inducible antisense-RNA system has been used to identify genes essential or critical for growth, leading also to a collection of “antisense strains,” each suitable as a hypersensitive, single-target-based whole-cell assay (12). For example, expression from a xylose-inducible promoter of the RNA antisense to *fabF* conferred hypersensitivity to the FabF inhibitor cerulenin. In a similar experiment, antisense-RNA expression led to reduction of FabI levels with a corresponding hypersensitivity of the antisense strain to the FabI inhibitor triclosan.

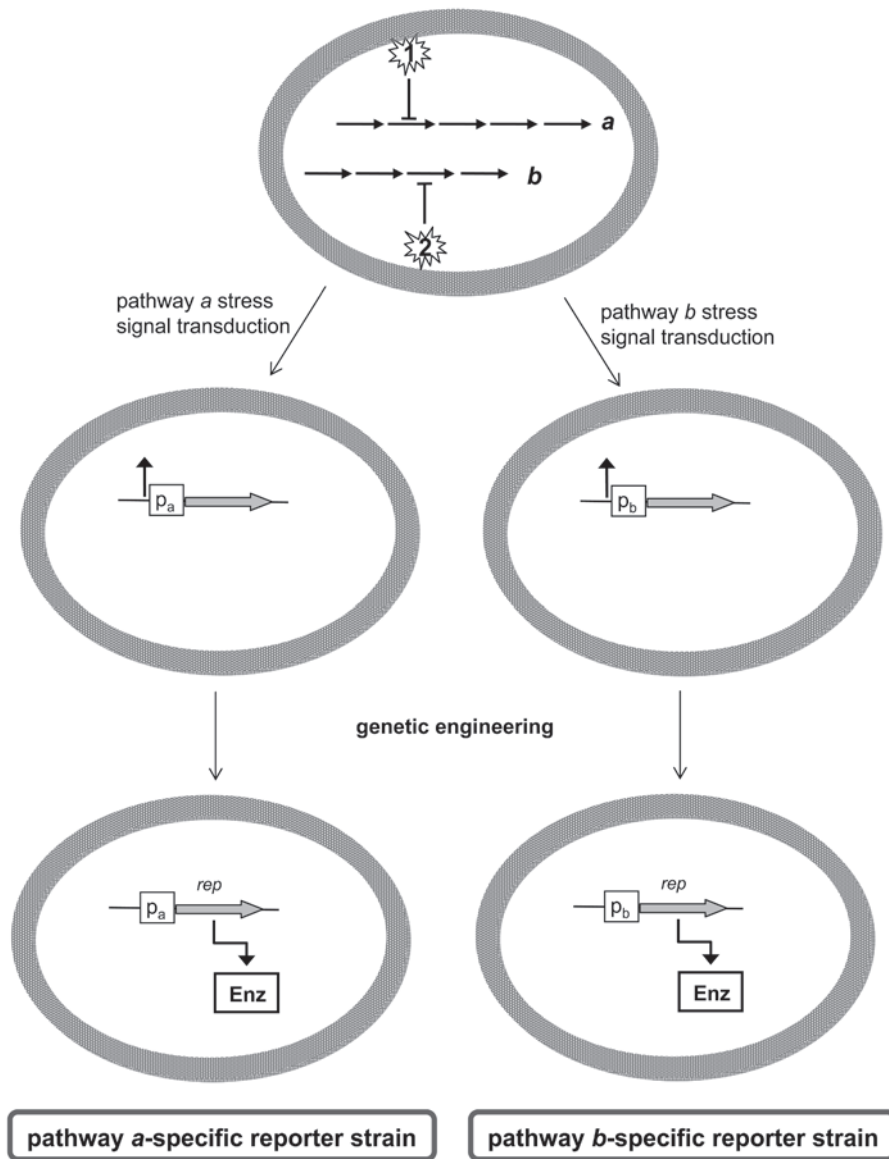

FIGURE 3 Concept of reporter assays. In a bacterial cell, the antibiotics 1 and 2 act on the different pathways *a* and *b*, respectively (top panel), leading to pathway perturbation due to specific stress-response signals and upregulation of genes under the same stimulum, as exemplified by the promoters p_a and p_b , which responds to perturbations in pathways *a* and *b*, respectively (middle panel). Two reporter assays can be designed by engineering cells so that expression of the reporter gene *rep* is under the control of the inducible promoter p_a or p_b , resulting in increased activity of the reporter enzyme *Enz* (bottom panel).

In contrast to reporter assays, antisense assays are intrinsically *differential* assays in which the response of the antisense test must be compared with that of an isogenic control. The standard approach to measure differential activity is to execute the assay in microtiter format, testing first all samples of the library for growth inhibition of the antisense strain. Then, the positive samples are retrieved, serially diluted, and simultaneously assayed on the antisense and control strains. This approach involves standard liquid-handling procedures, but identifies as positives all samples inhibiting the growth of the antisense strain, and only a small fraction of these will be preferentially active

on the antisense strain. If the positivity rate is relatively high (for example, microbial fermentation extracts from actinomycetes may contain detectable antistaphylococcal compounds at a frequency of approximately 10%), this approach would be extremely labor-intensive. An alternative approach is to perform the assay by agar diffusion, comparing the inhibition haloes observed on two agar plates, one seeded with antisense strain (the AS plate) and one with the control strain (42). The positive sample will show a larger halo on the AS plate compared with the control plate. An advantage of this approach is that it identifies directly the samples preferentially inhibiting the antisense

strain, but it requires preparing agar plates and measuring inhibition haloes, procedures once the staple of microbial product screening, but somehow alien to highly automated HTS operations.

As an example we report the discovery of FabF/FabH inhibitors. Samples (20 μ l) are applied to wells (prepared with well casters placed into the agar) on both the control and AS plates, which are then incubated at 37°C for 18 h. A clear, circular zone is formed in the presence of samples inhibiting cell growth, whose size depends on the concentration, potency, and diffusion rate of the inhibitor. Different concentrations of cerulenin and thiolactomycin (1, 0.5, 0.25, and 0.125 μ g/ml), selective FabH/FabF inhibitors, are used as positive controls, while any other antibiotic can be used as negative control. At those concentrations, cerulenin and thiolactomycin show a larger inhibition halo only on the AS plate, while the negative controls show no differences in halo size between the two plates. Samples showing a difference in zone size between the AS plate and the control plate of ≥ 15 mm are retested as serial dilutions on the two-plate system, thus defining the ratio between the concentrations giving identical inhibition haloes on the AS and the control strains. This approach led to the identification of a novel class of antibiotics (38).

5.2.3.3. Other Assays

A conceptual variation of the antisense assay modulates the level of an essential target by placing the corresponding gene under the control of a promoter whose activity can be controlled by adjusting the concentration of a transcription inducer. When target expression is decreased, the cell is expected to become hypersensitive to inhibitors of that target, while increased expression levels should lead to reduced sensitivity. This principle was validated in *E. coli* with the following target-inhibitor pairs: fosfomycin and MurA, triclosan and FabI, and kirromycin and EF-Tu (8). The test is performed in 96-well microtiter plates, reading A_{600} after overnight incubation at 37°C. Positives (samples showing A_{600} values of < 0.1 during the primary test) are then evaluated using the engineered strain grown under different concentrations of inducer. The potency of a target-specific hit is expected to decrease upon upregulation of the target. In this case, assay execution is conceptually similar to an antisense assay, as described above.

Another widely used assay type consists of the so-called *reversion assays*, in which the activity of a growth-inhibiting compound is reverted upon the extracellular addition of an excess of the inhibitor's target (*target reversion assays*) or of an essential nutrient whose synthesis is impaired by the inhibitor (*nutrient reversion assays*). Target reversion assays have been widely used to identify cell wall-active antibiotics by observing lack of activity in the presence of an excess of a bacterial cell wall preparation (24) or portions thereof (30). Those screens actually identified compounds binding to an intermediate in peptidoglycan formation rather than to enzyme inhibitors; thus, they employed nonprotein targets that, for example, are not amenable to antisense assays.

In a variation of this concept, a screen was implemented to detect inhibitors of the translation factor EF-Tu (35). Kirromycin, a known EF-Tu inhibitor, is used to validate the assay (positive control). The test is performed by using two agar plates, each inoculated with the test microorganism (i.e., 10^5 CFU/ml *S. aureus*). An appropriate number of 6-mm paper discs is then laid on the agar plates. On each disc, a 20- μ l drop of 5 mg/ml *E. coli* EF-Tu is loaded on the

reversion plate, while just 20 μ l of H₂O is placed on the control plate. Samples are then spotted on the paper discs and plates incubated at 37°C overnight. Scoring of inhibition halos proceeds as described above. This screen led to the identification of two novel antibiotics representative of a novel class of EF-Tu inhibitors (35). It should be noted, however, that this assay is possible insofar as the chosen target is relatively stable under the incubation conditions.

Nutrient reversion assays can be applied when (i) the essential nutrient is not available in an animal host, and (ii) the chosen microbial cell can effectively uptake the exogenously added nutrient. An example of this type of assay is the screening for inhibitor of the biosynthetic pathway transforming chorismate into *p*-aminobenzoic acid (32). The assay is again a differential assay in which a *B. subtilis* strain is grown on two separate agar plates, one containing minimal medium and the other the same minimal medium supplemented with 5 mM L-tryptophan, 5 mM L-phenylalanine, 5 mM L-tyrosine, and 5 mM *p*-aminobenzoic acid. As above, 6-mm paper discs are laid on the agar plates and spotted with 10 μ l of fermentation broth extracts. After overnight incubation at 37°C, inhibition haloes are scored, and the samples able to inhibit *B. subtilis* growth only in the unsupplemented medium are further evaluated. This screening led to the identification of a new class of antibiotics from a marine actinomycete (32).

5.3. SCREENING

5.3.1. Choice of Strains and Samples

As mentioned above, the choice of cell-based assays must also consider the chemical diversity available for screening. If a representative collection of samples is already available, target selection and assay format should be chosen on the basis of previous experience related to the frequency of known microbial metabolites and the performance of different assay formats.

When a sample library is not available, focus should be on the retrieval of strains offering a higher probability of producing new compounds. Historically, secondary metabolites with anti-infective activity have been identified from a variety of strains, with fungi and actinomycetes representing the most intensively screened groups. Strain novelty and diversity are key elements for identifying diverse molecules, but the ability to produce bioactive metabolites is not uniformly present in the microbial world. Furthermore, certain classes of metabolites are observed at higher frequencies than others, while ease of strain isolation and cultivation can greatly vary. Thus, a newly assembled collection should consist of strains that produce anti-infective compounds at an appreciable frequency, are underrepresented as producers of the frequent metabolites acting on the chosen target(s), and can be cultivated with existing methodologies and equipment.

The corresponding collection of samples can be generated by culturing the strains in appropriate media under suitable conditions, followed by sample processing, if required. While sample processing is essential when using cell-free assays (to remove interfering substances such as enzymes, salts, and nutrilites), it is not necessary with cell-based assays. Nonetheless, sample processing can be used to reduce the chemical complexity of the extracts, for example, by performing a prefractionation. By reducing the probability that a single sample contains more than one bioactive compound, sample prefractionation facilitates

the design of effective screening algorithms and the step of hit deconvolution (see below), but adds a substantial cost to sample preparation. Additional considerations on strain selection and sample processing can be found in a recent review (10).

5.3.2. Devising the Screening Algorithm

The examples provided above often illustrate that a screening program rarely consists of a single assay, but it requires a logical sequence of tests with well-defined threshold criteria. With differential assays, one secondary assay is dictated by the assay concept. In other cases, the selection of a secondary assay derives from experience or from results observed during assay development. The screening algorithm may include additional tests aimed at recognizing known classes of metabolites. As a rule of thumb, the higher the number of targets covered by the assay, the larger the probability of detecting known compounds and thus the need for additional tests in the screening algorithm.

Two parameters must be taken into consideration when designing and implementing the screening algorithm: the threshold level for accepting and rejecting a sample, and the concentration ratio of a sample active in experimental versus control tests.

With differential assays that rely on growth inhibition, threshold criteria are easy to set (i.e., a clear inhibition halo or 90% inhibition when measuring turbidimetry). In these types of assays, where the anticipated result is a different minimal concentration of sample required to inhibit growth in the experimental versus the control system, a concentration ratio of ≥ 8 is usually selected. However, the potency of each sample is not known, and a 1:2 dilution may be sufficient to dilute the bioactive compound(s) to result in a concentration insufficient to elicit a signal above the set threshold. Consequently, the screening team must decide whether such samples should be considered hits, bearing in mind that true specificity can be established only when a more concentrated batch of the sample has become available (which may require a new fermentation of the producer strain), or abandon them, with the risk of losing possible hits. Although there is no straightforward answer to this dilemma, a useful rule of thumb is to consider the actual positivity rate of the screen: in the presence of a few hits, it may be worthwhile to include samples with a twofold ratio.

In other cases, the assay readout may not just be growth of the test strain, and the threshold criteria for positivity relies on a combination of theoretical expectations and experimental validation. For example, reporter assays ultimately measure the activity of a reporter enzyme, and different metabolites may induce its expression to different levels, sometimes higher than the positive control. In some cases, a control reporter assay may be employed to recognize unwanted events, and desired metabolites may elicit partial responses in the control assay too. With the primary and control reporter assay threshold, criteria can be empirically set at levels that allow detection of desired compounds at reasonable concentrations, but not of unwanted compounds.

Before performing an HTS campaign, a pilot study is run on a significant number of samples (a few thousand) to ensure that no unexpected results are encountered (Fig. 2). This is particularly relevant for microbial product screening, because different strains, growth media, and extraction procedures may result in heterogeneous samples and lower signal-to-noise ratios. The pilot study performs all the steps of a true HTS program: execution of primary

assays; identification of positives; cherry-picking of an independent sample of the positives; repetition of the primary assay and execution of the secondary assay(s); data analysis; and, finally, hit declaration. Often, after the pilot study, the threshold criteria for the primary and secondary assays are adjusted, using appropriate statistical analysis (43). Furthermore, comparison with other screening programs may help to identify possible false positives and suggest strategies to recognize them. Often, the hits identified during the pilot study are processed (section 5.3.3) to identify the active molecules. This last step may strengthen the rationale for a full-scale HTS campaign or suggest additional secondary assays to recognize unwanted compounds.

5.3.3. Evaluating Hits

The ultimate goal of microbial product screening is to establish the chemical identity of the hits and their biological properties. Since this is a lengthy and expensive process, further filters are introduced to dedicate resources only to the most promising hits. These filters involve *dereplication* and *novelty evaluation* (Fig. 1).

Different hits discovered within a single screening program may actually contain the same bioactive principle. For example, they may represent different samples derived from the same strain (through the use of different production media or extraction procedures), or highly related strains may have been independently added to the library, or the same compound may be produced by unrelated strains. The process of choosing a single representative for each supposedly identical hit is designated *dereplication* in HTS jargon. Depending on the information available and the likely relatedness of the hits, dereplication may be performed querying the strain/sample database (in the case of hits derived from the same or similar strains), or it may require actual processing of the hits (see below). After dereplication, the sample showing the highest potency or specificity ratio is selected for further analysis. If the hit then shows interesting properties, it is advisable to reanalyze the strains/samples discarded during dereplication because they may produce lower amounts of different congeners; this will help to understand the structure-activity relationships of newly identified compound(s).

Novelty evaluation is a continuous process that involves comparing the properties of the bioactive compound(s) in each hit with those of natural products described in the literature, until its novelty is firmly established. The process at the beginning is based on negative evidence: lack of resemblance to known molecules is taken as an indication of possible novelty, and this comparison is repeated until convincing proof about the compound identity is established. Routinely, novelty evaluation involves a high-performance liquid chromatography separation of the sample, establishing which fractions contain the bioactivity observed with the primary assay. Simultaneously, data are acquired on molecular mass and UV spectrum of the active peaks. This information, together with additional chemical (chemical class, presence of particular functional groups, molecular formula, etc.) and biological (antimicrobial spectrum, target, producer strain) data, is used to query natural product databases. Detailed procedures for novelty evaluation have been described recently (10).

Depending on sample availability, complexity (weight per culture volume after extraction), and potency (i.e., highest dilution giving a measurable signal), novelty evaluation may be performed directly on the sample bank. On the other hand, when dealing with low-potency or high-complexity

samples, it may be preferable to confirm the activity by reprocessing the producing strain before performing novelty evaluation. Since different batches are likely to yield different concentrations of the active compound and of interfering substances, each sample preparation must be validated with respect to the biological selection criteria through the screening algorithm, and consistency of the results must be thoroughly checked.

Eventually, the activity observed during screening must be reconfirmed by growing the producer strain and preparing a new sample under conditions identical to those that yielded the original sample. Along with these filters goes biological profiling and the supply of increasing amounts of samples for analysis (Fig. 1).

In antibacterial and antifungal screening programs, hits are characterized for their activity on different microbial strains. When limited information on a hit is available, a microbial panel may include just a few isogenic antibiotic-resistant and -sensitive strains to assist in novelty evaluation. As the interest in the hit increases, panels include relevant pathogens and cytotoxicity tests. These activities are common to any anti-infective discovery program, independently of the origin of the inhibitor, and will not be described here. However, for low-purity samples care must be taken when evaluating spectrum and cytotoxicity, as well as actual MIC data, since samples may contain more than one bioactive substance and the molecule of interest may be present at low purity.

HTS requires investments in automation, data acquisition, and data management. Relevant to microbial product is also the availability of databases linking the producer strains to the screened samples and to the identified compounds, as well as queryable databases of known microbial products for novelty evaluation. When pharmaceutical companies were actively involved in natural product screening, each had built its customized database, containing relevant chemical and biological properties on microbial products described in the literature. These databases are particularly valuable for old compounds discovered when analytical tools were less sophisticated than they are today.

5.4. CONCLUSIONS

In this chapter, we have provided an overview of the possible cell-based assays for discovering novel antibacterial and antifungal agents. Because of the almost unlimited number of possibilities, we have focused our attention on assay formats that can be applied to different targets, because technical challenges in assay development are similar for tests of the same type. When performing several HTS programs using different cell-based assays, the use of one or a few formats facilitates assay development, execution, and hit dereplication.

We have tried to provide an overview focusing on key elements of the process and combining strategic considerations with selected detailed procedures. There are significant challenges in the screening for novel anti-infective agents from microbial sources, but also opportunities offered by newly discovered strains, by a better understanding of the large genomic potential of the known strains to produce metabolites, and by the possibility of designing effective assays to identify novel compounds. The recent discoveries of novel chemical classes (4, 5, 32, 34, 38) bode well for the future.

A successful screening program depends on the integration of different skills and experiences, and on the humbleness of not pretending to reinvent the wheel. Before

embarking on a screening program, we advise that valuable insights can be obtained from the detailed retrospective analyses by scientists who have witnessed several decades of microbial product screening (2, 24, 41).

Metabolomics for the Discovery of Novel Compounds

JENS C. FRISVAD

6

6.1. BACKGROUND

“Extrolites” is an ecological term for exported, potentially functional molecules produced by living organisms. These can be biopolymers and small molecules, also called secondary metabolites. Secondary metabolites are mostly found in bacteria, fungi, algae, and plants, and many of these have been shown to be bioactive, i.e., they can be effective antibiotic, anticancer, antiviral, cholesterol-lowering, anti-diabetic, immunosuppressant, anti-Parkinson, antimalarial, antistrongyloidiasis compounds, animal growth promoters, etc. (32). Even though new interesting lead compounds are constantly found, it is rare that a secondary metabolite makes it all the way to a commercial drug. For this reason screening a large number of organism extracts for new compounds is necessary to have a chance of finding new efficient drugs and drug leads. In the plant kingdom, this may be guided by human experience with use of plant extracts, but in microorganisms the search for new drugs is of a more fortuitist nature, like, for example, the discovery of penicillin by Fleming. Since a large number of secondary metabolites have already been discovered, dereplication of known compounds is a very important part of any screening campaign for new bioactive compounds in nature. In many screenings for bioactive compounds, a very large number of microorganisms have been examined to increase the probability of discovering new compounds. These microorganisms have often been obtained from animals, plants (endophytes), macrofungi, algae, or the natural environments of these organisms, including soil, freshwater, seawater (marine microorganisms), and extreme habitats (8, 45).

Metabolomics is, by definition, based on a full description of all metabolites taken up by, contained in, and secreted by an organism, often both in qualitative and quantitative terms. However, because of the many factors affecting the quantitative amounts of different metabolites at any one moment, i.e., a quantitative snapshot of the metabolic status of an organism, quantitative metabolomics is a very complex discipline, heavily depending on the analytical techniques used for detection of all the metabolites. Exometabolomics is a more restricted discipline, only concerned with detection of all secreted or cell wall-deposited secondary metabolites. Restricted this way, exometabolomics is a more approachable technique, often performed using secondary metabolite profiling (13, 16, 39), and is often, in the screening phase, a matter of qualitative

determination of secondary metabolites produced by any one microorganism under different nutritional and environmental conditions. However, even the less ambitious task of secondary metabolite profiling or metabolic footprinting (19, 39, 55, 56) depends on the growth media and environmental conditions, and on extraction, separation, detection, and identification techniques; no single method can cover all secondary metabolites produced by a microorganism. In addition, many microorganisms require a chemical signal from another organism to produce secondary metabolites that are usually not expressed because of histone silencing.

Combinations of secondary metabolites are occasionally much more effective than a metabolite alone, and therefore metabolite profiling can be of even greater importance than originally thought (62).

This chapter outlines the procedures for optimal discovery of new compounds, based on experience with filamentous fungi. However, the microscale technique recommended here is also useful for other culturable microorganisms, especially bacteria.

6.2. TAXONOMY AND IDENTIFICATION OF THE PRODUCING MICROORGANISMS

An often neglected aspect of screening for new compounds is the chemoconsistency of isolates of a particular species (31). It has been shown that filamentous fungi produce species-specific profiles of secondary metabolites (13, 21, 36), so to find new bioactive compounds from microorganisms, it is better to screen a large number of species than a large number of isolates. This will require correct identification of the microorganisms (see chapter 3, this volume), a goal that is achievable in well-known genera of microorganisms that have a high chemical diversity, such as *Streptomyces* (4, 5, 7, 9, 53), *Alternaria* (2), *Daldinia* (52), *Fusarium* (54), and *Penicillium* and *Aspergillus* (13, 18), but that is more difficult, for example, in endophytic microorganisms, which are notoriously difficult to identify. In bacterial genera such as *Salinispora* it has recently been recognized that these bacteria also produce species-specific profiles of secondary metabolites (28).

Sequencing of ribosomal genes is often used for identification in bacteriology and mycology, but experience within the fungi has shown that sequencing one or two housekeeping

genes gives a much more accurate identification at the species level than ribosomal genes alone. In a study by Skouboe et al. (47) of common secondary metabolite-producing *Penicillium* species, it was shown that only a few species could be identified accurately by ITS sequencing, and it was later shown that β -tubulin sequencing was much more effective in separating the individual species (42). Correct species identification will also help in the dereplication of already known compounds, because the profile of secondary metabolites produced is species specific (13, 18), and at least some of the secondary metabolites are known from literature data. On the other hand, many producers of bioactive compounds have been associated with a producer that was misidentified, so it is best to rely only on detailed and well-documented chemotaxonomic studies rather than on individual reports of secondary metabolite production by a known or new species. It is always advisable to identify microorganisms by use of a polyphasic approach, but for screening purposes sequencing of (parts of) rDNA in conjunction with sequencing of at least two housekeeping genes is very useful.

In mycology, a polyphasic approach has been used among others on the *Aspergillus* section *Nigri* (34, 40), *Aspergillus* section *Clavati* (58), *Aspergillus* section *Candidi* (59), *Aspergillus* section *Usti* (26), and *Aspergillus* section *Fumigati* (17, 41). The methods used included sequencing of the ITS, β -tubulin, and calmodulin genes or spacers, micro- and macromorphology, physiology, especially growth at different temperatures, and water activities and secondary metabolite profiling.

6.3. CONDITIONS FOR PRODUCTION OF SECONDARY METABOLITES

Many screening procedures have been suggested, but if a large number of microorganisms have to be examined, a microscale technique is very valuable. Some industrial firms have used liquid culture (shake or still culture) for screening, because the results from this screening can more easily be the basis of scale-up than results from agar cultures. However, liquid cultures require elaborated extraction and rinse-up procedures. In contrast, a few agar plugs cut out of an agar colony from a microorganism can easily be extracted without any rinse-up procedures and the filtered extract used for any separation method available. This so-called agar plug method was originally proposed for thin-layer chromatography (TLC) where the agar plug was placed directly on a TLC plate (10, 11), and later modified to be used in conjunction with high-performance liquid chromatography (HPLC) or mass spectrometry (MS) methods (48, 50). An additional advantage of using colonies of microorganisms grown on agar is that the growth and development of the colony can be monitored, and several differentiation phases can be analyzed. Furthermore, contaminations can easily be detected. By analyzing the colony itself, cell-associated secondary metabolites can be detected, and by analyzing the agar surrounding the colony, secreted secondary metabolites can be detected.

Bacteria and filamentous fungi grow and differentiate well on different kinds of agar media, but in general the media should contain trace metals, potassium, magnesium, sulfate, phosphate, a nitrogen source, and a carbon source. Often yeast extract, corn steep liquor, or enzyme-digested proteins (peptone, tryptone) are good nitrogen sources, and sucrose or glucose are good carbon sources. However, expression of some secondary metabolites requires other

simple carbohydrates or complex ones such as starch or cellulose. Plant extracts often contain these carbohydrates, and in addition, some plant secondary metabolites may stimulate secondary metabolite production in the microorganisms. Examples of these are malt extract, potato extract, and carrot extract. Particular metabolites may require special media. For example, siderophores are best expressed on a medium deficient of iron, and β -lactams such as penicillin are produced best if there is not too much carbohydrate in the medium. No medium can support production of all secondary metabolites produced by microorganisms, so several media should be used to detect as close to the full potential of secondary metabolites as possible. A new way of having silent gene clusters expressed is to use histone inhibitors, which have been shown to induce secondary metabolites that were otherwise only produced after triggering by plant secondary metabolites (12, 46, 60). A combination of genome mining (23) and chemical induction of silent biosynthetic pathways by suberoylanilide hydroxamic acid and 5-azacitidine in potato dextrose broth did show that several secondary metabolites were upregulated in *Aspergillus niger* ATCC 1015 and CBS 513.88, both full-genome-sequenced strains (12; see also chapter 7, this volume). However, many of these secondary metabolites indicated by expressed sequence tags were actually produced by a direct approach using yeast extract sucrose (YES) agar (34).

Incubation temperature, atmosphere, redox potential, pH, and water activity optimal for growth are not always the optimal conditions for secondary metabolite production, but microorganisms rarely produce secondary metabolites optimally far away from their growth optima. Some initial experimentation may be necessary to establish the optimal conditions for production of as many different secondary metabolites as possible. Incubation time is also important. For many microorganisms, 5 to 10 days of incubation will be optimal.

Miniaturized methods have been used for screening of enzymes in mutants of fungi (1), and the same kind of miniaturized methods and microwell methods can also be used for screening for secondary metabolites. Such methods are mostly used in biotechnological firms, but with the increased sensitivity in separation and detection methods, this is also an approach that can be used in exometabolomics.

6.4. EXTRACTION OF CULTURES

A very efficient extraction mixture for most secondary metabolites is ethylacetate/dichloromethane/methanol (3:2:1) with some added formic acid (48). Ultrasonication helps in extracting a large proportion of the secondary metabolites present in the agar plugs. This mixture is especially well suited for apolar and medium polar compounds. Usually the extraction mixture is then evaporated and the remaining dry extract redissolved in methanol. By use of the 3:2:1 mixture many "primary metabolites" are not included in the final extract being analyzed. For very polar compounds 75% methanol or 84% acetonitrile are also effective extraction liquids, and the resulting extract can be analyzed directly without any rinse-up. That rinse-up is not necessary is one of the advantages in the agar plug methods. However, many other extraction solvents appear to be effective, including dichloromethane, ethylacetate, and acetone. All these extraction solvents have been used extensively to produce crude plant or microorganism extracts.

6.5. SEPARATION OF SECONDARY METABOLITES

Volatile secondary metabolites are best separated by use of gas chromatography (29). However, most bioactive secondary metabolites are not volatile, so other separation methods are used. Even though micellar electrokinetic capillary chromatography appears to be a very effective separation technique (37), HPLC or ultra performance liquid chromatography (UPLC) are the methods of choice for general separation and simultaneous detection of secondary metabolites. UPLC has only been used recently (22, 57), but HPLC methods are still those used by most researchers. Many types of columns are effective, but reversed-phase columns have usually been used and acetonitrile/water gradients are nearly always used for elution (19, 20, 35). An alkylphenone retention index can be calculated and used in conjunction with retention time to partially identify the different secondary metabolites eluted (19). The more authentic standards of known secondary metabolites that can be analyzed together with the extracts of the microorganisms, the better.

Direct-inlet MS can be used without a need to separate the different secondary metabolites (22, 39, 49, 50, 51). By using electrospray conditions and weak ionization, many compounds will appear as their $M + 1$ mass peak (for positive ionization) or as their $M - 1$ peak (for negative ionization) and few fragments will be seen. If a high-accuracy time-of-flight mass spectrometer is used, it is often possible to calculate the molecular formula for each compound. Such an analysis takes 1 to 2 min, compared with an HPLC separation, which may take 15 to 30 min. Smedsgaard et al. (50) incubated isolates from 54 species of *Penicillium* on Czapek yeast autolysate agar and YES agar for 1 week at 25°C, and extracted three small agar plugs from these cultures by use of a two-stage extraction procedure using first ethylacetate/dichloromethane/methanol (3:2:1) with some added formic acid and then 2-propanol. After evaporation and redissolving in methanol, these extracts could be injected directly into the mass spectrometer. By using this method nearly all 54 species could be separated and several $M + 1$ ions could be directly related to different secondary metabolites produced by the isolates analyzed, as accurate mass detection was used.

6.6. DETECTION AND IDENTIFICATION OF SECONDARY METABOLITES

In addition to retention time, other informative spectrometric data will increase the chance of correctly identifying the known secondary metabolites. The two major ways of identifying the different peaks eluted from the HPLC are a hyphenated diode array detector (UV-visible spectra) or a hyphenated mass spectrometric detector. Many secondary metabolites have conjugated double bonds, and thereby they have more or less specific UV spectra. These UV spectra are often alike in biosynthetically related secondary metabolites, and new compounds with the same chromophore can be found, or known compounds can be deselected (3, 25, 31, 38). This can be accomplished by comparing UV spectra with use of image analysis techniques (25, 30). The same kind of image analysis techniques can be used for high-resolution mass spectra to deselect known compounds or to discover probable new compounds (24). Databases on secondary metabolites are not very detailed concerning UV spectra, often only providing the absorption maxima, but data for fungal metabolites can be found in Frisvad and Thrane (20) and Nielsen and Smedsgaard (35) and in the

original literature. Mass spectra are easier to use for identification, because most databases, such as ANTIBASE, have accurate monoisotopic masses listed for all compounds. The combination of taxonomy of the producer, retention time, UV spectrum, and high-resolution mass spectrum of the secondary metabolite under question, and available databases, will thus be sufficient to identify many known compounds, so valuable time is not wasted rinsing up and elucidating the structure of a known compound.

Nuclear magnetic resonance (NMR) techniques can also be used for screening secondary metabolites from fungi. Isaka et al. (27) used a combination of TLC and ^1H NMR for insect-associated fungi. Characteristic proton signals were used to indicate certain steroids and these were later separated by use of TLC, chemical color reactions, and repeated NMR confirmation of identity. This technique was used for certain hopane steroids that did not have a chromophore or had very poor mass sensitivity. However the TLC-NMR method is not very sensitive, and a new method based on microcoil probes (33, 43) and two-dimensional NMR spectra is very promising. The latter method was used for *Tolyposcladium cylindrosporium* to find new terpene indol alkaloids (44). New chemoinformatic methods can then be used to identify the metabolites (61).

6.7. CHARACTERIZATION OF NEW SECONDARY METABOLITES

Data from the screening of microorganisms are also useful to elucidate the structures of new compounds. The UV and mass spectra, in addition to taxonomic and biosynthetic reasoning, can in some cases help in proposing a chemical structure for a new secondary metabolite, but in most cases the new compound has to be purified, and characterized further by NMR, X-ray crystallography, infrared spectra, and circular dichroism. Closely related fungi often produce the same secondary metabolites; hence, a correct identification can be of value. For example, most, but not all, species in the *Aspergillus ochraceus* group (*Aspergillus* section *Circumdati*) produce five types of polyketides: penicillic acid, ochratoxins, xanthomegnins, aspyrones, and melleins (15), so if a new species in this group is discovered, it will probably produce some or all of those metabolites. New metabolites from a new species in that group would then probably be a terpene or a nonribosomal peptide, even though a fifth kind of polyketide could also be the bioactive compound. Many compounds of mixed biosynthetic origin have also been found, and the structure of those may be more difficult to predict based on taxonomic and biosynthetic reasoning. After deselection of known compounds, using, for example, UV and mass spectra, the effort can be concentrated on what appear to be new compounds. These are often purified based on the analytical results and separated by use of preparative reversed-phase HPLC, alternatively preparative TLC, or high-speed countercurrent chromatography (6). Dalsgaard et al. (6) compared reversed-phase HPLC and high-speed countercurrent chromatography to purify and elucidate the structure of two new cyclic peptides from *Penicillium*.

6.8. CONCLUSION

The discovery of new bioactive compounds requires a combination of methods and a systems biology approach, using both molecular and phenotypic data. It is recommended to use a combination of taxonomy, bioinformatics, optimal growth conditions, high-resolution separation and

identification techniques, and biosynthetic reasoning in the efforts to discover new lead drugs. Such a polyphasic approach needs to be made in such a way that it can be miniaturized and used in high-throughput screening; the use of microscale techniques is recommended. One of the most important parts of finding new compounds is to be able to quickly deselect already known compounds. The use of fast methods such a direct-inlet MS combined with databases is one possibility, while UPLC-UV-MS may also prove to be the chosen chemical screening technique for new bioactive natural products in the future.

Strategies for Accessing Microbial Secondary Metabolites from Silent Biosynthetic Pathways

ROBERT H. CICHEWICZ, JON C. HENRIKSON, XIAORU WANG,
AND KATIE M. BRANSCUM

7

7.1. INTRODUCTION

The theory and practice of microbial natural products research has been revolutionized by genomic technologies. The proliferation of fully sequenced microbial genomes during the past half-decade, many of which possess remarkable numbers of genes and gene clusters encoding for the production of unknown secondary metabolites, demonstrates that only a fraction of Nature's chemical bounty has been explored. This discovery has sparked significant interest in probing silent biosynthetic pathways (SBPs) for new and bioactive natural products and led to the rapid development of several innovative technologies for investigating these compounds. In this review, we examine the growing array of methods used to access microbial SBPs and discuss the challenges of effectively exploring this chemical resource.

7.2. SCOPE OF THE CHAPTER

Given the substantial scientific interest in this field, several review articles have been published within the past 5 years about microbial SBPs and we refer the reader to these excellent treatises for further discussion and alternative perspectives on the topic (5, 13, 18, 22, 23, 39, 45, 78, 80, 81, 85, 93, 95, 99). Unique to this chapter is a concentration on the methodological approaches used to access the products of SBPs, and we present a number of important case studies that are intended to help the reader evaluate the advantages and disadvantages of each technique. While we have attempted to provide a broad coverage of contemporary methods for accessing SBPs, we have found it necessary to exclude a number of studies to (i) avoid unnecessary redundancy describing investigations utilizing the same experimental approach and (ii) maintain the chapter's focus on techniques that have been successfully applied toward the exploration of SBPs.

7.3. BACKGROUND

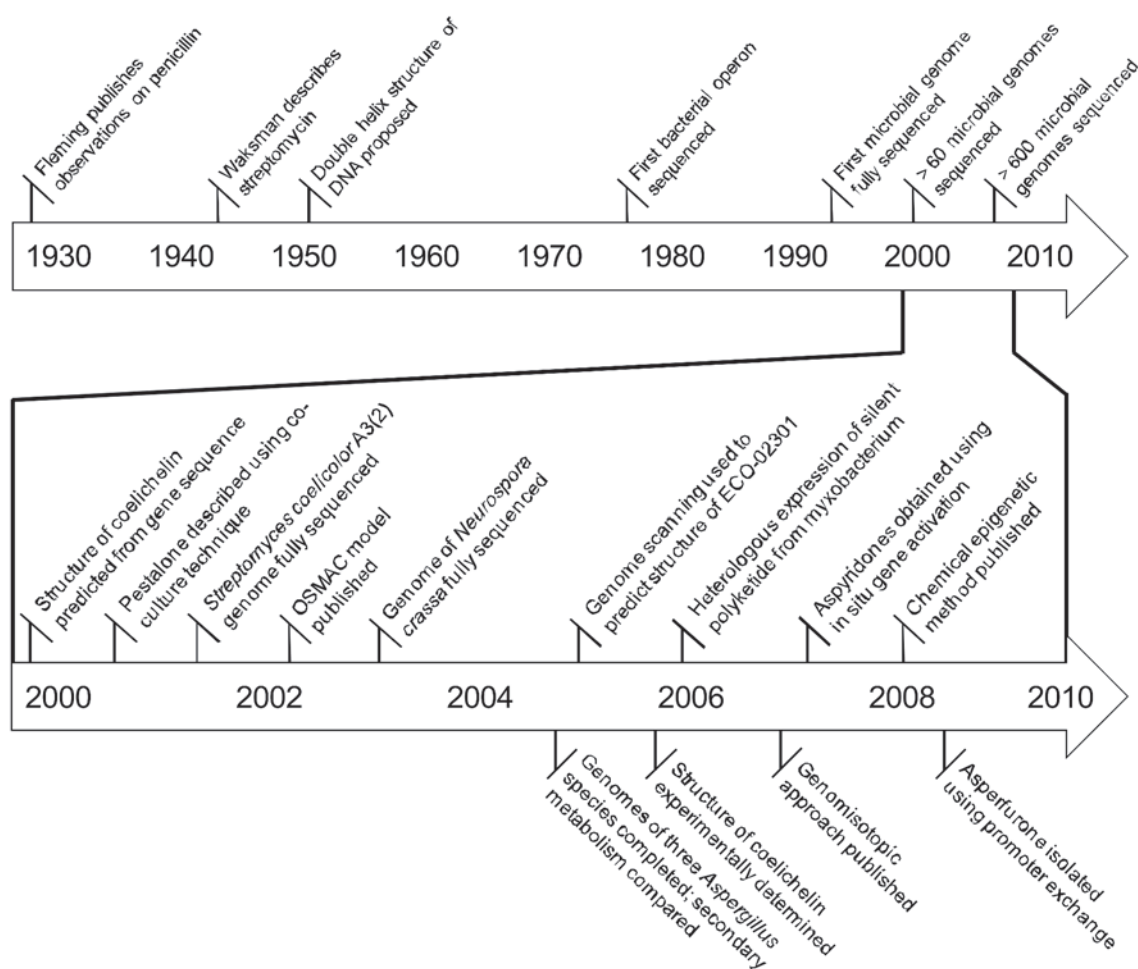

The concept of SBPs was born out of the realization that many microorganisms express only a fraction of their secondary-metabolite-encoding pathways under typical laboratory culture conditions (Table 1). In each of these cases, the numbers of secondary metabolites observed from laboratory-grown cultures fall short of their genetically

encoded biosynthetic potential. Several terms have arisen in the natural products literature as descriptors of this phenomenon. The words "silent," "cryptic," and "orphan" (45, 78) have all been used in reference to the refractory nature of these genes and the general inaccessibility of their biosynthetic products. Our group prefers the use of the word "silent" since this terminology offers a rather liberal definition for broadly encapsulating the concept of muted gene pathways and their corresponding enzymes and secondary metabolites. Our use of the term "silent" throughout this chapter is intended to include the broad range of suppressive transcriptional, translational, and biosynthetic mechanisms responsible for inhibiting secondary-metabolite formation. It is interesting to consider that some secondary-metabolite-encoding pathways that appear functionally silent might actually be transcribed at rather low levels, resulting in the generation of relatively minor concentrations of their respective biosynthetic products. Consequently, this low-level production could preclude the straightforward detection of a gene's or gene cluster's associated natural products (56). In other cases, SBPs have demonstrated complete transcriptional suppression under laboratory culture (38, 56). Irrespective of the cause, SBPs occupy the vast gulf that exists between our knowledge of what microorganisms are seemingly *genetically* able to produce and the natural products that researchers are capable of *chemically* detecting.

During the preparation of this chapter, we have found it extremely useful to consider each method in its chronological context (Fig. 1). An important benefit of this approach is that it provides a unique window through which the evolution of SBP studies can be viewed, and suggests the future trajectory for this field. Consequently, we have presented the methods for probing SBPs in their approximate chronological order of development to highlight significant research trends. In general, the reader will note a pronounced shift away from processes based strictly on culture manipulation toward more genomic-driven technologies. An exciting new dimension in SBP studies is the emergence of novel mechanism-based and other hybrid techniques that meld the technological simplicity of culture manipulation strategies with recent breakthroughs in our understanding of microbial molecular biology. This has yielded a new generation of approaches that are anticipated to greatly enhance SBP-mining practices.

TABLE 1 Numbers of PKS, NRPS, and HPN gene clusters in selected bacteria and fungi

Organism	Genome size (Mb)	Number of gene clusters			Reference(s)
		PKS	NRPS	HPN	
<i>Aspergillus fumigatus</i> Af293	29.4	14	13	1	65

7.4. MANIPULATION OF ABIOTIC AND BIOTIC CULTURE CONDITIONS

7.4.1. Malleability of Microbial Chemical Phenotypes

It has long been recognized that efforts to manipulate microbial culture conditions can have a profound influence on the production of microbial secondary metabolites. This understanding has served as the backdrop of numerous studies describing the variable impact that alterations of abiotic or biotic factors have on the biosynthesis of natural products. A key advantage of this approach is that efforts to alter a microorganism's phenotypic (chemical) traits can be made independent of genomic knowledge. That is to say, if one assumes that a microbe harbors SBPs, then altering its growth conditions is a viable way to trigger production of its hidden natural product potential. The significant disadvantage of this technique is the lack of rationale for which growth factors should be manipulated to elicit production of new natural products. Moreover, conditions facilitating SBP expression for one microbe are not necessarily conducive for other species (i.e., microorganisms respond nonuniformly to stimulants). Consequently, unique culturing methods must be developed independently for each set of SBP-derived natural products in each microbial strain.

The ability to activate SBPs by altering microbial culture methods was well known long before researchers were knowledgeable of the functional roles that DNA, RNA, and proteins played in their production. To demonstrate this point, it is informative to note some of the early accounts describing altered chemical profiles of microorganisms following the modification of their respective culturing conditions. At the turn of the twentieth century, there existed significant debate as to the roles that various nutrients

and chemical "stimulants" contributed to the phenotypic traits of microbes (86, 87). While most of these studies focused heavily on features such as cell mass accumulation and spore formation, it was also observed that culture manipulation resulted in significant qualitative and quantitative changes in an organism's chemical composition (76). For example, the addition of 0.01% ZnSO₄ to *Aspergillus niger* was shown to result in a 41% increase in the production of citric acid (Fig. 2), along with the appearance and greater yields of many other unidentified extractable small organic substances. Similarly, the effects of varying media/culture conditions were observed to appreciably alter the production of pigments and antibiotics including fumigacin (*Aspergillus fumigatus*) (94), clavacin (*Aspergillus clavatus*) (94), rubrofusarin and aurofusarin (*Fusarium culmorum*) (4), phoenicine (*Penicillium phoeniceum*) (31), and penicillins (*Penicillium* spp.) (21, 32, 51, 75, 84, 88) (Fig. 2). While this list of examples is by no means exhaustive, it does provide important evidentiary support for understanding the conceptual basis on which modern culture manipulation strategies have been designed.

7.4.2. Current Approaches to SBPs Using Culture Manipulation

In 2002, the idea of using culture manipulation techniques to probe SBPs for new natural products was formally reviewed and presented as the OSMAC theory (One Strain – MAny Compounds) (12). Although this approach had been widely used for decades, the compilation of data presented by the authors offered a compelling summary of disparate abiotic and biotic manipulation techniques for eliciting new natural products from bacteria and fungi (Table 2). For example, the fungus *Sphaerosidales* sp. F-24'707 was noted to be metabolically responsive to a broad range of different media, cultivation vessels, solid versus liquid fermentation

FIGURE 2 Representative microbial compounds identified by use of early culture manipulation techniques.

TABLE 2 Examples of some reported culture manipulation techniques

Microbe	Elicitation	Compounds	Reference
<i>Aspergillus ochraceus</i>	Variation of media composition, vessel, and oxygenation	Total of 15 compounds produced including seven new pentaketides	40
<i>Chaetomium chiversii</i>	Switch from solid to liquid medium	Chaetochromin A (liquid), radicicol (solid)	71
<i>Gymnascella dankaliensis</i>	Carbon source of media varied	Dankasterones A and B; gymnasterones A, B, C, and D	2
<i>Halomonas</i> sp. GWS-BW-H8hM	Addition of anthranilic acid	Aminophenoxazinones	11
<i>Paraphaeosphaeria quadriseptata</i>	Changing from tap H ₂ O to distilled H ₂ O	Cytosporones F-I, quadriseptin A, 5'-hydroxymonocillin III	71
<i>Phomopsis asparagi</i>	Addition of jasplakinolide (F-actin inhibitor)	Chaetoglobosins 510, 540, and 542	29
<i>Sphaeropsidales</i> sp. F-24'707	Variation of culture conditions	Cladospirones B-I	14
<i>Sphaeropsidales</i> sp. F-24'707	Addition of tricyclazole (inhibitor of 1,8-dihydroxynaphthalene pathway)	Sphaerolone, dihydrophaerolone	15
<i>Spicaria elegans</i>	10 media types with and without shaking	Spicochalsin A, aspochalsins M-Q	58
<i>Streptomyces</i> spp.	Addition of dimethyl sulfoxide and other organic solvents to cultures	Chloramphenicol, tetracenomycin C, thiostrepton	26
<i>Streptomyces</i> spp.	Addition of scandium and other rare earth elements	Increased production of actinorhodin and other metabolites	53
<i>Streptomyces</i> sp. Gö 40/14	Variation of media composition, oxygenation, and pH	Several metabolites from different structure classes	12, 79
<i>Streptomyces cellulosa</i> S1013	Changing culture vessels	Hexacyclinic acid	48
<i>Streptomyces fradiae</i>	Addition of dimethyl sulfoxide	Increase the production of tylosin	20
<i>Streptomyces venezuelae</i> ISP5230	Shifting temperature from 37°C to 42°C	Jadomycin B	36

techniques, and enzyme inhibitors resulting in the generation of 19 new and known spirobisnaphthalene, bisnaphthalene, naphthoquinone, and macrolide metabolites from this single strain (Fig. 3). Similarly, *Aspergillus ochraceus* DSM7428 yielded an impressive array of nine structurally diverse natural products of polyketide synthase (PKS) and nonribosomal peptide synthetase (NRPS) origins following culture modifications (shake versus static fermentations and different vessel types) (Fig. 4).

Over the past few years, several new compounds have been described from fungi and bacteria by the use of culture manipulation techniques (Table 2). Ascospiroketals A and B from *Ascochyta salicorniae* (82); chaetoglobosins 510, 540, and 542 from *Phomopsis asparagi* (29); cytosporones F to I from *Paraphaeosphaeria quadriseptata* (71); daldinins A to C from *Daldinia concentrica* (83); and dankasterones A and B from *Gymnascella dankaliensis* (2) represent pertinent examples demonstrating the value that culture manipulation strategies have for enhancing metabolite yields or inducing the expression of new natural products from microorganisms (Fig. 5).

7.4.3. Microbial Coculture Techniques

Based on the premise that bacteria and fungi live in complex communities involving a wide range of competitive, commensalistic, predatory, mutualistic, parasitic, and synergistic interactions, it has been proposed that cohabitating microorganisms might serve as eliciting agents for the production of natural products (43). Consequently, it was envisioned that agents capable of triggering SBP

production might include a variety of undefined signaling molecules (e.g., secondary metabolites, primary metabolites, complex cell wall materials, proteins, etc.), making coculture a highly promising approach for natural product discovery (19). Published accounts describe a wide variety of approaches that have been applied in coculture studies ranging from the simple mixing of multiple live organisms to the addition of purified or semipurified microbial-derived components to cultures of a different microorganism (Table 3).

Several outstanding examples using coculture methods point to the exceptional opportunities that this technique provides. For example, the microbial metabolite pestalone was reported in 2001 from a marine-derived *Pestalotia* sp. (Fig. 6) (30). Pestalone is a unique chlorinated benzophenone possessing significant antimicrobial activity against several bacterial strains. It is noteworthy that pestalone was not detected in appreciable amounts from monocultures of the *Pestalotia* sp. However, addition of live bacteria cells (an unidentified gram-negative unicellular bacterium described as strain CNJ-328) to the growing fungus resulted in accumulation of the metabolite. It is interesting that neither an organic extract of the bacteria nor a cell-free aliquot of CNJ-328 culture broth were capable of eliciting pestalone production. Later, these authors expanded their application of this cocultures approach to include the production of libertellenones A to D from a marine-derived *Libertella* sp. fermented with CNJ-328 (66) and emericellamide from the fungus *Emericella* sp. grown in combination with a marine actinomycete (*Salinispora*

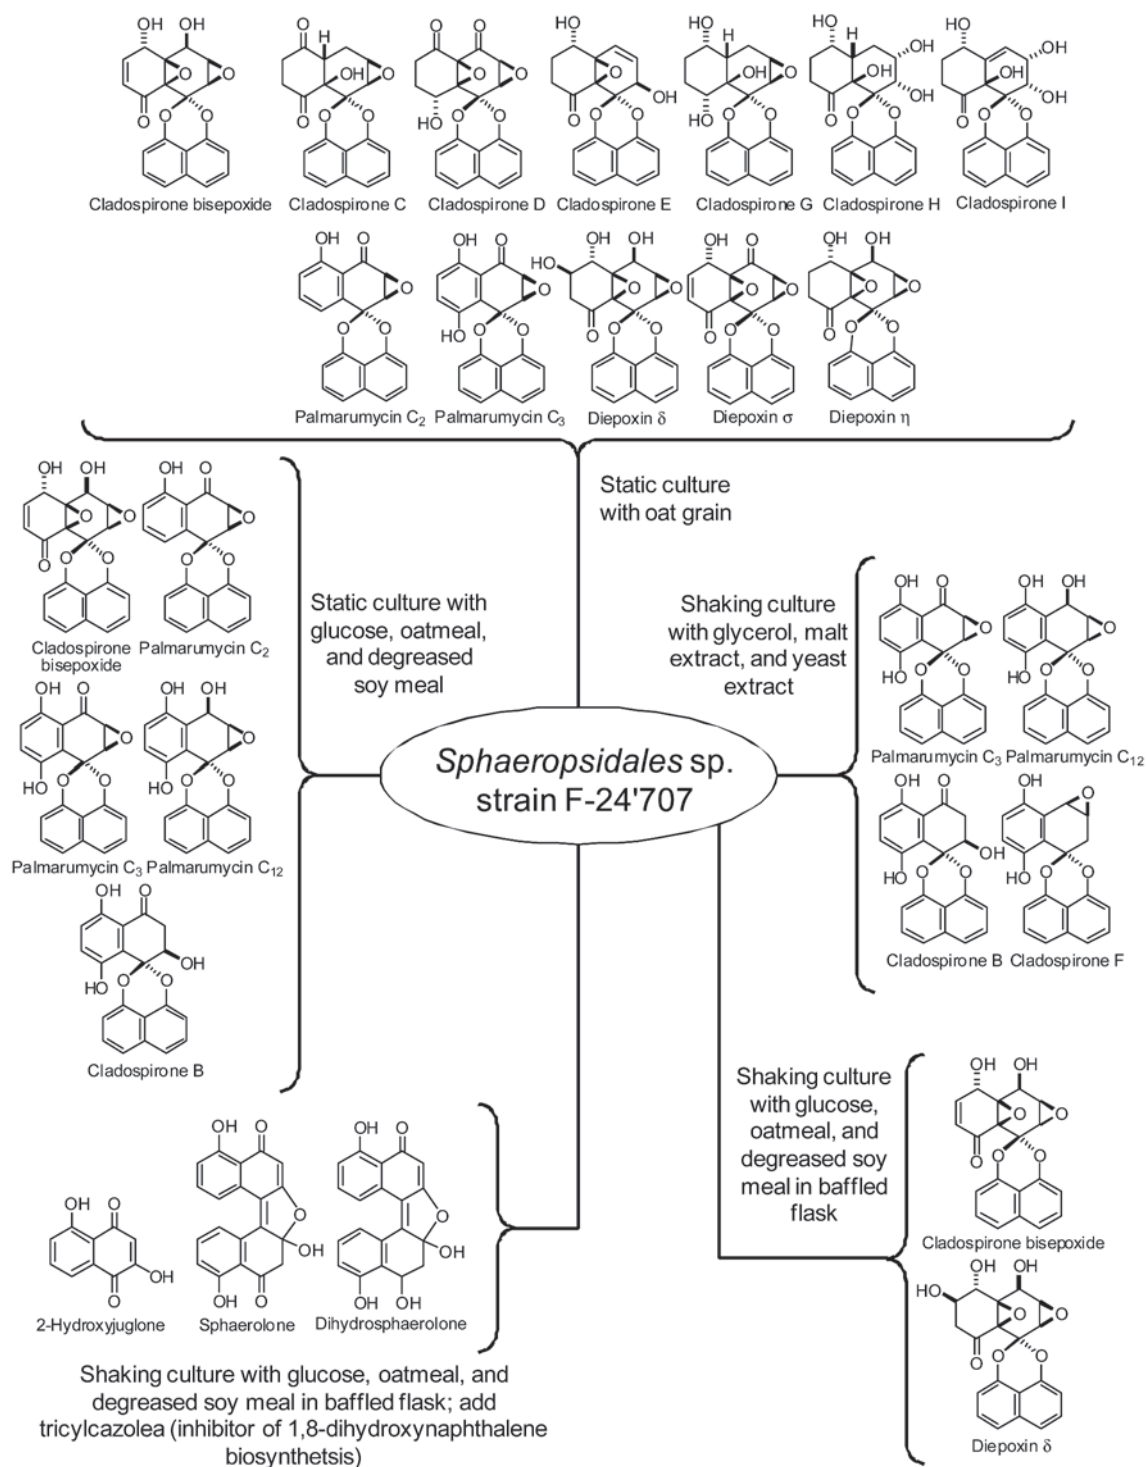

FIGURE 3 Compounds obtained from *Sphaeropsidales* sp. F-24'707 by use of culture manipulation.

arenicola) (Fig. 6) (67). The production of pyocyanin from mixed fermentations of marine-sediment-derived *Pseudomonas aeruginosa* and *Enterobacter* sp. (Fig. 6) was described recently (3). In liquid culture, neither isolate alone was found capable of generating the blue metabolite. By using a series of Boyden chamber experiments, the authors were able to demonstrate that a small-molecule membrane-diffusible factor(s) was generated by *Enterobac-*

ter sp., leading to the induction of pyocyanin production in *P. aeruginosa*.

7.4.4. Final Thoughts and New Directions for Using Culture Manipulation Techniques

An important point to note is that each of the described culture manipulation methods involves changes in the inclusion/deletion of single components (e.g., add or

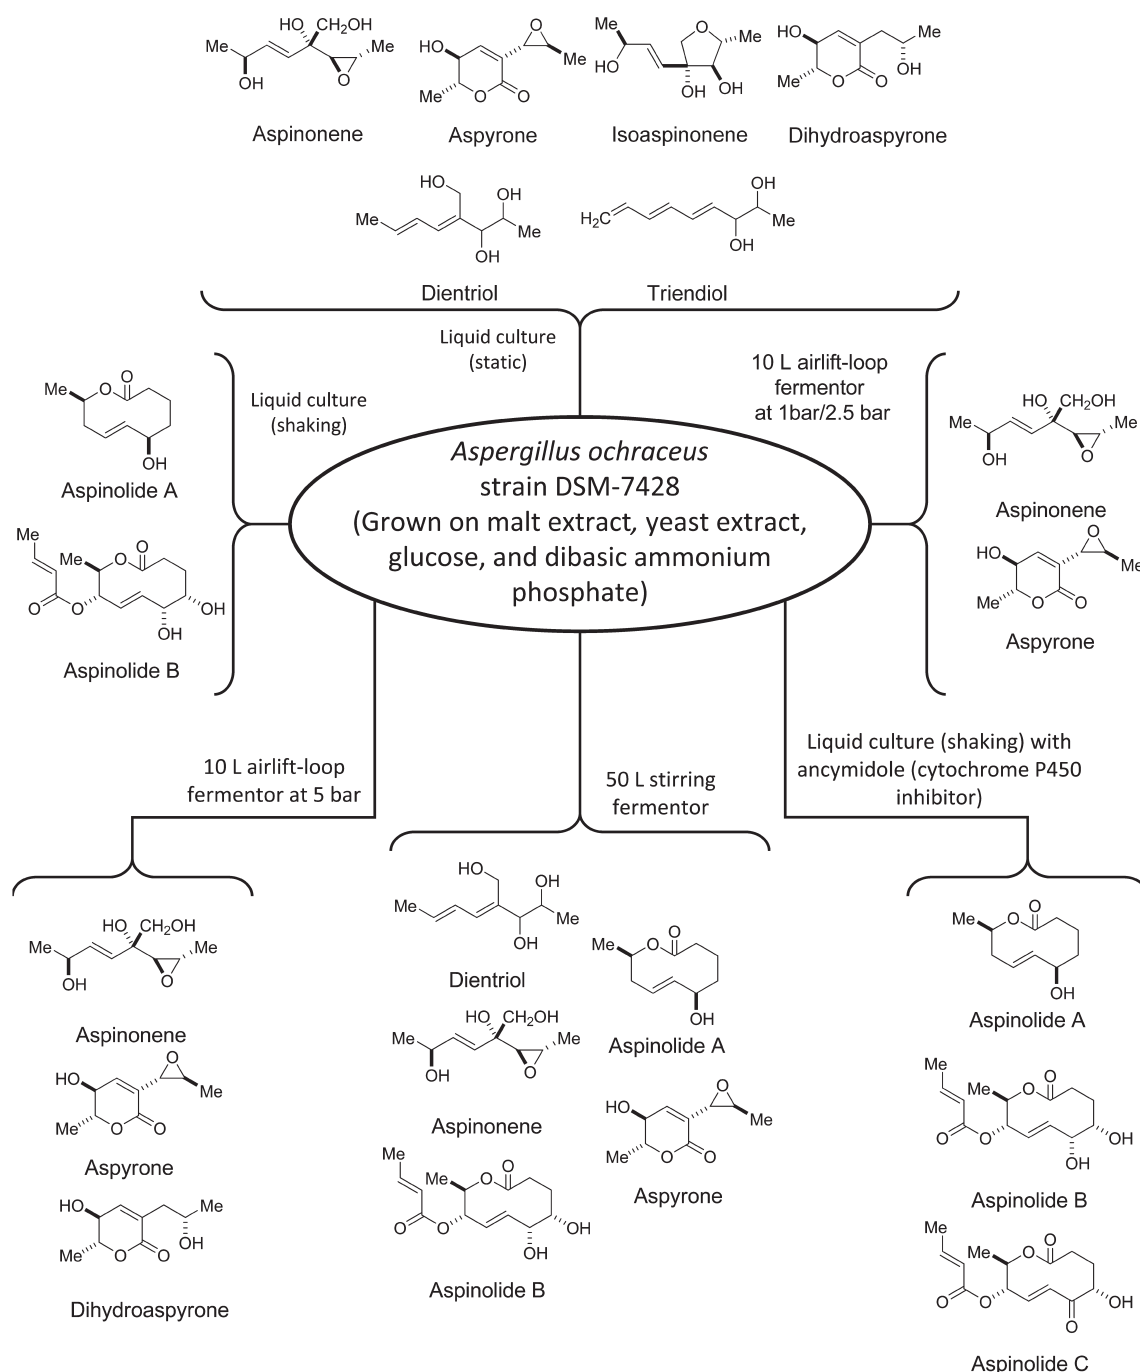

FIGURE 4 Compounds obtained from *A. ochraceus* DSM7428 by use of culture manipulation.

increase levels of NaCl, alter pH, add or increase various metals, etc.) or component mixtures (e.g., carbon source, media type, coculture species, etc.), or alteration in fermentation conditions (e.g., shake versus static cultures, culture vessel type, solid versus liquid media, etc.). It quickly becomes apparent that an unlimited assortment of culture parameters exist that can be altered singly or in combination. This makes the selection of which abiotic and biotic features to modify subject to considerable conjecture. Despite attempts to rationalize this process, there are no empirical rules or guidelines as to which culture conditions should be routinely evaluated. The arbitrary probing of

abiotic and biotic factors until a suitable parameter set is discovered for inducing SBP activation can create a tremendous workload for natural products researchers. In light of these difficulties, Bills and colleagues (10) have proposed the use of “nutritional arrays,” which allow for the parallel screening of hundreds of media conditions. Although conceptually appealing, this technique is likely to have only limited practical value because of the tremendous workload entailed in generating arrays and analyzing the large numbers of resulting samples.

The most detrimental factor limiting the effective use of culture manipulation techniques is the general lack

FIGURE 5 Examples of natural products obtained by manipulating microbial culture conditions.

of knowledge concerning which environmental cues microorganisms rely on to induce SBP expression. Coupled to this is the natural product research community's imprecise knowledge concerning the functional roles that SBP-derived secondary metabolites play under natural conditions (24, 33, 37). Conceivably, understanding the native functions of SBP-derived compounds could help researchers judiciously select which conditions should elicit metabolite biosynthesis. An exceptional example of utilizing an informed approach to identifying the product of an SBP is the discovery of coelichelin from

Streptomyces coelicolor M145 (Fig. 7) (23, 25, 55). Key to this compound's discovery were (i) the realization that the targeted natural product was predicted to possess hydroxamate functionalities (these are frequently found in siderophores) and (ii) the fact that the gene cluster controlling coelichelin's biosynthesis was positioned adjacent to a presumed iron-binding repressor. This permitted Challis and colleagues (55) to accurately predict that use of iron-deficient media would facilitate the production of coelichelin. Although significant insight from genome mining was used to advance this discovery (discussed

TABLE 3 Examples of cocultivation methods for investigating SBPs in microorganisms

Methods	Outcome	Reference
Marine bacteria were cocultured with live and heat-killed terrestrial bacteria	Marine bacteria strains produced uncharacterized antibiotics	64
Marine bacteria were cocultured with live and/or cell-free supernatants of marine and terrestrial bacteria	Marine bacteria strains produced uncharacterized antibiotics	19
Panels of up to 76 live <i>Streptomyces</i> species were cocultured together in a pairwise fashion	Many species were able to elicit and produce uncharacterized antibiotics depending on the coculture partner	90
Two live fungi species (<i>Acremonium</i> sp. Tbp-5 and <i>Mycogone rosea</i>) were cocultured together	Induced production of acremostatins A, B and C	35
A bacterium (<i>Lactobacillus plantarum</i> NC8) was cocultured with live and heat-killed bacteria (<i>Lactococcus lactis</i> and <i>Pediococcus pentosaceus</i>)	Induced production of plantaricin NC8	61
A bacterium (<i>Streptomyces californicus</i>) was cocultured with a fungus (<i>Stachybotrys chartarum</i>)	Induced production of an uncharacterized cytostatic immunotoxin	73

FIGURE 7 Combined approach leading to the discovery of coelichelin from *S. coelicolor*.

below in section 7.5.2), this work serves as a testament to the fact that, in the absence of similar guiding factors, culture modification strategies will continue to involve significant guesswork regarding which culture amendments will provide access to SBPs.

7.5. GENOMICS-DRIVEN APPROACHES TO INVESTIGATING SBPs

7.5.1. Overview of Genomic Technologies

Since the first report of a fully sequenced microbial genome (Fig. 1), growth in the number of bacteria and fungi whose genomes have been determined has been exponential. Given the recent emergence of a new generation of sequencing methods such as Applied Biosystems SOLiD, Helicos HeliScope, Illumina Solexa, Roche 454 GS FLX, and Pacific Biosciences SMRT (60, 62), the time and cost required to sequence microbial species has diminished significantly. These technologies are expected to facilitate the sequencing of microbial genomes at even greater rates, which is anticipated to provide natural products researchers with unprecedented capacity for identifying SBPs (13, 23, 93). Several resources have been created to address the critical need for sharing the massive quantities of data emerging from microbial genome-sequencing projects (Table 4). The centralized archiving of sequencing data will come to play increasingly important roles for the mining of SBPs. It is also likely that the evolving speed and efficiency of these techniques will lead to the further compilation of privately held (industry) generated genomes that will be largely inaccessible to the natural products research community. Hopefully, meaningful data-sharing plans will help to loosen restricted access to these resources and help foster additional discoveries.

7.5.2. Genome Scanning for SBPs

As a testament to the power of genome-scanning methods, Ecopia Biosciences, Inc. (now Thallion Pharmaceuticals, Inc.) developed a commercial enterprise based on the rapid generation and screening of bacterial genomic

information for the presence of secondary-metabolite-encoding gene clusters (98). Two principal features were key to facilitating the success of this method: (i) secondary-metabolite-encoding gene clusters are readily recognizable in microbial genomes because of the inclusion of distinctive conserved motifs, and (ii) gene cluster sequence information can be used in certain circumstances to predict the final biosynthetic protein's substrate specificity and to tailor functions with reasonable accuracy (this is particularly true for bacterial modular PKS and NRPS enzymes). Use of this approach led to the discovery of several new secondary metabolites, some of which are illustrated in Fig. 8. This includes the furanone-containing polyketides E-492, E-837, and E-975 (6); the glycosylated polyketide ECO-0501 (7); and a rather lengthy polyketide, ECO-02301 (63).

Beyond these discoveries, academic laboratories appear to be responsible for spearheading the bulk of genomics-driven discoveries of SBP-derived secondary metabolites. Many excellent examples can be found describing how the identification of silent genes in bacteria and fungi resulted in the discovery of novel microbial metabolites (13, 22, 23, 45, 78). A particularly elegant example of applying the genome-scanning approach has been described for coelichelin from *S. coelicolor* M145 (see above and Fig. 7) (23, 25, 55). It is important to note that, in each of these cases, the biosynthetic products of the investigated genes were ultimately obtained from the organisms by use of traditional culture techniques. What does one need to do to access metabolites if standard culture conditions prove completely incapable of facilitating the production of a target compound? This situation requires a different set of methodological tools, including heterologous expression and in situ gene manipulation, which are discussed in the following examples.

7.5.3. Heterologous Expression of SBPs

Heterologous expression techniques provide the opportunity to selectively transfer an SBP into a new host possessing a nontranscriptionally suppressive regulatory environment to produce the enzymatic machinery for silent natural

Sanger Institute Bacterial Genomes	Bacterial genomes and list of current genome projects http://www.sanger.ac.uk/Projects/Microbes/

^aNote: specialized databases limited to one or a few related genera have been excluded from this list.

FIGURE 8 Examples of microbial metabolites whose structures were predicted based on genome scanning. The structure of each metabolite was later confirmed by isolation and characterization using NMR and mass spectrometric analyses.

FIGURE 9 Examples of SBP-derived natural products that were identified by use of heterologous expression techniques.

product production. While this technology has been widely used for investigating numerous non-secondary-metabolite-encoding genes, its application to the study of natural products and SBPs has evolved dramatically in recent years. In 2006, genome scanning by Müller and colleagues led to the discovery of a type III PKS in the myxobacterium *Sorangium cellulosum* for which no corresponding secondary metabolite could be identified (44). The lack of production of the unknown metabolite was confirmed through gene activation by inserting a pOPB20 plasmid into the PKS coding sequence, resulting in no detectable changes to the microbial secondary metabolome. Cloning and subsequent transfection of the type III PKS into *Escherichia coli* and *Pseudomonas* sp. demonstrated that only the pseudomonad was able to function as an appropriate host for expression. The transfected *Pseudomonas* sp. culture turned visibly red and high-performance liquid chromatography profiling confirmed the presence of a new metabolite. The structure of the compound was determined to be the naphthoquinone flaviolin, which is readily generated from the oxidation of the actual biosynthetic precursor product, 1,3,6,8-tetrahydroxynaphthalene (Fig. 9).

An important advantage of heterologously expressing SBPs is the opportunity it affords to manipulate biosynthetic genes and enzymes, as well as study secondary-metabolite production in a cell-free environment. For example, the Canes group noted a terpene synthase of unknown function in *S. coelicolor* A3(2) and transfected the cloned gene into *E. coli*. Using gene manipulation, the researchers were able to produce a modified His₆-tagged translational product allowing the transgenic protein to be readily purified by Ni²⁺ affinity chromatography (57). In vitro incubation of the recombinant protein with farnesyl diphosphate in the presence of Mg²⁺ yielded the new sesquiterpene (+)-epi-isozaene (Fig. 9). The importance of this approach is that utilization of the recombinant protein product allowed the group to carefully analyze the reaction mechanisms and kinetics of the new terpene synthase, which is generally not possible in a cellular host.

Palmu et al. (70) have taken the idea of SBP manipulation one step further, leading to the production of new angucy-

cline analogs. This group observed that both *Streptomyces* sp. PGA64 and *Streptomyces* sp. H021 possessed PKS gene clusters, exhibiting significant homology to each other. Heterologous expression of varying portions of the gene clusters in *Streptomyces lividans* TK24 resulted in the generation of natural products bearing an angucyclic carbon skeleton (Fig. 9). These and other examples demonstrate the promise of using heterologous expression systems to manipulate SBPs. The ability to generate unique pools of natural and “unnatural” secondary metabolites presents an exceptional opportunity to identify new drugs and engineer novel chemical scaffolds.

7.5.4. Controlling SBP Expression by Means of In Situ Gene Manipulation

Despite its promising features, the routine use of heterologous expression systems for activating SBPs faces a number of significant difficulties. These challenges include handling large, multicomponent gene clusters, as well as identifying suitable expression hosts (81, 93). In light of these problems, methods to manipulate the in situ expression of SBPs hold great potential for rationally activating bacterial and fungal biosynthetic pathways. Although the concept of using promoter regulation to control natural product biosynthesis has been in use for years (1, 27, 69, 91), it was not until recently that this technique was applied to the activation of SBPs. The Hertweck group has presented evidence of a new and simple method for inducing SBP expression in a fungus (9). Having identified a silent hybrid PKS-NRPS (HPN) gene cluster in *Aspergillus nidulans*, the researchers cloned an associated putative activator gene (*apdR*) into a pAL4 vector and placed it under the control of an inducible alcohol dehydrogenase promoter (*alcAp*). Ectopic insertion of the *alcA-apdR* complex resulted in the inducible expression of *apdR*, which was confirmed by Northern blot analysis. Moreover, expression of *apdR* led to the transcriptional activation of the target HPN gene cluster and subsequent production of two new pyridone metabolites: aspyridones A and B (Fig. 10).

More recently, Chiang and colleagues noted the presence of two additional silent PKS gene clusters adjacent to one another in the *A. nidulans* genome (28). A homolog of the citrinin biosynthetic transcriptional activator was noted

FIGURE 10 Compounds obtained from SBPs following activation using promoter/activator manipulation.

adjacent to the PKS cluster and it was rationalized that this gene was responsible for controlling the transcription of one or both of the silent PKS gene clusters. Replacement of the putative promoter with an inducible *alcAp* resulted in the accumulation of two new (one major and one minor) metabolites under inducing conditions. Purification of the major metabolite yielded the new polyketide asperferanone, which is structurally reminiscent of the azaphilones.

7.5.5. Final Thoughts and New Directions for Using Genome-Based Techniques

The power afforded by genome-scanning and molecular mining methods for investigating SBPs offers unprecedented opportunities to the natural products community. By use of genomic data, it is now feasible to identify transcriptionally suppressed secondary-metabolite-encoding gene clusters and to manipulate their expression *in situ* or transfect them into novel hosts. The ability to directly link gene clusters to their resultant biosynthetic products is expected to provide important new insights into the evolution and function of SBP-derived natural products. While methods for working with bacterial SBPs have advanced significantly (5, 13, 23, 45), corresponding advances in the exploration of fungal SBPs have developed more slowly. This is due in part to the greater complexity of fungal natural-product-encoding pathways (e.g., incorporation of introns, strain-specific activation of polyketide acyl carrier protein domains, instability of large gene clusters in heterologous hosts, etc.) compared with their bacterial counterparts (81).

Despite the advantageous features and potential of genome-based methods, these techniques suffer from a variety of significant shortcomings that limit their utility. These problems include the lack of “standard” methods that would be widely applicable to a majority of microorganisms and diverse types of SBPs. Consequently, significant effort must be devoted to generating appropriate heterologous hosts or engineering suitable microbial strains for *in situ* manipulation. These problems appreciably reduce the speed and efficiency with which researchers are able to investigate SBPs. It is remarkable that the swiftness with which a microbial genome can be fully sequenced (<1 day), reasonably well annotated (days to weeks), and SBPs identified (<1 min using predetermined BLAST search parameters) far outpaces the speed of cloning and/or expressing a targeted biosynthetic gene cluster (typically months in academic laboratories). Until these limitations can be overcome, access to SBPs by use of genome-based methods will continue to be severely limited. New and widely applicable tools (e.g., universal heterologous hosts, novel vectors for routinely handling large gene clusters, etc.) are needed for probing the overwhelmingly large number of SBPs that are predicted to exist.

7.6. MECHANISM-BASED AND HYBRID STRATEGIES FOR ACCESSING SBPs

7.6.1. Advances in the Speed of Detection of SBP-Derived Natural Products

Up to this point, we have focused on two distinct sets of methods for accessing microbial SBPs: culture manipulation techniques and genomics-guided approaches. While both sets of methods have important strengths, they also present a number of limitations that restrict their usefulness. These weaknesses are particularly critical when considering each method's applications in high-throughput discovery settings where the speed

of preparing new bioactive substances from SBPs is crucial. Two new strategies offer great potential for rationally procuring SBP-derived natural products at an accelerated pace. These techniques, chemical epigenetics and genomisotopic methods, represent the hybridization of genomic- and molecular-based strategies with culture-based applications. It is anticipated that these methods will find widespread use for the discovery of SBPs and investigation of SBP-derived natural products.

7.6.2. Chemical Epigenetic Approach

As part of our research group's search for salient molecular mechanisms involved in controlling SBP expression, we were inspired by the work of Keller and colleagues, which provided tantalizing evidence for an epigenetic component to the transcriptional regulation of secondary-metabolite-encoding genes and gene clusters (17, 54, 74). To test this assumption, we had assembled a library of small-molecule epigenetic modifying agents that inhibit histone deacetylase and DNA methyltransferase/histone methyltransferase functions. Screening this library against a panel of filamentous fungi revealed that in 11 of 12 cases the addition of epigenetic modifiers to the culture medium resulted in the production of new and/or enhanced levels of secondary metabolites (96). Closer examination of two of the fungi yielded several new epigenetically induced metabolites that were not biosynthesized under typical culture conditions. These included the production of new oxylipins and perylenequinones from *Cladosporium cladosporioides* using 5-azacytidine (DNA methyltransferase/histone methyltransferase inhibitor) and suberoylanilide hydroxamic acid (histone deacetylase inhibitor), respectively (Fig. 11). Similarly, a *Diatrype* sp. yielded two new glycosylated polyketides, lunalides A and B, following treatment with 5-azacytidine (Fig. 11).

To further investigate the extent to which epigenetic modifying agents were able to alter the transcription of secondary-metabolite-encoding pathways, we treated *A. niger* with suberoylanilide hydroxamic acid and 5-azacytidine, and examined changes in the transcription of its 31 PKSs, 15 NRPSs, and 9 HPN gene clusters (38). Whereas less than 30% of biosynthetic genes were transcribed under typical laboratory culture conditions utilizing an extensive range of media types, cultures treated with histone deacetylase and DNA methyltransferase/histone inhibitors exhibited elevated transcription levels for the majority of these pathways (38). We have also begun the task of characterizing the new SBP-derived metabolites that are produced by *A. niger* following epigenetic modifier treatment. This has led to the identification of the new *N*-phenylpyridine metabolite nygerone A following addition of suberoylanilide hydroxamic acid to the culture medium (Fig. 11) (47). The chemical epigenetic approach holds substantial promise for activating a multitude of fungal SBPs in a mechanistically rational manner and providing a means for rapidly screening SBP-derived compounds for biological activities.

7.6.3. Genomisotopic Method

Beginning with an NRPS whose biosynthetic product was unknown, the Gerwick group tested the use of a hybrid genomisotopic method to identify the structure of the secondary metabolite produced by the gene cluster (46). The genomisotopic technique utilizes a combined approach consisting of structure prediction (based on a gene sequence) and isotopic labeling (based on feeding of isotopically labeled precursors expected to be incorporated into the metabolite) for detection of the target natural product (Fig. 12). Using this

FIGURE 11 Natural products obtained by using the chemical epigenetic induction of SBPs.

approach, *Pseudomonas fluorescens* Pf-5 was noted to contain a large NRPS cluster encoding for a decapeptide product. Four of the NRPS's modules exhibited highly conserved domains that were presumed responsible for the addition of leucine residues to metabolite. Using 1H - ^{15}N heteronuclear multiple bond correlation nuclear magnetic resonance (HMBC NMR), the

researchers were able to track the incorporation of ^{15}N -labeled leucine residues into a group of related secondary metabolites, which led to the isolation of orfamide A and its related congeners (Fig. 12). This technique is well suited for the exploration of SBPs, and it should provide an important new tool for microbial secondary-metabolite investigation.

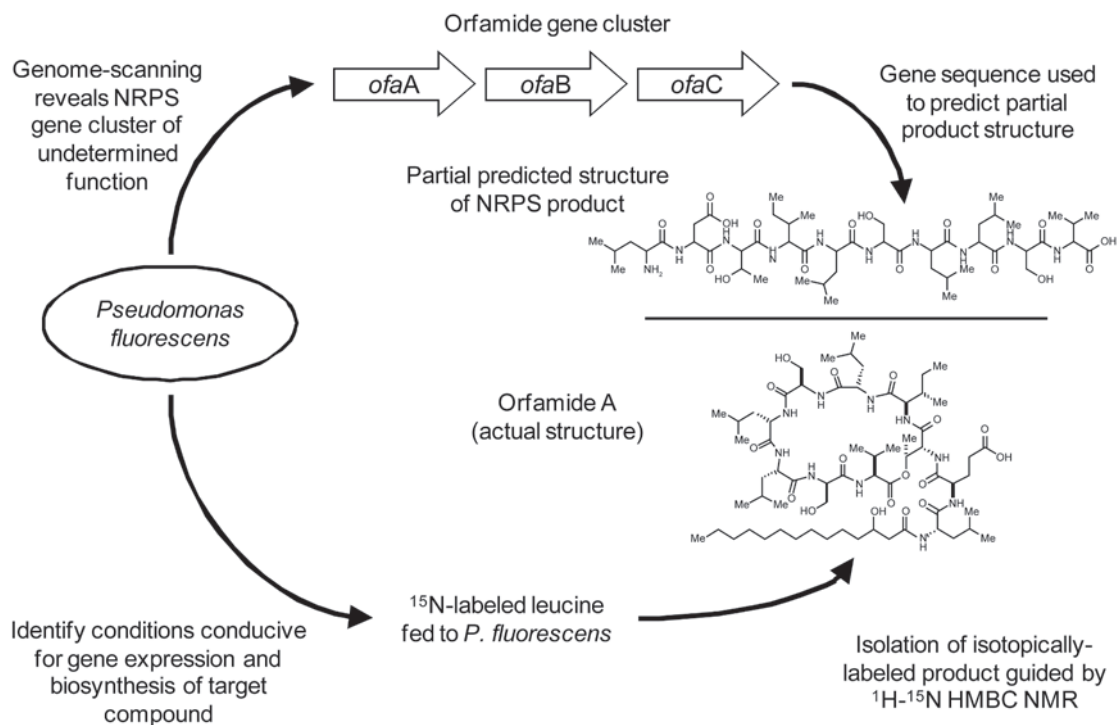

FIGURE 12 Overview of the genometopic method and its application to the study of the orfamide gene cluster in *P. fluorescens* Pf-5.

TABLE 5 Summary of the major strengths and weaknesses of methods for investigating microbial SBPs

Method	Technique	Advantages	Disadvantages
Culture-dependent approaches	Culture manipulation	Ease of use Low cost Technical simplicity Genomic information not required	Time- and labor-intensive No molecular targets defined a priori No direct link established between metabolites of interest and biosynthetic genes Same metabolites repeatedly observed; substantial dereplication efforts required
	Coculture	Ease of use Low cost Ability to utilize complex intercellular interactions to induce secondary-metabolite production Genomic information not required	Time- and labor-intensive Generation of metabolites by target organism not predictable Purported ecological relevance is uncertain Metabolite source difficult to identify in mixtures of live organisms
Genomics-driven approaches	Genome scanning and mining	In silico method enables rapid gene identification Full biosynthetic potential of microorganisms revealed (i.e., all secondary-metabolite-encoding pathways can be detected)	Additional efforts needed to produce and identify metabolite of interest Prediction of metabolite structure presents several challenges, especially for fungi Biological activity of target metabolite is unknown Predicted physiochemical properties of target compound may match other endogenous metabolites
	Heterologous expression	Offers potential for exceptional control over gene/gene cluster transcription Genes can be readily subjected to manipulation to create new “unnatural” secondary metabolites Biosynthetic pathways can be transferred to suitable hosts for ease of fermentation	Significant molecular biology experience required; may limit widespread use Thorough understanding of gene cluster function, tailoring enzymes, and essential metabolic precursors required Difficulties in handling and manipulating of large gene clusters (particularly fungi) Identification of suitable transgenic host can be challenging
	Promoter/activator manipulation	Handling of large gene clusters is eliminated All host-specific biosynthetic factors are intact and presumably functional Successful integration of relatively small “activator” gene into host microbe is less challenging compared with heterologous expression approach	Heterologous expression of promoter/activator may be problematic in poorly studied species Not applicable to high-throughput investigations Generalized applicability of this method has not been established Transcription-level manipulation may not directly correlate with changes in translation and metabolite biosynthesis
Mechanism-based and hybrid approaches	Chemical epigenetics	Rational approach targeting regulatory control of secondary-metabolite-encoding biosynthetic pathways Ease of implementation in high-throughput settings for bioactive compound screening Relatively inexpensive and rapid process for screening microbes without need for a priori genome mining	Transcription-level manipulation may not directly correlate with changes in translation and metabolite biosynthesis Limited to fungal systems; not all fungi are responsive Rapid biotransformation and degradation of epigenetic modifiers can limit the effectiveness of the epigenetic agents in certain cases
	Genomisotopic	Does not require transfer of target gene/gene cluster to heterologous host Potential for rapid metabolite identification when judiciously applied to appropriate biosynthetic targets	Extensive genomic-level knowledge of target gene required Testing of various media/culture conditions required to induce compound biosynthesis Accurate predictions of target compound's structure and biosynthetic precursors required Suitable conditions for precursor incorporation must be identified and isotopically labeled precursors must be unique substrate for target metabolite

7.6.4. Final Thoughts and New Directions for Using Mechanism-Based and Hybrid Approaches

Mechanism-based and hybrid techniques represent a powerful new generation of investigational tools that will help address the growing needs of natural products researchers to rapidly access SBPs and their secondary metabolites. Key to the significant utility of these methods is their cross-disciplinary blending of chemical and biological techniques to efficiently probe SBPs. However, if further methodological advances employing other translational approaches are to occur, new information concerning the molecular underpinnings of SBP transcription, translation, and biosynthesis are needed. Despite the fact that there have been many significant advances toward understanding the cellular events responsible for controlling secondary-metabolite production in microorganisms (49, 77, 97), there is still a woeful lack of information concerning universally applicable processes that are exploitable for accessing SBPs. Further molecular-based studies will be needed to help fill this gap in our current knowledge and provide new approaches to SBP discovery.

7.7. CONCLUSIONS AND PERSPECTIVES ON METHODS FOR ACCESSING SBPS

The investigation of SBPs has advanced significantly in the past 5 years, and it is expected that further advances in genome-based technologies will continue to fuel this trend. Currently available techniques for investigating SBPs fall into three discrete categories: (i) culture-dependent, (ii) genomics-driven, and (iii) mechanism-based and hybrid approaches. Each of these method sets present unique advantages and disadvantages for studying SBPs (Table 5). With so many new and exceedingly beneficial techniques becoming available, we anticipate that traditional culture-based approaches will have significantly diminished value as part of the repertoire of contemporary SBP research methods. Replacing these approaches will be a variety of new tools that offer increased speed and efficiency for evaluating SBPs in a high-throughput fashion. Consequently, we expect that microbial natural products will undergo a renaissance of renewed interest for utilization as a resource to discover new bioactive molecules.

One of the foreseeable outcomes of current trends in the field of SBP studies is the necessity for increased cooperation between chemists and biologists. Driving this need will be an exponentially increasing pool of genomic data containing enormous numbers of candidate genes for testing. Sifting through these massive quantities of data and identifying key parameters for choosing which genes to target will become increasingly important for efficiently mining this resource. In addition, new discoveries related to the molecular mechanisms contributing to SBP suppression are certain to require the need for novel biologically based solutions. Likewise, increasingly sensitive and sophisticated mass spectrometry and NMR tools will aid in the detection and structure confirmation of SBP-derived natural products. By focusing the complementary talents of multidisciplinary teams on SBPs, researchers are certain to uncover fascinating new insights into the structures, functions, and commercialization potential of the microbial world's hidden natural products.

FERMENTATION AND CELL CULTURE

THIS SECTION COVERS RECENT ADVANCES IN CULTIVATING MICROBIAL, plant, mammalian, and insect cells and their use for production of therapeutic compounds. The eight chapters include miniaturization of methods used to grow microorganisms, technologies used for cultivating them in solid phase, and culturing plant, insect, and mammalian cells. The use of plant cells to produce secondary metabolites is described, and that of bacterial, yeast and fungal, insect, and mammalian cell cultures to produce recombinant proteins is also illustrated.

Chapter 8 by Wouter Duetz and coauthors provides an excellent review of the history of small-scale cultures and the basic principles of culture miniaturization. Due to the very small size of the culture vessels, the problems encountered are quite different from those faced in larger-scale cultures. For example, surface tension and gas bubble size significantly affect performance of a miniaturized culture. Various types of microtiter plates used for this purpose, and the development of appropriate well closure systems and of the miniaturized sensors for oxygen and pH measurements, are described. An exhaustive discussion of use of these systems for screening for bioactive molecules can also be found in this chapter.

Chapter 9 by Ramunas Bigelis covers aerobic and anaerobic solid-phase fermentations, with their advantages and limitations. The author details variables that affect microbial growth and thereby product formation, such as temperature, concentrations of oxygen and carbon dioxide, moisture content, water activity, and physical properties of the solid substrate. Examples are given on the use of this technology to produce enzymes, primary metabolites like organic acids and ethanol, and secondary metabolites such as antibiotics, gibberellic acid, flavor compounds, and ergot alkaloids. Bigelis also discusses the use of food fermentations to enhance the flavor of food, change its physical characteristics, or increase its shelf life. Solid-phase fermentations used to prepare biocontrol agents are illustrated as well. A new development, mixed-phase (solid and liquid) fermentation, is described. The chapter concludes with an operating protocol for solid-phase fermentations that will be very useful as a starting point for process development.

The use of bacterial cultures for the production of proteins and other biological products is described in chapter 10 by Joseph Shiloach and Ursula Rinas. Bacteria have been used for a long time to produce small molecules, but in recent years they have also been used to make recombinant proteins. This chapter provides detailed information on all aspects of developing and operating a bacterial process to accomplish this, focusing on the processes that use *Escherichia coli*. The preparation of medium and inoculum, bioreactors and sterilization, instruments, necessary infrastructure, and procedures for initial product recovery are described in detail. The chapter also discusses products from bacteria other than *E. coli*.

Ninyan Zhang and Zhiqiang An give in chapter 11 a comprehensive report on heterologous protein expression in yeast and filamentous fungi. Just like *E. coli* among the bacteria, *Saccharomyces cerevisiae* has been the member of the fungi most commonly used for the production of heterologous proteins. One of the advantages that *S. cerevisiae* has over bacterial systems is its ability to glycosylate, as many antibodies require glycosylation for activity. The chapter notes the recent advances in fungal genetic technology and their effect on the enhancement of production. The authors describe the criteria for choosing an expression system and provide information on the vectors and promoters used and on the transcriptional and translational regulation of heterologous gene expression. Another yeast which has been widely used is *Pichia pastoris*, a methylotropic yeast that is capable of growing to very high cell density, e.g., a dry cell weight of 100 g/liter. Fermentation technology for this yeast is also well established. Many mammalian proteins need posttranslational modification, and both *S. cerevisiae* and *P. pastoris* are capable of doing this. Protein folding and glycosylation receive special attention in this chapter. The chapter concludes with a discussion of the use of *Aspergillus* species for heterologous protein production, including a description of the host strains, vectors, and promoters used as well as the regulation of posttranslational modification.

The two chapters by Jinyou Zhang on production of heterologous proteins in mammalian cells cover the entire process from selection of cells to downstream processing and regulatory considerations. Chapter 12 deals with the upstream part of the process, and chapter 13 with the downstream part. In the first chapter, Zhang surveys the biopharmaceutical industry to introduce the reader to the subject, and follows with a discussion of the suitability of mammalian cell cultures for the production of heterologous proteins. Coverage of the construction and selection of high-producing cell lines includes details on expression systems, host cell lines, screening for desired cell lines, and cell line engineering. Medium development for mammalian cell culture is also explored, including general features of cell culture media, animal component-free media, development of cell culture media, and development of feeds. Later, a discussion of process development comprises reactor systems, monitoring and control, optimization of culture conditions, scale-up and scale-down, and the relationship between process improvement and product quality.

The second chapter by Zhang dovetails seamlessly with the previous one, as it begins with the detailed description of downstream processing. This section comprehensively examines recovery separation, primary and additional purification, polishing chromatography, virus removal, and final

formulation. Next, formulation development and fill/finish issues such as preformulation, formulation stability, drug delivery, and fill and finish are considered in detail. Another important aspect of the production of biopharmaceuticals is quality control. For this purpose, Zhang discusses analytical method development and qualification. Specific items covered include lot release testing, glycosylation analysis, and assay development and validation. This chapter concludes with consideration of Good Manufacturing Procedures requirements.

Plant cell cultures have been used for several years. For chapter 14, Nancy Paiva has updated her contribution to the second edition of this book to describe various medium components and their function in supporting the growth of plant cells. The section on plant growth regulators deserves special mention. The need for extra care during the preparation of the medium is highlighted. It is emphasized that operating parameters such as the absolute necessity of a sterile transfer facility, and control of temperature, aeration, and exposure to light, are critical for good plant cell growth and maximum product formation. Special attention is given to the sterilization procedures to be used. Appropriately, the section on process development concludes with a description of issues pertaining to the use of bioreactor and scale-up. Most of the considerations with respect to the scale-up of microbial processes also apply to plant cell cultures, with the exception of high shear sensitivity. As a result, impellers capable of low shear or airlift fermentors have to be used. The chapter concludes with descriptions of procedures used for regeneration of plants from cell cultures and procedures for DNA transformation.

Although the development of insect cell cultures for biomanufacturing began later than the other systems mentioned, it is now mastered to an extent similar to mammalian cell culture. The application of baculoviruses as vectors for the production of recombinant proteins or for manufacturing of viral biopesticides is safe and is amenable to scale-up. Chapter 15 by Spiros N. Agathos describes the characteristics of various cell lines and the development of the cell lines commonly used for stable expression. Procedures for small-scale (250 ml) and large-scale (several hundred liters) cultures along with potential pitfalls are highlighted. A mathematical analysis of different strategies used for the operation—i.e., batch, fed-batch, and continuous cultures—is presented. Infection of insect cell lines with baculoviruses is thoroughly covered, including vector generation and amplification and infection of cell lines. For this last, important parameters are cell line selection, time and multiplicity of infection, cell density at infection, and time of harvest. The chapter concludes with a discussion of product recovery.

Miniaturization of Fermentations

WOUTER A. DUETZ, MATTHEW CHASE, AND GERALD BILLS

8

8.1. HISTORICAL CONTEXT AND APPLICATIONS OF SMALL CULTURES

Well into the 20th century, a large gap in cultivation scale continued to exist between agar colonies on the one hand and Erlenmeyer flask cultures on the other. Most laboratories had little incentive to reduce culture volumes below 50 ml, simply because the number of “house strains” and their mutants was rather limited. During the 1980s and 1990s, a number of new developments spurred the demand for and utilization of high-quality and parallel small-scale growth systems. First, several large-scale fermentative bioprocesses (such as those for antibiotic production) became fully mature, and it became increasingly difficult to find significantly improved mutants. In practice, this meant screening ever larger mutant libraries, and accepting that the improvement in the productivity of the best mutants would be less than 5 or 10% compared to the parent strain, and required an evaluation process with very low variability. This in turn created a demand for high-quality cultivation systems. The same trends held for medium optimization projects, where increasingly large numbers of medium parameters were being tested. Second, analytical techniques including chromatographic techniques such as liquid chromatography-mass spectrometry (LC-MS) and gas chromatography (GC), but also receptor binding assays and cell-based inhibition assays, were being improved to an extent that they could be performed with picogram or nanogram amounts of cell products, which in most cases is compatible with submilliliter culture volumes. The more sensitive bioassays, e.g., mode-of-action-based assays to detect anticancer or antibiotic activities of microbial metabolites, also enabled screening for new drugs and antibiotics, which are often secondary metabolites from actinomycetes or fungi, to be performed with much smaller amounts of extracts. Third, screening projects with extremely expensive medium components, such as ^{13}C -labeled substrates as used in flux-analysis studies, were financially feasible only when fermented in small culture volumes. Other application areas included the screening for new biocatalysts and the improvement of specific enzymes by screening large mutant libraries.

Initial ad hoc efforts on miniaturization were done in-house by industry in the 1980s, but systematic knowledge in this area started to accumulate only after several universities, including those in Aachen, Zurich, Munich, and

London, started dedicated research projects in the second half of the 1990s. Much research was focused on 96- and 24-well microtiter plates (MTPs), which were a logical choice because they were standardized and being widely applied in other research areas. Furthermore, a broad range of compatible equipment—pipetting stations, microplate readers, etc.—was available, which saved money and time. The relatively large size of the part of this chapter dedicated to MTPs (section 8.3) reflects their current importance in industry and academia alike. Sections 8.4 and 8.5 are dedicated to test tubes and other types of miniature cultivation systems, respectively.

8.2. BASICS OF CULTURE MINIATURIZATION

The knowledge that the average microbial cell is still more than 1,000- to 10,000-fold smaller than a culture vessel of 10-mm diameter leads microbiologists easily into believing that the effects of miniaturization on an individual cell are bound to be minimal. This intuition may be largely true for growth vessels with diameters above 10 mm, but not for smaller vessels, mainly as a result of surface tension effects and/or different behavior of gas bubbles.

8.2.1. Surface Tension Effects

Surface tension interferes with the flow and movement of the culture medium due to bubbling, stirring, or *g*-forces arising from orbital shaking. The importance of culture size becomes evident when comparing the movement of fluids inside vessels with various diameters during orbital shaking (Fig. 1). From these photographic studies it became evident that the effect of surface tension rapidly increases at vessel diameters below 8 mm: even at a *g*-force of 2.5, no significant movement of the culture fluid can be established in culture vessels of 3 or 4 mm. A moderating, although also complicating, factor (it may give rise to false positives during mutant screenings) is the reducing effect that culture broth components (e.g., cell membrane components, proteins, and extracellular glycolipids) exert on the surface tension. This lower surface tension does significantly improve the situation with vessel sizes around 6 mm (compare Fig. 1 and 3), but not at 3 or 4 mm (17). The absence of fluid movement as a result of surface tension effects generally results in low oxygen transfer rates (OTRs) and other problems (see also section 8.3).

FIGURE 1 High-speed photograph showing the ability of a g -force of 2.5 (generated by orbital shaking at 300 rpm and a shaking diameter of 50 mm) to induce a rotating movement of an aqueous solution of bromocresol blue (0.1% [wt/wt], surface tension of 72 dynes/cm) in round polyacrylate vessels with various diameters. The theoretical angle of the liquid/air surface with the horizontal plane of 68° is only reached at vessel diameters of 12 mm and higher. The angle of more than 68° at a vessel diameter of 16 mm can be explained by the situation that the shaking diameter for the bulk of the liquid is in effect approximately 60 instead of 50 mm. The practical absence of any movement of the liquid at 3 and 4 mm is due to the high surface tension.

8.2.2. Gas Bubble Size Effects

The behavior of gas bubbles becomes increasingly unpredictable at smaller bubble sizes. In the first place, small bubbles tend to ascend more slowly and are more easily deviated from an exactly vertical movement than is the case with large bubbles. The large variety of bubble patterns in duplicate miniature growth vessels may lead to large differences in hydrodynamics and OTRs and indirectly to poor reproducibility of process performance.

8.2.3. Methods for Determining OTRs

When assessing the applicability of a novel miniature cultivation system—especially if one wants to mimic the physicochemical situation in larger cultures—it is advisable to determine OTRs from the gas phase to the liquid phase. Various methods are available to determine OTRs in cultures smaller than 1 ml. The traditional and best-validated method is the cobalt-catalyzed oxidation of sulfite (22). In this method, the headspace of the vessel is flushed slowly (and at a constant rate) with an oxygen-containing gas (e.g., air). The medium in the vessel contains sulfite and cobalt as a catalyst. All oxygen diffusing into the medium is consumed in the oxidation of sulfite to sulfate so that the concentration of oxygen in the liquid phase remains close to zero. The OTR can be calculated from the difference in oxygen concentration in the gas inlet and gas outlet, or from the pH drop (using a pH indicator) associated with the oxidation of sulfite (22). A slight disadvantage of this method is the high salt concentration applied (usually 0.5 M), which reduces the maximal solubility of oxygen to a level well below that in low-salt culture media, which generally contains 0.1 to 0.2 M salts. Therefore, the maximal OTR is systematically underestimated, and a 20 to 30% correction factor is necessary when translating the results to microbial cultures (J. Buchs, personal communication). Another drawback of this method is the high surface tension as compared to microbial cultures (see earlier), leading to an underestimate of potentially achievable OTRs in small-scale cultures with well diameters of less than 8 mm.

Enzymatic methods (using oxygen-consuming enzymes such as oxygenases and oxidases) can also be used to determine OTRs in small vessels. Glucose oxidase in combination with diammonium 2,2'-azino-di-(3-ethylbenzthiazoline sulfonate) (ABTS) (16) and catechol 2,3-dioxygenase (C23O) are applicable, as they both give rise to colored products that are easy to measure spectrophotometrically. The C23O method (35) is preferred because the colored compound (a semialdehyde) is formed in a single-step reaction in a 1:1 proportion to the amount of oxygen consumed. The glucose oxidase method (16) shows a less clear stoichiometry and therefore requires calibration with another method (such as the cobalt-catalyzed oxidation of sulfite), but has the advantage that all reagents are available commercially.

A third possibility is to derive OTRs from the oxygen-limited growth phase of growth curves of aerobic strains such as *Pseudomonas putida* (15) or *Bacillus subtilis* (13). These latter methods provide a more realistic comparison with “real-life” conditions (also in terms of surface tension) but are more laborious and time-consuming, because it is necessary to sample the cultures (in order to be able to measure the optical density) at regular time intervals for 10 to 20 h.

8.3. CULTIVATION IN MTPs

Orbital shaking is currently the major method applied to obtain satisfactory OTRs in MTPs. It is popular because the force driving the increase of the gas-liquid interface, as determined by the centrifugal force, is applied identically to all wells in all MTPs mounted on a shaking platform, and therefore eliminates a potential source of well-to-well variation. In contrast, aeration by air sparging and magnetic stirring almost inevitably gives rise to well-to-well variations, especially at lower culture volumes.

During orbital shaking of microbial cultures in MTPs, two main factors determine the quality and reproducibility of the culture: (i) the well-closure system and (ii) the combination of orbital shaking conditions and the culture volume, which in turn determine the OTR and the degree of mixing.

8.3.1. Well-Closure Systems

The well-closure system for the individual wells should fulfill three functions: (i) prevent (cross)-contamination, (ii) permit the exchange of headspace air, and (iii) limit evaporation. Equivalent physical conditions in all wells is a further requirement: the wells in the corners should have exactly the same characteristics as the wells in the middle of the MTP, and uniformity is especially important in quantitative work, e.g., the comparison of certain (enzyme) activities in mutant libraries.

8.3.1.1. Sealing Tapes

Gas-permeable membrane filters (sealing tapes) are available from many suppliers, and are well suited when used in combination with humidified growth cabinets since the water vapor permeability is high for all sealing tapes (47) as long as the culture fluid does not come in direct contact with the sealing tape during shaking. The sealing tape will remain dry when deep-well MTPs are used in combination with relatively small culture volumes and mild shaking conditions and when no condensation appears. When sealing tapes are used in combination with high shaking speeds and/or shallow-well MTPs are used, however, culture fluid

may settle on the foil and cause a number of adverse effects on the quality of the culture. First, glue components may partially dissolve, and if a droplet falls back into the culture, it may influence the growth and/or subsequent analytical procedures. Second, the proportion of the membrane area covered by the droplets/aerosol will differ from well to well, contributing to well-to-well variation, both with respect to evaporation losses and to gas concentrations (oxygen, CO_2) in the headspace. Third, depending on the quality of the sealing tape, the glue may not hold when wetted, risking cross-contamination and airborne contamination. Apart from aerosols, sealing tapes can also become wet (and so hamper gas exchange) as a result of water condensation. Condensation readily occurs when the membrane is colder than the culture. This, in turn, may happen when the shaker table is (slightly) warmer than the air in the shaker cabinet, which often occurs when the shaker motor warms the shaker table. It can also result from heat generation by fast-growing cells. For further practical information on various types of sealing tapes and their relative permeabilities for water and oxygen, we refer to reference 47. In conclusion, sealing tapes are often well suited for qualitative work under relatively mild shaking conditions, but not under harsh conditions.

8.3.1.2. Sandwich Covers

A more generally applicable, though more complex, closure system consists of a silicone layer with small holes above each well in combination with suitable layers of bacterial filters, pressed onto the MTP at a sufficient force to prevent cross-contamination (15; Fig. 2; see also Fig. 1). Because the only connection with the ambient air is via the small hole in the silicone layer above the center of each well, the degree of exchange of headspace air (via passive diffusion) is fully determined by the hole's dimensions (diameter and length). Depending on the culture volume and the type of microbial strain, one can choose suitable hole dimensions. For fast-growing strains, the rule of thumb borrowed from the field of stirred-tank bio-

reactors (1 to 2 culture volumes of air supply per minute) has proven to give satisfactory results for small cultures as well. For culture volumes of 0.5 ml per well, the required headspace exchange rate of 1 ml air per minute can be achieved with holes that are 1.5 mm in diameter and 6 mm long (15). Higher or lower exchanges of headspace can be achieved by using larger or smaller holes, respectively. The exact rates of exchange of headspace air corresponding to varying hole size can be experimentally determined by measuring the water loss from a well after several days of incubation in a shaker cabinet with a defined temperature and humidity.

Such a rate of exchange of headspace air of 1 to 2 culture volumes per minute will keep the oxygen concentration in the headspace above 18% (vol/vol) under all conditions, and will limit culture volume loss through evaporation to a few percent per day, even at 50% ambient humidity in the shaking cabinet. The evaporation rate can be further lowered by increasing the humidity in the shaking cabinet, though one has to realize that long-term humidities over 75% may result in mold growth inside the shaking cabinet, which in turn can harm the health of laboratory workers who open the shaking cabinets and are exposed to spores, as well as increasing contamination levels.

The holes in the silicone layer of such covers may be obstructed when heavy splashing occurs inside the well, or when the culture volume is too high relative to the total well volume and the shaking conditions. It is therefore recommended to perform a range of tests first, such as the use of different volumes, different shaking conditions, etc., and inspect the sandwich cover for blockage of the holes. As with the sealing tapes discussed above, condensation on the silicone rubber may occur when the shaker table is warmer than the air inside the shaking cabinet or when the culture produces heat. Insulating the MTP from the shaker table, e.g., by using a layer of air or rubber sponge, may alleviate this problem.

A general advantage of sandwich covers is that shaking rates and thus OTRs can be higher: direct contact

FIGURE 2 Schematic view of the sandwich cover (section 8.3.1.2) used for (i) the prevention of (cross-)contamination of wells of a 96-square-deep-well MTP during vigorous orbital shaking and (ii) the limitation of evaporation.

between the culture fluid and the inert silicone layer does not have any adverse consequences. Cross-contamination will still not occur as long as the sandwich cover is not taken off during growth. However, if intermediate sampling (e.g., for optical density measurements) is required, one should preferably choose a suitable combination of culture volume, type of MTP, and shaking conditions so that the culture fluid does not touch the silicone layer; otherwise cross-contamination may occur when the sandwich cover is placed back onto the MTP after sampling.

8.3.2. OTRs

A sufficient degree of exchange of headspace air, as can be achieved using sealing tapes or sandwich covers as described above, is a prerequisite for a good oxygen supply, but does not automatically ensure that the oxygen in the headspace reaches the cells in suspension. To achieve this, a sufficient level of gas-liquid transfer needs to be established. Table 1 lists OTRs in various types of MTPs, at various culture volumes and shaking conditions. The current consensus in literature (especially on the basis of the work at universities in Aachen and Zurich) is that sufficient levels of OTRs (20 to 50 mmol liter⁻¹ h⁻¹) can be most easily reached when using a relatively high shaking amplitude of 25 or 50 mm in combination with a shaking frequency of 225 to 300 rpm (17). For 24-well plates (both those with square wells and round wells), good results can be obtained with either a 50-mm amplitude (even at 225 rpm) or a 25-mm amplitude (at 300 rpm). For all types of 96-well MTPs, a shaking amplitude of 50 mm gives far better results than 25 mm (up to threefold higher OTRs; see Table 1). This initially counterintuitive conclusion, i.e., the smaller a vessel is, the higher the shaker amplitude should be in order

to achieve a satisfactory OTR, becomes logical when one realizes that with large vessels (e.g., Erlenmeyer flasks), the largest part of the diameter at which the bulk of the liquid is swirling actually stems from the vessel itself, and not from the shaker. The contribution of the vessel diameter to the effective throw of the bulk of the liquid is insignificant in 96-well MTPs. A second explanation for the apparent need for a high *g*-force (as can be most readily achieved using a high shaking amplitude) is that this leads to an increase of the angle of the fluid with the horizontal plane (see also Fig. 1), which leads to a larger percentage increase of the gas-liquid interface area with 96-well MTPs than with, for example, 24-well MTPs.

High OTRs (above 20 mmol liter⁻¹ h⁻¹) can also be achieved in 96-well MTPs at shaking diameters of 6 or 3 mm, but only at shaking frequencies exceeding 800 and 1,000 rpm, respectively (23). Such high frequencies, however, are not achievable with most standard shaking equipment, and are therefore less practical for standard applications.

8.3.3. Turbulence and Mixing

In the process of choosing a suitable combination of a specific type of MTP, culture volume, and shaking conditions, it is important to realize that a satisfactory OTR does not guarantee a good degree of mixing. If thorough mixing is crucial, it is often advisable to employ MTPs with square wells; these generally give rise to a more turbulent hydrodynamic pattern (the walls act as a sort of baffle), and in addition allow a higher "filling height" for a given required OTR. Roughly, it can be concluded (see Table 1) that for an identical OTR, MTPs with square wells allow three- to fourfold higher culture volumes per well than MTPs with

TABLE 1 OTRs in various types of MTPs at various volumes during orbital shaking at 300 rpm and a shaking diameter of 50 and 25 mm

Type of MTP	Cells present?	Vol (liquid height before start of shaking)	OTR at 300 rpm (mmol of O ₂ liter ⁻¹ h ⁻¹)		Reference
			50 mm	25 mm	
96 shallow round wells, 6-mm diameter	No	0.2 ml (6.2 mm)	20 ^a	9 ^a	23

round wells. The higher turbulence in MTPs with square wells can be either a disadvantage where shear forces may affect growth negatively, or an advantage in a situation where the mass transfer between different phases is limiting (e.g., when working with two-phase systems or solid medium components). Figure 3 illustrates the higher degree of turbulence that can be achieved in MTPs with square wells in comparison to round wells.

8.3.4. Toxicants Leaching from the Plastic of MTPs

A trivial problem that occurs quite frequently is the negative effects on cell growth exerted by toxic compounds leaching from polypropylene (as used for both 24- and 96-square-deep-well MTPs). The compounds responsible are believed to be UV absorbers and antioxidants (e.g., phenols and phosphites), whiteners (coumarins and benzoxazoles), and heavy metals (such as cobalt), which are often used as additives in

polypropylene (4). In order to alleviate these toxic effects, it is advisable to soak newly acquired polypropylene MTPs in boiling NaOH (1 M) for 4 h and HCl (1 M, 70°C) for 4 h (15). Because this procedure is quite laborious, it is advisable to reuse such treated MTPs for as long as possible. Direct extraction of fermentation broth in MTPs with organic solvents, e.g., acetone or methyl ethyl ketone, may also result in extraction of plastic components along with metabolites in the culture extract. Such compounds may be detected by analytical techniques, e.g., LC-MS, and in some cases may interfere with analysis of microbial metabolites in the extracts. If planning direct extraction in the plates, we recommend extracting control MTPs with solvents to determine their background.

Polystyrene MTPs are generally nontoxic when used off-the-shelf, and are therefore often preferred, especially in the case of high-throughput projects. However, the

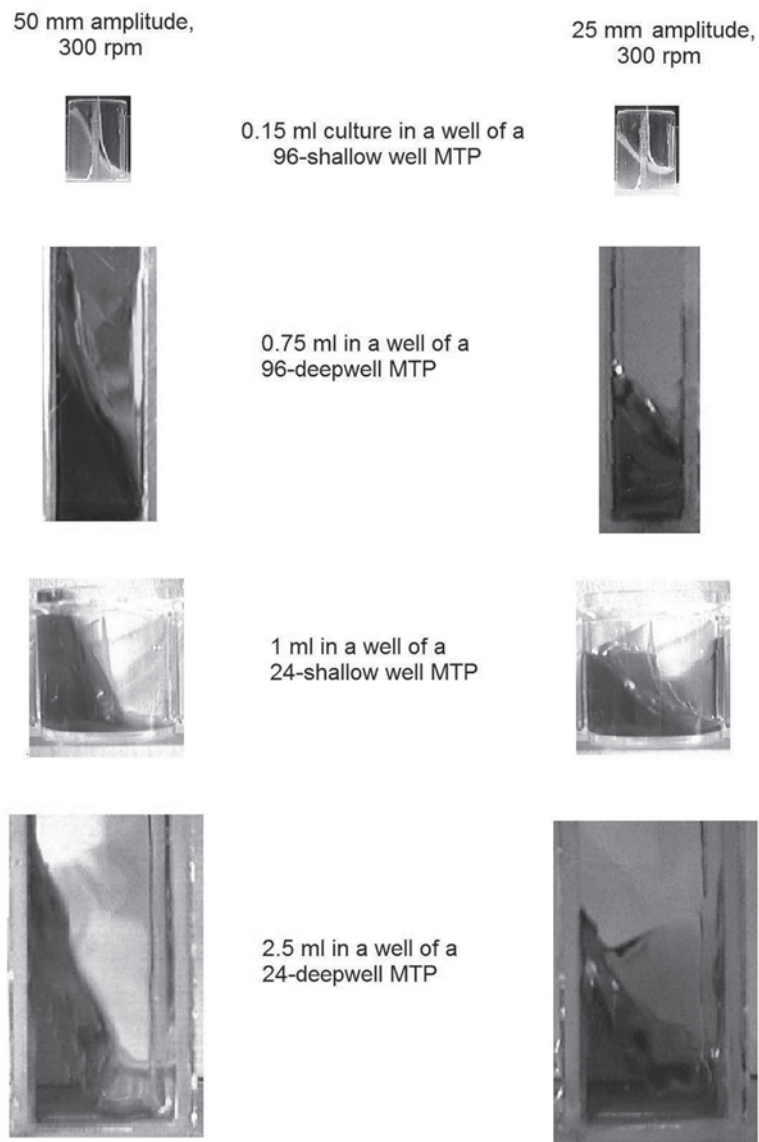

FIGURE 3 Photographs illustrating the hydrodynamic flow pattern inside wells of various MTPs during orbital shaking at 300 rpm, at a shaking amplitude of either 50 mm (left) or 25 mm (right).

choice in polystyrene MTPs is limited; currently no polystyrene square-deep-well plates are commercially available, although MTPs with 96 square shallow wells are available from various suppliers.

8.3.5. Applicability of Various MTPs for Different Purposes

In the process of choosing a suitable type of MTP for a specific application, a range of factors should be considered. As discussed in section 8.3.2 (and as can be seen in Table 1), for all types of 96-, 48-, and 24-well MTPs, OTRs exceeding $30 \text{ mmol liter}^{-1} \text{ h}^{-1}$ can be achieved, so this is generally not an important selection criterion. In most cases, the more relevant criterion is the minimum culture volume necessary for subsequent assays and analysis. However, even if only a few microliters are required for analysis, e.g., for GC or high-performance liquid chromatography (HPLC) analysis, it does not automatically suggest that the standard 96-shallow-well plates are the correct choice. It is often advisable to start performing tests with a range of different types of MTPs, and to specifically compare the variation between independent duplicates with regard to the relevant analyte concentration or other parameter to be considered for the different cultures (see protocol 1). As a rule, much lower standard deviations can be achieved with the relatively high culture volumes that are feasible in 24-well MTPs. The underlying reasons for the impact of culture volume on standard deviation are poorly understood, but pipetting errors (percentage-wise larger with smaller volumes) and a larger biological variation in small cultures, especially when cells do not grow fully suspended, have a substantial impact at smaller volumes. Also, the smaller amounts of biomass used for inoculation (which preferably should be exactly the same when comparing various cultures) will inevitably show a larger variation. The final choice for a certain type of MTP is often a trade-off between the throughput on the one hand and the standard deviation between independent duplicates on the other.

Protocol 1. Preparation of a Screening: Optimization of the Reproducibility

1. Decide what standard deviation between independent duplicates is acceptable. This will among other things depend on the expected percentage-wise improvement of the best mutants or culture condition.
2. Start with optimizing the reproducibility of the analytical procedure. If possible, apply HPLC-UV (in combination with relatively large injection volumes), infrared-based methods, or colorimetric/spectroscopic methods, since they generally give rise to the lowest standard deviations (1 to 3% once optimized). Methods dependent on internal standards (e.g., GC and LC-MS) generally result in relatively poor reproducibilities.
3. Test the standard deviations between duplicate cultures inoculated with the same (overnight) suspended culture (e.g., a shake flask culture) using a range of different MTPs and culture volumes, each at three- to eightfold. If applicable, also vary the cultivation/incubation times. On the basis of the resulting standard deviations, choose an MTP-culture volume combination that will allow you to detect the sort of mutants you are looking for (as defined in step 1).
4. Test the standard deviation between independent duplicates (inoculated with colonies from the same agar plate) using the MTP-culture volume combination selected in

step 3. In order to achieve a standard deviation close to the standard deviation achieved in step 3, it is often necessary to synchronize the cultures as described in protocol 2. It may be important to optimize the culture lengths of the primary and secondary cultures as well as the amounts of inoculation.

5. Now that the general framework of a suitable screening protocol has been established, it may take another few man-months to further reduce the individual sources of error that contribute to the overall standard deviation. Focus in this stage generally lies on pipetting methods (pipetting/robotic stations versus manual pipetting; manual pipettes versus electronic pipettes) and the minimization of biological variation by optimizing the inoculation procedures.

8.3.5.1. MTPs with 384 or 1,536 Wells

As a result of surface tension effects (see section 8.2.1), water-based medium in 384- and 1,536-well MTPs (well dimension in the horizontal plane 3 to 4 mm and 1 to 2 mm, respectively) cannot be significantly moved by the centrifugal forces that can be achieved with standard orbital shakers. The resulting absence of active mixing often causes cells to sink to the bottom, and OTRs are bound to stay relatively low. Therefore, the application of 384- and 1,536-well MTPs is mainly limited to projects with anaerobic strains or when the generation of small amounts of DNA is the sole objective.

8.3.5.2. MTPs with 96 Shallow Round Wells

Standard polystyrene 96-shallow-well MTPs (with round wells of $350\text{-}\mu\text{l}$ volume) are widely applied for the cultivation of large libraries (3,000 strains or more). Using appropriate sandwich covers (see section 8.3.1.2) with spacers, multiple MTPs can be stacked, and up to 80 MTPs (7,680 cultures) can be mounted on a single standard shaker. In practice, the application of polystyrene 96-shallow-well MTPs is mainly limited to strains that grow fully suspended, such as *Escherichia coli* or *Bacillus* species. The typical culture volume applied is $150 \mu\text{l}$, which allows shaking at 300 rpm and a 50-mm amplitude at OTRs of $30 \text{ mmol liter}^{-1} \text{ h}^{-1}$ (see Table 1). It is advisable to use a growth medium with a relatively low surface tension containing peptides and/or proteins, such as nutrient broth or Luria-Bertani (LB) medium. Such a medium will allow a thorough mixing up to the bottom of the wells (17).

Culture volumes of $100 \mu\text{l}$ or less can be used when high OTRs are desired ($40 \text{ mmol liter}^{-1} \text{ h}^{-1}$ or more). With such small culture volumes, limiting evaporation becomes increasingly important, which can be achieved by the application of sandwich covers with smaller holes for the exchange of headspace air and/or the humidification of the air inside the shaker cabinet. With culture volumes of $100 \mu\text{l}$ or less, it becomes increasingly difficult to aspirate the supernatant fluid after centrifugation without disturbing the cell pellet. A practical solution to this issue is to add sterile buffer or water (e.g., 100 or $200 \mu\text{l}$) after growth but prior to centrifugation. Of course, the resulting dilution will require correction of the subsequently measured analyte concentrations or other bioactivities.

The application of polystyrene 96-shallow-well MTPs for strains that grow in pellets or aggregates, such as actinomycetes, fungi (e.g., *Trichoderma*), etc., is generally not advisable for quantitative comparisons, due to poor well-to-well reproducibility.

8.3.5.3. MTPs with 96 Square Deep Wells

In comparison to the standard shallow 96-well MTPs discussed above, MTPs with 96 square deep wells have the advantage that culture volumes can be fourfold higher at the same OTR (up to 0.75 to 1 ml). Higher culture volumes are also associated with better reproducibility and an easier separation of pellet and supernatant fluid after centrifugation. In addition, the square shape of the wells gives rise to a more turbulent hydrodynamic shaking pattern, which may be a distinct advantage when working with actinomycetes (pellets are better dispersed) or when a sufficient mass transfer is required between two phases (solid particles) or with a solvent as a second phase (30). To achieve good mixing (up to the bottom) and high OTRs, it is strongly advisable to use an orbital shaker with a shaking amplitude of at least 50 mm, in combination with a frequency of 300 rpm (15; see also Table 1).

8.3.5.4. MTPs with 48 Round Shallow Wells

The advantage of polystyrene MTPs with 48 shallow wells is that at their well diameter of 11 mm, surface tension effects are almost absent (see section 8.2.1, Fig. 1), even when using mineral medium with a high surface tension, in contrast to 96-shallow-well MTPs. Compared to 24-shallow-well MTPs, an advantage is the higher ratio between the height of the wells (approximately 16 mm) and the diameter of the wells (11 mm), which allows a higher *g*-force to be applied (and so a higher shaking frequency) without the culture fluid reaching the tops of the wells. At culture volumes of 300 to 600 μl , OTRs of 30 $\text{mmol liter}^{-1} \text{h}^{-1}$ and higher (up to 280 $\text{mmol liter}^{-1} \text{h}^{-1}$ at 1,450 rpm, a shaking diameter of 3 mm, and a working volume of 300 μl) are readily attained (28). The poor compatibility of the 48-well format with standard MTP side equipment, such as microplate readers and multipipettes, is a distinct disadvantage, most particularly for smaller research groups that do not have the means to obtain custom-made tools and equipment.

8.3.5.5. MTPs with 24 Round Shallow Wells

Polystyrene MTPs with 24 round shallow wells with optimal culture volumes of 0.75 or 1 ml per well are very versatile when it comes to their application as growth vessels. For bacterial cultures, sufficient degrees of mixing and OTRs (30 $\text{mmol liter}^{-1} \text{h}^{-1}$) are readily achievable, even at the shaker speed of approximately 225 rpm in combination with a 50-mm amplitude, or at higher shaker speeds of preferably 300 rpm with shakers that only have a maximal shaker amplitude of 25 mm. In addition, MTPs with 24 shallow wells are also well suited for eukaryotic cell cultures that are sensitive to shear forces, because in contrast to 96-well MTPs, even at shaking frequencies of 150 to 200 rpm the mixing is still reasonable, and because surface tension effects play no role. Polystyrene MTPs with 24 shallow wells with various surfaces in terms of hydrophobicity (high binding, low binding) are commercially available from a range of suppliers.

8.3.5.6. MTPs with 24 Square Deep Wells

Polypropylene MTPs with 24 square deep wells (11-ml total volume per well) are the preferred choice when large culture volumes (up to 3 ml per well) and/or high OTRs (up to 60 $\text{mmol liter}^{-1} \text{h}^{-1}$) are required (16). As with the 24-shallow-well MTPs, good results in terms of mixing and OTR can be achieved with shaker amplitudes of either 25 or 50 mm (see Table 1 and Fig. 3). Also, shaking frequencies can be lowered to 150 or 200 rpm without the risk of a

poor degree of mixing, which might result in the movement of cells to the bottom. Important application areas include medium optimization projects and the screening of mutant banks where only slightly better activities/titers are expected (10% improvement or less). Standard deviations for independent duplicates of less than 3% have been shown to be achievable, even with pellet-forming actinomycetes. The low standard deviations make MTPs with 24 deep wells well suited for secondary screenings: the initial screening (of mutant banks of a few thousand strains) is performed with 96-well MTPs, and the secondary screening (on a selected number of mutants) is performed in MTPs with 24 square deep wells. This sequence often allows the rejection of false positives from the primary screening and achievement of a better quantitative insight into the real mutants.

Twenty-four-square-well MTPs are also often used in the discovery of new secondary metabolites. The relative ease with which high OTRs are achieved (13) ensures high biomass and sufficient secondary-metabolite production by anabolic pathways requiring oxygenases. Furthermore, culture volumes of 2 to 4 ml facilitate separation of cells, pellets, or mycelia from the supernatant fluid by centrifugation and provide adequate amounts of extracted compounds for multiple bioassays, such as those for antibiotic or anticancer activities.

8.3.5.7. MTPs with Six Shallow Wells

Polystyrene MTPs with six shallow round wells most prominently differ from all MTPs described above with regard to the ratio between their diameter and height, i.e., 35 mm and 18 mm, respectively. This high ratio sets limits to the shaking frequency and thus to the *g*-force that can be applied. On the positive side, shaking frequencies of 60 rpm already result in reasonable mixing, at a very low shear force. The liquid swirls gently, which makes such MTPs applicable for sensitive eukaryotic cells, such as plant cells. Accumulation of cells in the middle of the wells may occur, which may be counteracted by small baffles inside the wells.

8.3.6. Procedures for Inoculation and "Synchronization" of Cultures

When screening libraries of mutants, the inoculation procedure is crucial for reproducible results. In many cases, the mutant library will be initially available as single colonies on an agar plate. A robotic colony picker may be used to inoculate liquid medium dispensed in the wells of a 96-well MTP. Alternatively for small libraries, one may use toothpicks for this initial inoculation. After an appropriate well-closure system has been applied (see section 8.3.1.2), this primary MTP may be incubated in an orbital shaker for 1 to 2 days. In the case of a qualitative screening, e.g., to screen for the presence or absence of a certain gene, product, or enzyme, the resulting cell suspension can be used immediately for analysis or bioassay. For quantitative screenings, e.g., when searching for high-activity mutants, it is often advisable to use this primary MTP to inoculate a second MTP, by transferring 1 to 5 μl with a multichannel pipette. The rest of the primary MTP can be stored at -80°C , after addition of glycerol, for later use if desired (see also protocol 2). As can be seen in Fig. 4, the cultures in this secondary MTP will be more or less "synchronized," i.e., the cells grow in parallel and reach the stationary phase at the same time. The latter is especially relevant if the product is unstable or is prominently formed in the stationary phase. Nonsynchronized cultures (such as from direct inoculation starting from colonies) often give rise

FIGURE 4 Synchronization of 12 isogenic cultures (0.75 ml OF LB medium) of *E. coli* TOP10 in wells of a 24-shallow-well MTP during orbital shaking (250 rpm, 50-mm amplitude, 30°C). The initial cultures ($t = 0$) were inoculated manually with toothpicks from colonies on an LB agar plate. At $t = 20$ h, 5 μ l of each of the cultures (all in stationary phase) was used as an inoculum for 12 fresh cultures: the 12 cultures now grow in a “synchronized” pattern (reach the stationary phase at the same time), which will—in most cases—result in a smaller standard deviation of the parameter under study (e.g., an enzyme activity) and in relative ease of identifying high-activity mutants.

to large numbers of false positives, and possibly false negatives. In practice, synchronizing cultures becomes increasingly difficult at smaller culture volumes, most notably as a result of a larger variation in the size of the inoculum (see also section 8.3.5).

When starting with a library in 96-well MTP format (cells frozen in the presence of 15% [vol/vol] glycerol), one can use a 96-pin replicator with fixed pins to sample the library after melting the master plate. Alternatively, one can press a sterile spring-loaded replicator onto the frozen cultures (no melting required, so there is no viability loss of the remaining frozen cultures; see reference 15) to get a small film of cell suspension on the tips of the pins. In either case, one can subsequently transfer the sampled cells either directly into a liquid culture or onto an agar surface in a rectangular petri dish. The choice depends on the viability of the host strain in liquid medium after the cells have been frozen at -80°C . Many strains grow much better in liquid medium after having been precultured on an agar-based medium.

Protocol 2. Screening of a Mutant/Construct Library in *E. coli* or *Bacillus*

1. Fill all 96 wells of a sterile standard polystyrene shallow-well MTP (round wells with a total volume of approximately 0.35 ml) with 0.15 ml of an appropriate sterile rich medium (e.g., LB medium).
2. Inoculate each well with a single colony from an agar plate. Use sterile toothpicks or, alternatively, a colony-picking robotic system.
3. Cover the inoculated MTP with a sterile sealing tape or a sandwich cover (see section 8.3.1).
4. Incubate the MTP plus cover in an orbital shaker at 30 to 37°C for 16 to 24 h. Shaker conditions: 300 rpm, 50-mm shaking amplitude in case a sandwich cover is applied (see section 8.3.1.2, Fig. 2), or 200 rpm, 50-mm amplitude in case a sealing tape is applied (alternatively, 300 rpm, 25-mm amplitude).

5. Prepare a second MTP (as in step 1) in case synchronized cultures are desired (see section 8.3.6, Fig. 4).
6. Inoculate this second MTP by transfer of 5 μ l from each well of the first MTP. For this purpose, use either a 12-channel multipipette, a 96-channel pipetting machine, or a pipetting robot.
7. Repeat steps 3 and 4.
8. Optional: use the first MTP to prepare a frozen master plate for possible rescreening at a later time. Add 150 μ l of a 30% (vol/vol) glycerol in water solution to each well. Use a 12-channel multipipette (move up and down) for thorough mixing. Use wide-orifice tips in case cultures are viscous or are not fully homogeneous. Put on a polystyrene lid. Freeze at -80°C and store in a cryobox.
9. Harvest the cells and/or supernatant by centrifugation of the second MTP. Optionally: add 150 μ l sterile water or buffer prior to centrifugation; this will make it easier to take off the supernatant after centrifugation (see section 8.3.7).
10. Perform the assay on either the supernatant (in case of an extracellular product or enzyme) or lysed cells (in case of a cytoplasmic enzyme product).

8.3.7. Centrifugation and Filtration of Cultures in MTPs

Filters in MTP format, available from a range of suppliers in combination with a vacuum unit, can often be used effectively for the separation of cells and supernatant fluid, as long as the cell density is not too high, i.e., does not cause clogging of the membrane filter. Their use is not recommended for relatively dense cultures (more than 1 to 2 g dry wt/liter), which may cause clogging of filters, or if the cost of such filters is inhibitory. In such cases, centrifugation is the method of choice. Tabletop centrifuge rotors are available that can accommodate deep-well MTPs or multiple shallow-well MTPs. Depending on the type of strain, and

the strength of the MTP, a minimum speed of 2,000 to 4,000 rpm for 10 to 20 min is required, preferably under refrigeration. Removal of the supernatant using a robotic system or a multichannel pipette can be problematic, especially with small culture volumes. As already mentioned in section 8.3.5.2, addition of extra buffer prior to centrifugation may alleviate this problem (see also the 96-well plunger device described in section 8.3.10).

8.3.8. Glucose Feeding Systems

Many large-scale bioprocesses are fed-batch systems: when the glucose initially present (maximally 100 to 200 mM for toxicity reasons) is fully consumed, the continuous feeding of a highly concentrated glucose solution is started. Mutant or medium screenings aimed at an increased productivity of such fed-batch systems are ideally also done in a similar fed-batch mode. This may be a realistic option for 24 or 96 cultures using peristaltic pumps or syringe-based feeding systems, but such external dosing systems are not practically feasible for thousands of cultures. For large numbers of cultures in MTPs, two internal glucose delivery systems are applicable.

First, small silicone elastomer disks containing glucose crystals may be added to each well (26). The glucose will slowly diffuse from the disks into the medium. A second option is the addition of a combination of glucosidases and starch or cyclodextrin to each well. By varying the amount of glucosidase in the medium, the glucose supply rate can be adjusted to a level that mimics the large-scale bioprocess. This second strategy was patented by Green and Rheinwald from the Massachusetts Institute of Technology in 1975 (20), and recently further elaborated upon by Panula-Perälä et al. (36). In the latter paper, the starch is added into an agar gel on the bottom of each well, while glucoamylase is added to the growth medium itself. Distinct advantages of the silicone elastomer disks are that compounds other than glucose can also be used and that it can also be applied for strains that produce proteases (which would destroy the glucosidase used in the enzymatic method). A practical and logistic advantage of the enzymatic method is that the necessary components can be added as liquids.

The substantially higher cell densities that can be reached with these systems also make it more challenging to keep the pH within certain limits in the absence of an active pH control system. A relatively strong buffer (e.g., 0.15 to 0.2 M phosphate buffer) is recommended. Also, ammonia is preferably not used as a nitrogen source since with the consumption of each molecule of NH_4^+ one proton is released, and the medium may thus acidify rapidly. Use of an acid carbon and energy source (e.g., succinic acid or acetic acid) leads to a pH rise when consumed and may thus counteract a pH drop due to the consumption of NH_4^+ . If a sugar is used as a carbon and energy source, applying high OTR shaking conditions will keep the fermentative formation of acids to a minimum for many microbial strains.

8.3.9. Measurement of pH, O_2 , and Biomass during Growth

It is obvious that the small size of the cultures in MTPs sets limits to the methods used for monitoring culture parameters. The application of electrodes or other probes is not very practical, not least because of the required wiring. For these reasons, noninvasive methods such as optical sensors are generally preferred.

Frequently used for pH and oxygen determinations are fluorescence-based sensors made of thin, hydrophilic

sensing films consisting of an analyte-sensitive indicator and a reference fluorophore that are deposited on the bottom of the MTP. With the help of special readers, the change in pH and/or dissolved oxygen tension can be followed in time for all wells (3).

For the quantification of biomass inside the wells of MTPs, optical methods based on light scattering (reflection and refraction by the cells) can be applied. Essentially three approaches can be distinguished. In the first approach, a regular MTP reader is used to follow the optical density in time, either in the presence or absence of low-orbit shaking. During the measurement, shaking is interrupted. A limitation of this approach is that OTRs are generally low and that the unhindered transmission of light (the principle on which optical density measurements are based) becomes almost zero at optical densities higher than 3, resulting in a low accuracy at high cell densities. In the second approach (38), the bottoms of the individual wells of an MTP are illuminated using an optical fiber bundle (under an angle of 20 to 30°). The intensity of the light reflected by the cells growing inside the wells is measured continuously using a photodetector at the other end of the fiber bundle. As long as the shaking diameter is not too large (typically 3 mm), the shaking does not need to be stopped during the measurement; thus, mixing and O_2 supply are not interrupted. As one is free to choose different wavelengths for the excitation light and the emission light, this approach is also suitable for fluorescence measurements. The third approach consists of the mounting of a flatbed scanning device between the shaker and the MTPs (18). At regular time intervals, e.g., every hour, the shaker is stopped and the bottoms of the MTPs are scanned, immediately followed by an automatic restart of the orbital shaker. Subsequently, image analysis software automatically generates growth curves. A disadvantage of this third approach is the low oxygen supply during the scanning phase (20 to 40 s), which can have unpredictable effects and can cause stress reactions for certain strains. An advantage, however, is that the user is free to choose a large shaking diameter (e.g., 50 mm) if desired. The availability of high-resolution graphics of each well enables the user to study morphological aspects (formation of pellets, aggregates, wall growth, etc.). Both the second and the third approach (in contrast to the first approach) allow the quantification of relatively high biomass concentrations up to 20 to 50 g/liter cell dry weight.

8.3.10. Specific Aspects of Growth and Screening of Fungi in MTP Format

Parallel microfermentations of bacteria and yeasts in MTPs have gained widespread acceptance, but few cases have been reported that suggest that filamentous fungi could be effectively grown and that they would produce their enzymes or secondary metabolites in MTPs. MTP fermentation systems and pin tool inoculations were designed and developed for use with heterogeneous strain collections of aerobic bacteria and actinomycetes and clonal libraries in *E. coli* and yeasts, but protocols were not available for filamentous fungi. Several features of filamentous growth complicate manipulation of fungi in MTP systems. Strains that lack spores and that grow only as multicellular filaments cannot be transferred as homogeneous microliter volumes. Second, in heterogeneous collections of fungi, rates and patterns of hyphal growth vary enormously among species. Some species may grow very rapidly and produce enough biomass to overflow and escape from a microwell. When one is trying to move inoculum or pipette extracted mycelia, mycelial

masses clog and interfere with pipette tips. Furthermore, aeration of microwell cultures by orbital shaking may be ineffective because mycelia can quickly form solid masses. Therefore, new protocols were needed to adapt MTPs to the distinctive biology of filamentous fungi, especially those fungi that only grow as hyphae in culture.

The first obstacle to use of fungi in MTPs is difficulty in achieving consistent inoculation. MTPs can be used to grow fungi that sporulate abundantly in culture because spore suspensions can be reliably sampled from frozen inoculum using a 96-well pin tool or with tips of a multichannel pipette. This approach may be adequate when screening mutants or libraries of transformants in a heavily sporulating host, e.g., *Aspergillus niger*. However, in the context of secondary-metabolite discovery, using MTPs to only grow sporulating fungi limits screening experiments to only a small fraction of the culturable fungi diversity. Within a few well-studied orders of fungi, e.g., the Eurotiales (e.g., *Penicillium* and *Aspergillus*) and Hypocreales (e.g., *Fusarium* and *Trichoderma*), sporulation in vitro is common; however, the vast majority of culturable fungi only produce vegetative hyphae in culture. The best-known uses of MTPs for fungi are the phenotype microarray systems that measure patterns of carbon and nitrogen utilization and responses to cellular inhibitors which are predispensed in 100- μ l cultures in 96-well MTPs (9). Fresh conidial suspensions have been used in MTP assays of fungi in phenotype microarrays to inoculate plates for profiling substrate utilization or screening for enzymatic activity (11, 29, 40). In some cases, fungal growth characteristics were comparable among agar, shake flask, and 100- μ l cultures in MTPs, such as with *Hypocrea jecorina* (14).

The second obstacle in adaptation of fungi to MTPs is manipulation of filamentous growth in microwells. In an effort to obtain fungal growth compatible with microplate technologies, the filamentous fungus *Chrysosporium lucknowense* has been mutated for nonfilamentous growth and reduced medium viscosity so that it could serve as a eukaryotic host in high-throughput DNA library screening (43). However, agitated aerated growth in 96-well plates is likely unobtainable with most fungi because of the restricted space and tendency of fungi to adhere to the container walls, although 24-well plates permit some degree of agitation of fungal mycelium. For example, transformants of *Aspergillus nidulans* were screened for modified secondary-metabolite profiles by growing them in a 24-well MTP system (1). However, the space limitation in 96-well MTPs dictated that screening of filamentous fungi should adopt a solid-state fermentation strategy (6). Mycotoxin and secondary-metabolite production is routinely evaluated from agar growth in petri plates (19, 39). The successful application of agar plug microextraction techniques to fungi suggested that secondary-metabolite production in small-scale static fermentations in microwells would be feasible.

Recently the spring-loaded replicator (section 8.3.6) and sandwich covers (section 8.3.1.2) have been adapted for inoculation and growth of filamentous fungi in 96-well and 24-well formats. A technique was developed for efficiently generating inoculum from fungal hyphae and transferring inocula among microwells as hyphal suspensions (6). A simple screening system was established using heterogeneous collections of 80 fungi grown in a 96-well format. Fungal metabolites could be efficiently extracted from microwell plates, and metabolite production was adequate for detection of biological activity. Growth in 96-well plates can yield 500 to 1,000 μ l of mycelial extract

and supernatant, enough to carry out several assays, repeat them if necessary, and evaluate the extract via HPLC-LC-MS. Active strains discovered by high-throughput screening of MTP fermentations usually can be scaled up in shake flasks or static flask cultures in order to isolate and characterize active components (6, 21, 34). The 96-well or 24-well MTP format permits creative and high-throughput experimentation with fungi that normally is resource limited and cumbersome with conventional shake flask systems (1, 6–8).

Protocol 3. Inoculation and Growth of Filamentous Fungi in MTPs

1. *Equipment.* The equipment and materials for growth of fungi for secondary-metabolite production in static MTPs have been described in detail (6). An environmental chamber equipped with shaking platforms (5-cm displacement) and inclinable (approximately 75° angle) steel tube racks (25-mm diameter, 16 tubes per rack) is used to incubate and agitate seed inoculum tubes. Production cultures are grown in 96-well (2.5 ml per well) or 24-well (10.0 ml per well) deep-well polypropylene plates and incubated in environmental cabinets. Culture manipulations, master plate preparation, and plate replications should be carried out in biosafety cabinets.
2. *Preparation of inoculum: replication and growth of 80 fungi in microplate fermentations.* Select sets of 90 to 100 strains of freshly isolated fungi or fungi from a culture collection and grow for 2 to 3 weeks in 60-mm petri dishes. Grow fungi in YM agar (malt extract, 10 g; yeast extract, 2 g; bacteriological agar, 20 g, H₂O, 1,000 ml). Avoid heavily sporulating species with dry airborne spores (e.g., *Aspergillus* spp.) or species with extremely fast radial growth (e.g., *Trichoderma* spp.) to minimize the possibility of cross-well contamination. When using screening applications that employ fungi with dry airborne spores (*Aspergillus*, *Penicillium*) or aggressive growth (*Botrytis*, *Trichoderma*), consider using inoculation patterns that skip alternative rows or wells. Prepare seed medium in 25-by-150-mm glass tubes. Add two 22-mm² cover glasses to each tube. Agitation of the tubes on an orbital shaker causes the cover glasses to continually shear hyphae and mycelial pellets, resulting in a homogeneous hyphal suspension (Fig. 5). Dispense 8 ml of melted and homogeneously stirred Sabouraud's maltose yeast extract medium with 0.35% agar (maltose, 40 g; yeast extract, 10 g; neopeptone, 10 g; agar, 3.5 g; distilled H₂O, 1 liter) into each tube. The additional agar in the medium aids adherence of mycelial fragments to the replicator tips. Cap the tubes and autoclave. To inoculate the tubes, remove two 5-mm-diameter agar disks from each culture with a Transfer Tube (Spectrum Laboratories, Rancho Dominguez, CA). Push the Transfer Tube's plunger against the bottom of the tube to mash and extrude the agar disks against the glass, thus increasing the number of mycelial growing points. Agitate the tubes (200 rpm, 5-cm displacement) for 3 to 6 days. Most strains exhibit moderate to dense growth. However, tubes that appear to the unaided eye to have little growth, upon microscopic inspection often reveal a dense suspension of fine hyphal fragments.
3. *Preparation of master plate for replication.* From among the set of 100 tubes, select 80 strains with adequate growth to prepare master plates for replication (Fig. 6). A sterilized master plate holds the hyphal inoculum for replication. Use sterilized Transfer Tubes to transfer 1 ml

FIGURE 5 Preparation of fungal inoculum for master plate replication. Two microscope cover glasses are agitated with growing mycelium to produce a homogeneous mycelial suspension.

of hyphal suspensions to wells. After loading, the master plate is closed until replicated in fermentation plates. Freeze additional aliquots of each inoculum tube in 20% glycerol in 1.8-ml cryovials at -80°C .

4. *Preparation of fermentation media in multiwell plates.* Prepare fermentation media in advance in aliquots of 100 ml in Erlenmeyer flasks. Use 80 ml of the aliquot to fill the 80 central wells of the deep-well growth plate at 1 ml per well. Leave the first and last columns of the plates empty so those positions can be used for evaluation of

assay positive and negative controls. Media formulations are usually limited to soluble components; media with insoluble components or precipitates are mixed with a magnetic stirrer during dispensing.

Prepare seed-based solid media by filling an MTP with 200- μl wells with seeds (wheat, rice, millet, cracked corn) and leveling the seed depth to the tops of the wells. Align the open wells of an inverted growth plate on top of the seed-containing MTP, and flip the two plates rapidly so that a measured seed volume falls into each well. Add a liquid basal medium (700 μl) to the seeds; close the plates with the sandwich lids and autoclave the assembled plates.

5. *Replication of master plates across the nutritional array.* Sterilize the cryoreplicator pin tool (section 8.3.6) by immersing the pins in 70% ethanol for 1 min and then evaporating the ethanol on a hot plate. Lower the cooled cryoreplicator pins several millimeters into the hyphal suspensions of the master plate, and then raise them. Switch the master plate for a medium-filled growth plate, and lower the inoculum-covered pins to the bottom of the liquid medium. Switch the growth plate again for the master plate, and repeat the inoculation three to five times. Repeated inoculation from the master plate ensures that sufficient fungal cells are transferred to initiate growth. Repeat the process again for each different medium plate. Sterilization of the cryoreplicator during multiple transfers from the same master plate is unnecessary because the cryoreplicator press prevents accidental lateral movements, and the inoculum source for each well remains constant. Change and sterilize cryoreplicators between consecutive inoculations of master plates.

FIGURE 6 Loading the master plate with fungal mycelium suspensions. Afterwards, the cryoreplicator tool is used to replicate each well across multiple growth conditions in the nutritional array.

6. *Incubation.* The clamps used to press the sandwich cover onto growth plates and attach them to shaker platforms are awkward for static incubation and therefore are not used. Instead, incubate plates statically at about an 85° angle (Fig. 7). Inclined incubation increases the surface area of the liquid media and improves aeration. Plates are incubated for 2- to 3-week growth cycles at 22°C. During early experiments, the sandwich covers were held in place on growth plates with heavy rubber bands. A second-generation closure used modified carpenter's wood clamps to clamp lids securely to growth plates (Fig. 7, upper shelf). Finally, stainless steel plate holders that simultaneously clamped plates shut with two lateral wing nuts and supported them at an 85° angle were custom built (Fig. 7, lower shelf).
7. *Contamination and viability check.* After inoculating the medium plates, inoculate Omnitray plates filled with YM agar from the same master plate and incubate at 22°C. Inoculate a second Omnitray plate filled with Luria broth agar and incubate at 28°C to check for bacterial contamination. Replication of master plates onto agar verifies that each well contains viable inoculum and that strains are not contaminated.
8. *Extract preparation.* After growth, open plates and inspect for contamination. Replace the sandwich cover's 96-hole silicone mat with a solid silicone mat, and remove the breathable cotton layer. Pump 1 ml of a water-miscible solvent (acetone or isopropanol) into each fungal culture. Gently dislodge mycelia adhering to the well walls, and crush and mix mycelial masses with the solvent with the cryoreplicator tool. Reassemble sandwich covers with the solid silicone mats, clamp them on a shaker board, and agitate for 1 h. After about 30 min, reverse the shaker board to change the direction of agitation. Finally, centrifuge plates for 5 min to settle

mycelia to the bottom of the wells. To facilitate removal of extracts from growth plates, use a custom-built aluminum 96-well hollow plunger (Fig. 8) to push mycelium to the bottom of wells while the extract and supernatant fill the plunger's hollow columns. The hollow center of the plunger columns and open windows at the sides prevent spilling and overflow of the extracts and largely eliminate mycelial interference and facilitate pipetting with a liquid-handling robot. Transfer a total of 900 μ l of the acetone- or isopropanol-medium supernatant from each well to wells of a 2-ml recipient plate. To minimize metabolite precipitation during solvent evaporation, add 100 μ l of dimethyl sulfoxide (DMSO) to the 900 μ l of the culture extract. The culture-solvent-DMSO mixture is reduced to 50% of its original volume under a stream of N₂ from a 96-tip manifold or by vacuum evaporation. After solvent removal, approximately 500 μ l of aqueous extract with 20% DMSO remains per well, and extracts can be stored at -20°C until assayed. Extract plates can be thawed and briefly shaken on a plate mixer prior to assay.

8.3.11. Specific Aspects of Growth and Screening of Actinomycetes in MTP Format

Actinomycetes provide an array of opportunities to the industrial microbiologist. From an industrial point of view, actinomycetes are biosynthetic factories capable of producing a wide range of complex secondary metabolites. They are also efficient producers of enzymes useful for biocatalytic reactions, including many useful in mimicry of human metabolic reactions. In contrast to many nonactinomycete strains, which exhibit more homogeneous growth, the ability to screen hundreds of actinomycete strains for these capabilities can be complicated given the different growth

FIGURE 7 Static incubation of fungal growth plates for the nutritional array. The plates on the upper shelf are closed with carpenter's clamps and supported at an 85° angle by wood tongue depressors. The plates on the lower shelf are supported by a custom-made stainless steel support.

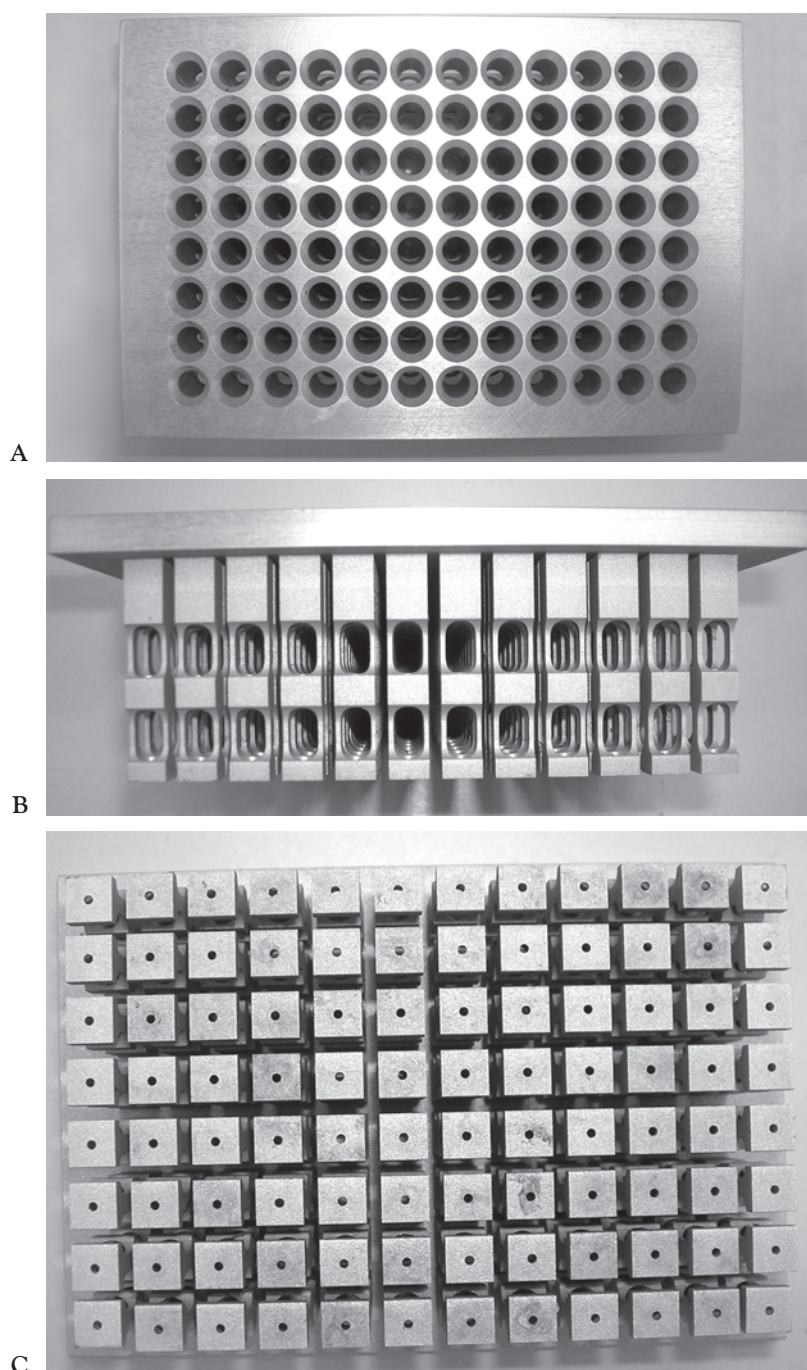

FIGURE 8 Custom-built 96-well aluminum plunger tool used to compress and separate fungal mycelium to bottom of each well while permitting solvent and culture supernatant mixture to rise to top of plate for pipetting. (A) Top view. (B) Side view. (C) Bottom view.

morphologies, lengths of culture periods, and varying medium requirements for growth and induction of pathways. However, given the need for new natural products in pharmaceutical discovery and the utility of biocatalytic derivatization of complex structures in, as examples, medicinal chemistry structure-activity relationship studies, metabolite syntheses, organic syntheses, and biotechnology initiatives, screening of actinomycete cultures is a tool industrial microbiologists must continue to utilize and improve upon. The

ability to quickly and effectively screen banks of mutant populations for improvements in these various activities is another effective use of the miniaturized format.

Growth of most actinomycete strains in liquid culture generally results in dispersed mycelial growth, clumped mycelial growth, or pelleted growth of some type. The reasons that determine submerged liquid growth morphology of one culture as compared to another may include the genus of the strain, inoculum quality, quantity of growth points such as

spores or mycelia fragments in the inoculum, medium composition, medium viscosity, and physical culture conditions. Physical culture conditions include factors such as the ratio of liquid volume to vessel volume, and vessel configurations such as baffling and agitation rate. As discussed previously in this chapter, physical culture conditions in miniaturized growth systems can typically be dictated by the revolutions-per-minute set point of an orbital shaker, the use of round or square well plates, the geometries of the wells of the plates, the volume ratio of medium in a particular well geometry, and the viscosity of the medium. Maximizing these conditions for a diverse population of strains can be difficult, but several steps can be taken to optimize multiple parameters around a set of distinct strains for particular purposes.

To begin any screening effort with actinomycetes, there must be a good working knowledge of the strains to be screened. Actinomycete strains will differ in growth rate, optimal growth temperature, medium requirements, and morphology, so decisions about strain selection for the purposes of populating the wells of a particular MTP may be driven by attempting to synchronize culture populations and growth requirements. In addition, the culture behavior as it relates to the needs of postfermentation processing will influence this design. For example, it might make sense to separate those strains typically growing as fragmented or dispersed mycelial cultures, such as many members of the nocardioforms, from those typically observed as pelleted, clumped, or thick and viscous cultures, such as many members of the streptomycetes. One may then be able to more effectively select postgrowth activities such as liquid-handling steps, filtration steps, extraction steps, or centrifugation steps between the more fragmented, filamentous strains and the pelleted or clumped strains. It is difficult to process 24 or 96 wells of actinomycete cultures simultaneously if 1 or 2 or 10 cultures do not effectively filter, clog filters of a solid-phase extraction plate, or are difficult to pipette, etc. If these difficult-to-process strains are absolutely required in the screen, then either more work must be done to understand the issues involved or it may be beneficial to segregate these problem strains to MTPs with those which behave similarly, or perhaps even screen them separately in flasks.

As mentioned above, distribution of actinomycete populations in MTPs for miniaturized growth and screening may have more to do with the practical aspects of physical manipulations and morphological characteristics than with taxonomy. With regard to morphology, it is known that in specific cases greater antibiotic productivity can result from cultures growing in a nonpelleted or dispersed mycelial morphology, so efforts may be made to reduce the pelleting of particular cultures (12, 42). Similarly, reducing the extent of formation of pellets may be required in biocatalyst screening since in such cases mixing, oxygen transfer, substrate availability, and effective active-site populations may be enhanced. In addition, and in consideration of scale-up of successful reactions or fermentations to larger bioreactors or fermentors, fragmented culture morphology may be desired for the same reasons just presented. Medium composition variations and addition of components to medium formulations known to increase the viscosity of liquids as well as that of several polymeric compounds have also been used with some success to limit culture pelleting (24, 32, 46). An excellent review of morphological forms of actinomycetes in submerged cultures lists strains that normally grow as pellets, as fragmented mycelium, or both, under shaken-flask conditions (45). This review is a great

source of information on the factors that may be influenced to control pellet formation.

Methods for preparation, preservation, and use of culture inoculum vary from laboratory to laboratory, and in most cases these methods are determined experimentally for each strain. Whether or not a particular strain will sporulate in a laboratory setting using standard solidified medium formulations is a factor in the procedures followed for preservation of the strain. Harvested spore suspensions containing a cryopreservative such as glycerol can be frozen in cryogenic vials and stored under liquid nitrogen or in liquid nitrogen vapors for extended periods or at -80°C . Others have reported cryopreservation of spore suspensions prepared directly from cultures grown on solidified medium in MTP wells (30). For strains that do not sporulate or are difficult to sporulate in a typical lab setting, one may choose to cryopreserve harvested mycelia either from homogenized scrapings from growth on appropriate agar plates or from mycelia obtained from submerged cultures harvested via centrifugation or filtration. Several techniques and procedures for preparing, preserving, and working with various types of strains are available (31).

The steps used in the preservation of inoculum are important for many reasons, including reproducibility. It has been reported for several filamentous microorganisms that the quality of a seed inoculum and the quantity of points of growth such as spores or mycelia fragments can affect the morphology of the culture in culture vessels (27, 45). These observed differences in morphology resulting from quality and quantity of inoculum are similar in miniaturized growth systems. One may observe increased incidence of pelleting with several actinomycete strains in 96-deep-well plates versus 24-deep-well plates in similar medium formulations and under similar inoculum conditions. Differences in mixing and turbulence, as discussed earlier in this chapter, between the different vessels may in fact affect the interaction of particles such as spores or mycelial fragments and thus pellet formation. Variations in either inoculum or inoculation conditions may therefore lead to wide-ranging culture morphology changes. These morphological changes may in turn affect culture viscosity and overall culture behavior. These effects may impact scalability, as well as reproducibility, with a strain from experiment to experiment or even between independent replicates.

Analysis of various culture preservation techniques and inoculum development techniques, with special attention to reproducibility of resulting cultures in terms of morphology (in MTPs and flasks), natural product yields and enzyme activity, and growth rates and nutrient utilization, is important. Techniques resulting in optimum performance in miniaturized culturing devices are generally successful in seed culturing flasks and therefore can be used for both. Cryopreserved inoculum can then be used to seed multiple identical "master plates" to be used to inoculate screening plates in future initiatives. These master plates are typically produced in sterile, labeled polystyrene 96-shallow-well plates with sterile polystyrene lids and stored in racks at -80°C or colder. These master plates can also be used to inoculate agar plates or MTPs containing solidified media. One may observe irreproducible results using 96-pin inoculation devices with diverse actinomycete strains, and thus attention should be paid to developing alternative techniques such as utilizing up to several hundred microliters of thawed cryopreserved inoculum per well from master plates, depending on the strain and on the MTP geometry. Growing strains on solidified medium in MTP wells can be used

for various biocatalyst screens when the substrate is known to be cytotoxic. One can overlay growth in each well with an appropriate buffer, dose with substrate, and shake in a shaking incubator at appropriate temperatures and speeds. One of the benefits of miniaturized growth systems is that one can perform these steps with multiple replicates to test various buffers and different pH values fairly easily and reproducibly. An alternative to this is to harvest mycelia from growing plate cultures by filtration or centrifugation and resuspend cell material as “resting cells” in an appropriate biocatalysis buffer system followed by dosing and incubation. The latter “resting cells” strategy may be more pragmatic from a scale-up perspective.

Many filamentous strains tend to adhere to the walls of MTPs at the “tide line” created by the medium during shaking. This wall growth will then typically continue to grow, and one may even observe sporulation with some strains. This presents a situation that can be very different from those conditions encountered in many shaking flask configurations as well as in fermentors and thus presents a potential scale-up issue, not to mention a potential source of irreproducibility. In addition, if the strains in these wells are to be screened for potential bioconversion capability and thus dosed with an organic compound, neat or suspended in a carrier solvent, the dosed material may get held up or absorbed by the wall growth and never completely make contact with the submerged culture. There is also the possibility of the absence of submerged growth in the medium because of adherence and wall growth. This phenomenon may happen to a greater extent in one miniaturized growth system configuration versus another, for example, 96-square-deep-well systems versus 24-square-deep-well formats. Medium formulation may also play a role in wall growth, as complex media formulations with insoluble components such as starch or Pharmamedia tend to facilitate more wall growth.

Other beneficial uses of the high-density and parallel format of miniaturized culture techniques include screening of mutant populations and optimization of medium components. Classical methods for strain improvement generally involve selection from large numbers of mutants, isolates exhibiting improved strain characteristics (44). Often, random mutagenesis is used to improve production strains with regard to yields of secondary natural product. Thousands of colonies of surviving mutants may be picked and patched into wells of 96-deep-well plates containing 0.5 ml of growth medium and grown up (with sandwich covers; see section 8.3.1.2) for cryopreservation and crossing into screen plates. Mutant cultures exhibiting improved productivity may then be screened in shaking flasks and ultimately in 20-liter fermentor studies over a 9-month period. Concurrently, medium optimization studies can be done in 96-deep-well plates utilizing the wild-type production strain. This wild-type strain can then be used to assay effectiveness of varying medium formulations and conditions such as carbon-to-nitrogen ratio as well as the selection and concentrations of various nitrogen and carbon sources. Use of the 96-well formats, once conditions for growth and natural product formation were identified, allows for testing of very large numbers of medium formulations, multiple controls, and culturing conditions, such as additions of sequestering agents like adsorbent resins, addition of various oils and fatty acid methyl esters, as well as potential inducers and pathway intermediates.

As can be surmised from the preceding, it is quite challenging to make generalizations concerning the miniaturization of hundreds of cultures of actinomycete strains. However, what is hopefully very clear is that the

success of miniaturized growth of actinomycete strains with respect to screening and reproducibility depends on several factors that must be determined using a strong, basic understanding of the microbiology and physiology of the strains of interest, combined with an experimental strategy. Important factors include the scheme employed for populating strains into the miniaturized format, the medium used for synchronous growth among the populations of strains in any one device, appropriate inoculation protocols, optimum strain preservation protocols, and choice of MTP format.

Protocol 4. Screening for an Improved Actinomycete Production Strain

1. Fill all 96 wells of sterile 96-deep-well MTPs (square wells with a total volume of approximately 2.0 ml) with 0.5 ml of an appropriate sterile rich liquid growth medium (e.g., yeast extract-malt extract medium [YEME]).
2. Inoculate each well with a single colony from an agar plate spread with an appropriately diluted mutagenized population. Due to the nature of many actinomycete strains growing on agar, picking of colonies may involve taking “core samples” from the agar plate.
3. Cover the inoculated MTPs with sterile sandwich covers (see section 8.3.1).
4. Incubate the MTP with cover in an orbital shaker at an appropriate temperature, typically 25 to 28°C, for 48 h. Shaker conditions: 300 rpm, 50-mm shaking amplitude (other conditions may be appropriate based on experimental determination with specific production strains; however, these conditions approximate those in “standard” lab shaking flask conditions with actinomycete strains).
5. Prepare a second MTP (as in step 1) with an appropriately optimized and tested production medium for the production strain.
6. Inoculate this second MTP by transfer of 25 μ l from each well of the first MTP. For this purpose, use an 8- or 12-channel pipette with wide-orifice tips. Use of robotics may be possible at this step depending on laboratory setup with respect to aseptic practices; culture morphology and medium viscosity are additional factors potentially affecting use of robotics.
7. Optional (recommended): use the first MTP to prepare a frozen master plate for possible rescreening at a later time. Add 100 μ l each of a 50% (vol/vol) glycerol solution and of the primary plate culture to each well of a sterile polystyrene 96-well plate. Use an 8- or 12-channel pipette (move up and down) for thorough mixing. Put on a sterile, labeled polystyrene lid and secure lid. Freeze at -80°C and store in a cryobox.
8. Incubate production culture MTPs in an orbital shaker at an appropriate temperature, typically 25 to 28°C, for an appropriate length of time for the particular production strain. As in step 4, shaker conditions: 300 rpm, 50-mm shaking amplitude.
9. Assay populations for titer, activity, or other targeted criteria:
 - a. Cell-associated natural products: perform extractions of cells/fermentation solids as necessary from centrifuged or filtered mass to extract compound of interest. Use extracts directly for LC-MS, HPLC, GC-MS, or cellular-based assays of titer or activity.
 - b. Extracellular products: collect supernatant by centrifugation or filtration. Transfer supernatant to 96-well

collection/storage plates. Use supernatant directly for LC-MS, HPLC, GC-MS, or cellular-based assays of titer or activity.

- c. Alternatives:
 - i. Extract entire well using liquid-liquid extraction techniques with an appropriate water-immiscible solvent such as ethyl acetate or dichloromethane.
 - ii. Apply entire well contents to an appropriate solid support such as Celite-filled 96-well filter plate devices followed by liquid-liquid extraction techniques with an appropriate water-immiscible solvent such as ethyl acetate or dichloromethane.
 - iii. Apply supernatant samples to appropriate 96-well solid-phase extraction devices followed by appropriate extraction and, if needed, concentration steps.

8.4. CULTIVATION IN TEST TUBES

While they are not an inherently parallelized system, one should not rule out the utility of test tubes for the culturing of small to large numbers of microbial strains, especially if one wishes to handle all cultures individually (which is difficult when using MTPs). Test tubes are used for various purposes by the microbiologist, but in the context of this chapter, focus is placed on use of test tubes for high-throughput culturing of microbes in small volumes. Ohta et al. screened 1,237 actinomycete strains for the ability to enzymatically hydroxylate cyclosporin A, thus mimicking human metabolism of this complex structure (33). In this case, all strains were inoculated from frozen vegetative mycelial stocks into 2 ml of medium in test tubes, and the tubes were grown on a rotary shaker at 210 rpm. In the end, 89 of the strains grown and screened in this manner were found to produce the hydroxylated metabolites of interest and several were successfully scaled up to 30-liter jar fermentors. Tormo et al. reported screening 250 diverse actinomycete strains in test tube cultures utilizing 10 different fermentation media for the purposes of identifying HPLC profiles of metabolites produced. This was intended to identify those media typically supportive of wider chemical diversity of the products (41). Each strain in this work was inoculated into 10 ml of each production medium in 25-by-150-mm test tubes and the cultures were grown in tubes at a 35° angle. The results of this screening of strains and various production media were ultimately supportive of the “one strain-many compounds” approach to microbial natural product screening (10) and also demonstrated the utility of test tubes in high-throughput microbial screening.

8.5. CONTROLLED MINI-BIOREACTOR SYSTEMS

The use of mini-bioreactor systems such as MTPs has aided scientists in a diverse range of microbiological applications. This chapter has primarily focused on MTPs of various well geometries and volumes, in the absence of medium, pH, and/or O₂ control. However, there exists a range of alternative mini-bioreactor systems each having potential for various applications. From the simple to the exquisite, the literature contains several examples of these other mini-bioreactor and fermentation systems. Betts and Baganz present an extensive review of miniaturized bioreactors and explore advantages and disadvantages of several of the current and emerging technologies (5). As explained in the review, there may be an advantage to selecting each

individual type of mini- or micro-bioreactor based on the application. Two specific examples of mini-reactor systems are described below.

Puskeiler et al. from the Technical University of Munich developed a reaction block with 48 mini-reactors with working volumes of 8 to 12 ml each, and free-floating and self-centering magnetic impellers (37). The shape of the impeller in combination with baffles caused the air to be sucked into the medium, leading to maximal OTRs of around 300 mmol liter⁻¹ h⁻¹. A robotic liquid-handling system (using syringes that can take samples, but also inject medium, acid or base) allows the system to function as a set of 48 fully controlled fed-batch bioreactors. In an automated, pH-controlled, fed-batch cultivation, an *E. coli* strain could be grown to a density of more than 20 g dry wt/liter.

The miniature bioreactor system described by Isett et al. (25) consists of a modified polystyrene 24-well MTP (with higher wells). pH and oxygen are continuously monitored using fluorescence-based sensors as described in section 8.3.9. The pH can be automatically adjusted to a set level by either CO₂ or ammonia via the gas phase. Orbital shaking at 500 to 800 rpm enables OTRs in the range of 10 to 15 mmol liter⁻¹ h⁻¹. Optionally, sparging of air can be used to supply extra O₂ to the cultures (leading to OTRs of approximately 25 mmol liter⁻¹ h⁻¹) (25). The system was evaluated with *Saccharomyces cerevisiae*, *E. coli*, and *Pichia pastoris* strains.

Although it was not miniaturized to the extent as the two examples above, we also want to mention here the development of a shaken-flask parallel system (2). Use of this system allows for growth of microorganisms in 14 parallel shaking flasks: 6 standard laboratory flasks for sampling as well as 8 specialized flasks for online measurements of OTRs, carbon dioxide transfer rates, and the respiratory quotient. This system allows for screening of various conditions, such as medium composition, while gaining information on the metabolism of the organism(s).

8.6. SUMMARY

Miniaturized cultivation systems are attractive not only in reducing demands for incubation space and medium but also in making the parallel handling of large numbers of strains more practicable. Provided the user is willing to invest a sufficient amount of time and effort on the optimization for their specific purpose, the presently available systems allow the cultivation at a 0.1- to 10-ml scale at a reproducibility and quality approaching those of larger-scale fermentation equipment. The presently available systems are almost without exception based on the MTP standard, which contributes—in combination with the use of other MTP-based equipment—to a continuous improvement of the time efficiency of screenings and medium optimization projects.

Solid-Phase Fermentation: Aerobic and Anaerobic

RAMUNAS BIGELIS

9

The science of solid-phase fermentation (SPF) draws on the same ancient origins that are the foundation of the field of biotechnology and of the modern methods used to grow microorganisms. This approach to culturing microorganisms has been used to produce chemicals, commodity enzymes, pharmaceuticals, high-value biochemicals, and diverse foods and beverages. It also serves as a valuable research tool for the discovery of new natural products. An earlier article by Sato and Sudo (131) covers small-scale solid-state fermentation, as do other reviews on SPF (4, 12, 34, 49, 65, 72, 80, 93, 96, 98, 102, 104, 106, 109, 110, 120, 125, 150).

9.1. GENERAL CONSIDERATIONS

9.1.1. History

The origins of fermentation date to prehistory and gave rise to the first, perhaps accidental, methods used to preserve food and prevent them from spoiling and causing illness (16). SPF is as old as leavened bread making in ancient Egypt (2600 BC) and beer making in Babylonia (6000 BC), centuries-old soy fermentations in south Asian cultures, and a variety of traditional food fermentations that spread worldwide alongside primitive agriculture.

The koji process, a form of SPF and a landmark development, originated in China and was brought to Japan in the seventh century as a fermentation with *Aspergillus oryzae* on steamed rice. Used as a “starter,” it still is the first stage in a second fermentation that produces miso, tempeh, soy sauce, sake, and other traditional Oriental foods. It is fitting that the word “koji” is an abbreviation of the Japanese word *kabi-tachi*, which means “bloom of the mold.” Its development and spread were seminal events in the history of SPF.

Significant commercial exploitation of SPF beyond food fermentations, however, occurred late in the 19th century (85, 91). In 1894, Jokichi Takamine patented a process for producing amylase by culturing *A. oryzae* on solid substrates via what is still called the Takamine process (143). These pioneering efforts evolved into industries that employed SPF for production of a variety of fungal and bacterial enzymes, citric acid, gluconic acid, and kojic acid. And, in part, they inspired the development of modern biotechnology (15, 17, 47, 52, 85, 91). Today, the impact of industrial SPF in Europe and North America is small; it

is more common in regions that lack modern fermentation equipment. However, interest in this method of culturing microorganisms has been renewed (40, 135).

9.1.2. Characteristics of SPF

As defined inclusively, SPF under either aerobic or anaerobic conditions is a process of culturing microorganisms on solid materials in the presence of little or no free water. The solid materials on which the organisms proliferate, and which they may penetrate, typically contain water (and often soluble nutrients) or have the capacity to absorb it. These substrates are commonly cereal grains, legumes, and various lignocellulosics. It can be said that SPF encompasses both solid-substrate and solid-state fermentation since solid-substrate fermentation employs a natural material as a carbon/energy source in the presence of little or no free water, but the broader designation, solid-state fermentation, includes the possible application of an inert, degradable, or poorly degradable solid support in a suitable medium. The inclusion of inert supports (26, 104) can play an important role in SPF and shape its definitions and classification. Krishna (80) discusses a number of such definitions of solid-state and solid-substrate fermentation as put forth by Moo-Young et al. (98), Pandey and Ramachandran (111), Aidoo et al. (4), Raimbault and Alazard (121), Raimbault (120), Lonsane et al. (86), Soccol (137), Hesseltine (72), Viniegra-Gonzalez (150), and others, and relates this terminology to the presence, absence, or irrelevance of added inert solid supports. Additionally, SPF can be subcategorized as to the nature of the microorganisms applied to the fermentation: natural-indigenous culture, mixed culture-cofermentation, and pure monoculture fermentation. Pure, defined cultures are generally used in most industrial SPFs since this approach is associated with greater quality control and reproducibility, though some fermentations with agricultural residues and food applications employ mixed cultures with benefit. All common definitions of SPF differentiate its various forms from submerged fermentation, termed liquid fermentation or liquid-phase fermentation (LPF), which is carried out in dilute solutions or slurries, in contrast to SPF, where little or no free liquid is present (26, 80, 86, 121, 137, 151). LPF is of major significance in industrial microbiology (23, 47) and is used to produce numerous and varied commercial products. Another approach, termed mixed-phase fermentation (MPF) by Bigelis et al. (26),

bridges SPF and LPF, and employs absorbent inert solid supports in abundant liquid medium to facilitate the discovery of new natural products.

The physicochemical nature of the substrate and the growth environment differentiate it from LPF. The solid substrate integral to this microbial process is generally heterogeneous; inherently low in moisture content; susceptible to heat buildup and moisture loss due to evaporation during microbial growth; and often difficult to agitate, mix, and, at times, aerate. Many SPFs are stationary and nonagitated, though rotary drum or fluidized-bed fermentors can be configured to allow substrate mixing. Moreover, the solid substrate in SPF predominantly supports surface growth rather than the homogeneously dispersed growth that typically occurs in an agitated liquid environment, and in the case of molds, it is quite often associated with aerial mycelia rather than pellet morphologies (74, 83, 104, 144, 155). Similar patterns have been observed with actinomycetes (37, 60). Generally, the nonuniform nature of the solid substrate in SPF is correlated with a nonuniform growth environment, resulting in conditions that can influence productivity and yield. Owing to these general characteristics, process control and optimization of SPF present considerably more challenges than do those of LPF.

The final processing steps of SPF may generate valuable by-products such as animal feed, compost, or fertilizer and significantly enhance the economics of the process.

9.1.3. Advantages and Disadvantages of SPF

9.1.3.1. Advantages

SPF may offer advantages, especially cost savings, over submerged fermentation (10, 42, 74, 75, 120, 125, 151). In a number of cases, SPF has been shown to be a simpler technology. It is (i) more productive; (ii) less susceptible to contamination by undesired organisms due to the reduced water activity (a_w); (iii) independent of agitation and mixing; and (iv) cost-effective since (a) substrate sterility (and pasteurization or autoclaving) may be nonessential, (b) culture media may be simple, consisting of agro-industrial residues, and (c) aeration needs may be reduced (39, 40, 42, 61, 86, 131, 148). Furthermore, SPF can use fermentors of reduced size and volume with concomitant reduced water needs and effluent production (4, 86), compact fermentation facilities, and undemanding culture conditions resembling a natural environment (128), requiring reduced processing and recovery with reagents and solvents (148). Processing of the fermented residues is usually very simple, only requiring quick drying of the low-moisture product to produce animal feed, fertilizer, or other dry commercial products (131). Finally, convenient production of conidiophores by the koji method provides readily available starter cultures. Such spores are reportedly more stable, robust after cryostorage, and resistant to dehydration than spores obtained by LPF (75, 83).

SPF is especially advantageous in fungal applications, and is more common with this group of microorganisms. The low moisture content of many solid media used for SPF makes it especially suitable for culturing molds and other filamentous fungi rather than bacteria, whose growth may be restricted by low a_w (131). SPF, which is commonly a stationary process, often avoids the shear stress and mechanical forces characteristic of LPF which disrupt mycelia. As a result, SPF may promote conditions for maximum production. Moreover, fungal SPF has a record of good production of secondary metabolites (11–13, 26, 45, 80, 125).

9.1.3.2. Disadvantages

The disadvantages of SPF may outweigh the advantages and force alternative fermentation strategies. The lack of scalability of this fermentation technology frequently limits its application. Another major drawback is the low thermal conductivity of the solid substrate, which makes temperature control difficult. Temperature increases, resulting from metabolic heat, can create local hot spots despite forced aeration and the application of thermal regulatory devices (132). Other disadvantages are linked to agitation and process control: difficulties in mixing of the substrate bed may lead to nonhomogeneity and uneven distribution of water, nutrients, biomass, heat, or pH control agents (131). As a consequence of poor mixing, product diffusion may also be limited and interfere with the desired physiological state and pathway regulation of the production organism. Various other disadvantages may involve (i) difficulty in measuring and directly monitoring microbial cell growth and fermentation parameters, (ii) inability to control critical fermentation parameters, (iii) uneconomical requirements for pretreatment of solid materials and substrates, (iv) impurity of the final product elevating product recovery costs, (v) significant moisture loss during long-lasting fermentations, (vi) the need for large inocula, and (vi) limitations due to the critical role of water and a_w (42, 131).

9.2. MICROBIAL GROWTH AND PRODUCTS

9.2.1. Microbial Growth

The growth characteristics of microorganisms during SPF are strongly dependent on the physicochemical nature of the solid substrate and its interaction with water and nutrients, and are associated with growth habits and morphologies that are distinct from those observed during LPF (7, 113). Mathematical models and empirical growth equations that describe fungal growth patterns in SPF have been developed for various molds that characterize growth kinetics in response to key environmental variables (43, 95, 123, 129, 149).

Complex microbial growth phenomena are associated with solid substrates that are typically heterogeneous and porous with void spaces. Fungal surface growth promotes formation of aerial mycelia in this ideal environment for differentiation, leading to sporangiophores bearing conidiospores or other sporulation structures (83, 144), somewhat comparable to sporulation processes in actinomycetes (37, 60). Hyphal penetration of interior spaces, however, can lead to different morphologies that may depend on changes in oxygen availability in the void spaces and nutrient availability in the substrate bed (75, 97, 129). Sudo et al. (140) have reported differences in amylase production associated with submerged and aerial mycelia in rice koji inoculated with *Aspergillus kawachii*. Akao et al. (5) have compared SPF cultures of *A. oryzae* with LPF cultures by subtractive cloning of cDNA, and shown differential gene expression, as well as higher enzyme levels and hyphal differentiation during SPF. Yamane et al. (156) have developed a model SPF system (“cellulose agar cube”) to simulate and study the mycelial morphology associated with glucoamylase production by *A. oryzae* during koji culture. A good match between the predictions of the model and the experimental results was observed.

Generally, upon germination of the spores, fungal hyphae form a mycelial mat that proliferates on the solid surface and then invades gaseous spaces and liquid-filled pores.

Moisture control determines the proportion of each of these two environments. Metabolic activities occur primarily on or near the surface and within void spaces, though such activity is also associated with aerial mycelia, which can exchange metabolites with penetrative mycelia. Secreted hydrolytic enzymes infuse into the substrate bed and promote digestion of its components, yielding nutrients. Gradients of nutrients, O_2 , CO_2 , pH, and secreted primary or secondary metabolites may develop during the course of the SPF, together with an uneven distribution of heat. The behavior of microorganisms during SPF as a microscale process has been discussed by Holker and Lenz (75), and as a bioreactor system by Mitchell et al. (96, 97) and Viccini et al. (149). Both microscale and macroscale processes are illustrated in Fig. 1 (149).

It should be noted that sporulation, a hallmark of SPF, is a key safety concern. Without proper safeguards fungal and bacterial spores can be a major health hazard (82), as can improperly handled grain-based materials that form dust (70).

9.2.1.1. Temperature

Temperature is a key factor in SPF (14, 96, 109, 142). The thermotolerance of the organism must be clearly established, since a buildup or uneven distribution of temperature may interfere with growth. In addition, hot spots can cause denaturation of products, especially thermolabile substances (75, 130). The systems for heat removal, recognizing the generation of considerable metabolic heat and the presence of temperature gradients in the substrate bed, must take into account bed dimensions, heat conductivity, and changes that may occur during the fermentation. Additionally, the effects of temperature on both product

formation and growth must be considered together since each stage of the process may have different requirements for each.

9.2.1.2. Moisture Content and a_w

Like temperature, the moisture content of the solid substrate strongly influences microbial growth (39, 62, 63, 96, 109). In fact, the two variables are closely related in that water evaporation increases as more metabolic heat is evolved. Water can be replaced with periodic additions or humidification. Excessive moisture loss reduces substrate swelling and microbial growth. On the other hand, excessive moisture reduces the porosity of the substrate, lowering gaseous diffusion and exchange.

When considering parameters critical to SPF, a_w is a more relevant representation of moisture limitations than is water content, since a_w represents the amount of water that is available to microorganisms. a_w is the ratio of the vapor pressure of water in a material (p) to the vapor pressure of pure water (p_o) at the same temperature and, being a ratio, has no units. Thus, it ranges from 0.0 (completely dry) to 1.0 (pure water). Relative humidity and a_w are related: multiplication of a_w by 100 gives the equilibrium relative humidity in percent. Many microorganisms thrive at an a_w of 0.99 and most need an a_w higher than 0.91 to grow (39, 131). Bacteria are typically less tolerant of low a_w than are yeasts and molds.

Since water is chemically bound by components of the substrate bed, making it unavailable to microbes, a sensor that measures a_w or equilibrium relative humidity (14, 96) provides critical data on the nature of the substrate, expected growth characteristics, a_w stress tolerance of the production organism (61, 148), and susceptibility of the

FIGURE 1 The macroscale and microscale processes that occur within an SPF bioreactor. (Adapted from reference 149.)

SPF to bacterial contamination. In fact, a full characterization of the production organism's tolerance to low a_w may be necessary (67). Astoreca et al. (8) have illustrated this point by showing how the interaction of a_w , temperature, and lag phase influenced three ochratoxigenic isolates of *Aspergillus niger* grown in various media. Lag times increased considerably at low a_w s, especially at low temperatures, for all studied isolates.

9.2.1.3. Oxygen and Carbon Dioxide

The monitoring of oxygen uptake and carbon dioxide evolution, coupled with aeration, is important for characterization and optimization of SPF (105). Such essential knowledge allows the estimation of biomass and growth rate, and a correlation with fermentation performance.

Efficient SPF aeration systems enable accurate maintenance of appropriate oxygen levels, desorption of carbon dioxide, regulation of moisture level, distribution of volatile metabolites, heat dissipation, and temperature control (63, 66, 80, 96, 97, 109). Mixing may improve oxygen transfer to pockets of moisture and water films around substrate particles, increasing gas exchange between the substrate bed and aerial mycelia. In addition, secreted digestive enzymes, especially amylases, may increase the microporosity of substrate particles and even cause some disintegration, influencing the availability of gaseous oxygen to mold mycelia in stationary and agitated SPF. However, excessive porosity and water in void spaces risk reduction of oxygen transfer.

Oostra et al. (105) explored intraparticle oxygen transfer with *Rhizopus oligosporus* grown on the surface of a solid medium. After direct measurement of oxygen levels in the fungal mat with microelectrodes, they found no depletion in the upper aerial layer, but steep oxygen gradients in the wet bottom layer. Oxygen consumption occurred mainly in the wet portion of the fungal mat. Since the contribution of aerial mycelia to overall oxygen consumption was minimal, it was concluded that optimal oxygen transfer in SPF depends on the available interfacial gas-liquid surface area and on the thickness of the wet fungal layer. Moreover, it was apparent that during SPF, moisture levels in the substrate matrix influence both of these parameters and interact with them to influence oxygen transfer.

Some undesirable characteristics of the solid substrate bed may restrict the diffusion of oxygen critical to an aerobic fermentation and limit performance. As would a medium of low porosity, an excessively deep bed may deter mycelial penetration of even high-moisture grains, kernels, beans, or other enriched substrates since oxygen transfer could be limited or prevented. In such cases, deviation from the theoretical respiratory quotient of 1.0 for an aerobic organism to lower values may indicate insufficient oxygen transfer. Such effects have been observed with molds in aerobic SPF. Illustrating these deleterious effects (95, 131), researchers have reported that (i) deeply submerged mold mycelia grow poorly in high-moisture rice koji, (ii) low oxygen levels increase lag time (but not growth rate) of *A. oryzae* grown on steamed rice, (iii) poor oxygen diffusion limits growth of *R. oligosporus* on cassava starch/ κ -carrageenan, (iv) low-moisture wheat bran affects oxygen transfer even during high aeration of an *A. niger* culture, (v) reduced oxygen concentrations reduce α -amylase production by *A. oryzae*, and (vi) a thickening of *A. niger* growth around starch-rich particles reduces porosity together with oxygen transfer to the bed.

In aerobic SPF, substrate mixing or agitation can significantly change productivity by oxygenating the solid substrate, as in the case of citric acid or ochratoxin production. In contrast, increased agitation (drum rotation) and aeration reduce ethanol production by *Saccharomyces cerevisiae* (131).

9.2.1.4. Physical Properties of the Solid Substrate and Particle Size

The SPF substrate is typically a natural raw material that serves as the carbon and energy source and is rich in polysaccharides, such as starch, cellulose, pectin, or lignocellulose. Such substrates are generally cheap agro-industrial by-products, often heterogeneous waste material (40). Solid substrates that have a large surface area (in the range of 10^3 to 10^6 m²/cm³) are chosen most often in order to enhance exposure to microbial action (111).

The particle size of the SPF substrate is an important variable that influences growth patterns of the production microorganism, similar to critical parameters such as heat and mass transfer (93, 96, 149). All of these parameters involve the exchange of oxygen and carbon dioxide and the movement of microbial products with respect to the solid surface (Fig. 1). They may change during the course of the fermentation in conjunction with particle degradation and changes in the substrate bed. The surface-to-volume ratio of the particle, as well as its packing density, influences the invasiveness of the microorganism and the exposure of the substrate to biodegradation (79, 109). The geometry of the particle also affects void spaces and, consequently, gas transfer. In general, small particles, owing to their larger specific surface area, are advantageous for prolific mold growth, heat exchange, and gas transfer—but only up to a point. Very small particles may reduce aeration and respiration by limiting the interparticle space. Very small particles may also lead to substrate agglomeration, and their use or appearance risks compression and contraction of the substrate bed, leading to channeling of airflow and thus to reduced respiration and poor growth. In some instances, large particles may be favored, with some drawbacks (110). Most SPF processes use a mixed range of particle sizes for optimal production and cost-effectiveness. For example, the commonly used SPF substrate wheat bran, available in two sizes, fine (<500 to 600 μ m) and coarse, can be used in different ratios (111).

Particle size and/or packing density has been shown to influence SPF with *Fusarium oxysporum* on rice, SPF with *Penicillium chrysogenum* on sugarcane bagasse, SPF with *A. niger* on barley, SPF with *Pleurotus ostreatus* strains on sugarcane bagasse, and fermentations for a variety of enzymes (90, 107, 111, 131).

9.2.2. Production of Enzymes

Enzymes that have been produced using SPF technology include the major classes of hydrolytic enzymes such as α -amylases, glucoamylases, β -fructo-furanosidases, cellulases, hemicellulases, pectinases, galactosidases, proteases, and lipases (19–22, 40, 49, 65, 66, 80, 109, 130). More recently, xylanases (40, 153), phytases (81, 114), and ligninases (41) have been added to this list, with more additions expected in the future (111). These enzymes have a history of use in the food, feed, fuel, textile, detergent, and pharmaceutical industries (23, 66, 151). SPF competes with LPF approaches for enzyme production; however, the latter fermentation method prevails in large-scale commercial enzyme manufacture. While many types of enzymes

have been produced by SPF and employed in industrial applications (36, 111), currently only phytases (81), proteases (65), and galactosidases (109, 134) are known to be manufactured on a commercial scale by such means (80). Reported advantages for enzyme production associated with SPF over LPF are (i) higher enzyme yields with selected strains (3, 11, 57, 77, 109, 149, 151), (ii) enhanced enzyme stability (2, 56), (iii) reduced levels of proteolytic degradation of the enzyme product (151), (iv) reduced catabolite repression (100, 119, 120, 131), (v) suitability of crude product with minimal or no downstream processing (103, 109), (vi) efficient growth and biomass production (126), and (vii) good biosynthetic efficiency at high levels of oxygen demand with limited mixing (in tray reactors) (126, 151). Additional advantages point to (viii) simpler fermentation equipment (109), (ix) reduced costs for dewatering and product concentration (109), and (x) lower expenditures for raw materials (40).

9.2.3. Production of Metabolites

SPF has a history of use in industrial mycology to manufacture food-processing aids and ingredients, fuels, chemicals, and pharmaceuticals.

9.2.3.1. Organic Acids

The worldwide industrial output of citric acid surpasses that of other primary metabolites derived by fermentation (24, 25, 111). Citric acid is used predominantly in the food/beverage and detergent industries. Today, virtually all production is by LPF with *A. niger* in large, computer-controlled, aerated fermentors of stirred or airlift design, although up to 20% of world output was obtained by surface fermentation and SPF late in the last century. Continuous processes with *Candida* yeast strains are performed only in small volumes (6).

Variations of the traditional koji process with *Aspergillus* species have been applied to citric acid production in Japan and Southeast Asia on a relatively small scale (85). Owing to economic advantages, the raw materials are residual pulps from starch manufacture or food processing, or similar by-products mixed with a solid support (40). The starchy material, bearing considerable cellulosic substrate, is soaked to a final water content of 65 to 70% and excess water is removed, steamed, cooled to yield a sterilized (or pasteurized) paste, loaded into trays or shallow pans, and spray inoculated with conidia of selected strains. Frequently, *A. niger* strains that are less responsive to metal ions are preferred. Separate or simultaneous enzyme pretreatment with commercial amylases may be used in the saccharification of the starch-based substrate (22, 25). The pH is maintained at about 5.5 (usually with CaCO_3) and temperature at 28 to 30°C for 7 to 10 days. Nutrients are often supplied to enrich the fermentation medium. Aeration is optimized in accordance with strain requirements, culture conditions, and the ratio of surface area to volume. Citric acid yields are generally lower than those obtained by LPF owing to difficulties in controlling process parameters and the presence of trace metals, which interfere with citric acid production. Yields of 60% of the theoretical are common; however, some reported yields reach the neighborhood of 80 to 85% of the weight of the initial carbohydrate with up to 90% recovery efficiency (85). A variety of additives and stimulants such as alcohols, metabolic inhibitors, trace elements, and ferrocyanide have been employed to improve citric acid yield (24, 25, 85). Recent attention has focused on SPF for citric acid with

A. niger using inexpensive raw materials and agroresidues, diverse food-processing wastes, and inert polymeric support systems (42, 111, 117). SPF for citric acid in flasks and bioreactors has been compared (147), with a focus on production and respiration rate (117). These optimization studies reported that strain selection was an important factor in achieving high citric acid yields, and that strains with high requirements for nitrogen and phosphorus were disfavored in SPF, while strains with low requirements were favored.

The production of citric acid, lactic acid, fumaric acid, gallic acid, and other organic acids by SPF has been reviewed elsewhere (24, 25, 40, 85, 91, 110, 111).

9.2.3.2. Ethanol

Justifications for bioethanol production by SPF have been proposed, and advantages claimed are diminished requirements for extraction and purification of carbon sources, reduced water demand and fermentor capacity, and lowered capital expenses for distillation and energy. However, most reported SPF processes are small-scale and many are still in the experimental stage. All remain linked to petroleum prices, labor costs, and other economic factors. As an alternative to LPF, SPF with yeast has been investigated using plant crops favoring substrates such as corn, beets, sweet sorghum, cassava, and other tubers, in addition to starchy substances such as cereal flours, cereal starches, and potato starch (131, 138). Also, solid wastes and biomass, such as fruit pomace, cassava bagasse, sugarcane bagasse, and other food-processing and agricultural by-products (40); wood residues, such as forestry, paper-mill, and wood-product manufacturing by-products; or even municipal solid waste, each offer unique economic advantages as substrates for SPF. Cellulase technology, perhaps with enzyme produced by SPF (35), will be an important component of any future biomass-to-ethanol process.

9.2.3.3. Natural Products

Natural products have extended the human life span by improving health and nutrition, and have advanced agriculture and animal health, with a major impact on the well-being and economics of society (46, 47, 52, 101). For these reasons, microbial secondary metabolites continue to attract the attention of applied microbiologists long after the end of one era, the Golden Age of Antibiotics (15, 48), and now well into another, the *new* era of natural products. Current natural products research blends more disciplines with modern biotechnology and also adds high-throughput screening for novel therapeutic targets and bioapplications (51, 60). An important additional discipline in natural products research involves SPF and innovative approaches for growing microorganisms.

9.2.3.3.1. Microbial Secondary Metabolites and SPF

The wealth of biodiversity in the microbial world is matched by its associated chemodiversity, and this remarkable variety is a driving force in natural products research. The value of microbial secondary metabolites for pharmaceutical discovery (46, 48, 49, 52, 101, 116) has inspired bioprospectors to investigate new species, unexplored environments, new culturing methods, and novel approaches such as metagenomics.

SPF is a valuable tool in the quest for new bioactive compounds (Table 1) (110) and offers technologies for scaled-up production (10–12, 29, 38, 76, 110, 125, 145). The mycelial state associated with SPF is well suited

TABLE 1 Production of bioactive natural products by SPF^a

Compound	Source	Substrate	Function
Aflatoxin	<i>A. oryzae</i> , <i>Aspergillus parasiticus</i>	Wheat, oats, rice, maize, peanuts	Mycotoxin
Ochratoxin	<i>Aspergillus ochraceus</i> , <i>Aspergillus carbonarius</i> , <i>Penicillium viridicatum</i>	Wheat, rice, corn, corn kernels	Mycotoxin
Bacterial endotoxins	<i>Bacillus thuringiensis</i>	Coconut waste	Insecticide
Gibberellic acid	<i>G. fujikuroi</i> , <i>Fusarium moniliforme</i>	Wheat bran, corncob, cassava flour, sugarcane bagasse ^b	Plant growth hormone
Zearalenone	<i>F. moniliforme</i>	Corn	Growth promoter
Ergot alkaloids	<i>Claviceps purpurea</i> , <i>C. fusiformis</i>	Sugarcane bagasse ^b	Disease treatment
Penicillin	<i>P. chrysogenum</i>	Sugarcane bagasse ^b	Antibiotic
Cephalosporin	<i>Cephalosporium acremonium</i>	Barley	Antibiotic
Cephameycin C	<i>Streptomyces clavuligerus</i>	Wheat rawa with cottonseed cake and sunflower cake	Antibiotic
Tetracycline, chlortetracycline	<i>Streptomyces viridifaciens</i>	Sweet potato residue	Antibiotic
Oxytetracycline	<i>Streptomyces rimosus</i>	Corn cob	Antibiotic
Iturin	<i>Bacillus subtilis</i>	Okara, wheat bran	Antibiotic
Actinorhodin, methylenomycin	<i>Streptomyces coelicolor</i>	Agar medium ^b	Antibiotic
Surfactin	<i>B. subtilis</i>	Soybean residue, okara	Antibiotic
Monorden	<i>Humicola fuscoatra</i>	Agar medium ^b	Antibiotic
Cyclosporine	<i>Tolypocladium inflatum</i>	Wheat bran	Immunosuppressive drug
Ustiloxins	<i>Ustilagoidea vires</i>	Rice panicles	Antimitotic cyclic peptide
Antifungal volatiles	<i>B. subtilis</i>	Impregnated loam-based compost	Antifungal compounds
Destruixins A and B	<i>M. anisopliae</i>	Rice, rice bran, rice husk	Cyclodepsipeptides
Clavulanic acid	<i>S. clavuligerus</i>	Wheat rawa with soy flour and sunflower cake	β -Lactamase inhibitor, antibacterial
Mycophenolic acid	<i>Penicillium brevicompactum</i>	Wheat bran

^bAs inert solid support.

for growth and production of such metabolites. SPF can elevate the yield of desired metabolites or facilitate the discovery of new ones undetectable after LPF (12, 26). The range of SPF applications is broad. Antibiotic production with fungi under such conditions has frequently been associated with higher yields compared to LPF methods (11, 12, 38, 125). SPF even overcomes current limitations in microbial flavor production, as well as widening the spectrum of metabolites useful for food technology (59). SPF has been successfully applied to the production of gibberellic acid with *Gibberella fujikuroi*, a source of this potent plant growth stimulant widely used in agriculture (145). A superior yield of 250 mg gibberellin/kg dry solid medium was obtained after SPF. Parallel observations with *Claviceps fusiformis* have reported enhanced yields (three to nine times higher) of ergot alkaloids, and production of a broader range of compounds of this class (146). SPF has been proposed as an effective means of cephalosporin (76) and cephameycin C (30) production with actinomycetes. Figure 2 compares lovastatin production by *Aspergillus terreus* under conditions of LPF and SPF with a polyurethane foam support. Superior productivity under SPF conditions was correlated with more intense transcription of lovastatin biosynthetic genes (13).

9.2.3.3.2. Microbial Secondary Metabolites and New Approaches—MPF

Innovative fermentation methods and medium formulations complement bioprospecting for natural products and offer new approaches for screening programs (29, 78). Variations of SPF and LPF can enhance the value of known and less-studied microorganisms as sources of new natural products. MPF, one such alternative approach, bridges LPF and SPF by employing inert solid supports in abundant liquid, and facilitates the discovery of new natural products from actinomycetes (27) and fungi (26, 28). Moreover, these approaches take advantage of increased surface area, promoting the diffusion of nutrients, metabolites, and gases—and thereby microbial growth. Solid support systems used in such new ways exploit the tendency of some microorganisms to adhere to solid surfaces, possibly simulating natural habitats. These environmental stimuli can affect differentiation and developmental programs that are linked to secondary metabolism in fungi and actinomycetes (32, 37, 50, 60). Some growth and metabolic responses may be linked to the microarchitecture of the support or substrate, initial steps involved in plant infection or pathogenesis, or responses to native environments that resemble soils or decaying plant matter.

FIGURE 2 Time course of lovastatin production by *A. terreus* in SPF (A) and LPF (B). Note the different scales in lovastatin concentration. pH evolution is shown in the upper part. (Adapted from reference 13.)

Three versions of MPF serve as examples of this fermentation approach: (i) stationary supports on agar surfaces, (ii) shaken supports in abundant liquid medium, and (iii) milled cereal grains or processed solid substrates dispersed on polyester cellulose carrying abundant liquid with or without dissolved nutrient supplements. Bigelis et al. (26) have used MPF with various inert polymeric substances (polyurethane foam, polypropylene, polypropylene cellulose, polyester cellulose) to facilitate the discovery of antimicrobial compounds from fungi (26) and to enhance the production of secondary metabolites (27, 28). In their reports, parallel studies with LPF revealed low or undetectable levels of these secondary metabolites. The MPF method generated low levels of unwanted compounds and medium components (after removal of biomass attached to the polyester cellulose support) in final extracts, and simplified harvesting, extraction, and purification.

A second approach with discs, cylinders, pulps, or other configurations has utilized solid supports in agitated liquid and revealed similar advantages (26, 28). Concentrated extracts of different fungi or actinomycetes grown by MPF in agitated flasks showed greater secondary-metabolite yield or diversity after liquid chromatography-mass spectrometry analysis than did conventional LPF extracts, thus identifying more candidate cultures for further screening. In addition, most fungi and many actinomycetes that were examined were immobilized and exhibited growth morphologies that differed from those observed after conventional LPF (26, 28). These distinctive growth patterns were possibly linked to group behavior, a sociomicrobiology trait (115) of mycelial aggregates firmly attached to each other and to the solid support, and to modified differentiation patterns (37, 50, 60). The ecological role of secondary metabolites in such aggregates may be related to cell-cell microbial communication, a proposed function that has been reviewed by Davies (44), Demain (45), Demain and Fang (50), and Yim et al. (157) and also discussed by Parsek and Greenberg (115) from the perspective of biofilm formation. Cell density-dependent regulatory networks in microorganisms control processes related to cell-cell interactions and may play a role in growth and metabolic pathways that influence secondary metabolism during SPF or MPF (73).

A third MPF approach has been applied to natural product screening programs with fungi in stationary flasks. It utilized coarsely milled cereal grains dispersed on cut strips of polyester cellulose saturated with water or media (28). A Schnitzer Grano 200™ electric grain mill performs the milling function very well. Liquid may be in excess or even be replenished during the fermentation. MPF with milled/dispersed cereal grains was superior to conventional SPF performed with whole cereal grains (28). The absorbent, porous solid support greatly increased accessible surface area (when combined with dispersed milled substrate), water availability and retention, nutrient and metabolite diffusion, as well as exposure to the gaseous phase in interstitial spaces. Fungal differentiation and exposure of substrate to mycelial infiltration were pronounced, and differed from growth patterns observed with compacted, unmilled, and nondispersed moistened grain. Typically, growth and secondary-metabolite yields were enhanced, residual unused solid substrate was significantly reduced, and carryover of unwanted substrate constituents into the final extract was diminished, benefiting high-performance liquid chromatography analysis and purification. Table 2 compiles formulations for conventional SPF fungal media and MPF versions that incorporate substrates dispersed on absorbent polyester cellulose (or other polymeric support). Other media useful for SPF and MPF have been compiled by Atlas (9).

9.2.4. Food Fermentations

Fermented foods are products of SPF that have been influenced by microbial action to produce desired biochemical changes (16, 18, 33). Such favorable modifications with edible fungi and bacteria may make the food material more nutritious and health-beneficial, increase digestibility and processibility, enhance flavor and other sensory aspects, modify physical characteristics, and even improve safety. Food fermentation is a cost-effective means of preservation that can prolong product life and reduce the dependence on refrigeration, food additives, specialized packaging or processing, or other energy-intensive food technological methods. SPFs with foods vary based on geography and dietary customs, but most often are classified according to substrate such

TABLE 2 Medium formulations for small-scale fermentation with solid-substrate system in 2.8-liter Fernbach flasks^a

Medium	Solid substrate (g/flask)	Liquid supplement ^b (ml/flask)	Support system ^c (g/flask: size of p-c supports)	Water ^d (ml/flask)
SPF corn (cracked)	81	90, 0.1% yeast extract	None	None
SPF rice (white)	102	90, 0.1% yeast extract	None	None
SPF alfalfa (dried)	27	65, 0.1% yeast extract	None	None
SPF milled Fiber One™ food	61	90, 0.1% yeast extract	None	None
MPF coarsely milled corn	81	90, 0.1% yeast extract	15 g (8 × 60 mm) p-c	75
MPF coarsely milled white rice	102	90, 0.1% yeast extract	15 g (8 × 60 mm) p-c	75
MPF homogenized alfalfa	27	90, 0.1% yeast extract	15 g (8 × 60 mm) p-c	75
MPF milled Fiber One™	61	90, 0.1% yeast extract	15 g (8 × 60 mm) p-c	75
Vermiculite	None	70, Czapek-Dox medium	21 g vermiculite	None

^aFor 250-ml flasks divide additions by 7. SPF inoculation: 20 ml of seed broth per flask distributed on substrate surface. MPF inoculation: 20 ml of seed broth per flask dispersed on substrate and support by manual shaking of flask culture; periodic manual shaking may accelerate growth.

^bLiquid medium supplement added aseptically after sterilization.

^cp-c, cut polyester-cellulose, KenAG milk-filter (KenAG Animal Care Group, Ashland, OH), dispersal system for milled grain.

^dTo promote adhesion of solids to p-c support, water is added to the support first before addition of processed solid substrate. Solids are dispersed on p-c by manual shaking of the flask, and then the medium is sterilized.

as cereal, dairy, fish, fruit and vegetable, meat, starch crop, and legume products. Mixtures of fermentation substrates and cofermentations with more than one microorganism are common. Fermented beverage production may involve SPF in whole or in part to produce beers (and lagers, ales, and malts), wines, spirits, liqueurs, and nonalcoholic beverages such as coffee, cocoa, and tea (16, 33). Fermented foods continue to provide consumers throughout the world with a significant portion of their nutritional needs, as they have over centuries. Mushroom biotechnology as a large-scale microbial technology has been reviewed elsewhere (154), along with composting processes for substrate production (71, 88).

9.2.5. Biocontrol Agents

SPF is used for inoculum production in processes yielding alternative biocontrol agents against fungal diseases that constrain crop production. The mass production of fungal spores is key to the manufacture of such agents, and SPF offers advantages for their production. De Vrije et al. (55) have discussed the relevance of SPF to the production of commercial products containing *F. oxysporum* (nonpathogenic), *Gliocladium catenulatum*, *Phlebiopsis gigantea*, and the *Trichoderma* spp. *T. harzianum*, *T. polysporum*, and *T. viride*, as well as that for the promising biocontrol agent *Coniothyrium minitans*. Other fungal biocontrol agents used in crop protection, such as *Beauveria bassiana* and *Metarhizium anisopliae*, can be readily produced as either aerial conidia or mycelia and blastospores. SPF allows production of aerial conidia, which are similar to those produced naturally on the surface of insect cadavers and superior to those produced by LPF.

9.3. PROCESS CONTROL

Key SPF process variables are related to the microorganism and its preparation, the choice of substrate and its pretreatment, and environmental factors which determine how the microorganism and the substrate interact, often in a large-scale bioreactor (80, 97). Successful process control depends on model-based strategies descriptive of mass and thermal transfer processes (43, 93, 131).

9.3.1. Preparation of the Organism and Inoculation

Inoculation protocols take into account the organism and its cellular state (spores or vegetative cells), medium choice,

density of the inoculum and its mode of application, and the nature and state of the substrate (temperature, pH, a_w , sterility, mixability). Compared to vegetative mycelia, spores are often preferred since they offer convenience; viability and storage advantages; and ease of quantitation, manipulation, and transfer, often by spray inoculation (83). They also provide multiple growth centers. Despite their hardiness, spores may display lag times as they grow out of dormancy, and require larger inocula and growth conditions quite different from those for vegetative growth.

Unlike LPF, where sterility is often required, pure culture techniques may be unnecessary in SPF, especially if the process organism is able to outcompete the contaminating organisms. While cleanliness is essential, aseptic operation may not be necessary and that may lower the cost (110).

9.3.2. Preparation of Materials

SPF substrates and starting materials may be pretreated before inoculation, when necessary, to facilitate mycelial penetration, and even conditioned to promote mixing, moistening, aeration, or diffusion of gases and nutrients. Dehulled rice, a common substrate for the koji process, for example, may be polished to remove up to 40 to 70% of its weight, and then steamed, raising its water content by 10 to 15% by weight (131). Steam pretreatment is used to sterilize or pasteurize the substrate. Steam may also enhance susceptibility of the substrate to degradation by carbohydrases (22). In addition to steaming or cooking, substrates such as cereal grains may be crushed, cracked, milled, powdered, or blended to meet the requirements of the SPF—or even roasted to enrich for flavor compounds in food fermentations.

Inexpensive raw agro-industrial wastes may be chopped or ground to decrease size and increase substrate exposure; cleansed and/or sanitized; cooked or steamed; partially degraded via additional combinations of physical, chemical, and/or enzymatic pretreatments; and enriched with nutrient supplements to promote microbial growth (120). The inclusion of an inert support in the substrate bed may aid in the retention of favorable physical and spatial characteristics during microbial action on its constituents, and improve the management of heat and mass transfer during the course of the SPF (104). The use of inert supports may also have processing advantages during product recovery (92, 104, 152).

9.3.3. Temperature, pH, and Moisture Control

The temperature optima for product formation and stability during SPF may differ from culture conditions most suitable for common fungi and bacteria, which typically grow within the range of 20 to 55°C. Some SPF substrates, especially starchy or lignocellulosic solid substrates, may not accommodate these optima owing to poor thermal conductivity and low water content. For example, heat buildup as a result of microbial metabolism can reach high levels, even as high as 80°C in a composting environment (71, 88), with thermal gradients extending vertically and horizontally. Thus, monitoring and control of temperature and humidity are essential to avoid drying of the medium, diminished a_w , and an associated reduction in nutrient availability (64, 69). Solutions to heat buildup focus on forced aeration, stirring, or evaporative cooling, although the last approach risks moisture loss and drying of solid materials. The temperature is generally measured in the solid layer, and is also monitored at entry and exit ports of a bioreactor. Thermosensors are usually spaced and inserted radially from the center of the fermentor. The sensors commonly employed are thermocouples, metallic probes, or thermistors. Thermistors offer the advantage of higher sensitivity and short response times, but may show lower long-term stability than metallic probes. Metallic probes, while simple and precise, may be more expensive and slower to respond. Thermocouples provide good fidelity, but drawbacks are associated with the measurement of relative temperature rather than absolute temperature via this technique. Various temperature-sensing techniques have been discussed by Bellon-Maurel et al. (14).

Control of pH is another essential aspect of SPF requiring management of excessive acidity (during accumulation of organic acids) or undesirable alkalinity (during protein hydrolysis). Owing to substrate nonhomogeneity, the lack of free water, and the limitations in pH electrode design, pH adjustment during SPF is generally inefficient. Thus, pH control is often accomplished by incorporating medium components (urea, ammonium salts, calcium salts) that introduce a buffering capacity without diminishing yield or productivity (87). The pH can also be managed by incorporating acids or bases in the cooling water added to the fermentation.

Water influences growth and metabolism during SPF, the activity of intracellular and extracellular enzymes, and transport processes such as the entry of nutrients, exit of metabolic products, and gas exchange. As a consequence of its central role, moisture levels must be carefully maintained. Fluctuations in water content during SPF occur as a result of evaporation caused by metabolic heat, and also via metabolic water production. Excessive moisture risks the development of impediments to gas transfer, particle agglomeration, and a reduced deterrence of bacterial contamination (via elevation of a_w). Inadequate water content (1, 34, 124) leads to suboptimal microbial growth and restricts metabolic activities, besides influencing the physical properties of the substrate bed. Moisture levels in a large-scale SPF bioreactor are often controlled by aeration with water-saturated air, while small-scale laboratory SPF may employ a culture chamber with saturated saline solution or spraying of sterilized cooled water. A model has been proposed (119) for diffusion of water in the substrate that takes into account the significant water retention of the fungal biomass layer (e.g., 2 kg/kg/dry substrate) and the shrinkage of the substrate matrix caused by the removal of water (99).

During SPF, water content is commonly assayed by measuring dry weight; however, this approach does not

discriminate between water content and a_w , which reflects water unavailable for microbial action. The most common online technique to measure a_w employs the capacitive sensor, a device with a slow response time often unable to respond to rapid changes in biological processes. Alternative approaches employ a system with a faster response time based on optical absorbance using a mirror that captures dew condensate. Bellon-Maurel et al. (14) have reviewed such techniques that measure a_w , together with online methods for controlling humidity and dew temperature, studying mass transfer limitations, and estimating the effect of humidity on productivity.

9.3.4. Monitoring of Microbial Growth

The mass of microbial cells is central to the control, characterization, and full evaluation of any fermentation process. The direct estimation of microbial biomass during SPF is prevented owing to its intimate association with the substrate, and with the solid support, if present, and the difficulty in separating these entangled fibrous or granular structures. Consequently, indirect measurements that assay cellular constituents are sometimes employed (53). However, the correlation of biomass with cellular components or activities can be inaccurate (53); i.e., the levels of biomolecules or activities can depend on the stage of fungal development or medium composition.

The quantitative determination of DNA, protein, total sugar, cell components like chitin or glucosamine, ergosterol, or ATP has provided an index of biomass levels, as have methods for other cell components (14, 53, 54, 89, 96, 131). Similarly, biological activities may be directly proportional to biomass, permitting its estimation by measurement, for example, of hydrolytic enzymes, nutrient consumption, reactivity to specific antibodies, or respiratory rates (14). The last-named method is commonly employed to analyze fermentor off-gases via respirometry and is used to measure microbial growth (106, 150).

The determination of CER (CO_2 evolution rate in g CO_2/g solid/h) via infrared spectroscopy permits estimation of cumulative cell concentration, which is accurate at high growth rates typical at the beginning of a fermentation. However, stationary-phase cells continue to produce CO_2 and may cause misleading biomass estimates by this method (120). Measurement of OUR (O_2 uptake rate in g O_2/g solid/h) also permits a convenient estimate of the biomass of aerobic microorganisms (14). Versatile online systems for monitoring of CO_2 and O_2 and control of gases during aerobic or anaerobic SPF have been developed. They have proved reliable for obtaining information on the physiological state and respiration rate of cultures in real-time processes, as well as providing estimates of specific growth rates for aerobic cultures (58, 133). New techniques have been proposed for biomass measurement that rely on image analysis, near-infrared spectroscopy, and Fourier transform infrared spectroscopy, but superior and more reliable online methods are still being sought (14, 68, 118).

General Procedure for SPF

1. *Culture*. Choose appropriate SPF microorganism, selecting a natural, mixed, or pure culture. Develop an archival culture storage plan. Define the seed preparation protocol and medium for generating dependable inocula. Evaluate the special needs of the organism, as well as its sensitivity to storage, handling, and mechanical forces of the SPF, aiming for culture stability and reproducibility.

2. **Safety.** Perform a safety evaluation and develop biohazard control for the SPF process and facility, complying with regulatory requirements and good laboratory practices.
3. **Pilot studies.** Perform preliminary studies with small-scale SPF to define the best conditions for growth, product formation, and eventual scale-up. Understand the growth kinetics in response to environmental variables, aiming for models that describe growth and production. Complete an economic assessment considering the cost of raw materials. Verify the stability of the product.
4. **Substrate, nutrients, solid support, and scale.** Choose a suitable solid substrate and nutrient formulation, and solid support if beneficial, based on medium studies. Confirm scalability. Understand the physicochemical characteristics of the medium, e.g., moisture content and retention, thermal conductivity, porosity, mixability, heat and mass transfer, and possible changes that may occur during the SPF, together with the micro and macro characteristics of the solid substrate.
5. **Pretreatment of solid substrate.** Review and evaluate pretreatment protocols for the solid substrate and its preparation, e.g., physical, chemical, or enzymatic processing; steaming or cooking; pasteurization; autoclaving; mixing with a support; and enrichment.
6. **Inoculation.** Initiate the SPF with a spore or mycelial preparation dispersed by spraying or mixing using a quantified inoculum of appropriate density to accelerate the fermentation.
7. **Fermentation and monitoring of parameters.** Perform the SPF under stationary or agitated growth conditions, with an appropriate bioreactor design that permits monitoring and process control of environmental factors on the desired scale. Manage moisture, a_w , temperature, aeration, O_2 , CO_2 , pH, mixing efficiency, and growth—and correlate with yield and productivity. Reduce the negative effect of by-products on yield, and enhance the value of potential coproducts.
8. **Processing and recovery of product.** Define product specifications and purity requirements, and execute the recovery plan with processing steps that maximize efficiency and yield, recovering/recycling solvents and processing materials whenever possible.

Example: Small-scale pilot fermentation with cereal grain

Place 100 g of rice in a 2.8-liter Fernbach flask with an air-permeable cover. Add 90 ml of 0.1% yeast extract before (for cooking) or after autoclaving. Cool and then inoculate with 10 to 20 ml of liquid seed by dispersal on sterile substrate surface. Incubate stationary for 1 to 3 weeks at 22 to 28°C, or as suitable for product formation. Process after lyophilization or drying, or extract as is, to recover product. Perform larger-scale SPF and compare results.

9.4. BIOREACTORS/FERMENTORS

Bioreactors, or fermentors, have been used in small- and large-scale SPF to produce diverse metabolites and enzyme products, as well as applied to processes involving fermented food products, feeds, edible mushrooms, biofertilizers, biopesticides, and bioremediation (93, 96, 109, 118). While laboratory-scale SPF employs flasks, jars, roller bottles, columns, and petri dishes, common bioreactor/fermentor systems used for industrial scale-up are tray fermentors, packed-bed fermentors, rotary drum fermentors,

and fluidized-bed fermentors. Most of these systems are aerobic and often require aeration, either intermittent or continuous. A few SPF processes are anaerobic and require no agitation or aeration. Some SPF processes do not require bioreactors: spreading the substrate on the ground will suffice, as with some forms of silage fermentation and composting (71).

9.4.1. Tray Bioreactor

A tray bioreactor contains an unmixed substrate bed without forced aeration. Multiple trays may be stacked in a chamber with a controlled environment, where air is circulated around the array and temperature and relative humidity are regulated to maximize efficiency and production. An open top and perforated bottom promote maximum surface area for gas exchange. Sterile water can be sprayed to maintain moisture levels. Manual mixing can be used to promote microbial growth and cooling. This traditional SPF method employing flat stationary trays (often on mobile trolleys) requires the allotment of considerable work space and labor for large-scale production and is often designed for continuous operation (31, 80, 93, 131). Automated handling systems have been described and some have been applied to the production of rice koji for sake, shochu, and soy sauce (31, 131). The PlaFactor™ automated technology developed by Biocon (Bangalore, India) (141) is a contained modular system that incorporates sealed trays, mixing arms with blades, and superior temperature control, all with space and energy savings.

The tray design is very simple and has limitations. The uncovered tray is usually filled with substrate to a depth of about 5 to 15 cm. The bed height cannot be increased because this results in overheating; thus the only option for scale-up is an increase in the number of trays or the tray area. Heat and mass transfer limitations, as well as temperature gradients, restrict the application of this method and add to a list of disadvantages for tray bioreactors, which also includes contamination risk and inefficient substrate utilization (122). The tray system is suitable mainly for circumstances with low-volume needs, and regions where technology is unavailable and labor costs are low (152).

The tray bioreactor is of historical importance since it is based on the koji process (91), and it was introduced to the Western world in 1891 by J. Takamine to manufacture commercial enzymes with *A. oryzae* grown on wheat bran (“Taka-koji”) (143). This type of reactor system was scaled up to manufacture citric acid in the 20th century (85).

9.4.2. Packed-Bed Bioreactor

The packed-bed bioreactor usually consists of a static bed in a cylindrical column with forced aeration through the substrate, which rests on a perforated base plate (93, 96, 131). Alternate versions of this system adapt a forced aeration device inserted into the center of the bed for improved performance (97). Packed-bed bioreactors are hampered by the formation of axial gradients, owing to end-to-end aeration (7). Temperature gradients, which reduce bed porosity, have a more negative impact on performance than does uneven distribution of oxygen (64). Water-saturated air can alleviate some of the effects of temperature and successfully remove metabolic heat, but this approach also increases evaporation and drying, thereby restricting microbial growth. A jacket for water circulation may serve as an alternate means for temperature control. A specially designed bioreactor termed the Zymotis packed-bed reactor (127), configured to remove heat by radial conduction,

employs closely spaced internal heat-transfer plates and has achieved superior enzyme yields and productivities as a result of improved removal of metabolic heat (93–95). Bioreactors with intermittently stirred beds resemble packed-bed systems, but contain an agitator, and are favored for large-scale operations that tolerate mixing (42).

Packed-bed bioreactors have limitations besides temperature gradients. Pressure drop (0.1 to 0.5 cm water per cm bioreactor) is a characteristic of packed-bed bioreactors that limits performance by reducing airflow, as well as promoting channeling of airflow and cracking of the substrate bed along the wall of the reactor (93). Additional drawbacks involve nonuniform growth, bed caking, scale-up difficulties, problematic continuous operation, and difficulties in product recovery (42).

9.4.3. Rotary Drum Bioreactor

A rotary drum fermentor employs a complex operational system that rotates a drum horizontally (or nearly so), continuously or intermittently (96). Air is blown across the top of the substrate through the headspace, unlike packed-bed systems. The rotating drum design may incorporate dampers to vary airflow or internal lifters, paddles, or baffles to enhance mixing. A major disadvantage to this type of bioreactor is the low fill volume; the substrate bed is mixed poorly if filled beyond 30% capacity. Other issues are related to poor mixing (slumping flow), heat and mass transfer, shear in the substrate bed, and axial temperature gradients (139). While the rotary drum bioreactor was used to produce α -amylase early in the 19th century and penicillin in the mid-20th century, currently this bioreactor system is rarely used owing to difficult operation and complicated reactor construction (152).

9.4.4. Fluidized-Bed Bioreactor

Fluidized-bed bioreactors employ both continuous mixing and forced aeration (93, 97, 112, 152). Gas is vigorously directed upwards through a perforated base plate to fluidize substrate particles, working best with fine particles. A bottom mixer may be included to prevent substrate agglomeration by large, cohesive particles, which may be difficult to fluidize. A high flow rate of gas ensures good heat and mass transfer between substrate particles and the gas phase. The gas-solid fluidized system has attracted research in recent years focusing on yeast biomass and ethanol production (84, 136). Despite the advantages of good heat and mass transfer, more research is necessary using these types of bioreactors to overcome the disruption of microbial integrity and function caused by continuous-agitation systems with high shear forces. Moreover, productivity gains achieved with this type of fluidized bioreactor must offset high energy costs associated with continuous aeration and high air velocity essential for fluidization (93, 136).

9.5. PROSPECTS FOR THE FUTURE

While the industrial application of SPF has waned in the last 50 years, research focusing on this technology has been renewed in the new century, as productivity and cost advantages are confirmed. With the advent of innovative “green” applications relevant to agricultural/industrial products, wastes, and hazardous by-products, together with progress in bioreactor design and mathematical modeling of biological phenomena, these efforts can be expected to accelerate (49, 108–110, 135, 152). New “bioproducts” and “bioapplications” related to SPF, e.g., biopesticides, bioherbicides,

biocontrol agents, biofertilizers, and bioremediation, are already offering unique biological solutions, and new opportunities for this traditional yet modernized fermentation technology. SPF continues as a versatile microbial technology: the “bloom of the mold” retains its allure.

Bacterial Cultivation for Production of Proteins and Other Biological Products

JOSEPH SHILOACH AND URSULA RINAS

10

10.1. INTRODUCTION

Large numbers of biological products are currently being produced on an industrial scale from microorganisms such as filamentous fungi, yeast, and bacteria. These products can be divided into several groups: primary metabolites such as acetic acid, ethanol, and amino acids; secondary metabolites such as antibiotics; and recombinant products, especially proteins that are produced for pharmaceutical purposes and technical applications. In this chapter, we concentrate on the production of biological products from bacteria. Since the basic steps of the production processes of the various products mentioned above are similar, we describe one of these processes in detail to give the reader the necessary information. Based on this information, the reader will be able to design production processes for different types of products from various types of microorganisms. The process we describe in detail is the production of recombinant proteins from *Escherichia coli* (34, 36). This process includes the following steps: (i) preparation of the bacterial strain (not described in this chapter); (ii) determination of the growth and production parameters such as growth strategy, production strategy, medium composition, pH, and optimal concentration of dissolved oxygen (DO) and temperature (not described in this chapter); (iii) preparation of the growth vessels; (iv) preparation of the starter culture (inoculum); (v) bacterial growth and product formation; (vi) process termination and preparation for the protein recovery step; and (vii) protein recovery and purification (not described in this chapter).

10.2. RECOMBINANT PROTEIN PRODUCTION FROM *E. COLI*

10.2.1. General Process Description

Following the determination of the batch production size, the proper growth vessels are prepared: this includes the bioreactors used for growth of the starter culture (in some cases, the volume required is large and more than one transfer is needed) and for production. The preparation involves (i) making the culture medium for growth and production, (ii) electrode calibration and installation, (iii) assembly of hoses to transfer the culture from one growth vessel to another (in cases where there is no permanent pipe connection between the various growth vessels), and

(iv) sterilization of the bioreactor. In addition, there is the need to prepare and/or calibrate various follow-up instruments such as pH meter, spectrophotometer, conductivity meter, glucose analyzer, and microscope. The recombinant bacteria are removed from storage (working cell bank) and transferred to the starter culture shake flask or bioreactor containing the proper medium and are grown to the required density (which was determined when the process was developed). In some cases, cells are first transferred to an agar plate and a single colony is used to inoculate the starter culture; in other cases, freshly transformed cells are needed for inoculation of the starter culture. When the starter culture reaches its designated density, it is transferred to the production bioreactor and then the production process commences. In most cases, the production process involves two phases, i.e., a growth phase and a production phase. In the growth phase, the bacteria are grown to a high density by implementing a fed-batch growth procedure (see section 10.2.6.3). The second phase is associated with the production of the recombinant protein by inducing its biosynthesis. In some cases, the growth conditions after the induction are different from those before the induction. After the bacteria have synthesized the desired recombinant protein to the expected level, the culture is cooled down and the cells (if the product is accumulated in the cells) or the supernatant fluid (if the product is secreted into the outside medium) are collected and processed. The process flow is summarized in Fig. 1.

To give the reader a better feeling for the general process described above, we provide here details on the production process of recombinant *Pseudomonas aeruginosa* exotoxin A in *E. coli* (5), which has been adapted for routine production. For a batch production size of 50 liters, a bioreactor with 50 liters of medium is prepared and sterilized. One liter of starter culture is prepared by inoculating a 2.8-liter Fernbach flask containing 1 liter of medium with a frozen culture stock. After 12 h of growth at 37°C, the starter culture is transferred to the bioreactor and the bacteria are grown at 37°C at a 30% DO concentration and a pH of 6.8. When the culture's optical density reaches the value of 40 (measured at 600 nm), the inducer isopropyl- β -D-thiogalactopyranoside (IPTG) is added to a final concentration of 100 mmol liter⁻¹ and growth is continued for 30 to 60 min; the culture is then cooled down and the cells are collected and processed.

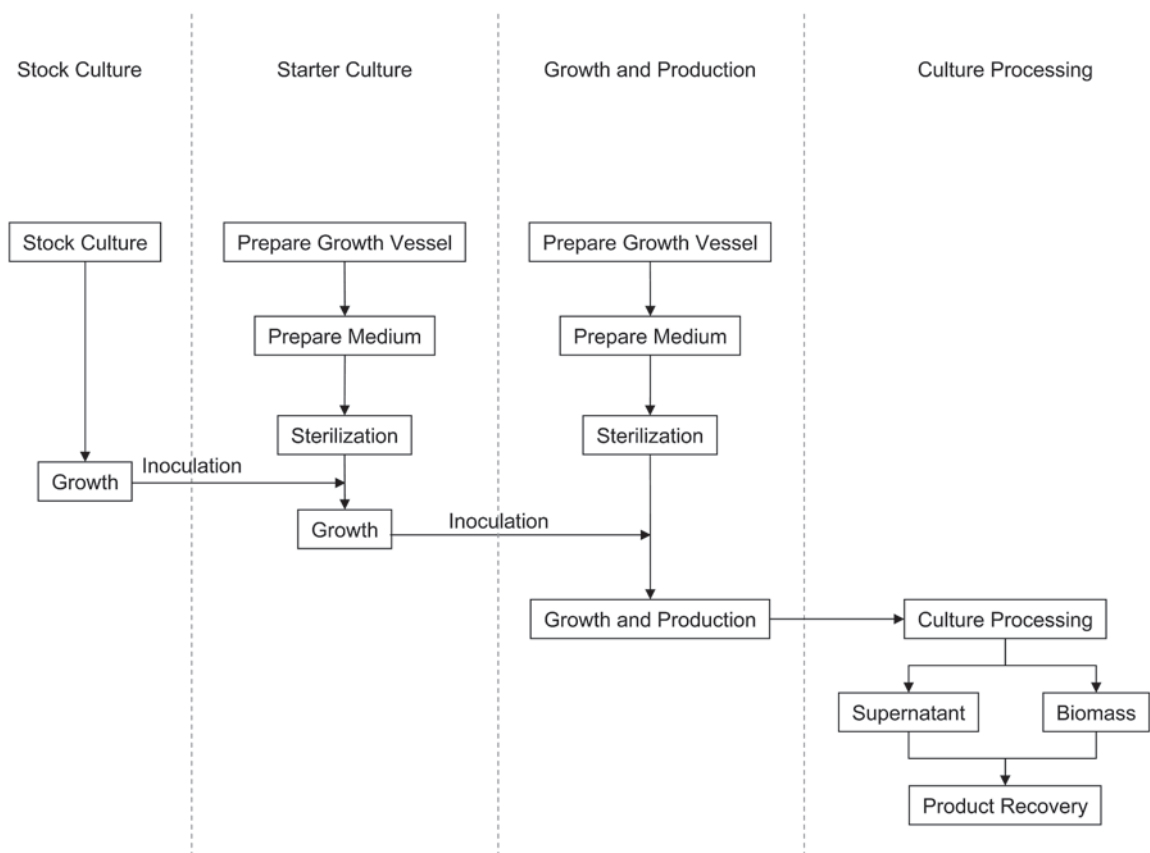

FIGURE 1 General layout of the bacterial cultivation process for production of proteins and other biological products.

10.2.2. Instrumentation and Infrastructure Required

To conduct a process of recombinant protein production with *E. coli*, the investigator needs to have access to the following instrumentation.

1. Cold storage equipment: a -80°C freezer to store the bacterial master and working cell banks; a -20°C freezer to store collected samples; a 4°C cold room; and 4°C refrigerators to store samples, medium, agar plates, etc.
2. Sterilization equipment: a steam-operated autoclave that can hold a benchtop stirred-tank bioreactor in a volume up to 10 liters.
3. Propagation equipment: incubators in the range of 20 to 45°C to grow the bacteria on agar plates; incubator shakers that can accommodate different sizes of shake flasks, from 50-ml Erlenmeyer flasks to 2.8-liter Fernbach flasks, which are needed for the initial growth of the culture from the plates; and stirred-tank bioreactors in various sizes to be used for both starter culture growth and protein production. Depending on their size, these bioreactors can be divided into two types: one group includes bioreactors up to 10 liters. These are called benchtop reactors and, in most cases, are sterilized in the autoclave. The other group includes bioreactors with higher volumes that are sterilized-in-place. In most cases, the bioreactors used for bacterial growth are stirred-tank reactors equipped with air inlet, air outlet, impellers, baffles, air sparger, and numerous inlets and outlets for removal of samples and medium and for adding various

solutions to the growing culture. These include nutrients and growth factors to support growth and production, acid or base for pH control, and antifoam for foam control. The bioreactor is also equipped with openings for installation of various probes, especially for pH and DO. A general scheme of the stirred-tank bioreactor can be seen in Fig. 2. To add various solutions to the bioreactor, it should also be equipped with variable-speed pumps, either sterilizable or outfitted with sterilizable tubing. The bioreactor is supported by instrumentation to measure and control agitation, airflow, temperature, pressure, pH, DO, and foam. In some cases, it can also include instruments to analyze the concentrations of CO_2 and O_2 in the off-gas. The measurements of all these variables are collected by a digital control unit that can also be used for process control based on the analysis of one or more process variables. The bioreactor is connected to a source of water, air, oxygen, and steam and also to a drain. Since during the process foam can be generated by the growing culture, the bioreactor should be equipped with a foam probe that detects the foam level and triggers the addition of antifoam solution (see section 10.2.4). Another instrument is a level probe that can detect the liquid level in the bioreactor. General information on bioreactor principles and operation can be found in several comprehensive books (3, 15, 32).

4. Analytical instrumentation: to control and follow bacterial growth and protein production, access is needed to the following analytical instruments: (i) optical microscope

FIGURE 2 General scheme of a stirred-tank bioreactor.

to check the condition of the bacterial culture; (ii) spectrophotometer for the measurement of bacterial density; (iii) pH meter; (iv) benchtop centrifuge to separate the bacterial mass from the supernatant fluid; and (v) additional instrumentation required for product measurements, such as gel electrophoresis, enzyme-linked immunosorbent assay apparatus, and in some cases, equipment to measure the composition of the off-gas (e.g., mass spectrometer).

5. Processing equipment: equipment is needed to separate the bacterial biomass from the medium. The separation can be done with a continuous centrifuge or a tangential flow device (4).

10.2.3. Seed Culture: Preparation and Storage

Following the research and development stage, a bacterial producer strain or strains are selected. These strains are usually stored frozen at -80°C or stored as freeze-dried samples (lyophilized). The currently accepted procedure is to grow the selected strains in their specified medium and to collect the cells at the mid-logarithmic phase. Once collected, the cells are prepared for storage. The cells (e.g., *E. coli*) are suspended in an equal volume of a special freezing medium with the following composition: 6.3 g K_2HPO_4 , 1.8 g KH_2PO_4 , 0.45 g sodium citrate, 0.09 g MgSO_4 , 0.9 g $(\text{NH}_4)_2\text{SO}_4$, 44 g glycerol, and 450 ml water. The suspended cells are divided into 0.5-ml aliquots in cryogenic tubes and stored in the -80°C freezer. Preparation of freeze-dried aliquots of other bacteria requires special equipment and is not described in this chapter. Detailed descriptions

of preservation methods for different bacteria can be found in *ATCC Preservation Methods* (30) and in *Maintenance of Microorganisms* (11). The aliquots prepared from the grown culture are kept as the master cell bank. An aliquot from the master cell bank is then used to prepare a working cell bank in the same way. When there is a need to start a production process, a sample from the working cell bank is taken out and used for inoculum preparation that later will be used for the production process.

10.2.4. General Information on Medium Composition, Preparation, and Sterilization

Chemotrophic bacteria need various chemical compounds designated as substrates for cell maintenance, cell growth, and production. Most bacteria used for the production of low- and high-molecular-weight organic compounds (e.g., acids, DNA, proteins) are chemoorganotrophic; thus, in addition to inorganic substrates, they also need organic substrates for cell maintenance, growth, and production. The substrates required by these bacteria can be grouped into two categories: (i) substrates that serve as an energy source and as a building unit to generate more cells or product, and (ii) substrates that only serve as building units for generating more cells and product, but their transformation by the bacterial cells does not generate energy.

Carbon substrates such as glucose, glycerol, and other compounds containing carbon atoms can be used by these bacteria for the generation of biomass and product and for

the generation of energy through substrate-level phosphorylation, and during complete oxidation using the respiratory pathway. Other substrates, such as salts containing nitrogen, phosphorus, and sulfur atoms, only serve as building units for generating more cells and/or product. For example, the elemental composition of *E. coli* grown on a defined medium is $\text{CH}_{1.85}\text{O}_{0.574}\text{N}_{0.22}$ plus 12% ash (10). This elemental composition does not vary significantly with the growth rate. In addition to these elements, cells need phosphorus for the formation of RNA and DNA, and sulfur for the formation of the amino acids methionine and cysteine. Other trace elements, such as metal ions, are required by various enzymes for their proper function. Some metal ions are required in high concentrations, such as iron needed for the heme-containing enzymes of the respiratory chain. Other trace metals are required in small amounts, such as copper, as there are few copper-containing enzymes. In some cases, bacteria have specific requirements for compounds that they cannot synthesize; these compounds must be added to the medium in order to allow cell growth. An example is the protein producer *E. coli* K-12 strain TG1, which is a thiamine auxotroph and therefore requires supplementation with thiamine when grown on a chemically defined medium (10, 12).

The composition of a defined medium that can support both small-scale (test tube or shake flask) and large-scale batch cultivations of *E. coli* is described in Table 1.

Preparation of the Medium

1. Dissolve KH_2PO_4 , $(\text{NH}_4)_2\text{HPO}_4$, and citric acid in ~800 ml of deionized water in a beaker.
2. Add trace element solutions.
3. Adjust the pH of this solution to 6.8 using 5 mol liter⁻¹ NaOH and fill it up to 900 ml using deionized water. Transfer to a 1-liter bottle.

4. Add MgSO_4 into a 50-ml bottle and fill up to 20 ml.
5. Add glucose into a 100-ml bottle and fill up to 80 ml.
6. Sterilize these three bottles in an autoclave for 30 min at 120°C.
7. Mix all three components under sterile conditions. You can store the sterile medium for approximately 4 weeks at room temperature.
8. Add the volume of medium you need to sterile flasks.
9. If necessary, add filter-sterilized thiamine (4.5 mg liter⁻¹) and antibiotics.

When this medium is used in larger-scale bioreactors, KH_2PO_4 , $(\text{NH}_4)_2\text{HPO}_4$, and citric acid are added directly to the bioreactor and heat-sterilized. The other solutions are prepared in concentrated form in separate containers. It is important to note that some compounds should be heat-sterilized separately. For example, magnesium and phosphate should not be heat-sterilized together as they will form a precipitate that will not dissolve again. Also, glucose should be heat-sterilized separately, as it forms brown Maillard products when heat-sterilized with other compounds, e.g., amino acids. Another group of medium components are heat-labile and therefore need to be filter-sterilized. Most antibiotics and compounds such as thiamine and IPTG, a common inducer used to initiate recombinant protein production, are not heat-sterilized and need to be filter-sterilized through a 0.22- μm -pore-size filter.

For growth of *E. coli* to high cell densities, it is important to supply the required substrates in such a way that their concentrations are below growth-inhibitory values in the bioreactor. For example, cells will not grow when the glucose concentration exceeds 50 g liter⁻¹, the phosphate concentration 10 g liter⁻¹, and the ammonium concentration 4 g liter⁻¹. On the other hand, magnesium phosphate has a very low solubility, and therefore for high-cell-density cultivations it is recommended to add the majority of

TABLE 1 Defined medium using glucose as carbon substrate^a

A. Components of medium			
Component	Concn (g liter ⁻¹)	In vol of H ₂ O	
Glucose·H ₂ O	12.00	80 ml	
MgSO ₄ ·7H ₂ O	1.20	20 ml	
KH ₂ PO ₄	13.30	900 ml	
(NH ₄) ₂ HPO ₄	4.00		
Citric acid·H ₂ O	1.70		
B. Trace elements			
Trace element	Concn (mg liter ⁻¹)	Concn in stock solution (mg ml ⁻¹)	Add vol (ml)
Fe(III)citrate	100.80	12.00	8.40
CoCl ₂ ·6H ₂ O	2.50	2.50	1.00
MnCl ₂ ·4H ₂ O	15.00	15.00	1.00

^aThis medium can be used to grow *E. coli* in test tubes, shake flasks, and batch bioreactor cultures.

TABLE 2 Defined medium to grow *E. coli* to high cell density using fed-batch culture technique or to grow *E. coli* in continuous culture

Medium components	Batch culture	Feeding solution, fed-batch culture	Feeding solution, continuous culture
Glucose·H ₂ O	27.5 g liter ⁻¹	875.0 g liter ⁻¹	11.0 g liter ⁻¹
KH ₂ PO ₄	13.3 g liter ⁻¹		2.7 g liter ⁻¹
(NH ₄) ₂ HPO ₄	4.0 g liter ⁻¹		0.8 g liter ⁻¹
(NH ₄) ₂ SO ₄			8.0 g liter ⁻¹
MgSO ₄ ·7H ₂ O	1.2 g liter ⁻¹	20.0 g liter ⁻¹	1.0 g liter ⁻¹
Citric acid·H ₂ O	1.7 g liter ⁻¹		0.35 g liter ⁻¹
Fe(III) citrate	100.8 mg liter ⁻¹	40.0 mg liter ⁻¹	12.0 mg liter ⁻¹
CoCl ₂ ·6H ₂ O	2.5 mg liter ⁻¹	4.0 mg liter ⁻¹	0.5 mg liter ⁻¹
MnCl ₂ ·4H ₂ O	15.0 mg liter ⁻¹	23.5 mg liter ⁻¹	3.0 mg liter ⁻¹
CuCl ₂ ·2H ₂ O	1.5 mg liter ⁻¹	2.3 mg liter ⁻¹	0.3 mg liter ⁻¹
H ₃ BO ₃	3.0 mg liter ⁻¹	4.7 mg liter ⁻¹	0.6 mg liter ⁻¹
Na ₂ MoO ₄ ·2H ₂ O	2.1 mg liter ⁻¹	4.0 mg liter ⁻¹	0.5 mg liter ⁻¹
Zn(CH ₃ COOH) ₂ ·2H ₂ O	33.8 mg liter ⁻¹	16.0 mg liter ⁻¹	1.6 mg liter ⁻¹
Titriplex III (EDTA)	14.1 mg liter ⁻¹	813.0 mg liter ⁻¹	1.7 mg liter ⁻¹

needed phosphate at the beginning of the cultivation and the needed magnesium continuously during the cultivation (12, 27). Nitrogen addition to high-cell-density cultures is done in a similar way, since adding all the required nitrogen at the beginning will inhibit growth. The nitrogen is added continuously to the growing culture as ammonium hydroxide in response to the change of the pH. An example of defined medium used for growing nonrecombinant *E. coli* to high cell densities of 128 g liter⁻¹ dry cell mass using glucose (12) and 165 g liter⁻¹ dry cell mass using glycerol as carbon source (23), and for production of recombinant proteins (1, 7, 27), is given in Table 2. This medium has also been successfully applied to produce 27.5 g liter⁻¹ amorpho-4,11-diene, a precursor of the antimalarial drug artemisinin, with a genetically engineered strain of *E. coli* in high-cell-density culture (37). The feeding solution of this medium can be adapted for usage in carbon-limited continuous culture experiments by decreasing the phosphor and increasing the nitrogen content (10).

10.2.5. Starter Culture Preparation

The starter culture (inoculum) preparation for the recombinant protein production process can be divided into the following steps. (i) Choose the proper growth vessel to accommodate production batch size. The starter culture volume is usually between 0.25 and 1% of the initial production volume. For starter culture volumes of up to 4 to 5 liters, shake flasks are sufficient, but for higher volumes, it is better to grow the starter culture in a bioreactor. (ii) Prepare the medium and the growth vessels; for details refer to section 10.2.6.1. (iii) Inoculation of the starter culture is usually done in two phases. In the first phase, an aliquot of the working cell bank is removed from the -80°C freezer and transferred to a small shake flask, containing usually between 50 and 100 ml of medium. In some cases, the first culture will be inoculated from a single colony of freshly transformed cells or from a single colony of a fresh agar plate generated from the working cell bank. In the second phase, this culture, when it reaches the desired density, is used to inoculate the starter culture vessel or vessels.

10.2.6. Growth and Production

10.2.6.1. Bioreactor Preparation

The bioreactor preparation process can be divided into the following steps. (i) Making sure that the bioreactor is clean, that it is equipped with an inlet and an outlet air filter in good shape, and that all the valves controlling the addition ports, the sampling ports, and the harvest port are working satisfactorily. (ii) Installing the *on-line* probes and calibrating them. In most cases, the only probes required are those for pH and DO. (iii) Medium preparation: the medium is usually composed of heat-stable and heat-sensitive reagents (see section 10.2.4). The heat-stable reagents can be sterilized directly in the bioreactor and the heat-sensitive reagents are filter-sterilized as concentrated solutions in a separate container that can be connected aseptically to the bioreactor. Sometimes, it is not possible to heat-sterilize certain reagents together, and there is a need to separately prepare concentrated solutions of those heat-stable ingredients and to heat-sterilize them in the autoclave in a separate container that can be aseptically connected to the bioreactor following the sterilization.

As indicated above, there are two types of bioreactors: those that are sterilized in the autoclave (not more than 10 liters in working volume) and those that are sterilized-in-place (above 10 liters). To sterilize the bioreactor in the autoclave, it is important to ensure that the air outlet is open and that all the inlet or outlet ports (which are submersed in the growth medium) are either plugged or connected to a port that is not submersed. The air inlet filter is usually sterilized separately and is hooked to the sparger port after sterilization. A 10-liter bioreactor should be sterilized for an hour. Following the sterilization, the bioreactor is placed next to its controlling instruments, the air source is connected to the inlet of the air filter, and the outlet of the air filter is connected to the sparger. The bioreactor is allowed to cool to the growth temperature and is ready for inoculation. When dealing with sterilized-in-place bioreactors, the sterilization process has several steps that are coordinated and monitored, in most cases, by a programmed controller. The following is a description of the process. (i) Agitation

is turned on, and the bioreactor is heated up by steam that flows into the bioreactor jacket. (ii) When the temperature reaches 100°C, the steam is allowed to go directly into the medium through the air inlet filter, sterilizing the air filter at this time and raising the medium temperature to 121.5°C. (iii) At this point, it is advisable to sterilize all the auxiliary ports. Each port is equipped with its own steam inlet and condensate outlet. The bioreactor is kept at this temperature for at least 20 min and is allowed to cool down to the growth temperature by circulating cold water through the bioreactor jacket. (iv) It is essential to confirm that when the medium temperature reaches below 100°C, air can flow into the bioreactor to compensate for pressure loss due to condensation. (v) When the vessel reaches the growth temperature, it is ready for inoculation.

Specific details of the recombinant *P. aeruginosa* exotoxin A production process adapted to routine production are based on procedures described before (5).

Preparation of a Bioreactor Containing a 50-Liter Working Volume

1. DO and pH electrodes are installed; the bioreactor is filled with 45 liters of distilled water containing 250 g of yeast extract (Difco), 500 g of tryptone (Difco), 250 g of NaCl, 250 g of K_2HPO_4 , and 5 ml of antifoam P-2000 (Fluka).
2. The bioreactor is then heat-sterilized. Three solutions are heat-sterilized separately: (i) 4 liters of 50% glucose solution in a 5-liter transferring bottle, (ii) a 500-ml solution of 123.24 g (1 mol) $MgSO_4 \cdot 7H_2O$ in a bottle, and (iii) 50 ml of trace element solution ($27.0 \text{ g liter}^{-1} FeCl_3 \cdot 6H_2O$, $2.0 \text{ g liter}^{-1} ZnCl_2 \cdot 4H_2O$, $2.0 \text{ g liter}^{-1} CoCl_2 \cdot 6H_2O$, $2.0 \text{ g liter}^{-1} Na_2MoO_4 \cdot 2H_2O$, $1.0 \text{ g liter}^{-1} CaCl_2 \cdot 2H_2O$, $1.0 \text{ g liter}^{-1} CuCl_2$, $0.5 \text{ g liter}^{-1} H_3BO_3$, $100 \text{ ml liter}^{-1}$ concentrated HCl). In addition, a 500-ml solution of 5 g ampicillin is filter-sterilized.
3. Following the sterilization of the bioreactor, the above solutions (glucose, $MgSO_4$, trace element solution, and ampicillin) are added into the bioreactor.

4. In addition, a solution of 50% ammonium hydroxide (approximately 2 liters) for pH control is prepared in an aspirator bottle equipped with silicone tubing suitable for peristaltic pumping and connected to the bioreactor. At this point, the bioreactor is ready for the inoculation.

10.2.6.2. Inoculation

The volume and density of the starter culture (inoculum) depend on the process development parameters and on the volume of the production bioreactor. In general, the starter culture should be in the middle of the logarithmic growth phase, and the volume can be somewhere between 0.25 and 1% of the initial production volume. After verifying that the starter culture is not contaminated (using a light microscope) and that it is in its proper growth phase, it is transferred aseptically to the production vessel. To ensure that the starter culture is not contaminated, it is advisable to streak an agar plate for later visual colony inspection. If the starter culture grew in another bioreactor, it is transferred directly from that bioreactor to the production bioreactor via a sterilized hose using a pump or by pressurizing the starter culture bioreactor. If the starter culture is grown in shake flasks, it is transferred first to a transfer container and from this container into the production bioreactor by either pressure or pump.

The details associated with recombinant *P. aeruginosa* exotoxin A production are as follows. (i) One liter inoculum is grown for 12 h at 37°C in the following medium: 5 g liter^{-1} yeast extract, 10 g liter^{-1} peptone, and 5 g liter^{-1} NaCl. (ii) After overnight growth, the pH and the optical density (OD) are analyzed, and if they are in the accepted limits, the culture is transferred to the bioreactor to start the growth and production process.

10.2.6.3. Growth Strategies

There are three major strategies to grow bacteria—batch, fed-batch, and continuous culture—shown schematically in Fig. 3. When cells are grown in a batch procedure, all nutrients are added at the beginning of the cultivation, and the cell growth and production process ends when the essential nutrients are depleted. The limiting essential nutrient, in

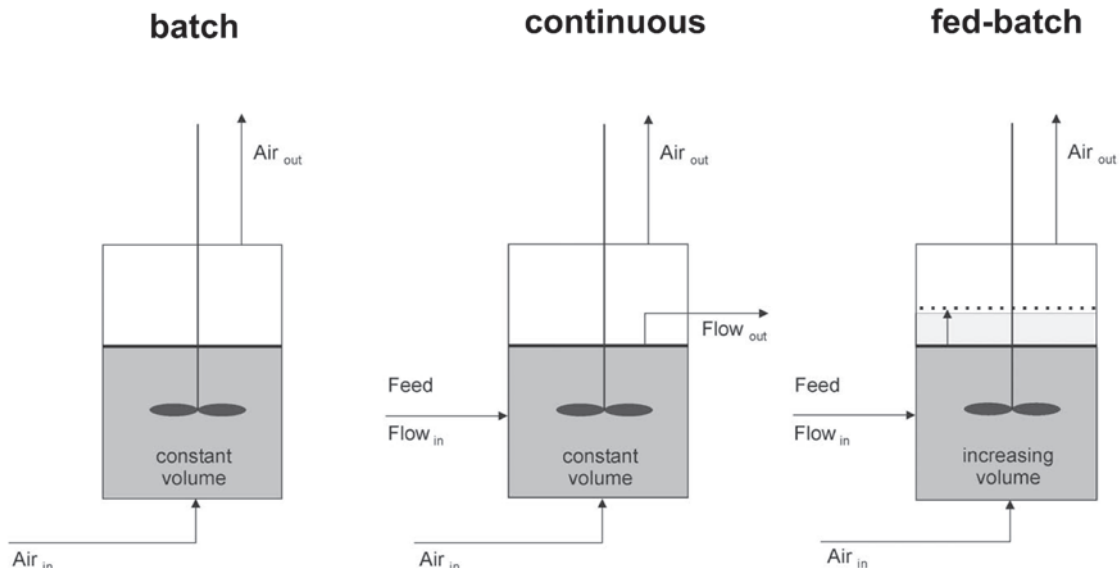

FIGURE 3 General scheme of cultivation strategies.

most cases, is the carbon source, and in the *E. coli* growth process it is usually glucose. Since most *E. coli* strains are sensitive to high glucose concentrations, the final cell density and the final product concentration are relatively low. *E. coli* strain B is exceptional in its capability to tolerate glucose concentrations as high as 40 g liter⁻¹ without excessive acetate formation and therefore can grow to a relatively high density and consequently produce a higher level of product while growing in a batch mode strategy (21). The batch culture technique is simple to implement and can be handled in laboratories that cannot accommodate sophisticated growth strategies. For recombinant protein production in batch culture, it is recommended to use either a complex medium, e.g., Luria broth (LB) or terrific broth, supplemented with either glucose or glycerol as an additional carbon substrate or a defined medium as described in section 10.2.4. With the defined medium described in section 10.2.4, cell densities of approximately 10 g liter⁻¹ dry cell mass (corresponding to an optical density of approximately 20 at 600 nm) can be obtained in batch culture for *E. coli* K-12 strain TG1 at 20 g liter⁻¹ glucose (12). The maximum protein concentration that can be reached is affected by the properties of the protein and the expression vector used for production.

In order to obtain higher productivities, fed-batch culture strategies are being used. In these growth strategies, one of the essential growth components, usually the carbon source, is added continuously to the growing culture. As stated above, in batch cultivations the final cell concentration is limited by the initial glucose concentration. However, high glucose concentrations usually cause acetate formation, which will decrease the biomass yield on glucose or even completely inhibit bacterial growth (28, 29). Fed-batch cultivation eliminates acetate formation by adding the glucose continuously into the bioreactor but keeping its concentration below a detectable level. When using this growth strategy, it is important that all other nutrients are in excess, so that the growth is controlled only by the available carbon source. To allow growth at a defined but restricted growth rate under carbon-limiting conditions, the glucose (or another carbon substrate such as glycerol) is added to the bioreactor as follows (12):

$$m_s(t) = F(t)S_F(t) = \left(\frac{\mu(t)}{Y_{X/S}} + m \right) V(t)X(t) \quad (1)$$

where m_s is the mass flow of substrate (g h⁻¹), F is the volumetric feeding rate (liters h⁻¹), S_F is the concentration of the substrate in the feeding solution (g liter⁻¹), μ is the specific growth rate (h⁻¹), $Y_{X/S}$ is the biomass/substrate yield coefficient (g g⁻¹), m is the specific maintenance coefficient (g g⁻¹ h⁻¹), X is the biomass concentration (g liter⁻¹), and V is the cultivation volume (liters). In a fed-batch system, the following growth equation applies:

$$\frac{d(XV)}{dt} = \mu XV \quad (2)$$

Assuming μ (growth rate) does not change with time, one obtains on integration of equation 2, when starting the feeding at time t_f :

$$X(t) V(t) = X_{t_f} V_{t_f} e^{\mu(t - t_f)} \quad (3)$$

Thus, by introducing equation 3 into equation 1, the substrate mass feeding rate for a constant specific growth rate (μ_{set}) follows as

$$m_s(t) = \left(\frac{\mu_{set}}{Y_{X/S}} + m \right) V_{t_f} X_{t_f} e^{\mu_{set}(t - t_f)} \quad (4)$$

To allow *E. coli* to grow to high cell densities, a growth rate must be chosen (μ_{set}) that does not lead to the formation of acetic acid. It is generally the case when the specific growth rate μ is below 0.15 h⁻¹. This feeding strategy allows exponential growth at a constant specific growth rate when the yield coefficient $Y_{X/S}$ and the maintenance coefficient m do not change with time. It implies that the same amount of biomass is generated per amount of carbon consumed and that the cells always use the same amount of carbon per biomass and time unit for maintaining vital cell functions. This exponential feeding strategy, called "predetermined feeding protocol," does not depend on the measurement of any growth variables. There is no need to continuously measure the bacterial concentration, the oxygen consumption, or the carbon dioxide production. It is only required to know the time for starting or changing the feeding, the culture volume and the biomass concentration at these time points, and the yield and maintenance coefficients, and to choose the desired growth rate (μ_{set}). As a rough assumption, a yield coefficient $Y_{X/S}$ of 0.5 and 0.45 for glucose and glycerol, respectively, and a maintenance coefficient of $m = 0.025$ g g⁻¹ h⁻¹ for both substrates can be considered. If a desired specific growth rate (μ_{set}) of 0.12 h⁻¹ is chosen, formation of acetic acid should not be observed. For temperature-induced production of recombinant proteins, the desired specific growth temperature should be reduced to 0.08 h⁻¹ after raising the temperature to 42°C (1, 25, 27).

Fed-batch cultivations are normally preceded by batch culture growth, and the fed-batch phase of the cultivation is started when the glucose of the batch phase is consumed. This can be followed by monitoring the DO concentration, which will sharply rise after all glucose has been consumed. It is possible to start the feeding according to equation 4 after this rise in the DO concentration. Another option is to wait until the acetate that accumulated in the batch phase has been consumed by the cells. This can also be followed by monitoring the DO concentration. After the sharp rise in the DO concentration as a result of glucose depletion, the bacteria will start to consume the accumulated acetate; this will be indicated by a slow decline of the DO concentration. When the DO concentration rises again, all acetate has been consumed by the cells and feeding can be started.

The fed-batch procedure described above is a simple feed-forward strategy allowing exponential growth at a constant specific growth rate as long as the carbon source yield and maintenance coefficients do not change with time, as assumed in equations 1 to 4. In cases when programmable pumps are not available, it is possible to manually adjust the carbon source feeding rate by stepwise increases in such a way that it follows a pseudoexponential increase as predetermined by that same equation.

Another, simpler fed-batch strategy involves linear feeding. In this case, the amount of glucose or any other carbon source added per unit time does not vary with the culture time. A drawback of this linear feeding strategy is that it leads to declining growth rates with the increase in biomass. In some cases, mixed fed-batch strategies are applied. First, an exponential feeding strategy is implemented to allow growth at a constant specific growth rate. The culture is grown in this way until the supply of DO reaches its limitation. At this point, the feeding is switched to linear feeding. Fed-batch cultivation strategies can also be based on the metabolic activities of the growing culture, such as oxygen consumption or pH changes. For example, the change in the DO concentration activates a pump that delivers the carbon source in such a way that a certain DO concentration is maintained (17).

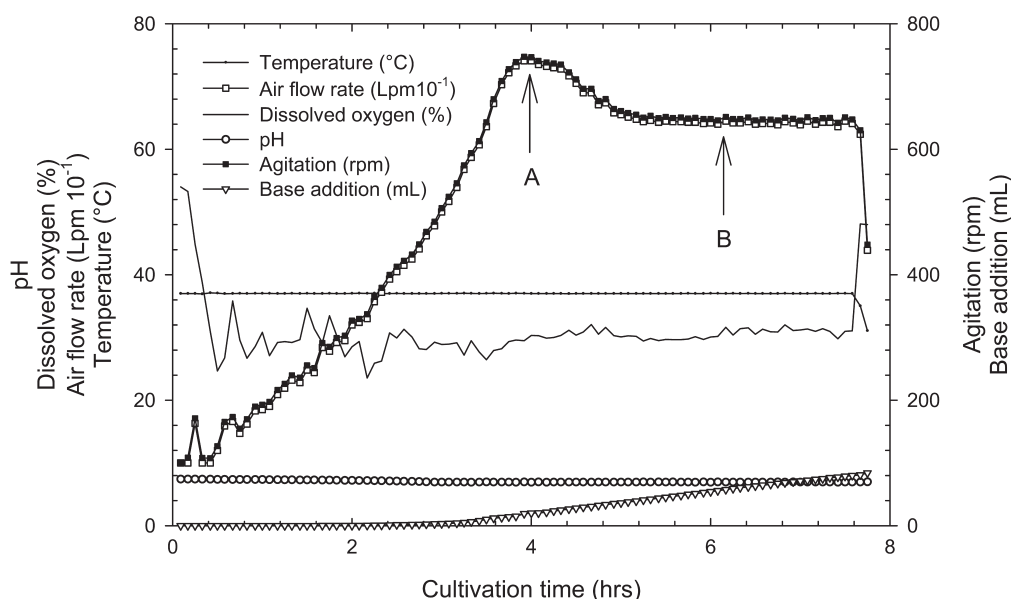

FIGURE 4 On-line data on batch cultivation process for production of recombinant exotoxin A from *E. coli* in 5-liter bioreactor. Arrow A indicates the point of introducing oxygen-enriched air to the culture; arrow B indicates the time when IPTG was added to the culture.

More-detailed discussions on the pros and cons of different fed-batch strategies can be found elsewhere (13, 22).

Fed-batch processes are the most common strategies in industrial settings. However, in some cases, continuous culture techniques are used. In continuous culture the carbon source is added to the growing culture at a certain rate, but unlike the fed-batch technique, where the culture volume increases with time, in the continuous culture the total volume of the culture is kept constant and the excess culture volume, containing cells and product, is collected at the same rate. Theoretically, the highest productivities are reachable in continuous cultures, provided the bacteria exhibit sufficient genetic and physiological stability (16). In most cases, high-producer strains designed by genetic engineering or traditional mutagenesis will lose their production capabilities in long-term continuous cultures.

10.2.6.4. Following Growth and Production

The growth and production process starts after the bioreactor has been inoculated with the starter culture. The follow-up of the process is done by monitoring both on-line and off-line data. The common on-line data are DO concentration, pH, agitation (revolutions per minute), airflow (liters per minute), temperature, bioreactor pressure, and the accumulative volume of acid or base added to keep the pH at its predetermined value. In some cases, other on-line data are monitored, such as the CO₂ and O₂ concentrations in the outlet air, and the turbidity. The DO concentration and the pH are important variables that have direct effects on the growth and production process and therefore must be continuously monitored and controlled. In most protein production processes by recombinant *E. coli*, the DO concentration is kept around 20 to 30% air saturation by varying the agitation, airflow, and pressure independently, sequentially, simultaneously, or based on a specific control strategy. The pH is controlled usually at around 7 by the addition of acid or base depending on the medium. In the case of an *E. coli* recombinant protein production process, the carbon source is usually glucose and the pH is controlled by the addition

of ammonium hydroxide, and seldom by the addition of sodium hydroxide. As was mentioned in section 10.2.1, this process has usually two phases: in the first phase the cells are grown to the desired density, and in the second phase the recombinant protein production is induced. An example of on-line variables during an *E. coli* protein production run is shown in Fig. 4. It is important to note that a specific control algorithm is implemented to keep the DO at 30% saturation by increasing the agitation and the airflow with time. In addition, base is added to keep the pH at a value of 7.

The off-line data are measured using a sample removed from the bioreactor through a special sampling port. These data include the bacterial concentration, concentrations of various substrates such as glucose or metabolites such as acetic acid, and the product concentration. Bacterial concentration is usually evaluated by measuring the turbidity of the culture using a spectrophotometer. This method provides quick information on the bacterial concentration when the medium is clear. If the medium is not clear, it is not possible to assess the bacterial concentration by turbidity measurement, and in such cases, the packed cell volume can be an alternative. Other methods, such as dry cell mass measurements and cell counting, are time-consuming and do not provide data in real time. Glucose concentration can be measured by high-pressure liquid chromatography or by a glucose analyzer based on the enzyme glucose oxidase. In most cases, the amount of the product cannot be determined during the production process itself due to the time required for analysis and therefore is done later on stored samples. An example of measuring off-line bacterial concentration by OD at 600 nm and glucose concentration by glucose analyzer (YSI Inc., Yellow Springs, OH) is shown in Fig. 5.

Additional details of the process for recombinant *P. aeruginosa* exotoxin A production are listed here. The following on-line variables are monitored during the process: DO concentration, pH, airflow, agitation, pressure, amount of base added, and temperature (Fig. 4). Throughout the process, the DO concentration is kept at 30% air saturation and

FIGURE 5 Off-line data on batch cultivation process for production of recombinant exotoxin A from *E. coli* in 5-liter bioreactor. The arrow indicates the time when IPTG was added to the culture.

is controlled by simultaneously increasing the agitation and the airflow. The pH is kept at 6.8 by adding 50% ammonium hydroxide solution automatically, and the amount of the base added is monitored continuously. The following variables are measured off-line: bacterial concentration is determined by the OD value at 600 nm and the glucose concentration is measured using the glucose analyzer made by YSI (Fig. 5). *E. coli* BL21, the strain used for the production, can tolerate glucose concentrations as high as 40 g liter⁻¹ (21); therefore, the cultivation is carried out as a batch process.

10.2.6.5. Bioprocess Calculations

Growth of most bacteria, including *E. coli*, occurs by cell division. Thus, during unlimited growth (as found in the batch phase when all nutrients are in excess), growth can be described as follows:

$$\frac{dX}{dt} = \mu X \quad (5)$$

or in the integrated form:

$$X = X_0 e^{\mu(t - t_0)} \quad (6)$$

where X is the biomass (g) at time t (h), X_0 the biomass at t_0 (usually the beginning of the cultivation; $t_0 = 0$ h), μ the specific growth rate (h⁻¹), and e the Euler number (2.718281828...).

The specific growth rate can be determined from measurements of the bacterial biomass (e.g., analysis of the optical density) at different time points as follows:

$$\mu = \frac{\ln X - \ln X_0}{t - t_0} \quad (7)$$

During carbon-limited fed-batch cultivation when no acids are produced, the growth of bacterial cells can also be determined on-line by following the ammonia consumption (26). Thus, when ammonia is used for pH control, it does not only serve as a base for pH control but also as a nitrogen source. In contrast to the biomass yield coefficient for carbon substrates such as glucose, $Y_{X/C_6H_{12}O_6}$, which is not

constant, the biomass yield coefficient for nitrogen, such as ammonia, Y_{X/NH_3} , is constant and is not affected by the metabolic status of the cells.

When Y_{X/NH_3} (g g⁻¹) and the concentration of ammonia in the feeding/base solution are constant, their absolute values are not required and the actual specific growth rate, μ , (h⁻¹), can be calculated from the time-dependent change of the natural logarithm of the dimensionless signal of the ammonia balance, M_{NH_3} (g g⁻¹), according to equation 8.

$$\mu = \frac{d \ln(M_{NH_3})}{dt} \quad (8)$$

The actual biomass in the bioreactor, X (g), can be calculated according to equation 9:

$$X = M_{NH_3} C_{NH_3} Y_{X/NH_3} \quad (9)$$

where M_{NH_3} (g) is the mass of the ammonia solution added into the bioreactor (g), C_{NH_3} is the concentration of ammonia in this solution (g g⁻¹), and Y_{X/NH_3} is the average biomass yield coefficient with respect to ammonia (7 g g⁻¹).

The volumetric oxygen and carbon dioxide transfer rates (OTR and CTR, respectively) (g liter⁻¹ h⁻¹) can be calculated from the mass balance of the gas phase as follows (10):

$$OTR = \frac{M_{O_2} F_G^{in}}{V(t) V_M} \left(x_{O_2}^{in}(t) - x_{O_2}^{out}(t) \frac{1 - x_{O_2}^{in}(t) - x_{CO_2}^{in}(t)}{1 - x_{O_2}^{out}(t) - x_{CO_2}^{out}(t)} \right) \quad (10)$$

and

$$CTR = \frac{M_{CO_2} F_G^{in}}{V(t) V_M} \left(x_{CO_2}^{out}(t) \frac{1 - x_{O_2}^{in}(t) - x_{CO_2}^{in}(t)}{1 - x_{O_2}^{out}(t) - x_{CO_2}^{out}(t)} - x_{CO_2}^{in}(t) \right) \quad (11)$$

where M_{O_2} and M_{CO_2} are the molecular mass of oxygen and carbon dioxide (g mol⁻¹), respectively; F_G^{in} is the volumetric inlet airflow (liters h⁻¹) at standard conditions; $V(t)$ is the working volume of the bioreactor (liters); V_M is the mol volume of the ideal gas (liters mol⁻¹) at standard conditions; $x_{O_2}^{in}$ and $x_{CO_2}^{in}$ are the molar fractions of oxygen

and carbon dioxide (mol mol^{-1}), respectively, in the inlet air; and $x_{\text{O}_2}^{\text{out}}(t)$ and $x_{\text{CO}_2}^{\text{out}}(t)$ are the molar fractions of oxygen and carbon dioxide (mol mol^{-1}), respectively, in the outlet air of the bioreactor. For calculation of specific rates, the convective flow of oxygen and carbon dioxide can be neglected and the transfer rates OTR and CTR can be considered to be identical to the oxygen uptake and carbon dioxide evolution rates. Specific rates can then be calculated by dividing volumetric rates by cell concentration.

10.2.6.6. Initial Product Recovery

Depending on the process and the product, the recombinant protein can accumulate inside the cells or can be secreted into the growth medium. When the product is secreted into the medium, the bacterial biomass is separated from the medium by either centrifugation or filtration and the protein is recovered from the supernatant. When the product accumulates in the cells, it is possible to recover the protein either from the biomass after its separation from the medium or, especially when the cell concentration is high, directly from the complete broth containing both the cells and the growth medium without further separation. Details on continuous-flow centrifuges and tangential filtration systems can be found in several books dealing with downstream processing and protein purification (4, 33).

For example, the following steps are required for the downstream processing of *P. aeruginosa* exotoxin A after termination of its production in the bioreactor. The protein is secreted into the periplasmic space, thus accumulating inside the cells. The initial downstream processing involves the separation of the cells from the medium, followed by lysis of the cells by osmotic shock, which releases the accumulated protein into the supernatant. The recovery and clarification of the supernatant and final purification of the protein are described in detail elsewhere (8).

10.3. OTHER PRODUCTS FROM *E. COLI*

Recombinant protein production from *E. coli* started in the late 1970s and early 1980s with insulin as the first recombinant protein product (9). In addition to recombinant proteins for biopharmaceutical use, *E. coli* is also used to produce other recombinant proteins such as enzymes for technical applications, polysaccharides and other biopolymers such as plasmid DNA, amino acids, and primary metabolites such as organic acids. The production principles and the overall procedures are similar to the recombinant protein production procedure as described in section 10.2. The differences are in the medium composition, the growth strategy, and production variables such as pH, DO concentration, temperature, cell density, and length of cultivation. Below are some examples of processes for production of biological products other than recombinant proteins. One is the production of the amino acid *L*-alanine by genetically engineered *E. coli*, the second is the conversion of ferulic acid to vanillin by recombinant *E. coli*, and the third is the production of polysialic acid by a selected *E. coli* K1 strain. Two more examples are associated with two new products: one is plasmid DNA and the other is a precursor of artemisinin, a promising antimalarial drug, which is being produced in a two-phase partitioning bioreactor, a novel approach for the biosynthesis of organic compounds.

- *Production of the amino acid L-alanine by metabolically engineered E. coli* (39). The modified *E. coli* strain is grown anaerobically on a defined medium of the following composition (14), in mmol liter^{-1} : 19.92 $(\text{NH}_4)_2\text{HPO}_4$,

7.56 $\text{NH}_4\text{H}_2\text{PO}_4$, 2.0 KCl, 1.5 $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, and 1.0 betaine·KCl. The following concentrations are in $\mu\text{mol liter}^{-1}$: 8.8 $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, 1.26 $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 0.88 $\text{CuCl}_2 \cdot \text{H}_2\text{O}$, 2.2 ZnCl_2 , 1.24 $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 1.21 H_3BO_3 , and 2.5 $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$. The trace metal stock solution (1,000 times concentrated) is prepared in 120 mmol liter^{-1} HCl. The concentration of the carbon source glucose is 120 g liter^{-1} . The growth is carried out at 37°C and the pH is maintained at 7 by automatic addition of 5 mol liter^{-1} NH_4OH . The product accumulates in the medium. The major differences between this process and the recombinant *P. aeruginosa* exotoxin A production process described above are the utilization of defined medium, the anaerobic growth, and the high concentration of glucose.

- *Production of vanillin*. Vanillin, an organic compound with the formula $\text{C}_8\text{H}_8\text{O}_3$, is a flavoring agent used in foods and beverages. The compound is produced by genetically engineered *E. coli* by conversion of ferulic acid (2). The process has two phases: in the first phase, the engineered *E. coli* strain is grown in a complex medium to generate the required biomass, and in the second step, the cells are collected and resuspended in a buffer containing ferulic acid. The suggested process is as follows. (i) The cells are grown in LB medium (10 g liter^{-1} tryptone, 5 g liter^{-1} yeast extract, and 5 g liter^{-1} NaCl), containing 25 mg liter^{-1} tetracycline, at 37°C in an aerated bioreactor. (ii) At the end of this growth phase, the cells are collected, washed, and resuspended at a concentration of 4 g liter^{-1} in M9 saline/phosphate buffer (4.2 mmol liter^{-1} Na_2HPO_4 , 2.2 mmol liter^{-1} KH_2PO_4 , 0.9 mmol liter^{-1} NaCl, and 1.9 mmol liter^{-1} NH_4Cl) containing 0.5 mg liter^{-1} yeast extract and 5 mmol liter^{-1} ferulic acid. (iii) The cells, now in a resting phase, convert the ferulic acid to vanillin. This way, 2.5 g liter^{-1} vanillin can be produced (2).
- *Production of long-chain polysialic acid*. Polysialic acid is a polymer that is being investigated as a potential additive to different biomedical applications such as tissue engineering. In the following example, the production process of this polymer from *E. coli* is described (24). In this process, the selected *E. coli* K1 strain is grown in a defined medium containing 1.2 g liter^{-1} NaCl, 1.1 g liter^{-1} K_2SO_4 , 13 mg liter^{-1} CaCl_2 , 0.15 g liter^{-1} $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 1 mg liter^{-1} $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 1 mg liter^{-1} $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 6.67 g liter^{-1} K_2HPO_4 , and 0.25 g liter^{-1} KH_2PO_4 . Additionally, the medium includes 13.3 g liter^{-1} glucose and 10 g liter^{-1} $(\text{NH}_4)_2\text{SO}_4$. The cells are grown aerobically (the DO is measured throughout the cultivation) at pH 7.5 and 37°C. The overall process lasts 25 h, the bacteria grow exponentially for 10 h, and the polysialic acid accumulates during the following 15 h. Following production, the cells are removed by continuous centrifugation and the polysialic acid is recovered from the supernatant fluid.
- *Production of plasmid DNA*. Plasmid DNA is produced by *E. coli* in a process similar to recombinant protein production. The plasmid DNA is amplified when the culture temperature is increased to 42°C. The cells are initially grown at 30°C to high cell density. After the completion of this growth phase, plasmid DNA production is commenced by increasing the temperature to 42°C for several more hours (20, 38).
- *Production of amorpho-4,11-diene*. This compound is a precursor of the new antimalarial drug artemisinin (6). This natural product is made in *E. coli* containing a heterologous nine-gene pathway (18). The production

procedure has two phases. In the first phase, the culture is grown in the medium containing 12 g liter⁻¹ tryptone, 24 g liter⁻¹ yeast extract, 14.9 g liter⁻¹ phosphate, and 10 g liter⁻¹ glycerol. The medium also contains three different antibiotics (ampicillin at 100 mg liter⁻¹, tetracycline at 5 mg liter⁻¹, and chloramphenicol at 25 mg liter⁻¹). During this phase, the DO level is kept around 30% air saturation and the pH at 7 by the addition of 10% NaOH. In the second phase, production of amorpha-4,11-diene is induced by adding 0.5 mmol liter⁻¹ IPTG. At 30 min following induction, 20% (vol/vol) dodecane is added. This represents a cultivation process called “two-phase partitioning bioreactor,” where the product accumulates in the organic phase and is recovered continuously by condensation (18). Growing the cells in the complex medium described above in a batch procedure to low cell density resulted in 0.5 g liter⁻¹ amorpha-4,11-diene (18). Further improvement of the strain, utilization of a defined growth medium, and the application of a carbon-limited fed-batch procedure increased the product concentration to 27 g liter⁻¹ (37).

10.4. PRODUCTS FROM BACTERIA OTHER THAN *E. COLI*

The list of biological products that can be produced from different bacteria is long. It includes enzymes such as amylases, proteases, and pectinases; metabolites such as amino acids, ethanol, and acetone; organic acids such as acetic, citric, lactic, and glutamic acids; and nucleotides, vitamins, antibiotics, insecticides, polysaccharides, vaccines, and bacterial biomass that is needed for processes such as biotransformation. The list of the producing bacteria is also long and includes genera such as *Bacillus* for enzymes and insecticide production, *Streptomyces* for antibiotics, *Corynebacterium* and *Brevibacterium* for amino acids, *Clostridium* for acetone and butanol, *Lactobacillus* for organic acids, and *Acetobacter* for polysaccharides. The production principles are similar to those described for recombinant protein production using genetically engineered *E. coli*. The differences are in the medium compositions and the growth and production variables. Following are three examples of production of biological products using different types of bacteria. The first two examples describe classical production processes using genetically unmodified bacteria: production of the antibiotic streptomycin by *Streptomyces griseus* and production of glutamic acid by *Corynebacterium glutamicum*. The third example is the description of succinic acid production by a novel, genetically engineered strain of *Mannheimia succiniciproducens*.

- *Production of the antibiotic streptomycin using S. griseus.* The streptomycete can be grown in a defined or complex medium. A typical complex medium composition is 1% glucose, 1% soybean meal, and 0.5% sodium chloride. The aerobic cultivation takes place at a temperature between 25 and 30°C and at a pH in the range of 7 to 8. The production process takes about 80 h and has two phases. The first phase is biomass production, and the second phase is streptomycin production. The process is terminated when there is no further increase in streptomycin production. Increasing the glucose concentration and adding ammonium sulfate prolong the production phase and increase the final concentration of streptomycin (31).

- *Glutamic acid production from C. glutamicum.* The aerobic production process can last 70 h, the pH is controlled at 7, and the growth temperature is in the range of 30 to 35°C. Typical medium composition is glucose 4.75%, calcium carbonate 1.25%, urea 0.07%, KH₂PO₄ 0.05%, MgSO₄ 0.01%, and ferric sulfate 8 ppm. It was found that maintaining a low biotin level increased glutamic acid production. Moreover, controlling the pH by feeding urea increased biomass and glutamic acid production (35).
- *Succinic acid production from M. succiniciproducens.* A genetically engineered strain of *M. succiniciproducens*, deficient in several catabolic genes leading to unwanted by-product formation, was employed for succinic acid production (19). The cultivation was carried out in a batch procedure using a semisynthetic medium containing (per liter) glucose 18 g, yeast extract 5 g, NaCl 1 g, K₂HPO₄ 8.708 g, CaCl₂·2H₂O 0.02 g, and MgCl₂·6H₂O 0.2 g. The cultivation is carried out at anaerobic conditions, leading to final concentrations of 15.5 g liter⁻¹ succinic acid, corresponding to a final product yield of 0.86 grams of succinic acid per gram of glucose. In this case, the agitation speed was identified as an important variable affecting the final product yield.

10.5. SUMMARY

Bacterial cultivation for production of proteins and other biological products is a broad topic. It is not possible to cover all the variations of these processes in this chapter since they depend on the microorganism on the one hand and on the products on the other hand. However, the general principles of the process, as outlined in Fig. 1, are similar for all the different processes. They involve the following phases: (i) preparation of the growth vessels both for the starter culture and the production culture, (ii) preparation of the growth and the production medium, (iii) sterilization of the medium and the growth vessels, (iv) preparation of the auxiliary equipment, and (v) performing the production process itself. A large amount of work has to be done on development and optimization of the production process before commercial production can be initiated. This includes optimization of the medium composition, growth conditions (such as temperature, pH, and oxygen saturation level), growth strategies (batch, fed-batch, or continuous), and the length of the process. Production of recombinant proteins from *E. coli* was chosen as an example and described in detail, but as was shown in section 10.2, the optimized parameters and methodologies are different for different processes. For example, in some cases the process is carried out anaerobically, and in other cases the process has two distinct phases where after the growth phase the bacteria are given the opportunity to produce the desired product from a specific precursor. Thus, when dealing with a specific production process, it is clearly advisable to consult the vast scientific literature related to a specific product.

Funding was provided by the intramural program at the NIDDK, NIH and HZI. We thank D. Livant for proofreading the manuscript.

Heterologous Protein Expression in Yeasts and Filamentous Fungi

NINGYAN ZHANG AND ZHIQIANG AN

11

11.1. INTRODUCTION

Development of recombinant DNA technologies in the late 1970s laid the foundation for the advancement of various heterologous protein expression systems, including those based on microbial platforms. In the early 1980s, *Escherichia coli* and *Saccharomyces cerevisiae* expression systems were developed and used for heterologous protein expression (47). Many comprehensive reviews of these two expression systems are available (12, 29, 41, 48, 60, 72, 74, 110, 134). Development of other microbial expression systems, such as the methylotrophic yeast *Pichia pastoris* (72) and filamentous fungi (74), followed quickly, and the broad utility of these systems is becoming increasingly apparent.

Heterologous protein expression technologies are widely used in both academic research and industrial applications. In basic research, heterologous gene expression serves as an important tool to prepare proteins and enzymes that are either at limited levels or difficult to purify in their native context. Heterologously expressed proteins and enzymes are used across the entire spectrum of biology. Many enzymes and proteins are of commercial importance, and therefore improved processes for large-scale production of industrial enzymes and proteins are of great interest. Since different enzymes and proteins possess different molecular and biochemical characteristics, different expression systems with specific features are required to meet the growing need for heterologous protein expression at the level of both basic and industrial research.

With the steady advancement in gene expression technology, such as new vectors for gene delivery, improvement in throughput of screening for strain selection, and genetically engineered hosts, production of recombinant proteins has become more efficient with broader applications. In addition, introduction of fusion tags such as hexa-histidine (6× His) and inducible promoters has allowed rapid detection and purification of recombinant proteins and increased expression titers. Since enzymes and proteins have diverse physical and biochemical properties, expression yields vary widely from microgram to low-milligram (37, 57) to multi-gram levels (62). Choosing a suitable expression system for a protein of interest is one of the most critical steps for the development of a high-expression process. Some advantages and drawbacks for commonly used heterologous protein expression systems are listed in

Table 1 (138). *E. coli* expression systems provide quick and easy molecular manipulation and, in general, require low-cost growth media. However, the protein expression in *E. coli* cannot be used if foreign proteins require transcriptional and/or posttranslational processing and modifications. By contrast, fungal protein expression systems including yeast and filamentous fungi can provide high expression levels and posttranscriptional and posttranslational processes and modifications of eukaryotic proteins. Similar to *E. coli* protein expression systems, fungal expression systems need low-cost culture media, the technologies needed for scale-up of fungal fermentation processes are well developed, and the organisms are Generally Regarded As Safe (GRAS) (24, 127). In contrast, insect and mammalian expression systems require special culture conditions and relatively high-cost culture media and often have lower expression titers.

When choosing a heterologous protein expression system, the following general criteria should be considered: (i) requirement of translational modification and processing of the protein; (ii) authenticity of the expressed proteins; (iii) protein expression level and scale-up requirement; (iv) localization, e.g., intracellular, membrane-bound, or secreted proteins; (v) cofactor requirement; and (vi) cost, safety, and other regulatory-related issues. Each protein expression system offers a unique set of properties, and for successful production of a heterologous protein, it is often required to tailor a process specifically based on the properties of the protein to be produced and the expression system used.

Many filamentous fungi and yeast species have been used for heterologous protein expression (32, 34, 53, 54, 89, 94, 101, 105, 110, 112, 132, 133). There are numerous reviews addressing foreign protein expressions in each of the fungal protein expression systems (14, 20, 21, 44, 63, 101, 107, 110). Most reviews are focused on one specific system. Furthermore, some address specific aspects of the expression system, such as protein secretion in *S. cerevisiae* (121) and glycosylation of proteins in *P. pastoris* (11). Significant progress has been made in recent years in the production of therapeutic proteins and antibodies using humanized yeast (40). This chapter covers the most commonly used fungal expression systems (*S. cerevisiae*, *P. pastoris*, and *Aspergillus* species), with a focus on vector systems, promoter and leader sequences, posttranslational modifications, and fermentation scalability.

TABLE 1 Pros and cons for some commonly used heterologous protein expression systems

Expression hosts	Pros	Cons
<i>E. coli</i>	Easy genetic manipulation, rapid growth, simple media requirements and low cost to grow, no human virus carried	Inclusion bodies, no secretion into media, lack of posttranslational process
<i>S. cerevisiae</i>	Low-cost culture and easy to grow, genetic regulation well known, secretion protein, no risk for human virus infection	Overglycosylation at N-linked sites, cell difficult to break, expression level limited
<i>P. pastoris</i>	High-level expression, low cost and easy to grow, genetic regulation well known, secretion protein, no risk for human virus infection	Royalties can be expensive, potential for overglycosylation, cell difficult to break
Filamentous fungi	High level of expression, good secretion system, some level of posttranslational modification, culture medium is inexpensive	No good commercial vectors are available, longer culture time, spores are concerns for health problems, not well documented for production of therapeutic proteins
Insect cells	Easy to grow up to 400 liters, easy to manipulate genetically for baculovirus, can grow in the same-style tanks as mammalian cells	Relatively low expression, serum-free medium is expensive, royalties for the commercially available systems can be costly, few contractors have current Good Manufacturing Practice experience
Mammalian cell lines	Authentic protein expression and proper posttranslational processing and assembly for therapeutic proteins and other mammalian proteins of interest, extensively used, reasonable expression level, endotoxin is not a concern	Medium is expensive, special tank, require CO ₂ , potential risk of human virus in culture, longer expression time

11.2. *S. CEREVISIAE* FOR HETEROLOGOUS PROTEIN EXPRESSION

S. cerevisiae, a unicellular yeast, is one of the most studied eukaryotic microorganisms. Its genetics, physiology, biochemistry, metabolism, and fermentation are well researched and a wealth of information is readily available. Thousands of genes from *S. cerevisiae* have been characterized (43) and its genome sequence has been determined (33). *S. cerevisiae* has been extensively used as a host for heterologous gene expression of eukaryotic proteins for research and industrial applications (44, 110).

S. cerevisiae is a GRAS organism and has been used for centuries in the brewing and baking industries. Similar to *E. coli*, *S. cerevisiae* requires simple culture media for growth and is easily scaled up for large-volume fermentations. On the other hand, unlike *E. coli*, *S. cerevisiae* is capable of accomplishing many posttranslational modifications, such as proteolytic processing, disulfide bond formation, glycosylation, and other posttranscriptional and translational processing unique to eukaryotic organisms. Many vector systems containing a variety of promoters and auxotrophic or dominant selectable markers have been developed, allowing constitutive or regulated gene expression. Several methods for transformation of foreign DNA into *S. cerevisiae* with high efficiency have also been developed (31, 85). As a result, *S. cerevisiae* is one of the most widely used microbial hosts for heterologous gene expression. However, there are limitations to using *S. cerevisiae* for heterologous gene expression; for example, the specific rate of production can vary from protein to protein, ranging from as low as 0.03 g/kg/h to as high as 4.5 g/kg/h (44). The use of episomal vector systems for heterologous protein expression in *S. cerevisiae* often results in plasmid instability during fermentation, which may lead to a lower growth rate and reduced overall protein yield. Furthermore, since many proteins of therapeutic interest are

secreted glycoproteins, the tendency of *S. cerevisiae* to hyperglycosylate proteins not only reduces the efficiency of protein secretion but also may lead to undesired changes in the immunogenic properties or biological activities of the expressed proteins (23, 39, 40, 44, 84).

11.2.1. Vectors

S. cerevisiae expression vectors usually are shuttle plasmids that contain sequences for propagation and selection in both *S. cerevisiae* and *E. coli*. Two types of vectors have been described based on their mode of replication: episomal and integrating vectors (Table 2) (16, 18, 27, 45, 73, 86, 108, 109, 111, 138). Episomal vectors can be characterized according to their copy numbers, mode of replication, and stability. There are three major types of episomal vectors: YRp, YCp, and YEp. YRp-type vectors contain an autonomous replication sequence from the *S. cerevisiae* genome and have an average copy number of 1 to 10 per cell, even though higher copy numbers (up to 100 copies per cell) have been reported (44). These vectors are unstable, and plasmid loss rates can be as high as 10% per generation (44). This instability greatly limits their use in large-scale fermentation processes. YCp-type vectors are derived from the incorporation of *S. cerevisiae* centromeres into YRp plasmids and have improved plasmid stability. However, YCp-type vectors have lower copy numbers, typically at 1 to 2 copies per cell. The most commonly used episomal vectors are of the YEp type derived from the naturally occurring plasmid called 2 μ circle in *S. cerevisiae*. These vectors are present at an average of 40 copies per cell and exhibit higher stability than the YRp and YCp vectors (5, 16). Consequently, YEp vectors are the best-developed vectors for heterologous gene expression in *S. cerevisiae*. These vectors are especially useful for controlled expression of toxic proteins. More than 80 compact expression vectors have been developed based

TABLE 2 Vector systems used for heterologous protein expression in *S. cerevisiae*

Vector	Copy number per cell	Reference
Episomal		
YE _p : 2 μ -based	25–200	27
YC _p : centromere	1–2	18
YR _p : replicating	1–20	86
Regulated copy number	3–100	16
Integrating		
YI _p	>1	45
rDNA-integrating	100–200	73
Ty δ	<20	111
Transplacement	1	109

on the pRS series of centromeric and 2 μ plasmids (26). The GATEWAY vectors (Invitrogen Life Technologies, Carlsbad, CA) incorporated some of these features into their systems in order to provide fast cloning and transfer of genes to different vectors for heterologous expression in most strains of *S. cerevisiae*. Other 2 μ -based expression vectors available from commercial sources include YE_pFLAG-1 from Sigma (St. Louis, MO), YES vectors from Invitrogen, and pESC vectors from Stratagene (La Jolla, CA).

Integrative vectors contain selectable *S. cerevisiae* genes and lack sequences for autonomous replication. These vectors are highly stable but usually present at low copy numbers. They include the YI_p-type vectors, and their integration can be directed by homologous recombination between sequences carried on the plasmid and its homologous counterpart in the *S. cerevisiae* genome. Some integration vector systems use repetitive elements such as delta sequences, Ty elements, or tRNA genes for heterologous gene integration (119). A system for multiple-site integration of a heterologous gene into the ribosomal DNA (rDNA) 9.1-kb segment has also been developed (73). Stability of the genome-integrated expression cassette can be maintained under selection. However, a decrease of copy numbers of the integrated expression cassette was observed under nonselective culture conditions (44).

11.2.2. Promoters

An array of *S. cerevisiae* promoters has been used for heterologous gene expression. There are constitutive promoters derived from genes such as *CYC1* (cytochrome C oxidase), *TEF2* (translation elongation factor), and *GAPDH* (glyceraldehyde-3-phosphate dehydrogenase), as well as regulated promoters such as *GAL1* (galactokinase/galactose epimerase 1), *ADH2* (alcohol dehydrogenase 2), *CUP1* (metallothionein), and *PHO5* (acid phosphatase) (6, 10, 15, 46, 51, 55, 56, 58, 65, 66, 80, 97, 98, 124). It is often advantageous for improving expression titer to couple the protein production phase with cell growth phases if there is no toxicity issue for the protein of interest. Some inducible promoter systems that work well at the shake flask scale, such as temperature-regulated promoters, do not always function well in large-scale fermentation due to operational restraints (44). Hybrid promoters such as *GAP/GAL* and *GAL10/CYC1* have also been reported (6). Several reviews on promoters and their applications in *S. cerevisiae* are available (108, 128, 138).

11.2.3. Transcriptional and Translational Regulation

In order to fully utilize the transcriptional, translational, and posttranslational regulatory machinery and to get efficient heterologous gene expression in *S. cerevisiae*, it is very important to match the expressed protein with the proper expression vector system. There have been many studies and extensive reviews on these aspects (22, 44, 82, 123). Generally, the use of strong promoters and robust transcriptional terminators of *S. cerevisiae* is essential for maximal expression since most prokaryotic or higher eukaryotic transcription terminators are not active in *S. cerevisiae*. More importantly, mRNA levels are controlled by the rate of transcription initiation and the transcript turnover rate (mRNA stability). In addition to upstream regulatory elements, downstream activation sequences are also required for maximum transcription initiation in *S. cerevisiae* (123). Expression levels of some foreign genes with high AT content (>60%) in *S. cerevisiae* can be low or absent due to incomplete transcript elongation (108). Transcript-destabilizing sequence elements have been reported in the 5' nontranslated regions, coding regions, and 3' nontranslated regions of different mRNAs (22). Therefore, if the titer is low due to the instability of mRNA, it may be necessary to use a stronger promoter, to delete the transcript-destabilizing sequence elements, and to introduce alternative codons. It has been shown that secondary structure of mRNA is one of the most important factors affecting the rate of initiation and translational elongation (123). For secreted proteins, posttranslational processes such as proteolytic cleavage, N-terminal modification, and glycosylation are critical to both proper protein folding and high protein yields. Consequently, it is worthwhile to evaluate the effect of the posttranslational steps when strong promoters and different strains fail to produce desired product yields.

S. cerevisiae has been used for expression of many eukaryotic proteins in both intracellular and secreted forms. For production of secreted proteins, secretion signals can come either from native protein signal sequences or from *S. cerevisiae* secretion protein signal sequences. Due to the limited studies available in the literature on the effects of different signal peptides on the yield of heterologous protein expression in *S. cerevisiae* (120), it is a good starting point to include the signal sequence of the foreign protein in the initial test of expression cassettes. Alternatively, *S. cerevisiae* signal sequences from invertase (SUC2, 19 amino acids), acid phosphatase (PHO5, 17 amino acids), and the most widely used α -factor pheromone (MF α 1, 20 amino acids) can be incorporated into the recombinant construct(s).

An important step among posttranslational modification processes is glycosylation. Heterologous glycoproteins expressed in *S. cerevisiae* are glycosylated at both N-linked and O-linked sites (64). Little is known about O-linked glycosylation, but more information is available on the process of N glycosylation. In *S. cerevisiae*, a core sugar moiety consisting of two N-acetylglucosamines (GlcNAc), nine mannoses, and three glucoses is added to the N-amide of asparagine at the Asn-X-Ser/Thr sequence in the endoplasmic reticulum (ER) in the early process of N glycosylation (67). Three glucose residues and one mannose residue are subsequently removed in the early Golgi apparatus. It is in the Golgi apparatus where further modification takes place that results in major differences between *S. cerevisiae* and higher eukaryotes in oligosaccharide structures. In higher eukaryotes, additional mannose residues are removed and several other sugars such as galactose, sialic

acid, and fucose are added (39, 40). *S. cerevisiae* maintains the core mannose scaffold and is often extended with a large number of additional mannose residues. This often results in a hyperglycosylated outer chain containing more than 50 mannose residues with many branch chains. Many examples of hyperglycosylation of heterologous proteins in *S. cerevisiae* have been reported (23, 68, 84). Since specific glycosylation patterns are important for the immune response in mammalian systems, wild-type *S. cerevisiae* is not a good system for the production of therapeutic proteins such as monoclonal antibodies that have complex sugar structures.

11.2.4. Industrial Protein Production in *S. cerevisiae*

Many heterologous proteins have been produced in *S. cerevisiae* and large-scale fermentation processes have been developed (43, 108). Nevertheless, most heterologous protein production in *S. cerevisiae* remains in shake flask cell cultures. The first therapeutic recombinant protein expressed in *S. cerevisiae* was human alpha interferon (47). Since then, many other therapeutic proteins have been expressed in *S. cerevisiae*. These include the hepatitis B surface antigen (126), human insulin (122), the human papillomavirus (HPV) vaccine Gardasil™ (93, 135), and many others. In the case of Gardasil, the four vaccine components were expressed in *S. cerevisiae*, which were transformed by pGAL110-based yeast expression vectors, each containing the gene of interest coding for HPV L1 types 6, 11, 16, or 18 (75, 104). An excellent review by Vasavada (128) details a comprehensive list of foreign proteins expressed in *S. cerevisiae* at small and large industrial scale. Various strategies have been reported to improve the expression levels of different heterologous proteins in *S. cerevisiae*, such as screening of various host strains with different expression vectors, altering host genetics by molecular engineering, and optimization of fermentation conditions (83, 115, 128). Since there are no defined conditions that can be used for all protein production, it is a general rule of thumb to examine different parameters to develop an optimized process for heterologous protein expression in *S. cerevisiae*.

11.3. *P. PASTORIS* FOR HETEROLOGOUS PROTEIN EXPRESSION

Pichia expression systems have been widely used for expression of heterologous proteins from a diverse array of organisms, including bacteria, fungi, protists, plants, invertebrates, nonhuman vertebrates, and humans (72). Similar to *S. cerevisiae*, protein expression systems in *Pichia* have the advantages of well-established, cost-effective fermentation technology and comprehensive understanding of the host molecular genetics. *P. pastoris* is a methylotrophic yeast and has strong preference for respiratory growth (72). Cell cultures can reach extremely high density, with dry weight mass reaching as high as 100 g/liter (44). Most of the *Pichia*-based protein expression systems use a tightly controlled and highly inducible promoter derived from the alcohol oxidase 1 gene (*AOX1*). Under methanol-induced conditions, a single protein such as alcohol oxidase can reach as high as 30% of the total cell proteins (44, 72). Similar methods used for the molecular genetic manipulation for *S. cerevisiae* can be applied to *P. pastoris*. Extensive studies have been published on the use of *Pichia* systems in heterologous protein expression. A recent review article by Cregg

et al. (14, 20) listed 241 individual studies of heterologous proteins expressed in *P. pastoris*, more than 80 of which were human proteins. Expression levels for heterologous proteins differ greatly, ranging from microgram-per-liter to gram-per-liter levels. For example, a hydroxynitrile lyase from a tropical rubber plant (*Hevea brasiliensis*) was expressed at levels as high as 22 g/liter (42). There are numerous reports on heterologous protein expression in *P. pastoris* (9, 91, 94, 107, 113, 114, 130, 138).

11.3.1. Expression Vectors and Host Strains

A fully developed *P. pastoris* expression system is commercially available (Invitrogen). The *Pichia* vectors can be grouped into two categories based on their promoters used: (i) inducible promoters derived from the *AOX1* gene or the formaldehyde dehydrogenase gene (*FLD1*) (117), and (ii) a strong constitutive promoter derived from the *P. pastoris* glyceraldehyde-3-phosphate dehydrogenase gene (*pGAP*). The methanol-inducible *AOX1* promoter provides tighter control of gene expression. The *FLD1* promoter can be induced by either methanol as the sole carbon source or certain methylated amines such as methylamine as the sole nitrogen source. Alternatively, the constitutive *GAP* promoter does not require cultures to be shifted from one carbon source to another for the induction of heterologous gene expression. However, if the foreign proteins to be expressed are toxic to the host cells, constitutive expression of the enzyme or proteins may cause inhibition of cell growth or result in loss of the expression vector from the cell.

There are no stable episomal expression vectors available in *P. pastoris*, and the expression genes need to be integrated into the genome to obtain stable expression strains. The simplest way of integration is single crossover homologous recombination by digesting the vector at a unique site with a restriction enzyme within either the marker gene (e.g., *HIS4*) or the promoter sequences (e.g., *AOX1*) (117). In the case of *HIS4* as the selectable marker, transformants of auxotrophic mutant strain (*HIS4*) can be selected for His⁺ cell growth. Alternatively, expression strains can be generated with *AOX1* flanking sequences at both the 5' and 3' terminals by cutting the vector in the *AOX1* sequence region. The flanking *AOX1* sequences at both ends can stimulate gene replacement events at the *AOX1* site in the *Pichia* genome, and this can result in a gene replacement integration. Heterologous proteins expressed in *P. pastoris* can be retained inside cells (intracellular expression) or secreted into medium depending on signal sequences in the expression vector systems. Commercial vectors for secreted protein expression often carry a leader sequence from MF α 1 (mating factor) of *S. cerevisiae* as a secretion signal (117). Other leader sequences, such as the alkaline phosphatase (PHO) signal sequence from *P. pastoris* and some native protein leader sequences, have also been used for secretion of foreign proteins in *Pichia* (79). To facilitate protein detection and purification, most vectors have 6 \times His or *c-myc* tag sequences fused at the C-terminal or N-terminal end.

A variety of selection markers are available for *Pichia* protein expression. Some can be used for selecting multi-copy gene integration, such as the drug resistance markers zeocin and blasticidin, while others provide auxotrophic selection such as his4⁻ mutant strains. Commercially available *Pichia* host strains for protein expression include X-33, GS115, SMD1168, and KM71. Additional host strains for

P. pastoris heterologous protein expression are reviewed by Cregg et al. (20).

11.3.2. Protein Folding and Glycosylation in *P. pastoris*

P. pastoris, similar to *S. cerevisiae* and other fungi species, can perform protein posttranslational modifications, such as cleavage of signal sequences for secreted proteins, N- and O-linked glycosylation, and formation of disulfide bonds (71, 72). It has been well documented that overexpression of heterologous proteins in *P. pastoris* can have a deleterious effect on its secretion pathway. Protein folding in the ER and Golgi is often the rate-limiting step for heterologous protein expression. Overloading the secretion pathway can lead to accumulation of partial or misfolded heterologous proteins in cells. Existence of high levels of unfolded or misfolded proteins in cells may induce a stress reaction termed the "unfolded protein response" (UPR), which triggers the expression of folding chaperones and enzymes in addition to other physiological responses. Both heat shock protein 70-type chaperone (BiP) and a protein disulfide isomerase (Pdi1) were reported to be induced when cells face UPR in *Pichia* (44, 72). BiP and Pdi1 showed synergistic effects on improving secretory capacity (136).

Glycosylation is one of the most important posttranslational modifications for heterologous protein expression, since it not only affects proper folding and secretion of the protein but also has a direct impact on the biological activities of proteins. Both N- and O-linked glycosylation have been reported using *Pichia* systems for heterologous protein expression (20). The consensus sequence for N-linked glycosylation in *Pichia* is the same as that in *S. cerevisiae* (Asn-X-Thr/Ser), in which Ser or Thr provides a hydroxyl group for glycosylation. Similar to *S. cerevisiae* and other fungal organisms, *Pichia* transfers a lipid-linked oligosaccharide unit, Glc₃Man₉GlcNAc₂, to an amino acid (Asn) in the ER. This oligosaccharide core is further modified in the Golgi. Unlike hyperglycosylation (>50 Man) occurring in *S. cerevisiae*, the most commonly found N glycosylation structure in *P. pastoris* is Man₁₄GlcNAc₂. There has been no α -1,3-mannosyltransferase activity detected in *P. pastoris*; only α -1,6 and α -1,2 linkages were found in glycosylated proteins in *Pichia* (11). The O-linked oligosaccharides in *Pichia* are also reported, but a consensus sequence for O-linked glycosylation is not available. The O-linked oligosaccharides in *P. pastoris* are generally short (<5 residues) and contain only α -1,2-linked mannose units. Phosphorylation of oligosaccharide units has been found in *P. pastoris* expression systems, but the exact sites of phosphate linkage on saccharides are unknown (72). In order to produce antibodies for therapeutic use, extensive glycoengineering efforts have been carried out to make humanlike glycoforms in *Pichia* (39, 40). Fully humanized sialylated antibody was produced successfully in a humanized *Pichia* strain (39). It is noteworthy that unlike antibodies produced in mammalian cells, antibodies produced in humanized *Pichia* do not contain fucose in the core carbohydrate structures and the afucosylated antibodies showed increased binding affinity to Fc γ receptor IIIA, which in turn results in higher antibody-dependent cellular cytotoxicity (70).

11.3.3. Heterologous Protein Production in *Pichia*

Expression levels of heterologous proteins in *P. pastoris* vary greatly depending on copy numbers of the foreign gene integrated and the stability of both mRNA and protein.

Since expression levels are correlated with gene copy number, it is important to achieve high copy numbers of gene integration. To obtain multiple copies of the target gene integrated in *Pichia*, one can screen large numbers of transformants in a 96-well plate format, applying high concentrations of the selection agents (e.g., zeocin and blasticidin), or construct multiple copies of the gene in tandem repeats *in vitro*.

In addition to the high-copy-number transformants, optimization of the expression process is vital to achieve high-level expression of heterologous proteins in *Pichia*. Although some proteins can be expressed well in flask cultures, it is common that expression levels are greatly enhanced in a controlled environment. Cultures in fermentor vessels offer several advantages over flask cultures, such as control of pH and dissolved oxygen levels, and continuous feeding of carbon and other components during cell growth and protein expression (49, 72). Since *P. pastoris* cells have a preference for respiratory growth, cultures can be grown to extremely high cell densities (up to 500 absorbance units at 600 nm) (20, 21). This is particularly important for secreted proteins since the concentration of the expressed proteins is often proportional to the concentration of cells in culture. Common defined media for *P. pastoris* protein expression are composed of glucose and glycerol as the carbon source and Casamino Acids and/or ammonium salts as the nitrogen source in addition to biotin and trace elements. The *Pichia* fermentation for heterologous protein expression can be separated into two phases. The first phase is that of growth using glycerol as a carbon source, and at this stage the AOX1 promoter is fully repressed. After depletion of glycerol, a transitional phase may be added to feed more glycerol at a growth-limiting rate. The second phase of feeding methanol starts induction of the AOX1 promoter and heterologous gene expression. Detailed protocols for fermentation of *P. pastoris* can be found in various articles (30, 50, 72, 90, 96).

Similar to other heterologous protein expression systems, proteolytic hydrolysis often causes instability of foreign proteins in *Pichia*. In addition to use of proteinase-deficient strains, several fermentation strategies can be applied to control proteolysis of foreign proteins. Some common approaches that have been used successfully to reduce hydrolysis of heterologous proteins in *Pichia* include (i) adding amino acid-rich supplements such as peptone or Casamino Acids; (ii) culturing at more acidic pH values (*Pichia* cultures grow well between pH 3 and 7); (iii) using a protease (PEP4, vacuolar protease gene)-deficient strain; and (iv) controlling culture temperature (44, 72). Another limitation of heterologous protein expression in *Pichia* is inefficient secretion of some mammalian proteins. In these cases, alternative protein secretion sequences can be tested first, followed by the consideration of more extensive molecular engineering approaches to improve protein chaperone and folding machinery.

11.4. HETEROLOGOUS PROTEIN EXPRESSION IN FILAMENTOUS FUNGI

Filamentous fungi, most notably *Aspergillus* species, can produce high levels of proteins and are capable of secreting proteins into the media. Many industrial enzymes, such as amylase, invertase, pectinase, and cellulases, that are used widely in the food industry for production of high-fructose corn syrup, fruit juice, and wine are produced in *Aspergillus*

species. The most well-known species for producing commercial enzymes include *A. oryzae* and *A. niger*; both have been given GRAS status by the U.S. FDA (116) for production of enzymes and proteins (35). The GRAS status makes them more attractive for use in the production of enzymes and proteins for the food industry and for pharmaceutical products such as therapeutic proteins and antibodies (29, 131). However, in comparison with *S. cerevisiae* and *P. pastoris*, filamentous fungi are less studied for heterologous protein production with respect to their transcription and translation control, mRNA stability, glycosylation, and regulation of protein secretion. With growing demand for the production of therapeutic proteins including antibodies, there is renewed interest in developing cost-effective fungal expression systems including yeast and *Aspergillus* species for heterologous protein production. In recent years, many advances have been made in the use of filamentous fungi for protein production (74, 87, 129).

11.4.1. Host Strains and Selection Markers for Transformation

Unlike *Pichia* and *Saccharomyces*, there are no commercially available protein expression systems for *Aspergillus*. However, there are several Web-accessible organizations such as the ATCC (American Type Culture Collection), the FGSC (Fungal Genetics Stock Center), the NRRL (Agricultural Research Service Culture Collection), and the BCCP (Belgium Culture Collection) from which the necessary tools for heterologous protein expression in filamentous fungi can be obtained.

For heterologous protein expression in *Aspergillus* species, the first step is to select a suitable host strain. The expression host must be either auxotrophic or antibiotic susceptible so that it can be used for efficient transformation and selection of transformants. The most genetically accessible strain is *A. nidulans*, but *A. niger*, *A. awamori*, and *A. oryzae* are more extensively used because of their capacity for high-level expression of commercial enzymes. *A. niger* can efficiently secrete many enzymes including food-related enzymes. *A. oryzae* has become more amenable to molecular analysis, and current research is focused on the identification of strong promoters to improve expression of industrially valuable enzymes. Due to the limited number of studies on *Aspergillus* strains and patent restrictions on the

use of some strains and markers, more studies are warranted to fully utilize the potential of *Aspergillus* host strains for heterologous gene expression.

Transformation of host strains can result in chromosomal integration of plasmids, either through a random mechanism or through site-directed integration. Markers commonly used for transformation of auxotrophic strains are listed in Table 3 (7, 13, 59, 81, 100–102, 125, 137, 138). The *pyrG* gene (uracil/uridine auxotrophs) from *A. niger* is a common marker found in many plasmid vectors. The *A. nidulans argB* gene is also used extensively for efficient transformation of suitable auxotrophic host strains. For example, Buxton et al. (13) described the complementation of an auxotrophic *A. niger* strain with the *A. nidulans argB* gene. More recently, there was a report on the complete disruption of the *argB* gene on chromosome I in *A. niger* (69). The *A. niger argB* deletion strain can be complemented by the *argB* genes from both *A. niger* and *A. nidulans* and can serve as a useful host strain for heterologous protein expression in *A. niger*.

Although plasmids can be readily integrated into the chromosome (stable and multicopy integration) during transformation of *Aspergillus* species, it is desirable to have a replicative plasmid for heterologous protein expression in filamentous fungi. Sequences have been isolated that allow one to perform replicative transformation in *A. nidulans* (2). Initial work with linear plasmids containing human telomeric elements was encouraging, but later these were shown to be unstable (3). To date, a synthetic *Aspergillus* replicative plasmid of wide utility is not yet available (74).

11.4.2. Expression Vectors and Promoters

Promoters commonly used for heterologous protein expression in *Aspergillus* species are listed in Table 4 (17, 25, 35, 38, 61, 99, 103). Constitutive promoters include the *trpC* and the *gpdA* promoters from *A. nidulans*. Other frequently used promoters are the starch-inducible promoters, α -amylase and the glucoamylase promoters from *A. oryzae* and *A. niger*. The glucoamylase promoter responds to maltose as a carbon source and is repressed by glucose. More recently the *TEF1- α* promoter of *A. oryzae* has been studied for use as a strong constitutive promoter (61).

TABLE 3 Selectable markers used for heterologous gene expression in *Aspergillus* species

Gene markers	Enzyme	Cellular function	Gene host	Reference
Auxotrophic				
<i>argB</i>	Ornithine carbamoyltransferase	Arginine biosynthesis	<i>A. nidulans</i>	13
<i>pyr4</i>	Orotidine 5'-phosphate decarboxylase	Uracil biosynthesis	<i>Neurospora crassa</i>	7
<i>pyrG</i>	Orotidine 5'-phosphate decarboxylase	Uracil biosynthesis	<i>A. niger</i>	81
<i>trpC</i>	Phosphoribosylanthranilate isomerase	Tryptophan biosynthesis	<i>A. nidulans</i>	137
<i>amdS</i>	Acetamidase	Acetamide or acrylamide assimilation, N ₂ source	<i>A. nidulans</i>	59
<i>niaD</i>	Nitrate reductase	Nitrate assimilation, N ₂ source	<i>A. niger</i>	125
Dominant				
<i>hph</i> (HmB ^r)	Hygromycin B phosphotransferase		<i>E. coli</i>	100
<i>phleo^r</i>	<i>E. coli</i> transposon Tn5 <i>phleo^r</i> DNA			102

TABLE 4 Promoters used in heterologous gene expression in *Aspergillus* species

Gene	Enzyme	Species	Reference(s)
Strong inducible			
<i>alcA</i>	Alcohol dehydrogenase 1 (ADH1) (ethanol inducible)	<i>A. nidulans</i>	25
α -Amylase	Starch inducible	<i>A. oryzae</i>	17
<i>glaA</i>	Glucoamylase (starch and maltose inducible)	<i>A. nidulans</i>	36
Constitutive			
<i>gpdA</i>	Glyceraldehyde-3-phosphate dehydrogenase	<i>A. nidulans</i>	99, 103
<i>trpC</i>	Phosphoribosylanthranilate isomerase	<i>A. nidulans</i>	38
<i>TEF1-α</i>	Translation elongation factor 1- α	<i>A. oryzae</i>	61

Another suitable promoter for the expression of heterologous proteins in filamentous fungi is the ethanol-regulated promoter *alcA* for alcohol dehydrogenase from *A. nidulans*. Genes for ethanol utilization in *A. nidulans* are efficiently transcribed. The *alcA* promoter is tightly regulated through *alcR*, a *trans*-activating gene, and is subject to repression by the major carbon catabolite repressor CreA (25). In a recent report, expression of antisense *creA* in *A. nidulans* increased levels of expression for glucose-repressible enzymes in the presence of glucose (8). The derepression effect by the *creA* antisense DNA did not alter cell morphology and growth parameters, as observed in a *creA* null mutant. The *alcR-alcA* regulatory system from *A. nidulans* has been transformed into *A. niger*, which does not possess an inducible *alc* system (88). The *alcR-alcA*-transformed strain of *A. niger* showed similar levels of heterologous expression of the reporter enzyme β -glucuronidase, as in *A. nidulans*.

Ishida et al. (52) reported that the tyrosinase gene promoter (*melO*) was four times stronger for the heterologous expression of β -glucuronidase from *E. coli* in a submerged culture as compared with other gene promoters, such as *amyB*, *glaA*, and *agdA*, previously used for heterologous gene expression in *A. oryzae*. The *melO* promoter was used to produce the *glaB*-type glucoamylase in a submerged culture of *A. oryzae* and achieved maximum yield of 3.3 g/liter and 99% purity. This work establishes the *melO* promoter for high-level expression and high-purity production of heterologous proteins in *A. oryzae*.

11.4.3. Posttranslational Regulations

Large numbers of mammalian enzymes and proteins have been expressed through genetic engineering; however, secretion of heterologous proteins is often much less efficient than the secretion of native fungal proteins. During the last 10 years, the production levels of heterologous proteins in *Aspergillus* have been improved by fusing the protein of interest to the 3' end of a highly expressed gene encoding a protein that is efficiently secreted from the host. The gene fusion or carrier protein strategy has been used with the glucoamylase gene from *A. niger* or *A. awamori*. Increases of 5- to 1,000-fold in protein production levels have been observed (87). Gouka et al. (36) extensively reviewed the production levels of different proteins fused to the glucoamylase carrier gene. They also performed detailed experiments on the production levels of various proteins with carrier fusions to the glucoamylase protein in isogenic, single-copy strains of *A. awamori*. The glucoamylase gene

can be divided into three distinct domains: the catalytic N-terminal domain, the C-terminal starch-binding domain, and a flexible linker region that separates the two domains. The C-terminal starch-binding domain can be replaced by a heterologous protein. The glucoamylase carrier proteins are believed to improve translocation in the ER, to enhance proper protein folding, and possibly to afford protection against proteolysis. In the secretory pathway, the carrier protein can be cleaved by a KEX2-like protease at a specific proteolytic cleavage site separating the glucoamylase carrier and the protein of interest. The amino acid sequence (NVIKSR) of the cleavage site is derived from the propeptide of glucoamylase. The carrier approach appears to be the first choice in attempts to produce secreted proteins in *Aspergillus* species. There are many reports on the use of carriers for heterologous protein secretion. A recent study reported a successful secretion of laccase (*lac1*) (an industrially useful enzyme for the oxidation of *p*-diphenols) from *Pycnoporus cinnabarinus* that used either the native laccase signal sequence or the *A. niger* glucoamylase pre-pro-sequence as a carrier for the heterologous enzyme expression in *A. niger* (106). The fusion of the glucoamylase pre-pro-sequence increased expression levels 80-fold in comparison to the levels observed with the laccase signal peptide sequence. Another advantage of using the glucoamylase pre-pro-sequence as a carrier for laccase in *A. niger* is the production of the 70-kDa protein, which is similar to the molecular mass of the native protein (106). However, it was reported that laccase expressed in *P. pastoris* had an estimated 110-kDa molecular mass due to hyperglycosylation in the yeast (76, 77, 106). Human interleukin-6 (IL-6) secretion was also improved using the native glucoamylase as a carrier when expressed in *A. niger* (74). It has been reported (4) that the UPR, i.e., the deliberate upregulation of "foldases" and chaperones, can also improve the secretion of heterologous proteins.

Efficient heterologous protein production in fungi cannot always be achieved by alleviating the limitations of transcription. Posttranslational regulations such as glycosylation, protein folding, and secretion often pose challenges for successful expression of heterologous proteins in *Aspergillus* species. Another major limiting factor in protein production in filamentous fungi is proteolytic degradation by high levels of intracellular and extracellular proteases. *A. niger* has four predominant extracellular proteases, two aspartyl proteases (PEPA and PEPB) and two serine carboxypeptidases (PEPF and PEPG). In *A. nidulans*, neutral and alkaline proteases often are the dominant ones affecting the

yields of heterologous proteins. Efforts to eliminate specific protease activities through mutagenesis or gene disruption have improved protein production levels. Van den Hombergh et al. (127) reviewed fungal proteases and described the development of a set of tester strains of *A. niger* that may be used to identify the appropriate genetic background for a particular protein.

Posttranslational modifications such as N glycosylation are particularly important for many pharmaceutically relevant proteins because of their impact on biological activities (19). High mannose-type glycosylation is observed in filamentous fungi, but it is much less extensive than that seen in proteins produced in *Saccharomyces* and *Pichia* species. Maras et al. (78) have nicely reviewed the fungal glycosylation pathway and approaches and compared the carbohydrate structures with proteins produced in mammalian cells.

Successful expression of *Drosophila melanogaster* xanthine dehydrogenase in *A. nidulans* is a recent example of proper posttranslational modification of a heterologous enzyme in filamentous fungi (1). In comparison to the baculovirus expression system, which produced only about 10% of active xanthine dehydrogenase enzyme due to incomplete incorporation of the cofactor molybdenum and two iron-sulfur clusters, *A. nidulans* produced 40% of active enzyme with relatively more complete cofactor incorporation.

11.4.4. Scale-Up of Fermentation and Protein Production in *Aspergillus*

In addition to the molecular genetic approaches, a combination of host strain selection, strain development, and production process development including media optimization have resulted in commercially attractive protein yields in *Aspergillus* protein expression systems (101). For example, IL-6 gene carrier fusion in *A. nidulans* in combination with host strain development and growth optimization resulted in a 200-fold increase in production of active IL-6 (101). A combination of gene dosage and growth condition optimization for the improvement of protein expression in *A. oryzae* resulted in a high production titer of phospholipase A₁ (PLA1) at the industrial scale (118). Transformants with 15 to 20 copies of the PLA1 gene were integrated in the chromosome of *A. oryzae* and produced 60- to 7,500-fold higher activity than the native expression level. In addition, improvement of the mycelial morphology from a pellet form to a filamentous form improved production of PLA1 in scaled-up fermentations and resulted in production of PLA1 at 1.8 g/liter consistently. This is consistent with the observation that improvements in oxygen transfer and broth rheology obtained with the pellet form of growth often resulted in increased protein production.

It has been recognized that fungal morphology plays an important role in determining process productivity in mycelial fermentations. This has led to investigations into alternative ways to conduct fermentations to optimize production yields. Papagianni et al. investigated the effect of cell immobilization on protein production and secretion (92). They reported on cells of *A. niger* that were immobilized by attachment to metal surfaces or by spore entrapment, and subsequently grown on Celite beads. They noted that cell attachment on metal surfaces decreased secretion of proteases and increased glucoamylase production. It was observed that growth on Celite beads in shake flasks reduced the secreted proteases by half and almost doubled the specific activity of glucoamylase. In bioreactor cultures,

conditions can be better controlled than in flask culture and effects of culture conditions on protein yields are much greater.

11.5. FUTURE PROSPECTS

The demand for production of a variety of proteins and enzymes in heterologous hosts for research and industrial applications is growing continuously. It is of great interest to develop and optimize diverse host systems for heterologous protein expression to meet the growing demand. Fungal expression systems offer many advantages over other expression systems and have been widely used for production of heterologous proteins from many organisms. Discovery of new promoters and development of new vectors will provide more choices for different protein expression needs. Greater understanding of transcriptional control, mRNA stability, glycosylation, protein folding, and other posttranslational processes will allow us to overcome the difficulties associated with heterologous protein expression in fungi, such as hyperglycosylation in yeasts and poor secretion associated with some mammalian proteins. It has been documented that the use of protease-deficient strains can increase the yield of recombinant protein production (28, 95) and that the use of specific mutants may eliminate hyperglycosylation problems with some proteins expressed in *Saccharomyces* (115). The exponential increase in fungal genomics and proteomics in recent years will no doubt fuel the advancement of filamentous fungi as heterologous protein expression hosts (74). Collectively, fungal protein expression systems have been and will continue to serve as a choice for heterologous protein production in small or large quantities.

We want to express our gratitude to Prakash Masurekar and Arnold Demain for spending time editing and reviewing this article.

12.1. OVERVIEW OF THE BIOPHARMACEUTICAL INDUSTRY

Combining various definitions (178–180, 235), biopharmaceuticals are medical drugs produced using biotechnology, that is, therapeutic products created through the genetic manipulation of living cells or organisms. They are pharmaceuticals with complex structures that are used for therapeutic, prophylactic, and even in vivo diagnostic purposes, including proteins, peptides, nucleic acids, and other large molecules, and are produced by means other than chemical synthesis or direct extraction from natural biological sources. Their production employs modern biotechnological tools, such as recombinant DNA and hybridoma technology, and is carried out in engineered biological systems. Included in biopharmaceutical categories are recombinant forms of natural proteins (insulin, interferon, interleukins, cytokines, erythropoietin, etc.), biologics derived from natural sources (most vaccines, enzymes, polypeptides, coagulation factors, etc.), and nucleic acid-based products (DNA, RNA, gene therapy, plasmids, etc.). Monoclonal antibodies (MAbs) are the single largest group of biopharmaceuticals.

In recent years, while the pharmaceutical industry as a whole has suffered from only single-digit growth, thinner pipelines, and pressure from an ever aggressive generics industry, biopharmaceuticals have represented the fastest-growing sector of the pharmaceutical industry, with more than 200 marketed products and hundreds more in development (203). During the period from 2003 to 2006, regulators in Europe and the United States approved 32 biopharmaceuticals for human use (44), and the growth rate of this market was expected to be at 12% annually for the next decade (108). The biopharmaceuticals market in 2007 reached ~\$106 billion out of the \$650 billion global pharmaceuticals market (172). This market segment has expanded rapidly owing to the significantly higher clinical success rate of biopharmaceuticals compared with new small-molecule chemical entities, their greater potential for curing diseases rather than just treating symptoms, and their greater efficacy and reduced side effects (219).

While biopharmaceutical segments such as replacement hormones and traditional vaccines are mature, segments such as MAbs and modern vaccines are maturing. In particular, the MAb therapeutics segment is thriving and boasts one of the most active and promising pipelines in the industry. MAbs are by far the predominant modality and

leading segment of biopharmaceuticals, being increasingly used in therapy because of their high specificity, low toxicity, long half-life, predictable pharmacokinetics, and high dose demand. With global sales of \$21 billion in 2006 (59, 140), \$27 billion in 2007, and \$33 billion in 2008 based on one report (141), MAbs represent the fastest-growing sector within the biopharmaceutical industry (161, 187). They are expected to achieve a compound annual growth of 14% between 2006 and 2012, easily outstripping the 0.6% growth rate of the more traditional small-molecules market (18, 28). Currently, MAbs play an important role in the treatment of cancer and autoimmune and inflammatory diseases. In 2004, 6 of the 12 new biopharmaceuticals approved in the United States and European Union were MAb-based products (236), and by 2009 a total of 26 have been approved by the FDA for the market (Table 1; www.fda.gov), with many new MAbs expected to be approved within the coming years. Newer MAbs, which include chimeric and humanized MAbs, had the greatest success with FDA approval. For example, 26% of the chimeric MAbs in development reach the market, while the approval rate for murine products, by comparison, is 4.5% (30).

12.2. MAMMALIAN CELLS AS DESIRED EXPRESSION SYSTEMS FOR PROTEIN BIOPHARMACEUTICALS

The majority of biopharmaceuticals are of protein nature and are expressed in recombinant hosts. For expressing certain biopharmaceutical proteins, microbial systems are attractive because of their low cost, high productivity, and rapid implementation. In addition, there is no adventitious virus concern to regulatory authorities. Indeed, relatively simple recombinant proteins, such as insulin (35, 226) and bovine growth hormone (226), have been successfully produced in *Escherichia coli* or *Saccharomyces cerevisiae*. Antibody fragments are readily produced in microbial systems (27). For example, *E. coli* is used to produce antibody fragments, followed by PEGylation to decrease rate of clearance in vivo (104). A nonglycosylated whole antibody can be produced in *E. coli* that is secreted into the periplasm (215). Filamentous fungi such as *Aspergillus* are also used to produce antibodies (239). The considerations in selecting an expression platform (85), the process development for microbial biopharmaceuticals (46), and the manufacturing of recombinant therapeutic

TABLE 1 FDA-approved monoclonal antibody products

Product	Manufacturer	Date	Indication/target ^a	Host cell
Orthoclone OKT3	J & J	1986	Transplant rejection/ <i>T-cell CD3 receptor</i>	Hybridoma
ReoPro	Centocor/Lilly	1994	Cardiovascular disease/ <i>glycoprotein IIb/IIIa</i>	Sp2/0
Rituxan	Genentech	1997	Non-Hodgkin's lymphoma and diffuse large B-cell/ <i>CD20</i>	CHO
Zenapax	Roche	1997	Organ rejection/ <i>IL-2 receptor a</i>	NS0
Simulect	Novartis	1998	Organ rejection/ <i>IL-2 receptor a</i>	Sp2/0
Remicade	Centocor	1998	Rheumatoid arthritis and Crohn's disease/ <i>TNF-α signaling</i>	NS0
Herceptin	Genentech	1998	Breast cancer/ <i>ErbB2</i>	CHO
Synagis	MedImmune	1998	Respiratory syncytial virus/ <i>F protein epitope</i>	NS0
Mylotarg	Wyeth	2000	Acute myelogenous leukemia/ <i>CD33</i>	NS0
Campath-1H	Genzyme	2001	Lymphocytic leukemia/ <i>CD52</i>	CHO
Zevalin	Spectrum Pharmaceuticals	2002	Non-Hodgkin's lymphoma/ <i>CD20</i>	CHO
Humira	Abbott	2002	Rheumatoid arthritis and Crohn's disease/ <i>TNF-α signaling</i>	CHO
Xolair	Genentech	2003	Asthma/ <i>immunoglobulin E</i>	CHO
Bexxar	GlaxoSmithKline	2003	Non-Hodgkin's lymphoma/ <i>CD20</i>	Hybridoma
Raptiva	Genentech	2003	Plaque psoriasis/ <i>CD11a</i>	CHO
Erbitux	Imclone/BMS	2004	Cancer (colorectal)/ <i>epidermal GF receptor</i>	Sp2/0
Avastin	Genentech	2004	Cancer (colon or rectum)/ <i>endothelial GF</i>	CHO
Tysabri	Biogen Idec	2004	Multiple sclerosis and Crohn's disease/ <i>T-cell VLA4 receptor</i>	NS0
Vectibix	Amgen	2006	Cancer (colorectal)/ <i>epidermal GF receptor</i>	CHO
Lucentis ^b	Genentech	2006	Macular degeneration/ <i>vascular endothelial GF</i>	<i>E. coli</i>
Soliris	Alexion	2007	PNH (hemolysis)/ <i>complement protein C5</i>	NS0
Cimzia ^c	UCB-Celltech	2008	Rheumatoid arthritis and Crohn's disease/ <i>TNF-α</i>	<i>E. coli</i>
Simponi	Centocor	2009	Rheumatoid and psoriatic arthritis, ankylosing spondylitis/ <i>TNF-α</i>	CHO
Ilaris	Norvatis	2009	Cryopyrin-associated periodic syndrome/ <i>IL-1</i>	Sp2/0
Stelara	Centocor	2009	Psoriasis/ <i>IL-12 and IL-23</i>	Sp2/0
Arzerra	GSK/Genmab	2009	Chronic lymphocytic leukemia/ <i>CD20</i>	CHO

proteins in microbial systems (91) have been well established, and are covered in other chapters of this book.

However, there are things microbes simply cannot do. Many biopharmaceutical molecules are too large and complex to be made by simple prokaryotic bacteria, or even the lower eukaryotic forms such as fungi and yeasts. Complex biomolecules, such as functional MABs or highly glycosylated proteins, require the posttranscriptional metabolic machinery only available in mammalian cells (35). Glycosylation of MABs is important for their biological function and pharmacokinetics (17, 110). Proper posttranslational modifications convey higher or "humanlike" quality and efficacy to the protein when compared with proteins produced by microbes. Aglycosylated forms of glycoproteins tend to be misfolded, biologically inactive, or rapidly cleared from circulation (45). Eukaryotic fungi and yeast can glycosylate proteins, but the resultant glycans are not the structures normally found on human proteins (83). While this inability of microbes is being tackled by a genetic engineering approach that humanizes the glycosylation machinery of the yeast *Pichia pastoris* for desired glycosylation of recombinant protein products (86, 95, 245), the best yeast

production systems like *P. pastoris* are proprietary and require license to use (115). As for the eukaryotic insect cells, they possess only limited glycosylation capabilities and are mostly used as vehicles for production of genetically engineered viral vaccines using baculovirus expression systems (193).

As the need for producing properly folded protein molecules including MABs with appropriate glycosylation patterns grew, the industry shifted in the 1980s toward the use of mammalian cells. Mammalian cells are the preferred hosts for the production of most complex protein therapeutics, since their functionally and pharmacokinetically relevant posttranslational modifications are highly human compatible. Stable cell lines, the prerequisite for manufacturing biopharmaceutical proteins, can be created by introducing exogenous DNA containing the product gene into host cells by transfection of a nonviral vector system. The economic concern about low productivities from mammalian cells has been eased by the 1- to 2-g/liter yield commonly achieved and 10-g/liter yield recently claimed on the production scale (157). Therefore, during the past 2 decades, despite the well-known lower production yield,

higher manufacturing cost, and other challenges compared with microbial systems, cultured mammalian cells have become a widely used platform for producing recombinant proteins (250), and cell culture capacity has grown from less than 300,000 liters to around 3 million liters today, driven by the demands for MAbs (219).

About one-half (212, 237) to two-thirds (152) of all the approved biopharmaceuticals are glycosylated proteins produced by mammalian cell culture, such as MAbs, blood factors, anticoagulants, thrombolytics, erythropoietin, specific interferons, hormones, and various therapeutic enzymes. In 2007, there were 15 biopharmaceuticals approved in the United States and European Union (238), including 6 erythropoietin-based products, 3 antibodies, 2 hormones, 1 recombinant vaccine, 1 growth factor, and a fusion product. Eleven of these 15 are produced in mammalian cell culture systems, 2 in *E. coli*, 1 in *S. cerevisiae*, and 1 in a baculovirus/insect cell-based system, confirming the prominence of mammalian-based expression systems in the biopharmaceutical sector. The rapid increase of MAbs as product candidates in recent years has been enabled by improvements made in the recombinant expression technologies that use mammalian cells. While there are 2 nonglycosylated MAb Fab fragment products from *E. coli* fermentations, Lucentis (for macular degeneration) and Cimzia (for Crohn's disease), which recently were approved by the FDA (18, 180), the other 24 MAb products currently on the market are produced in mammalian cells (Table 1) (186, 237, 263), of which all but 2 are produced by recombinant technology. In addition, in the last 2 decades, recombinant therapeutic protein yields from mammalian cells in batch and fed-batch processes have increased dramatically due to the utilization of highly productive cell lines, improved media, and better bioprocess conditions that enhance cell viabilities in high-density suspension cultures (94), thus easing the major concern of using mammalian production systems. It is obvious that mammalian cell culture will continue to be the cornerstone of large-scale production for biopharmaceuticals, especially for MAbs.

This review will summarize the recent development of biopharmaceutical production using mammalian cell culture. Since it is not practical to attempt to cover all categories of biopharmaceutical products, this chapter will focus on MAbs, which is the most dominant and most rapidly developing sector in the biopharmaceutical industry, and its large-scale production the most established. The concepts and methods described below should nevertheless be applicable to the production of other biopharmaceutical molecules derived from mammalian cells. Specific development and manufacturing information for vaccines can be found in the published literature (204, 227).

Mammalian cells are fragile because they are approximately 10- to 50-fold larger than microbial cells, without the tough cell walls of microbes, and they are sensitive to impurities. Simply getting these cells to thrive and reproduce in culture is a challenge in itself. The fundamental and unique aspects of mammalian cell culture characteristics, growth kinetics, cell metabolism, bioreactor development, process monitoring and control, and process issues in large-scale mammalian cell cultures were well reviewed in the last edition of this manual (174). The history of the discovery, development, and production of therapeutic antibodies is covered in a recent review (114). In the present review, the recently published literature from peer-reviewed journals, but not conference presentations or Web seminars, etc., is summarized, including each of the major mammalian culture process development steps for MAbs such as cell line, medium, and cell culture. Other important aspects

such as purification, formulation, fill/finish, analytics, and current Good Manufacturing Practices (cGMPs) will be covered in another chapter. Only the systems currently commonly used in the industry are described, but references are given for unique or emerging technologies. Where multiple sources exist, the more recent ones are usually cited.

12.3. CONSTRUCTION AND SELECTION OF HIGH-PRODUCING CELL LINES

Mammalian cells have become the dominant system for producing recombinant protein products for clinical application because of their capacity to properly fold and assemble proteins and add humanlike posttranslational modifications. In fact, all cell lines used for biopharmaceutical protein production so far have originated from mammals (44). However, mammalian cell line development is often very time-consuming. In addition, the mammalian cell culture process is hampered by low yields and unstable expression by the cells (130). Productivity and stability of expression are the prerequisites for developing commercially viable processes. So the ultimate goal of cell line development is to obtain clonal cell lines that secrete the protein of interest with high specific productivity (Q_p), and at consistently high levels over an extended number of cell generations, allowing for scale-up and cost-efficient manufacturing. Expression vector and cell line engineering are the keys for achieving this goal.

Advances in cell line generation include new expression vectors and transfection technology to introduce the genes into cells, novel parental cell lines that have been selected or designed to grow to maximum density, and robust screening technologies that in combination can enable rapid generation of production cell lines. Fine-tuning of vector construction, identification and use of selectable markers, optimization of transfection in production media, gene targeting, and high-throughput screening have led to high Q_p ranging from approximately 20 to 60 pg/cell/day (20, 192). The challenge is to create cell lines that not only have high Q_p but also have the growth characteristics that will lead to high volumetric productivity in the manufacturing process. This can be achieved by selecting cell lines with the combination of high Q_p and ability to achieve a high integral of viable cell concentration (IVC) and consequent high volumetric production rate in a screen designed to mimic the final production process (24). The resulting cell line also needs to be selected for stability, growth in suspension culture using an animal-free medium, and the ability to make the desired posttranslational modifications such as glycosylation. In addition, the cell line must be able to grow to high density at a reasonable growth rate.

Despite the progress, protein expression levels in mammalian cells are relatively low and often unstable during the time of development (4, 250), resulting in high development and production costs for therapeutic proteins. Although ~30-g/liter antibody titers have been achieved at the laboratory scale with the introduction of certain novel technologies (173, 207), the highest reported yields at industrial scale in mammalian cells are about 5 g/liter (35, 212, 250), which are still about threefold lower than those claimed in bacteria and yeast (8, 23, 86, 247). In addition, cell line construction and selection, which ideally should create a high enough producer that could be used for manufacturing throughout, in reality often yields to the demand for a shorter timeline to go to clinical trial to prove the concept and to obtain the safety profiles. Therefore, there is often a need to create an improved second-generation

cell line at a later stage of product development. Also, as with any other steps, the potential benefit of utilizing proprietary expression and engineering technologies need to be carefully weighed against the costs, in particular that for intellectual property rights, which may lead to downstream royalty stacking.

12.3.1. Expression Systems

Many component technologies are included in an expression system, such as vector construction, host cell, transfection method, selection and amplification approach, and screening tool (181). The most important factors in choosing an optimal expression system are productivity, process economics, product quality and safety, production stability, lead times, scalability, and regulatory acceptance. For glycoproteins, expression titers are mainly determined by the promoter construct, its copy number and site of integration into the chromosome, and the type of proteins in question (43). Despite the fact that a variety of new expression systems have been developed for recombinant protein production, the basic aspects and components of the expression systems used in large-scale biopharmaceutical manufacturing have changed little over recent decades (181). The situation is exemplified by a handful of companies controlling a great majority of the world's large-scale (10,000- to ~20,000-liter) biopharmaceutical manufacturing capacity and using only established systems, mostly Chinese hamster ovary (CHO) and murine myeloma (NS0, Sp2/0) expression systems. This is particularly true for manufacture of MAbs, which requires high capacity because of administration in repeated high dosages. These high-Qp cell lines and their high-density growth significantly favor process economics in cost of goods and use of plant capacity, and their well-established posttranslational modification patterns help to ensure product qualities, including glycosylation and protein folding, which largely determine the molecules' biological activities. In addition, these two expression systems are very familiar to regulatory authorities (Table 1).

12.3.1.1. Vectors

Biopharmaceutical production processes predominantly use systems in which the gene of interest is randomly integrated into a host chromosome, and the protein product is almost always secreted into an extracellular medium for ease of downstream processing. The cell line's ability to deliver high volumetric productivities [= Q_p ($\mu\text{g}/\text{cell}/\text{day}$) \times IVC ($\text{cell} \cdot \text{day}/\text{ml}$)] lies in the efficient transcription of the antibody gene by a well-designed expression vector (promoter construct, intron, copy number, and site of integration into chromosome, etc.), as well as the efficient translation of the antibody mRNAs with sufficient capacity in assembling, modifying, and secreting the complete antibody molecules. To create a production cell line for an antibody, expression vectors containing the heavy- and light-chain genes under control of strong mammalian promoters are introduced into the host cell line. Usually, a selectable marker is included, so that cells carrying the genes can be easily selected in the presence of an inhibitor that would kill the cells not expressing the selectable marker activity. Other genetic elements are also included, such as transcription termination sequences [poly(A)] and translation control sequences. Two expression vector systems dominate antibody production in mammalian cell culture, one based on dihydrofolate reductase (DHFR) genes (198) and the other on glutamine synthetase (GS) genes (16). Additional expression vectors and their selectable markers are available (24). To achieve

high levels of MAb gene expression, DHFR and GS vectors usually have strong promoters to drive expression of the immunoglobulin (Ig) genes, while the GS and DHFR genes themselves are under control of relatively weak promoters. The strong promoters are typically of viral origin (e.g., human cytomegalovirus) or they are derived from genes that are highly expressed in a mammalian cell (49). The details of vector elements were reviewed (145) and the use of their new combinations were studied (124).

In a DHFR expression system, the folate analogue methotrexate (MTX) is used to inhibit the function of DHFR, an essential metabolic enzyme for purine and pyrimidine, which produces a cofactor for thymidylate synthetase. Transfection with an expression vector containing the DHFR gene prevents MTX from poisoning transfected cells. Selection occurs in the absence of glycine, hypoxanthine, and thymidine. Frequently, an antibiotic resistance gene is used in DHFR expression vectors to act as the selectable marker, turning the primary function of the DHFR gene to facilitating vector amplification. A weak promoter, such as one from simian virus 40, is usually used to control the DHFR gene to reduce promoter interference due to read-through from the upstream promoter, which inhibits expression from the downstream promoter. Despite the usually long amplification time (up to five cycles, with up to 12 weeks per cycle), the DHFR system is effective and has been used in conjunction with other aspects of cell line development to achieve MAb expression levels of multiple grams per liter (114).

GS synthesizes glutamine from glutamate and ammonium. Since glutamine is an essential amino acid, transfection of cells lacking endogenous GS, such as NS0, with the GS vector confers the ability to grow in glutamine-free media (12, 23). Selection occurs in the absence of glutamine. Even for cells that do express functional levels of GS activities, such as CHO, including in the medium the GS inhibitor methionine sulfoximine (MSX), an analogue of glutamate, enables use of the GS expression vectors. GS expression vectors also contain the GS gene downstream of a weak promoter from simian virus 40, minimizing the promoter interference, thus increasing expression of the Ig genes. GS selection can be used to select high-expressing cell lines without amplification, which reduces the time compared with the DHFR selection approach. The GS system has enabled the rapid identification and selection of production cell lines expressing up to 20 to ~50 pg/cell/day and productivity of multiple grams per liter. According to Lonza (Basel, Switzerland) (www.lonza.com), more than 85 global pharmaceutical/biotechnology companies are currently using this technology and several products using the GS system are on the market, including Synagis (179) and Zenapax (12).

12.3.1.2. Stable Expression

Efficient delivery of a vector to host cells is variable depending on the techniques used, which should be based on the requirement for transient, episomal, or stable transfection of the cells. Compared with other physical and chemical methods, electroporation has been traditionally used for the generation of stable transfectants, because it requires smaller quantities of DNA (241), can be used on a variety of cell lines, and has a much lower cost but higher transfection efficiency than chemical reagents (166).

Transcription can be increased by several approaches, such as gene amplification and insertion into a transcriptionally active region. Gene amplification is usually achieved by linking genes of interest to an amplifiable gene

such as GS or DHFR. Transfected cells are then gradually exposed to increasing levels of specific enzyme inhibitors at concentrations substantially higher than those used for selection. Only the cells that overproduce these essential enzymes can survive. The overproduction of the enzyme (e.g., GS or DHFR) is usually caused by the increased levels of its particular mRNA, resulting from either an increase in the integrated vector copy number in host chromosomes (amplification) or from more efficient transcription (88). During this process, other tightly linked sequences on the vector, including the genes of interest, are often coamplified, leading to high copy numbers of transgene, which may increase the Qp of the cells, especially with the DHFR expression system (24). However, it can also have a detrimental effect on other cellular properties, resulting in poor growth performance of the cell population and/or altered cellular metabolism. In addition, amplification and the varied copy number can change the inherent stability of expression; thus the continued presence of the selective agent may be required. Some of the selective agents are toxic and thus require safety measures in operation and demonstration of their removal during purification. Also, the Qp will vary among clones, so the identification of high producers will require the screening of hundreds or thousands of cell lines.

Some systems do not rely on gene amplification to achieve high productivities, including GS and certain DHFR variants (24). Instead, they rely on chromatin remodeling technology. In these cases, insertion of plasmid DNA containing antibody genes into an actively transcribed region of the genome (euchromatin), instead of a condensed and thus transcriptionally inactive region of the genome (heterochromatin), is desired since the former favors high and stable expression of the recombinant genes, whereas the latter results in the repression of gene expression. The transcriptionally active regions are easily available to the enzymes that transcribe all the genes integrated at these sites into RNA, thereby increasing the rate of transcription. Recent improvements include incorporation into transgenes of the constructs of DNA elements that can either act as an enhancer or prevent expression silencing by integration into heterochromatin, improving stability and possibly productivity while reducing the number of clones to be screened (78, 130). For example, expression vectors can be constructed that contain a specific targeting sequence that will direct the vector to integrate by homologous recombination into a particular active site. Such a sequence was identified in the Ig locus of NS0 (101), and most high-producing NS0 cell lines use vectors containing this sequence. Logically, the sequence flanking the transcriptionally active locus can also be incorporated into the vector, which will cause the random integration site to become transcriptionally active and available to the enzymes that transcribe the genes, creating a favorable environment for expression that is independent of its integration site into the genome. Methods of target integration of transfected plasmid DNA to transcriptionally active sites of the genome have been developed to generate high-producing cell lines (7), but the consistency of such methods and the long-term expression stabilities of the cell lines generated have yet to be established (94). Vectors incorporating matrix attachment regions (MARs) (38, 67, 120) from Selexis (Marlborough, MA) and ubiquitous chromatin opening element (UCOE) (19) from Millipore (Billerica, MA) are two major types of elements currently used that function to create a region of transcriptionally active chromatin. The MAR elements are inserted into the vector to surround the

IgG genes, thus imposing an open chromatin configuration, allowing RNA polymerase and other transcription factors to access promoters and enhancers found in the expression vector. This increases the number of independently transformed cells that express the desired protein and makes possible expression levels in the initial transfectants of as high as 50 to 70 pg/cell/day (114). Success was reported (www.selexis.com) (67, 207) in using MAR elements (currently known as Genetic Elements™) to boost productivity in various recombinant proteins, including MAbs in CHO, HEK-293, BHK, and other cell lines. UCOE consists of regions that are rich in the sequence CpG, which increases the accessibility of the surrounding chromatin and thus the expression levels of linked genes (19). UCOE also exhibits non-tissue-specific preventive activity against transcriptional silencing (14) and can be incorporated into expression vectors to increase transgene expression (250). Stimulating and anti-repressor elements (STAR) (129) from Crucell (Leiden, The Netherlands), flanking sequences of the CHO elongation factor-1 α gene (49), and expression augmenting sequence elements (EASE) (160) from Amgen (Thousand Oaks, CA) have also been shown to increase and maintain transgene expression. These are being applied to immunoglobulin (Ig) genes, enabling higher transcription levels in a higher percentage of transfectants. In addition, use of the artificial chromosomal expression system (ACE) from Chromos Molecular Systems (Burnaby, Canada), which functions as stable, nonintegrating vectors with large capacity and allows multiple copies of the same transgene, has resulted in fourfold higher expression levels over the DHFR-CHO system (60). Transgene expression can also be increased by enhancing promoter strength using engineered zinc-finger protein transcription factors that bind a DNA sequence within a promoter (188).

Loss of recombinant gene copy number and the appearance of nonproducing populations of cells appear to be the predominant causes of instability of production, but there are several other factors that may affect expression levels and stability of production, as molecular loci exist at which instability may most likely be engendered (14). Some of the expression instabilities are caused by gene silencing at the level of chromatin—the so-called epigenetic gene silencing, which can be interfered with to enhance and stabilize transgene expression by employing epigenetic gene regulation tools, such as targeting histones, including specific DNA elements, and targeting sites of high expression (130).

12.3.1.3. Transient Expression

Before a stable manufacturing cell line becomes available, rapid and cost-effective expression technologies are frequently employed to quickly deliver milligrams to grams of protein materials for development needs. The methods include the use of uncloned transfectant pools and the use of transient gene expression (251). HEK-293 and CHO cells are the two major host lines for producing recombinant proteins using the transient gene expression or extrachromosomal expression technology (11). The current scale for this method goes up to 100-liter (55). The particular transfection reagents and methods, as well as cell culture parameters, differ from those for production from stably engineered cell lines.

12.3.2. Host Cell Lines

Current biomanufacturing processes require cell lines to be capable of achieving unclumped and robust growth in suspension culture, stably and productively integrating heterologous DNA, producing high antibody concentrations

in a given system, and performing desired posttranslational modifications with uniform product characteristics (40). In addition, the availability of a suitable expression system and the speed at which a high-yielding clone can be obtained may also influence the cell line choice. For regulatory approval, production cell lines must be well characterized and genetically stable; thus, using a cell type familiar to regulators will limit the intensity of their scrutiny. Some cell line-specific differences can significantly affect the performance of a production system; for example, glycosylation of a given protein varies with the type of mammalian cells used (111), and even two subclones from the same parental line can differ greatly in metabolic requirements (121).

Over two-thirds, or 140, of the recombinant therapeutic proteins currently on the market are produced in suspension culture-adapted CHO fibroblast cells (237). In addition, over 60% of all new target proteins currently in clinical trials are produced using CHO cells (152). CHO was chosen as the host for tissue plasminogen activator, the first recombinant therapeutic protein from mammalian cells to gain regulatory approval. Other manufacturers continued to use CHO cells because these were considered an acceptable host system for products intended for intravenous administration in humans. With time, other mammalian cell lines such as murine myeloma lymphoblastoid-like cells (NS0 and Sp2/0-Ag14), baby hamster kidney fibroblast cells (BHK-21), and human embryonic kidney epithelial cells (HEK-293) became acceptable (250). BHK-21 was once used for monoclonal antibody production (106), and HEK-293 was initially the producer for Humira. But BHK and HEK cells are now used to a lesser extent, mainly for virus and vaccine production (42, 176). CHO and NS0 remain the tested and most commonly used workhorses, with known safety and productivity profiles and capabilities (40, 44). These parental cell lines are also the ones commonly used for the antibodies currently in clinical trials. Among the 24 full MAb products currently approved by the FDA (including 8 blockbuster drugs) (Table 1), over 40% are produced in CHO, 25% in NS0, and 25% in Sp2/0 cell lines, despite the well-known differences in glycosylation between CHO and NS0 (10, 213). Murine hybridomas and some new cell lines such as the human PER.C6 are also being used (113, 114). It should be noted that the MAb products produced in hybridoma cell lines generally have lower dose requirements and are also older than those produced in highly engineered systems such as CHO, NS0, and Sp2/0. Since glycosylation of IgGs is "species specific," it is necessary to select the proper cell line to express recombinant IgGs for therapy in humans (182, 183).

12.3.2.1. CHO

CHO, established from a Chinese hamster's ovary biopsy over 40 years ago, is the most widely used and the best-understood mammalian host cell in the industry. Because of the widespread adoption of this host cell line, the growth characteristics, metabolism, behavior in bioreactors, virulence factors, and likely host cell-related impurities that might be in a process or product are well understood. Moreover, because there is a strong regulatory history of CHO cells, more and more products in development are now made using CHO cells.

Most biopharmaceuticals on the market are produced in CHO-K1 or CHO-derived cell lines such as DHFR⁻, DG44, and DUK-B11 cells (9, 40, 92), because they enable amplification of specific genes through selection with an amplifiable marker such as DHFR or GS. The most commonly used CHO strains with DHFR-based vectors are DUK-B11 and

DG44, both of which lack DHFR, while the GS system uses CHO-K1 or its suspension-adapted derivative, CHO-K1SV (189). Although CHO-K1 expresses functional GS, inclusion of the GS inhibitor MSX in the media allows use of GS expression vectors. MSX is cytotoxic at 3 μ M, at which endogenous GS is inhibited. At 50 μ M, only those cell lines that have stably incorporated the expression vector into a transcriptionally active locus will form transfectant colonies, producing enough GS enzyme both to titrate out MSX and to synthesize glutamine from glutamate and ammonium for cellular needs. CHO cells offer the advantage of producing and secreting recombinant proteins with efficient humanlike posttranslational modifications, as exemplified by N-linked carbohydrates that are compatible with prolonged *in vivo* activities in humans (112). The glycosylation patterns of native and CHO-derived recombinant proteins are similar (24). For example, glycosylation of the IgG1 form of Campath expressed in CHO cells is consistent with normal human IgG (213).

Wild-type CHO strains have adherent cell morphology and require serum supplementation for growth. It would take up to 9 months to adapt the recombinant CHO cell lines from adherent to suspension culture and further to simple serum-free, animal-free media. The current industry practice is to preadapt the parental CHO cell line to suspension growth in the desired media, thus cutting short the overall cell line development timeline to about 6 months (189, 217).

12.3.2.2. NS0 and Sp2/0

The murine lymphoid cell lines NS0 and Sp2/0-Ag14 were both derived over 20 years ago from a plasmacytoma cell line originated from a BALB/c mouse (12, 214). The starting cell lines underwent numerous rounds of cloning and, in the case of Sp2/0, fusion with spleen cells from another BALB/c mouse, to generate these two parental cell lines. Since the parental cell type is a differentiated B cell that is inherently capable of high levels of Ig production, while these cell lines lack the ability to synthesize and secrete Ig protein due to evolution, these two cell lines are favored for manufacturing antibodies at high yields. In addition, these two myeloma cell lines tend to grow well in suspension when adapted to serum-free media. Sp2/0 has an extensive record as a null parent for hybridomas and transfectomas. Half of the antibody products on the market use these two myeloma cells (Table 1). However, it should be noted that instability and relatively slow growth have been reported for murine myeloma cell lines (13).

NS0 and Sp2/0 cells contain very low levels of endogenous GS compared with CHO cells and are obligate auxotrophs for glutamine, which means the glutamine independence can be conferred upon transfection with a functional GS gene. Therefore, a GS expression system is often used for NS0 cells. Unlike NS0 cells, mutants from Sp2/0 cells that no longer require glutamine occur spontaneously with relatively high frequency, raising some concerns about using the GS expression vector in this cell line (24). It should be pointed out that unlike CHO and human cells, NS0 is known to add the nonhuman antigenic sugar residue Gal α 1-3Gal (170) onto the N-glycans of proteins it makes; however, there is no evidence yet that its presence on recombinant IgG is immunogenic in humans. For example, IgG1 and IgG4 forms of Campath expressed in NS0 cells include two potentially immunogenic glycoforms which contain either one or two nonreducing terminal α -linked galactose residues (213).

12.3.2.3. PER.C6

In recent years, the human PER.C6 cell line attracted attention (113) because of its human glycosylation and other

posttranslational modification machinery. The cell line was specifically designed for biopharmaceutical production. Rather than by viral transformation, PER.C6 was derived from a single healthy human embryonic retinal cell by transfection with the adenovirus E1 region followed by selection for transfectants with an immortal phenotype; thus the cells can replicate indefinitely, allowing them to be cultured in single-cell suspension under serum-free conditions. It was shown (122) that the IgG1 antibody produced in PER.C6 had few mannose or hybrid structures in its glycosylation pattern, which is biantennary with core fucose, very much like the IgG1 found in human serum. These cells do not synthesize potentially immunogenic MAb glycan structures. This expression platform requires no amplification of inserted genes or selection agent to deliver stable clones with high levels of protein expression within a few months. A low copy number is sufficient to retain stable and efficient protein expression. The cell line has been adapted to grow to very high density, and productivity of >2 g/liter in fed-batch culture can be routinely achieved. Lately, with the use of this cell line, a very high production titer of 27 g/liter was reported using a unique combination of fed-batch and perfusion approaches (173). It appears that PER.C6 and other human cell lines may become reliable, safe, scalable, and economical alternatives to the widely used CHO and myeloma cell lines.

12.3.2.4. Hybridoma

MAbs were first produced from hybridomas consisting of a murine B cell producing a specific antibody fused to an immortal murine lymphoid cell line (125), which are specifically designed to secrete MAbs. After being injected into the abdomens of mice, the hybridoma cells grow and MAb-rich ascites fluid accumulates, which can be withdrawn by needles at intervals. The collected ascites fluid is very complex and highly contaminated, but can often reach the 1-g/liter level. One commercial MAb is produced in this way. In vitro culture is later developed, and improved cell density, longevity, and antibody titer are achieved by fed-batch system. Still, these cell lines are generally difficult to engineer for high levels of protein expression and usually grow to only moderate densities in bioreactors. In addition, hybridomas are not suitable for obtaining high-affinity antibodies (159, 224). Therefore, hybridomas are mostly used for creation and production of murine MAbs for research and analytical use, or as limited-dose therapeutics. It is also possible to make human antibodies using murine hybridoma technology (47), in which the spleen cells are taken from a transgenic mouse that has the murine Ig locus replaced by the human genes, or by directly employing primary human B cells for generating hybridoma cell lines (136).

12.3.3. Screening for Desired Cell Lines

After transfection with vectors bearing the antibody light- and heavy-chain genes, cells are screened for highly productive cell lines through growth recovery, serum-free and suspension adaptation, amplification, single-cell cloning, and final clone selection. These steps can vary in order and are as needed. To improve outgrowth and transfection efficiency, transfection is predominantly performed in serum-containing media, but using host or parental cell lines preadapted to grow in suspension and serum-free media reduces adaptation times and increases the likelihood of reaching high cell densities and high product yields in serum-free suspension culture. Recent progress in using serum-free, protein-free transfection conditions (133)—thus the fact that all steps listed above can now be executed

under serum-free conditions—has significantly speeded up cell line development while complying with regulatory requirements (201). Usually, the transfected cells in 96-well plates are first screened for fast growers, then their productivities are analyzed to identify the candidates with the best production potential and growth characteristics, followed by amplification with increasing concentrations of inhibitors to the selective markers. The key parameters, such as secretion rates, intracellular amounts of the product, and gene copy numbers, are followed (127). The surviving transfectants are single-cell cloned by methods such as limited dilution, and the promising clones are adapted to grow in the enriched or large-scale production medium, with a similar feed scheme, in shake flasks. The leading candidates are cryopreserved as the pre-master cell bank (pre-MCB) and are evaluated for passaging stability that should cover the longest possible manufacturing duration. In addition to phenotypic stability, the amplified cell lines need to be evaluated for genetic stability (14) in the absence of selective pressure, which generally is not applied at the production stage. Once the stable and highly productive cell line is identified, the MCB is generated under cGMP conditions (71, 72) before initiation of process development for commercial production. Mammalian MCB cells must be characterized to be free of adventitious agents, be demonstrated suitable for large-scale culture, offer high-yield production, be genetically stable, and provide integrity of the protein product, which is assessed by a battery of protein and carbohydrate analytical methods (142, 197). Then the MCB needs to be subcultured to provide seed stock that produces working cell banks (WCB) for all future production runs.

Transfectants with high Q_p are rarely generated, so stringent selection is needed for an increased frequency of high producers. Levels of about 15 to 20 pg/cell/day are considered appropriate for initial transfectants for antibodies (114), with greater productivity arising from optimized cell culture conditions or amplification using selective pressure. Since a transfectant with high Q_p does not necessarily perform well in the production process, a sufficient number of cell lines need to be generated to allow for the attrition when screening for other desired characteristics. It is suggested (23) that a few thousand transfectants should be screened after enrichment by a stringent selection system in order to be confident of getting multiple cell lines with the desired productivity characteristics. A large number of high-producing transfectants is also needed to screen against the additional growth criteria that contribute to high productivity in a manufacturing process.

Selecting the final clone can be complicated and difficult because of the harsh environment in which single cells are generated through limited dilution or facilitated cloning. The survivor cells after selection are often subjected to serial dilution in secondary containers like 96-well plates, and the resulting cells that show as single colonies are subsequently expanded in larger containers like 12- or 24-well plates. The process is lengthy primarily due to the fact that many cell lines have a transfection efficiency of <1% (54), and most cells need to communicate with surrounding cells to enable growth. Supplementing with serum or preconditioned medium can improve the probability of a single cell multiplying successfully (54), but during serum-free scale-up some cell clones will be lost, as they cannot survive without serum. The conventional manual limited-dilution cloning from a transfection pool is labor-intensive and time-consuming, as it involves initial analysis and consequent monitoring of single-cell wells. Typical timelines from single-cell seeding to clone productivity evalu-

ation can be about 6 to 12 weeks, and the effort required is proportional to the number of clones selected. To make things more challenging, regulatory guidelines recommend at least two rounds of dilution cloning.

The recovery of cell lines with high Q_p has been improved through the development of high-throughput screening tools (31). Combining image processing and highly mechanized robotics to identify and pick mammalian colonies of interest, many automated systems have been developed that can aid cell line development by assessing cell growth from a single-cell clone and isolating higher expressers for further expansion. This allows a much greater number of clones to be analyzed without the need for multiple operators. Some systems, like fluorescence-activated cell sorting (FACS), can identify cells secreting high levels of antibody and sort them away from the low producers. The system employs a fluorescence-tagged antibody against the product expressed either on the cell surface or in a microgel bead (31, 102), or an artificial affinity matrix on the surface of viable cells (25), followed by isolation using FACS. The feasibility of using FACS in conjunction with a nonfluorescent reporter protein molecule that can be detected by a fluorescent antibody has also been demonstrated for identifying the high producers from the sorted single-cell clones (51). Other advanced systems include ClonePix (Genetix, Boston, MA) and Cell Xpress (SAFC Biosciences, Lenexa, KS), both of which employ fluorescence technology to detect high-expressing cells from among thousands. To shorten the time for clone selection, miniaturized bioreactors or shaking flasks are also being used that can simulate standard production bioreactor conditions (246). This technology usually employs high-speed automation to streamline liquid handling and analytical capability for early evaluation of growth and productivity profiles of candidate clones. Despite their high expenses and lack of a track record, at the present time these high-throughput screening methods can reduce the time taken to create a robust cell line from 12 to 18 months to 6 to 12 months and provide high-throughput analysis while maintaining and selecting clones (54).

The fundamental mechanisms that dictate clonal productivity and stability are still unknown. The most likely molecular loci at which instability may be engendered were highlighted for CHO and NS0 (14). DNA microarrays and two-dimensional electrophoresis on 11 GS-NS0 cell lines showed that major functional class changes between low and high producers are in protein synthesis and cell death/growth (211). Another report suggested there is a positive correlation between the Q_p and the ratio of heavy- to light-chain mRNA expression of an antibody produced by a GS-NS0 cell line (15). In GS-CHO, it was found that the optimal MAb production represents a compromise between heavy-chain abundance and the requirement for excess light chain to render MAb folding and assembly more efficient (200). Obviously, in addition to high Q_p , growth characteristics such as the IVC, harvest titer and viability, clone stability, and product quality are all important selection criteria for production cell lines. A single-cell secretion assay coupled with cell sorting was used to screen subclones with altered production kinetics or improved stability (25).

As an alternative to cell line engineering for improved performances (see below), the parental cell line or its recombinant derivatives are often selected from many different phenotypes obtained during initial screening that show characteristics applicable to bioreactor scale-up

scenarios and growth under high-density situations during the production phase (94). For example, the cell sensitivity to osmolality and pCO_2 may need to be considered as well because the cells may have to counteract high osmotic pressure and elevated dissolved carbon dioxide (dCO_2) levels at large scale. A CHO-DG44 variant with 500-mOsm/kg osmolality resistance was stable for at least 75 generations while exhibiting higher Q_p (163). The success of these screening schemes depends on the use of a model that is proven predictive of the manufacturing process. In many cases, shake-flask fed-batch culture serves well as the tool of choice.

12.3.4. Cell Line Engineering

The manufacturing cost can be very high because of unpredictable stability and productivity issues in MAb and non-antibody therapeutic protein production by mammalian cell lines. To lower both the cost and risk, most development programs now include cell engineering strategies toward the ultimate production of stable and high-yield cGMP cell banks. These strategies include vector optimization, chromosomal DNA and mRNA elements engineering, integration method improvement, genetic or pathway enhancement, and others (118). Since the recombinant cell lines currently used were mostly constructed using expression vectors developed to give high mRNA levels, transcription is probably not limiting antibody secretion (24). It is likely that with modern cell lines, events downstream of transcription are the limiting factor for productivity; thus, only a few of them can be addressed by vector engineering. For a panel of GS-NS0 cell lines at Q_p from 1.2 to 23 pg/cell/day, there was no correlation observed between Q_p and mRNA levels (221).

To enhance Q_p , targeted approaches to affect posttranslational modifications of antibodies (229) and antibody secretion (26) have been demonstrated. Since antibody production is likely limited at folding and assembly reactions, an approach is to modify the translational or secretory pathways to increase Q_p (57). Based on the fact that foldases and chaperones exist as large multiprotein complexes, it was proposed that global expansion of all components of the secretory pathway is required for generic improvement of antibody secretion rather than overexpression of selected proteins. It has also been proposed to overexpress proteins known or suspected to have a functional role in modulating signaling pathways, such as BLIMP-1 (57). Alternatively, zinc-finger protein transcription factor libraries, which can modulate the expression of any genes, can be randomized, so that a specific phenotype can potentially be created with enhanced recombinant protein production (171).

The combination of high Q_p (pg/cell/day) and high IVC (cell · day/ml) leads to high antibody titers (g/liter) in cell culture. Maximum IVC can be achieved by screening for a cell line capable of growing to a high density, then maintaining the cell viability for as long as possible, which requires the cell death rate to be minimized. For essentially all industrially used cell lines, such as CHO, myelomas, hybridomas, and HEK-293, apoptosis, or programmed death, is the major cause of cell death, which is the obstacle for these cells to survive high cell densities. Apoptosis is induced by various chronic insults and is mediated by several mechanisms (2, 131). Various strategies were implemented to inhibit apoptosis (6, 23), including the prevention of nutrient limitation by fed-batch operation, which can delay the onset and extent of apoptosis, and engineering of resistance into the cell line, such as the regulatory Bcl-2 family of

proteins, which affect the activation of apoptosis pathways in cells (144). However, while the overexpression of anti-apoptotic Bcl-2 family members can be employed to protect industrially important cell lines from stresses typically experienced during cell culture operation, productivities are often compromised (65, 107, 216), and the behaviors of the engineered cell lines are rarely reported. It can thus be concluded that inhibiting apoptosis, whether through the Bcl-2 method or simply by limiting cell culture nutrients, will enhance cellular viability but will not necessarily increase productivity (44), because overexpression of exogenous genes may have unintended consequences with regard to other cellular functions, resulting in cells with undesirable phenotypes. Still, the integration of the antiapoptotic genes *E1B-19K* and *Aven* has recently been reported to improve performance of CHO cell culture (65). The coexpression of cell proliferation genes and antiapoptotic genes into CHO cells has also been reported to improve cell culture performance (105). Alternatively, parental cell lines or recombinant derivatives with elevated resistance to apoptosis may be selected, based on survival under cultivation conditions with increased cell stress. This approach may be more likely to succeed than the host engineering strategy, given the complexity of apoptotic pathways (94).

In addition to limiting apoptotic death, recent studies have also examined regulating the life cycle for metabolic control of cell growth. The cyclin-dependent kinase family of proteins is a good target for control of cell cycle transitions from growth to cell death. The binding of cyclin-dependent kinases with cyclins leads to formation of complexes with cyclin-dependent inhibitors such as p21 and p27 (79, 80); overexpression of p21 and p27 causes cell cycle arrest at G₁ phase, and an increase in recombinant productivity as a consequence. It was shown that overexpression of p21 increased recombinant productivity in CHO cells by fourfold because of cell cycle lengthening, which increased mitochondrial mass and activity and improved ribosome biogenesis (20). The application of recently available “-omics” tools has started to provide a better understanding of the cell biology that defines the desired cell line phenotype. When GS-NS0 cell lines with various antibody production rates were compared in their proteomes, it was demonstrated that changes in productivity were associated with the changes in the abundance of several proteins (221).

Product quality is also the subject of cell line engineering. One such example is to alter the cell's ability to perform posttranslational modifications, particularly glycosylation, which is believed to play a role in effector functions of the antibody, such as antibody-dependent cellular cytotoxicity (ADCC). Reports show that oligosaccharide engineering may optimize ADCC, and thus antibody potency, because the degree of galactosylation, fucosylation, and sialylation and the proportion of bisecting GlcNAc residues have all been implicated in modulating effector functions (110). In a CHO-DG44 host cell with deleted α -1,6-fucosyltransferase activity, the ADCC of the resulting antibody was 100-fold higher than the fucosylated form (256). Also, overexpression of *N*-acetylglucosaminyltransferase III in CHO cells increased the proportion of bisecting GlcNAc residues, increasing ADCC substantially compared with the parent molecule (229). It is also possible to screen for NS0 clones that exhibit a low incidence of Gal α 1-3Gal because of their genetic makeup. Targeted knockout of mammalian host cell genes is now possible using RNA interference (66) or engineered zinc fingers (230). This technology was used to

modify the glycosylation machinery in CHO cells targeting fucosyltransferase, resulting in MAbs with reduced fucosylation and thus increased ADCC (158).

12.4. MEDIUM DEVELOPMENT FOR MAMMALIAN CELL CULTURE

Obtaining a good-producing clone through cell line construction and selection makes it possible to achieve high productivity and the desired product quality. For the cell line to achieve its full potential, it is important to create a suitable culture environment that provides the optimal chemical and physical conditions for cells to grow and produce. A culture medium determines the chemical environment and thus can have a dramatic effect on cell growth and product yield, and even on product quality. Consequently, when development reaches the late clinical phases, as in the case of the cell line, change in culture medium should be avoided. This requires the selection of the right components and careful formulation and optimization of the medium before product development reaches the final stage. Medium development is an important part of process optimization, which has led to the improvement in biopharmaceutical manufacturing for several decades (93); therefore this topic is reviewed here as a separate section. It should be pointed out that detailed information on medium development and medium compositions is usually proprietary and not available in the public domain.

12.4.1. General Features of Cell Culture Media

Whereas most microbes easily flourish in a simple and defined mixture of carbon, nitrogen, phosphorus sources, and mineral salts, mammalian cells in addition frequently need vitamins, amino acids, nucleotides, lipids, precursors, protectants, reducing agents, and even growth factors. Based on this author's own experiences, there are several key aspects of cell culture media that are different from the traditional microbial fermentation media. A cell culture medium is usually highly cell line and clone specific in the absence of serum, and individual optimization can normally improve production levels two- to fivefold (32). The presence of animal-derived components such as serum creates a more natural environment for better cell growth, but results in serious safety concerns about the biopharmaceuticals produced (148); yet the common non-animal replacements such as recombinant proteins are usually very expensive and carry their own impurities (196). Mammalian cells are unique in their ability to “adapt” to new medium formulations, voluntarily or involuntarily selecting variants. Another unique feature is that the medium performance is culture history dependent, and a conclusion about a new medium can only be drawn after multiple passages. Additional difficulties include the large variations in medium evaluation methods, such as growth assessment by cell counting, which can vary by about 10 to 20%; thus, quantum change in the measured parameters is needed to draw conclusions about an impact. In addition, there can easily be over 50 components in a typical cell culture medium, making it practically very difficult to fully optimize the composition. Finally, optimized batch medium is rarely optimal when a fed-batch culture is employed, and optimized growth medium is frequently nonoptimal for production.

12.4.2. Animal Component-Free Media

As more MAbs are being employed as therapeutic agents, their production methods are coming under increasing

regulatory scrutiny. Among the concerns is the presence of animal-derived components in the media employed to grow mammalian cells, because animal-derived substances can potentially introduce contaminants (adventitious agents) into the process and thus potentially into the final product. There are clearly risks associated with using animal-sourced materials, as these materials could be a source for prion protein transmission (81) and viral contamination (149); therefore, the regulations have become more stringent in order to ensure that the biopharmaceutical production process is free of potential contamination by these adventitious agents. For example, regulatory authorities specifically require that non-animal alternatives be used where available and demand that “manufacturers shall always justify the use of materials of animal origin” (62).

For better composition definition, reduced contamination by adventitious and infectious agents, and lowered cost, serum-free media are now commonly used in industry. However, to preserve the multifaceted beneficial functions of serum, many of the serum-free media still contain some bovine-derived large-molecule components, particularly bovine proteins such as albumin, insulin, transferrin, and lipoproteins, some of which act as carriers of certain essential nutrients such as lipids while others facilitate cell metabolism (29, 52). Because any animal-derived proteins could carry a theoretical risk of introducing prions (191) or other adventitious agents (97), it is highly desirable to develop animal protein-free media for cell culture processes (148). Although very often recombinant proteins can be employed to replace their animal-sourced counterparts, using organic or inorganic small molecules where possible may dramatically lower the medium cost and minimize even the indirect risks, such as those potentially from fermentation raw materials used for production of these recombinant protein medium components. An entire medium formulation can now be made animal free, because all components, including small molecules such as amino acids that are usually animal derived, are available from fermentation, synthetic, or plant sources (109, 263). Not only animal protein-free media but also protein-free media for CHO and NS0 have also become commercially available, and some can be found in the literature (202, 260, 263). In addition, a host of chemically defined media were reported to support high-density cell culture and to facilitate small-scale development activities (54, 222, 263, 266). Chemically defined media are inherently less expensive and make downstream processing more straightforward as there are fewer, and known, contaminants to monitor and remove. Process optimization is also easier in a defined environment. It should be pointed out that the definition for chemically defined medium varies in the literature, with some included recombinant proteins such as insulin-like growth factor-1, transferrin, and insulin, etc., as signals for cell growth (114). In this author's view, a chemically defined medium should only contain well-characterized components, with known identity and structure and consistent purity/impurity profiles; it can contain animal-derived components such as cholesterol, galactose, and amino acids, but should not include any protein components that are generally less defined. Those that contain minimal quantities of small-mass proteins should be termed as low-protein media (29).

Significant progress has been made in substituting animal components in media with non-animal materials for mammalian cell growth and recombinant protein production (90, 109, 119). Specifically, (i) bovine serum albumin could be replaced by recombinant human albumin, although costly and not straightforward (29), plus

an organic carrier for lipids (cyclodextrin) where needed (109, 263); (ii) bovine lipoprotein by synthetic cholesterol and plant-derived fatty acids (90); (iii) bovine insulin by recombinant human insulin or zinc ions (249, 263); and (iv) bovine transferrin by small-molecule tropolone (150) or other iron-chelating agents (196, 264) for iron delivery. Animal protein-free media are currently the most prevalent platforms being developed by many companies, and can contain complex ingredients like hydrolysates (157). All the popular industrial cell lines mentioned above (CHO, NS0, Sp2/0, and PER.C6) can now be cultured efficiently in these serum-free, animal component-free media.

12.4.3. Development of Cell Culture Media

Cell culture media are usually developed by selecting a commercially available, well-established, and chemically defined basal formulation and supplementing it with additives specific to the cell line or recombinant construct. In addition to the difference in host cell lines, most clonal derivatives present their own metabolic phenotypes, so cell culture optimization is often regarded as cell line or clone dependent. Therefore, the basis of medium development is a better quantitative understanding of the nutritional requirements of the cells, often helped by analysis of nutrient depletion followed by supplementation of the relevant nutrient in the medium or feed. The development process is usually iterative until the desired growth and production levels are achieved at large scale, together with satisfactory product purification and product quality. The commonly used strategies for medium formulation and optimization include (i) literature survey to identify possible growth requirements based on related cell lines or constructs, (ii) component swapping and titration to improve performance in a simple and straightforward way, and (iii) medium blending to select the best composition in an evolutionary manner (69). Other approaches are also used, such as (i) material balance to estimate minimum nutritional needs based on cell compositions and available intracellular stoichiometry (253, 255), (ii) spent medium analysis to identify and fortify limiting nutrients (82), (iii) statistically designed experimentation to gain rich data including component interactions without exhaustive experiments (228), and (iv) microarray analysis to identify ligands to the expressed receptors that can be included as medium components (1). The latter few methods have been employed less frequently in cell culture medium development because of the incomplete understanding of metabolic pathways and the huge numbers of medium components, in addition to their high complexity. However, high-throughput systems are being developed and their implementation has begun to speed up medium development (50, 84). This is occurring in conjunction with the promising advancement in high-throughput analytical measurements, such as measuring antibody yields in 96-well format.

An example of medium development involves the delivery of iron to cells. Iron is essential for cell respiration and metabolism, and without iron cells stop growing and eventually die. Iron is traditionally delivered by transferrin, but the bovine form carries the risk of viral contamination, while the recombinant form is often costly. As for the non-animal small-molecule iron delivery vehicles, some have been patented, such as tropolone (64). Selenium is an essential trace element for cell growth and development *in vivo* and *in vitro* and can protect cells from oxidative damage (259). Accordingly, selenium (as selenite salts) has been extensively used as a supplement in mammalian cell culture media (98, 123). A recent finding revealed that selenite also

serves as an effective carrier in animal protein-free media to deliver the essential iron to mammalian cells for high-level cell growth and production (264). Another example that deserves mentioning is the delivery of water-insoluble cholesterol and fatty acids to cell lines such as NS0 and PER.C6, which require them to grow. For animal protein-free and defined media, since the natural carriers like bovine serum albumin cannot be used, carrier molecules like cyclodextrin were found effective in delivering these molecules (234). Such media require careful preparation in order not to affect other aspects of the cell culture (169). Interestingly, it has been reported recently that NS0 cells, which were thought to be cholesterol auxotrophs, can be successfully grown in the absence of cholesterol (33). Overexpression of 17 β -hydroxysteroid dehydrogenase type 7 in NS0 cells also led to cholesterol-independent growth (210).

Non-animal-sourced hydrolysates have been commonly added to defined basal media to increase cell density, culture viability, and productivity (34, 155). Plant or yeast hydrolysates are protein digests composed of amino acids, short peptides, carbohydrates, vitamins, nucleosides, and minerals, providing a variety of nutritional supplements to media. The inclusion of hydrolysates has resulted in significant improvements in MAb yields in various industrially important cell lines. The exact mechanism for this hydrolysate-induced increase is yet unknown. Initial investigations reported that certain hydrolysates provided nutritional benefits, which resulted in increased cell numbers and final titers (168, 199). But further studies suggested that the benefits from hydrolysates were not just nutritional, since some peptides may exhibit antiapoptotic effects (34, 76, 225), affect the metabolism of the cells (75, 168), affect the cell cycle (77), and/or improve specific antibody productivity (34, 77, 225). However, the exact mechanisms of how peptides act as antiapoptotic agents or improve specific productivity are not fully understood. Different sources of hydrolysates may be preferred for different expression systems in order to maintain production stability, with yeast-derived hydrolysates less suitable to DHFR and plant-derived hydrolysates less suitable to GS, based on considerations of the relative amounts of nucleosides or glutamine-containing peptides in these hydrolysates (unpublished results). Due to their complex composition and possible lot-to-lot variations, hydrolysates can be a significant source of medium variation, so prescreening is necessary to ensure that the lots used meet the performance criteria (138). There are efforts toward developing a chemically defined replacement for hydrolysates (48, 223) and toward the use of more defined size-excluded fractions of hydrolysates (41, 63).

Irrespective of the characteristics of the medium developed, for suspension culture it is common to include a synthetic polymer such as Pluronic F-68 to act as a protectant against the damage to cells by sparging gases (139). To prevent foaming caused by sparging, antifoam may be used, for which the non-animal-sourced FoamAway™ Irradiated AOF is available from Invitrogen (Carlsbad, CA; www.invitrogen.com). In addition, some supplementation to a standard medium is often required at the time of use to provide components that are too labile to include in the basic formulations, or optional to standard use, or vector-determined selection agents or inducing agents, or to support cell line- or application-specific requirements (243).

12.4.4. Development of Feeds

Common goals for feed supplements include replenishing depleted nutrients, adding a particular substrate to drive an alternative metabolic pathway, introducing materials

to specifically influence apoptosis, and altering culture metabolism from growth into production mode (244). This last category may often be achieved by changing pH or overall tonicity, increasing specific ion complements (e.g., acetate), specifically inhibiting cell division or DNA replication (190, 242), and introducing toxic or cytostatic agents (e.g., butyrate). Apoptosis can be controlled by directly adding antiapoptotic agents (6) or supplementing cultures at the appropriate time with identified nutritional components, antioxidants, or growth factors.

High amino acid and carbohydrate concentrations can be used in basal serum-free media for convenient batch culture, with NaCl omitted to maintain desired osmolality. But in fed-batch culture, beginning with a much leaner base medium can offer even greater efficiency. High initial levels of glucose, while contributing to an early boost in culture expansion, can induce many cultures to shift to “Crabtree effect,” which inhibits oxidative metabolism and results in production of lactate, leading to premature cellular stress or apoptosis. High concentrations of glutamine can cause ammonium levels over 10 mM, impeding not only cell growth but also aspects of product formation such as protein glycosylation (39). Therefore, an approach is to use low glucose and/or glutamine in basal media and leave those substrates as part of the controlled nutrient feeding (265), allowing cultures to detoxify themselves from inhibitory metabolites and reducing accumulation of amino acid by-products, thus increasing both culture and product quality (3). Despite the fact that the accumulation of inhibitory metabolites such as lactate and ammonium can be minimized by maintaining low glucose and glutamine concentrations (254), frequent or continuous feeding is practically less desirable in large-scale manufacturing due to its operational complexity. Stepwise bolus addition of feed solution is commonly used in industry because of its simplicity and scalability.

For feed solutions used in large-scale fed-batch culture, the most common approach is to develop concentrated basal medium, with salts lowered to avoid high osmolality (103). In addition to glucose and glutamine, a feed formulation may include (i) nutrient concentrates (amino acids, vitamins, minerals) to increase both biomass and product, (ii) lipid preparations for specific needs of the cell line or clone, (iii) product enhancers such as butyrate to increase specific productivity, (iv) acid/base/buffers to restore pH to growth optimum or adjust to production optimum, (v) antioxidants or growth factors to promote culture longevity and thus production, and (vi) silicone-based surfactants to reduce shear stress and foaming (244). Certain key components such as phosphate may need to be added at extra strength to reach high density (56). Non-animal protein hydrolysates are commonly added as part of a feeding supplement and serve as a nutritive replenishment of free amino acids, carbohydrates, vitamins, minerals, nucleotides, and others. The bioactive small peptides in the hydrolysates can potentially activate specific pathways within the cells, act as survival signals, and suppress apoptotic death (76). Asparagine, arginine, and cysteine are among those amino acids that often have disproportionately higher use rates. Others, such as alanine, proline, and isoleucine, tend to vary greatly in use between cell lines or even individual clones. Some vitamins and metals provide significant benefits, and some can be tolerated at many times the levels found in commercial basal media. At mid culture, the cell density is much higher than the seeding density; thus high molar levels of feed components can be brought in to promote special pathways or cellular responses without detrimental effect (35). More specific approaches include influencing (even controlling)

particular cellular metabolic pathways or activities, such as feeding with nucleotide sugars or their precursors to enhance product glycosylation (10). It is important to also optimize the timing and rates of feed administration.

Like media, feed solution development is an iterative process, based on the analyses of nutrient consumption, by-product accumulation, and the balance between growth and production. Usually the first one or two rounds will show the most improvement, but eventually no increase in cell mass or product will be obtained even when every measurably depleted component is replenished, because nutrient depletion is not the only limiting factor in a cell culture system (244). A fully optimized feed often exists as two or more separate solutions for storage stability reasons. Lipids and very hydrophobic ingredients usually require their own separate concentrate solutions (243). During the concentrated feed solution preparation, pH and/or temperature may need to be adjusted to completely dissolve some low-solubility components. Both the physical stability of a concentrated feed solution and the chemical stability of its components are practical issues. Varying solution pH can drastically increase the solubility of the amino acid constituents. Blending concentrates of previously solubilized individual components, rather than sequential addition of powder to one solution, can lead a higher total concentration of each.

12.5. PROCESS DEVELOPMENT FOR MAMMALIAN CELL CULTURE

In the last 2 decades, volumetric yields from recombinant mammalian cell lines have increased dramatically (94). In addition to the generation of high-specific-productivity cell lines and formulation of media and feeds to support high-density cell cultivation, as described above, there have also been significant advances in understanding cell culture processes and in sustaining cell viability in high-density cultures for optimal production (5, 94, 157). There are two crucial issues facing modern process development: to minimize the time taken to provide material for clinical studies and to develop a process that can deliver sufficient drug product to meet market demands at an acceptable price per dose (24). For the first goal, platform technologies are often employed, which in upstream processes means the same host cell line, generic media and feeds, and standard growth or operation conditions. For the second goal, individual optimization of the cell culture medium and process is needed in order to fully realize the potential of the final clone selected, aiming to deliver maximum productivity at manufacturing scale, along with desired product quality and safety in a consistent and economical way.

A typical cell culture process starts with (i) thawing a working cell bank vial; (ii) expanding the culture through increased size or number of vessels at about 1:5 to 1:20 split ratio to reach sufficient cell viability, density, and volume; (iii) seeding the culture to production bioreactors of up to 20,000 liters; (iv) operating fed-batch systems to continue cell growth and accumulate product in culture medium; and (v) harvesting to deliver clarified broth to downstream purification. There are some fundamental considerations in developing mammalian cell culture processes, including (i) cell generation number (affecting product yield and quality); (ii) production bioreactor seeding age and density (affecting productivity during the given cycle time); (iii) medium performance (making a direct difference in product titer or even quality); (iv) feed or perfusion rate (determining how long cell growth and production will be sustained); and (v) parameters such as dissolved oxygen (DO), dCO_2 ,

pH, osmolality, lactate and ammonium level, etc. A step-by-step process development approach is illustrated in the literature (74), which led to titer progression by 30-fold to 4.3 g/liter for an antibody.

12.5.1. Reactor Systems for Biopharmaceutical Production

Anchorage-dependent cells generally require large surface areas to generate sufficient biomass for the required productivity, which can be achieved by using multiple tissue culture flasks, multitray bioreactors, roller bottles, microcarrier culture, and hollow-fiber bioreactors. Cell growth in suspension culture is not dependent on two-dimensional surface areas; it is thus far more straightforward to cultivate than adherent cells, because no enzymatic treatment is necessary, meaning less manual handling and contamination risk. For these reasons suspension culture dominates the biopharmaceutical industry and will be the focus of this review.

There are several fundamental differences between suspension mammalian cells and microbial cells that can affect bioreactor configuration and operation (116). The time needed for cells to double, which reflects growth rate, can be counted in minutes for microbes but upwards of a day for animal cells. Mammalian cell culture bioreactors therefore require added contamination safeguards because of the long culture cycle, such as the use of magnetic-coupled bearing housings and threadless welded ports. In contrast to microbial cells, mammalian cells often overreact to small changes in temperature and pH. They can only tolerate a very narrow temperature range, typically around 37°C; therefore mammalian cell bioreactors require a regulation capability of $\pm 0.1^\circ\text{C}$, unlike the $\pm 1^\circ\text{C}$ for microbial fermentors. While specific microbes thrive in conditions with a typical range of pH 2 to 10, a pH drop of just 0.4 can lower antibody titers from >500 mg/liter to 50 mg/liter (205). Mammalian cells require a narrow pH range of 6.8 to 7.4, so indirect addition of acid for pH control by CO_2 sparging must be used to avoid a harsh environment, and nitrogen can be sparged to neutralize the effect of CO_2 and thus raise pH. Due to the fact that the DO will be influenced by the amount of sparged CO_2 and N_2 (if used), an interactive four-gas controller may be ideally used to balance each gas component. Due to the low growth rate and the limited growth mass reached by mammalian cell culture, its oxygen uptake is much lower than in microbial fermentation, so the airflow-control capabilities of mammalian bioreactors must be more refined (delivering up to 0.5 vvm) than those for microbial fermentors (delivering up to 2 vvm). Unlike microbial cells, which can allow an agitation rate of 800 rpm or higher by radial-type impellers (such as Rushton turbines) at large scale, mammalian cells are extremely shear sensitive, in that just stirring the liquid medium can break up these fragile cells. Thus, usually no more than 150 rpm of agitation can be used even with specialized low-shear impellers (such as marine or pitched-blade), and forced-air sparging is the major means of introducing air into the mix. Finally, direct sparging of gas and high protein content in culture medium are the two main culprits in foaming, but the addition of antifoam via a peristaltic pump controlled by a foam sensor, as used in microbial culture, is usually not adopted in mammalian cell culture. Instead, manual addition of antifoam based on need is generally the practice.

To meet the rapidly growing demands of large production capacity, two types of suspension culture systems remain suitable for large-scale manufacturing: fed-batch and continuous-perfusion culture (21, 40, 100). During perfusion culture (or repeated-batch), fresh medium is

added continuously, which is in balance with the volumetric removal rate of the product-containing, cell-free spent medium. The culture time in a perfusion system is thus long and the harvest volume high, yet the product titer is relatively low per liter of medium consumed. The operation is also complex, involving the use of internal or external cell-retention devices (233). The continuous changing of medium conditions and long culture times frequently lead to inconsistent processes, higher contamination risks, and variable glycosylation and other posttranslational modifications in the product over time in culture, making the process difficult to scale up and generally less robust (137, 151). The key advantage of such a system is that smaller reactors can be used for production of large quantities of product. As an example, a 500-liter industrial perfusion system was claimed to operate for about 15 to 35 days, generating multi-kilogram quantities of a MAb, at a throughput about 10 times higher than that achieved in a batch or fed-batch system (53). Recently a successful scale-up from 200-liter to 1,000-liter perfusion cell culture in disposable stirred-tank bioreactors has been demonstrated (167, 252). However, since per-cell yields or specific productivities have dramatically improved of late, which leads to high product titers in bioreactors (250), the above advantage of perfusion systems has been reduced. Another use of perfusion is for those sensitive protein products whose accumulation can inhibit or be toxic to cell growth (201) or that are themselves particularly labile. The cell viability was often found to be high, while residual host cell protein and DNA were often low in harvests of perfusion culture.

Different from batch and perfusion systems, fed-batch cultures are supplied with a concentrated nutrient solution at particular intervals to replenish the depleting nutrients, with no spent medium removed, leading to increased broth volume, high harvest titer, and easier scale-up, and ultimately to greatly increased IVC and volumetric productivity (244). The advantages of a fed-batch system include (i) reduced direct cost (e.g., reduced medium consumption, waste generation, and personnel requirement); (ii) ease of process validation and characterization; (iii) reduced footprint and turnaround time; (iv) greater lot consistency and definition; (v) ease of downstream clarification, harvest concentration, and storage; and (vi) overall reduced time to product approval. Despite the continued debate over fed-batch versus perfusion for large-scale production (143), fed-batch processes are currently by far the most commonly used in the biopharmaceutical industry because of their robust, reproducible, scalable, and reliable manufacturing outcomes (244), and they are now being operated at scales as high as 20,000-liter working volumes. While the capital investments in a manufacturing facility using fed-batch culture are higher than those for a perfusion-based facility, the overall costs of goods for the two are similar (114). The development of improved feeds in particular has made a significant contribution to increased antibody yields. The industry is now converging on using fed-batch suspension culture in stirred-tank bioreactors with controlled feeding.

The stainless bioreactor system is robust in design and is proven in small- and large-scale production. However, it has high capital costs and high maintenance needs and requires sterilization and cleaning validation. As an alternative, the use of disposable-bag bioreactor systems has become an integral part of the bioprocess in the last decade, with 20- to 1,000-liter working volume systems commercially available (61, 162, 232). The systems are particularly useful for seed culture development (153) and for rapidly meeting early development needs, because they are flexible and quick

to implement, eliminating the need for cleaning-in-place and sterilizing-in-place, along with significant economic benefits (220). This is particularly advantageous for GMP manufacturing and can reduce the expensive investment in a stainless steel bioreactor facility. A wide range of small to semilarge disposable bioreactors are currently available (218), including Wave (175), Xcellerex (68, 167, 252), and SUB (single-use bioreactor) (61). Critical components for the practical use of disposable bioreactors are now available, including disposable mixing technologies, aseptic connections, and sensing technology. In-process monitoring and control conferred by traditional stirred-tank bioreactors have been incorporated into disposable systems (185).

12.5.2. Monitoring and Control of Cell Culture Processes

While disposable bioreactors are gaining popularity for smaller-scale production, and while up to 5,000-liter airlift reactors have also been used (22), large-scale cell culture has been and will continue to be typically carried out in stirred stainless steel tanks. Electrochemical sensors for pH and DO remain the most commonly used in bioprocess monitoring, and optical sensors for DO and dCO₂ are now commercially available (96). Online monitoring of intrinsic chemical and biological parameters other than the traditional pH, DO, and temperature is limited due to the lack of reliable online electrochemical sensors. Cell density, major nutrients, metabolites, and antibody products are mostly measured offline through daily sampling, using instruments such as Cedex, Guava, and Vi-Cell (for cell counting); BioProfile, YSI, and high-performance liquid chromatography (for nutrients and metabolites); blood gas analyzers or radiometers (for CO₂, O₂, and pH); and enzyme-linked immunosorbent assay, high-performance liquid chromatography, and Biacore (for products). Systems from YSI Inc. (Yellow Springs, OH; www.ysi.com) and Nova Biomedical (Waltham, MA; www.novabiomedical.com) allow real-time monitoring of about 10 nutrients and metabolites. Recently, several novel online monitoring biosensors have become available, mostly for development scale, including a biomass probe (36) and a glucose probe (117). There have also been great advances in online sampling for at-line analyses of nutrients, metabolites, and amino acids, etc. (132). For example, both YSI and BioProfile analyzers can now take samples directly from bioreactors. The next phase will likely involve the implementation of online probes for measuring viable cell density for commercial processes, which is important because multiple decisions such as seed transfer and feed additions are dependent on the viable cell density of the culture. In addition, the advances in instrumentation and data analysis algorithms have made nondestructive near-infrared spectroscopy a useful tool for measuring multiple components simultaneously from a single probe, including glucose, glutamine, lactate, ammonium, and even protein product concentration in cell culture broth (258). These in-process, online, at-line, and offline measurements are applied to improve process control and performances, such as optimizing nutrient feeding strategy, identifying critical process parameters, and initiating appropriate control actions to main process and product consistency.

Bioreactor control methods compare either measured or derived values with mathematical simulations to determine the timing and interval of feed introduction to mammalian cell culture (177). In the standard "closed-loop" strategy, the orchestrated nutrient supplementation is based on precise mathematical formulas, while the "open-loop" methods use real-time process measurements to provide feedback to

controlling devices and guide their actions (146). When a simple formula cannot describe a process due to lack of accurate data, the nonlinearity of many functions, or delays in biological response to control inputs, recent statistical and nonformulaic techniques such as “fuzzy logic” and “neural networks” are becoming prevalent (194). A proportional-integral-derivative type of controller is frequently used to integrate the control algorithms into electronic and mechanical hardware for reactor control, which brings values to their set points and maintains them without overshooting by controlling various actuators (e.g., peristaltic pumps for glucose feeding). Control features different from microbial fermentors are reflected in the reactor design for mammalian cells (231), in order to ensure minimum stress to cells while maintaining adequate mixing and mass transfer of not only oxygen but also CO₂. DO level is regulated by the controlled sparging of air, and oxygen gas if needed. The pH control is achieved by CO₂ and N₂ sparging, or alkaline agents such as NaHCO₃, Na₂CO₃, or NaOH. The latter should be used in a well-mixed zone of the reactor to avoid high local departure from the set pH point (240).

12.5.3. Optimization of Culture Conditions

Enhancements in recombinant MAb production on a per-cell basis are often the result of combined improvements of cell line, culture medium, and culture conditions. The almost 10-fold improvement in titer every decade since 1980 (250) has been partially due to improvements in expression technology and clone selection, as noted above, and partially due to the optimization of cell culture processes (52), which include media and feeds and culture conditions. As a result, much higher cell concentrations can now be achieved in bioreactors (easily >1 to 2×10^7 viable cells/ml), and the cells can be maintained in a viable state for a much longer period, leading to dramatically enhanced productivity or titer ($= Q_p \times IVC$). If culture duration cannot be extended due to limitations of the cell line or plant throughput considerations, efforts should then be focused on increasing Q_p and maximum cell density. Strategies for developing media and feed solutions were described in the previous section, as well as in published literature (247). As for the optimization of a fed-batch process, it involves a delicate interplay among such variables as feed solution constituents and concentrations, the timing and duration of feed introduction, and control limits for reactor operating parameters (134, 195, 248). The overall aim of the fed-batch approach is to increase maximum cell concentrations in the bioreactor and to prolong the production phase without decreasing Q_p . By this approach, the productivities of NS0 (52) and Sp2/0 processes (195) were improved by about 1 order of magnitude. It should be noted that a preferred cell growth condition may not be the optimal condition for productivity and vice versa; therefore, optimization of culture conditions needs to balance cell growth with antibody production.

In addition to maintaining nutritional supply to cells through feeding, a key factor to consider is the toxic effect of accumulated catabolites such as ammonium and lactate. It has been demonstrated that these metabolites can be inhibitory to mammalian cell growth and production (39). It is possible to use stoichiometric feeding of key energy substrates (glutamine and glucose) to reduce these metabolites (195, 254). Accumulation of ammonium can be substantially reduced by eliminating the main source, glutamine, in the medium, which can be the case when cell lines have endogenous GS or are constructed with GS-containing vectors; thus the growth does not require glutamine in the medium. An ~45% increase in the specific production rate of both lactate

and ammonium was observed when osmolality was elevated from 316 to 450 mOsm/kg in a CHO culture (267).

For most mammalian cell culture, pH is normally controlled within the range of 6.8 to 7.4. High pH is preferred for initial cell growth, whereas low pH facilitates antibody production (170, 195). However, high pH is usually associated with increased anaerobic cell metabolism, which converts more glucose to lactate and drives down the medium pH. The control mechanism for pH in bioreactors then causes more base addition to the medium, resulting in increased osmolality, which can delay cell growth and accelerate cell death. So the suggested control mechanism is that once fast cell growth is achieved, the pH set point is shifted to a lower level to minimize base addition and to allow the best antibody production (135). For most cell culture processes, lactate is consumed in the later stage, so pH can rise by itself.

In addition to pH control agents, addition of feeds can lead osmolality to reach growth-inhibitory levels. However, due to the fact that elevated osmolality also enhances Q_p (261), the final titer may not be much affected (267). CO₂ concentration in large-scale bioreactors can also reach inhibitory levels (>120 mm Hg) in cell culture, decreasing the specific growth rate and specific production rate (164, 267), which is why sufficient air sparging needs to be maintained in large-scale bioreactor operation—not only to supply enough DO but also to strip out the accumulated CO₂ adequately. The challenge is that a high sparging rate often leads to a tendency to foaming, so control of a bioreactor run is an act of balancing various interacting factors. By using either antifoam with sparge stone or an open pipe sparging in a 1,000-liter CHO culture, the dCO₂ was reduced from ~180 to ~70 mm Hg, resulting in twofold higher titer (164). DO is usually considered a less significant factor in mammalian cell growth, so it can be controlled in a wide range of 20 to 100% air saturation (135). But DO can change product quality: it was reported that a reduction in DO caused decreased glycosylation of a MAb's N-glycan chains (128).

The maintenance of cells at a high density without growth can be achieved by different means, including temperature reduction or addition of chemicals that interfere with cell physiology, resulting in enhancement and stabilization of viability. For example, manipulating the cell cycle in CHO cell culture through a temperature shift can extend culture longevity. It was found that lowering temperature from 37 to 30°C at 48 h postinoculation can retain cells in the G₁ phase longer and thus delay the onset of apoptosis (156). It was also found (126) that growth arrest by lowering temperature following 37°C growth of CHO-K1 cells leads to increased recombinant protein productivity, and a number of key regulatory proteins and pathways were identified as modulating the cell response to mild hypothermia.

12.5.4. Process Scale-Up and Scale-Down

The scale-up of cell culture processes remains poorly understood, which often leads to altered yields and product quality attributes. While the exact criteria are still unknown, a successful process scale-up depends on determining, measuring, and monitoring critical scale-independent process parameters, then designing and operating equipment appropriately to deliver those same parameters at large scale (87). The least directly scalable process parameters in cell culture production are fluid mixing and oxygen transfer. The shear sensitivity of mammalian cells is no longer considered a serious issue in scale-up, because with no gas-liquid interface present, the local energy dissipation rate the mammalian cells would experience is orders of magnitude lower than that demonstrated to be catastrophically damaging to them

(154). Successful examples of scale-up of antibody cell culture processes can be found in the literature (206, 257). A systematic approach was proposed (58) to address the incompatibility between lab procedures and pilot scale and manufacturing, such as batch versus continuous operations, and theory versus reality. Other factors include raw material differences and dissimilar bioreactor hydrodynamics at different scales. Even scheduling and work-shift difference needs to be taken into consideration (89).

Using a good laboratory model is an easy and sometimes the only practical way to troubleshoot and improve a large-scale production process. Much of the feed and process optimization today is accomplished in scaled-down physical models built by imitating conditions existing in full-scale production reactors (50). Often the best small-scale conditions are sacrificed in favor of approximating those that can be actually achieved in a large-scale system. Newer technologies such as SimCell miniaturized bioreactors (www.bioprocessors.com) promise to accelerate optimization with more accurate scaled-down conditions. Scale-down models are also needed for process validation studies, in which a lab-scale version is validated for its ability to accurately represent a development process, then used in setting performance ranges and specifications for ultimate implementation in a manufacturing plant (184). Worst-case conditions, which pose the greatest chance of process or product failure (37), are tested to establish the operating ranges.

12.5.5. Process Improvement versus Product Quality

Frequently, change in productivity is not the only response cells exhibit to process modifications. It is possible that product characteristics alter as well, e.g., increased aggregation, different glycosylation, or faster degradation, potentially resulting in clinical implications for efficacy and safety. Glycosylation variation, which can affect *in vivo* IgG functions and product stability, is one of the most sensitive quality attributes that is dependent on cell line and cell culture conditions (110). Because the biosynthesis of glycans does not follow a genetic “code” like protein biosynthesis does, many variations are possible, thus leading to glycan heterogeneity. The biosynthesis of glycoproteins in mammalian cells and their characterization are reviewed in a recent paper (147). Due to the sensitivity of MAb glycosylation profiles to host cell enzymatic systems and bioreactor conditions (182, 209), selection of host cells and culture conditions must consider the requirement for stably producing each specific glycosylation pattern. Differences among the mammalian expression systems are well documented, particularly for CHO and NS0 cells (10). The effect of cell culture media and conditions on antibody glycosylation has been extensively studied (110, 112). Factors such as medium serum, glucose, ammonium, nutrient availability, particular sugar component, DO, dCO₂, and broth osmolality were reported to cause glycosylation changes in different cell lines (73, 208, 209, 262). The reason for this is that these factors likely affect monosaccharide transferase activities and/or sugar transport to the Golgi apparatus, the major glycosylation site in mammalian cells. Culture pH difference changed the galactosylation of glycans for a murine antibody (165). Different medium components can reduce Gal α 1-3Gal content on NS0 glycoproteins (10, 99). Some modifications can occur even on the antibody backbone under certain cell culture conditions. For example, the IgG heavy-chain C-terminal lysine is normally cut off through posttranscriptional modification by carboxypeptidase B. The activity of this type of metal enzyme can be affected by

the trace element concentrations in the medium, resulting in charge variants (135). It is thus important to monitor product quality attributes during process optimization in order to ensure comparability across various clinical stages and commercial manufacturing. A recent regulation has provided comparability guidelines for biotechnological and biological products (70).

12.6. SUMMARY

Biopharmaceuticals, particularly MAbs, have been growing at a much faster rate than the traditional pharmaceutical industry in recent years, and the trend is continuing. Mammalian cells are the dominant production system due to their capacity for adding humanlike posttranslational modifications to complex protein therapeutics. High productivities and desired product qualities have been achieved by the development of high-yielding and stable cell lines, animal-free and productive media, high-density fed-batch cell culture conditions, and successful scale-up to large manufacturing bioreactors. Novel technologies such as enhanced expression systems, automated screening methods, cell line engineering, improved process monitoring, and disposable apparatuses are leading to more productive and efficient production of biopharmaceuticals by mammalian cell culture.

Manufacture of Mammalian Cell Biopharmaceuticals

JINYOU ZHANG

13

Following the discussion in the previous chapter on cell line development and cell culture production for biopharmaceuticals, the present chapter reviews other important aspects of the manufacturing of biopharmaceuticals in mammalian systems. These include recovery, purification, formulation, fill and finish, bioanalytics, and current Good Manufacturing Practices (cGMP). As in the previous chapter, the dominant sector in the industry, monoclonal antibody (MAb) production, is used as an example where available. Only the common systems currently used in the biopharmaceutical industry are described, but references are given for unique and emerging technologies. When multiple citations exist, the more recent ones are usually listed.

13.1. DOWNSTREAM PROCESS DEVELOPMENT FOR BIOPHARMACEUTICALS

Historically, the major bottleneck in production of biopharmaceuticals was cell culture capacity. As described earlier, the industry responded to capacity shortage by developing processes with ever higher titers from both new and novel expression systems, developing and optimizing new and existing growth media, and increasing mammalian cell densities by bioreactor technology improvement. All of these advancements have helped to increase the productivity of upstream processes, with the best examples of optimized MAb cell culture achieving yields of approximately 27 to 31 g/liter at development scale (4, 122). Just since the turn of the century, the industry has gone from considering 1 g/liter as impressive to seeing that as the baseline. Now about 60 to 70% of the industrial titers are in the 1- to 3-g/liter range (38), and 15,000- to 20,000-liter bioreactors are used in sets of four or six. This means that severalfold more products are coming from mammalian cell culture, which necessitates severalfold-higher downstream processing capability.

However, the chromatography resin capacity has not been increased dramatically, so larger filter and column sizes, higher product and buffer volumes, and longer processing times are needed and are becoming issues. Therefore, the bottleneck of manufacturing has been pushed downstream (99), mostly with respect to the first product capture step. At the same time, in-process impurities have increased, mainly due to the use of more complex media and higher cell densities with lower cell viabilities, thus introducing elevated levels of host cell proteins (HCPs), lipids, and nucleic

acids into the process (133). In addition to the non-product impurities, large amounts of undesirable product-related isomers are now also present. As a result, there are three major challenges in developing an efficient downstream process for MAb manufacturing with highly productive cell culture: (i) process capacity, (ii) removal of process impurities, and (iii) removal of product-related impurities. Unless radically new product recovery methods become available and accepted quickly, product concentrations higher than 2 to 5 g/liter may not even be considered as desirable (74).

Over the past few years, to cope with the much higher cell culture titers, an increasing emphasis has been placed on developing effective and economic downstream purification processes. Downstream recovery has become a significant portion of total manufacturing cost and also has begun to limit overall facility throughput. Rather than investing in greater infrastructure, which can be costly and risky and ultimately is limited by column sizes, the MAb industry is moving more toward using current capacity more efficiently (24). This is being achieved by (i) altering the order of operations, (ii) integrating and combining unit operations to reduce overall processing steps, (iii) introducing improved chromatography matrices such as membrane separation, (iv) using new resins with enhanced dynamic binding capacity (71, 138, 186), and (v) employing disposable technologies as opposed to fixed equipment (32, 115, 177). In addition, a platform approach that begins with a boilerplate purification process that is adjusted and optimized for a given project is gaining popularity. This maximizes the efficiency of the purification process and product purity while minimizing the development time for early-phase therapeutic antibodies (39, 72). New techniques and technologies such as single-use apparatus, cation exchange membrane adsorbers, simulated moving bed chromatography, single-pass tangential flow filtration, high-performance tangential flow filtration, precipitation, and crystallization are being introduced, which may help utility use and overall cost of goods, and overcome bottlenecks in existing facilities (28, 143). The improved efficiency also leads to other cost benefits, including reductions in raw material use, buffer consumption, waste disposal, and downstream processing facility requirements.

13.1.1. Overview of Downstream Processing

In the biopharmaceutical industry, downstream processing is a series of unit operations that starts with a large volume

of a complex biological mixture and refines it to a small volume containing the purified product in bulk form (134). The stepwise process begins with cell separation, followed by concentration and purification steps of increasing specificity or resolution based on molecular size, electric charge, solubility, and/or binding affinities. For economic reasons, volume reduction is the first concern. For regulatory compliance and patient safety, inactivation and/or removal of contaminants takes the highest priority. For the sake of product, solubility and structural integrity are of greatest importance.

Three major types of operations are used in biopharmaceutical downstream processing. (i) Fluid filtration is vital to the clarification, concentration, and refinement of process streams, whether using tangential flow filters (cross flow) or depth filters (normal flow). Ultrafiltration (UF) and microfiltration (MF) are most often used in bioprocessing, with UF as a pressure-driven convective process using semipermeable membranes to separate or concentrate soluble species by molecular size or shape (109, 141), and MF as a lower-pressure process to separate micron-level particles (including cells) for solution concentration or clarification (135, 168). One advantage of this technique is the creation of a particle-free harvest stream that requires minimal additional filtration. Normal flow filters are used where clarification and/or bioburden reduction is desired in streams with relatively modest solid contents. They protect or enhance downstream operations or final polishing to achieve sterility. Positively charged depth filters have been used for a variety of applications, including the removal of endotoxin and DNA (35), HCPs (165, 181), and retrovirus as well as parvovirus (165). Membrane filters often find their use by supplementing chromatography steps, by providing clean feed streams, buffer exchange, product concentration, virus removal, and sterile filtration. But membrane fouling due to filter clogging or accumulating layers of cake- or jelly-like sedimentation can cause protein precipitation and aggregation, leading to product loss. Chemical additives and periodic backwashing can keep it from happening. Air must be kept to a minimum in process streams to prevent foaming, and low flow rates and pressures must be used for delicate proteins. (ii) Liquid chromatography now forms the basis of industrial purification processes after 5 decades of innovation (26). Usually two or more different types are employed, and a process chromatographic capture-purify-polish regimen is ubiquitous. The basic chemistries involved for large-scale application are mostly based on liquid adsorption, i.e., molecular affinities, ion exchange, and hydrophobic interaction. The steps typically include column packing, sample load, and product elution. Elution at large scale is mostly achieved by using displacement, while pH or salt gradient is the common choice for analytical application. Ion exchange chromatography (IEC) is the "workhorse" method, and most bioseparations can be assumed to include at least one IEC step (146), because of its high binding capacity, high selectivity, fairly inexpensive resins, and straightforward scale-up, ideal for relatively large volumes. (iii) Centrifugation separation is most often engaged at the front end of a downstream process, where it separates nonsoluble material from cell culture supernatant, preventing filter fouling at the later steps. Disk-stack desludging centrifuges offer continuous operation, making their throughput consistent with the desire to limit the time for harvest, and therefore have been popular for removing cells and cell debris (146, 156). But the operating conditions (flow rate, revolutions

per minute, etc.) for disk-stack centrifuges frequently require some empirical optimization (156). In addition to these three operations, other techniques have been or are being developed for bioseparations, such as protein precipitation with concomitant virus kill (16), perfusion chromatography using monoliths (163), and displacement chromatography (76).

By and large, however, the regulatory acceptance of filtration and chromatography in their various forms supports their dominance in the industry. The latest trend is in fact the combination of chromatographic chemistries with filtration media for what is known as "membrane chromatography," a niche application that is ideally suited to capture large molecules from diluted feed streams (187). In flow-through polishing steps, these targets are critical impurities such as nucleic acids, viruses, endotoxins, and host proteins. A disposable membrane is typically oversized for these highly diluted contaminants and is particularly attractive for virus clearance validation (26). In addition, unlike the traditional column chromatography, membrane chromatography can be used in a "plug-and-play" manner. Despite the concerns about its cost, relatively low binding capacity, and issues related to integrity testing, due to the current focus on disposable processing solutions, this technology is establishing a position in the bioseparations arsenal, particularly in MAb purification (103).

For MAb production, the industry has moved to the development of platform technologies to shorten the timeline (43, 72, 155), although case-by-case optimization still remains a challenge for manufacturers with diverse product types. After clarification from cell culture medium, the vast majority of MAbs on the market and in clinical trials are first purified with protein A affinity chromatography for product capture, followed by anion-exchange (AEX) chromatography in flow-through mode to extract negatively charged contaminants such as HCPs, endotoxins, host DNA, and leached protein A, and then cation-exchange (CEX) chromatography or hydrophobic interaction chromatography (HIC) in bind-and-elution mode to remove positively charged contaminants, including residual HCPs and undesired product-related derivatives such as aggregates or degradation products (13, 71). Size exclusion chromatography can also be used for polishing. The bulk product is filtered through a 20-nm filter for removal of viruses, both large and small (139, 164); concentrated to target concentration in the final formulation buffer using an ultrafiltration/diafiltration (UF/DF) device; and finally, sterile filtered through a terminal 0.2- μm membrane filter. Typical yields from an overall downstream process for MAbs range from 60 to 80%.

Purification process optimization must examine the operation of units in concert with one another, and the ultimate goal is to make as much purified product as possible by the cheapest, quickest, most reproducible, and most robust and efficient route. Process time is critical because, due to the limited stability of biomolecules and the high likelihood of an adventitious agent growing in the spent medium environment, any decrease in time will improve process throughput. In addition, the optimization efforts should also focus on system capacity, resin cost, endotoxin removal method, aggregation at higher antibody concentration, worldwide regulatory compliance, and chemical and equipment compatibility (80).

Process impurities include HCPs, nucleic acids (DNA, RNA), leached protein A, potential viral contaminants, and certain medium components (e.g., insulin, methotrexate).

The accepted levels according to current guidelines from regulatory authorities are <5 ppm for HCPs, <10 ng/dose for ribosomal DNA (rDNA), and <5 ppm for leached protein A (43). The most critical concern in mammalian cell processes is viral clearance (142). The virus removal steps should achieve a log reduction sufficient to ensure theoretical viral counts no higher than 1 per million doses, and the ability of purification steps has to be demonstrated for sufficient removal of a range of virus types through virus clearance validation studies (42, 54).

13.1.2. Recovery Separation—Removal of Cells and Cellular Debris

The harvest process separates the antibody products released in the culture supernatant from the cells. A primary clarification step is usually achieved by centrifugation or a membrane process such as tangential flow (or cross-flow) microfiltration (133, 156). Although depth filtration can be used as a primary harvest method, it is commonly seen to follow the primary harvest step to provide additional clarification (180). The unavoidable bioreactor variability has little effect on sizing of primary harvest operations because they are scaled based on bioreactor volume, not product concentration. Due to improved centrifuge design by leading vendors (Westfalia, Oelde, Germany, and Alfa Laval, Lund, Sweden) and the changeover flexibility (171), continuous centrifugation has become the most common harvest method for large-scale cell culture broth volumes of 2,000 and 20,000 liters (156). The cell turbidity of the cell-free supernatant can vary with the total number of shots (full or partial) and the buffer volume per shot (100); therefore the supernatant needs further clarification through depth filtration. Because depth filters do not have an absolute pore size cutoff rating, the clarification needs to be followed by an in-line 0.2- μm dead-ended microfilter to effectively remove any residual particulates for the subsequent capture chromatographic step. The optimal depth filtration is dependent on filter type, flux, and total membrane area. Large-scale depth filtration can now be readily scaled up with process-scale housings and disposable filter modules. Often, the filter can not only reduce the turbidity, but also remove up to 50% of DNA impurities and 15% of HCPs at neutral pH (100). Another widely used harvest technique is a tangential flow MF-based strategy, particularly at scales at or smaller than 2,000-liter, because centrifugation is considered a significant capital investment. The development of an MF harvest method is outlined step by step (135), and its optimization for cell culture harvest has been well studied (34, 82, 128, 172). Benefiting from the evolution and evaluation carried out in the past 15 years, harvest techniques for mammalian cell culture systems can now be expected to operate with high yields (>98%) and minimal cell disruption (156). The very high titers that can be achieved in cell culture operation, as described above, mean that the current cell culture scales are likely to stay with us for some time, so the improvements in harvest and clarification are likely to be in the form of gains in efficiency and throughput and improved understanding of existing unit operations.

13.1.3. Primary Purification—Initial Product Capture and Concentration

At present, MAbs or Fc fusion proteins dominate the biopharmaceutical industry pipeline, and the use of affinity chromatography resin continues to be the mainstay of antibody purification, which offers a simple and effective

way of reducing the number of processing steps by incorporating both a capture and concentration step with a high degree of purification. Protein A is an affinity ligand that binds specifically the Fc region on immunoglobulin G (IgG) molecules, allowing everything else to wash through; then a high-salt or low-pH buffer is applied to desorb the antibody from the column. Matrix fouling can happen if a large number of impurities are present. Wider columns can be used to accommodate larger sample volumes, and regeneration and reuse are critical. It can be repeatedly used to capture and purify the product to up to 98% purity and to remove most process impurities including protease in one step, with step yield easily over 95%. Also, protein A resin can offer greater vendor reliability, improved resin packing permeability, or lower nonspecific binding than cheaper alternatives (80). Regulatory authorities also have familiarity with protein A affinity chromatography. Therefore, despite the growing trend of searching for alternatives due to its very high cost (about 10 times that for the less specific ion exchange resins) (8, 118), stability concern related to cleaning-in-place regimes, ligand leakage, and limited capacity (<50 g/liter) (97), protein A affinity chromatography remains the most efficient purification step for antibodies and is unlikely to be replaced for the foreseeable future in the primary capture step, which is the most significant bottleneck of all (26, 89).

Two major types of resin dominate the industry—agarose-based (GE Healthcare, Amersham) and glass bead-based (Millipore, Billerica, MA) resins. Both are robust enough to handle high flux and resist most cleaning chemicals including alkaline. Dynamic binding capacity is in the range of 20 to 50 g of antibody per liter of resin, and both can be reused up to 200 times. The difference is that agarose-based resin has very low nonspecific binding, but it is less mechanically rigid, so a linear flow rate of ≤ 300 cm/h and a bed height of ≤ 20 cm should be employed. On the other hand, glass bead resin can tolerate high flow rate and bed height without significant back-pressure, but it has higher nonspecific binding and is also sensitive to caustic solutions. To minimize proteolytic degradation of antibody product and protein A resin, a low loading temperature (12 to 18°C) should be used. Other operation conditions should be optimized to achieve maximal binding capacity (through resin type and loading residence time), minimal residual HCP and rDNA levels (through composition, pH, and volume of wash buffer), and minimal turbidity, conductivity, and aggregation in eluate (through composition and pH of elution buffer). High-capacity resins are needed to keep column and tank sizes low, to minimize buffer consumption and disposal, and to make the best use of facility space. The dramatically improved cell culture titers have put downstream processing as the rate-limiting step for antibody production, but the “true bottleneck in recovery processes is the first adsorptive column” (105).

Usually after protein A affinity chromatography, a viral inactivation step at low pH follows. This is because viruses are best removed early in the first purification steps so they don't complex with antibodies to get a “free ride,” which can ease quality and regulatory concerns. At pH of approximately 3.4 to 3.8 for 60 to 120 min at room temperature, the inactivation is effective on enveloped RNA viruses such as the retrovirus murine leukemia virus (MuLV), while nonenveloped DNA viruses such as murine minute virus (MMV) are not efficiently killed. In some cases, antibody is captured onto a protein A matrix, followed by low-pH hold and elution, which is effective as a combined purification

and virus inactivation step (81). After low-pH inactivation, the subsequent pH up-adjustment sometimes results in turbidity, which can be removed by a 0.2- μm membrane filter or a depth filter, a step that may also reduce HCP and rDNA levels, and even some MuLV and MMV viruses at 2 to 4 log reduction units (165).

13.1.4. Additional Purification—Removal of Bulk In-Process Impurities

Post-protein A, among several chromatography methods, AEX is perhaps the most powerful in removing residual amounts of negatively charged impurities such as endotoxin, rDNA, HCPs, and viruses. AEX is generally carried out in flow-through mode under a pH lower than the pI of the MAb but higher than most impurities, so that the negatively charged impurities bind to the resin while the positively charged antibody product flows through. The Q Sepharose (strong) and the DEAE Sepharose (weak) anion exchangers (GE Healthcare) are commonly used. To permit high volumetric flow rates, a large-diameter column with specific bed height is required for proper flow distribution (43, 182). This leads to a large column volume, which is optimized for fast flow but not for binding capacity. To overcome this disadvantage, membrane chromatography has been developed. Current Q membrane technology offers major advantages over packed-bed resin chromatography for antibody purification, including fast operation, low buffer consumption, disposability (thus no requirement for cleaning and storage validation), easy and quick qualification, good scalability, and high antibody recovery (>98%) (75, 92).

13.1.5. Polishing Chromatography—Removal of Specific, Low-Level In-Process Impurities

Typical polishing objectives are to remove high-molecular-weight aggregates, product isomers, leached protein A, and remaining trace amounts of HCPs and rDNA. CEX in bind-and-elution mode is a powerful tool for removing product-related impurities left behind after protein A affinity chromatography and also those that cannot be taken care of by AEX. While it is not considered a significant mechanism for viral clearance and HCP/rDNA removal compared to AEX, an ideal CEX resin can leave the majority of residual HCPs, DNA/RNA, and endotoxin in the flow-through fraction. Deamidated or acidic by-products can be separated in the front peak, while the amidated or basic materials and dimers/aggregates can be isolated in the tailing part. CEX is the major mechanism to remove antibody aggregates. CEX resins should be screened for low HCP binding, high dynamic binding capacity under high conductivity, and high resolution to remove product variants (100). Linear gradient elution provides better purity, process monitoring and control, and reproducibility, while stepwise elution obviously is mechanically simpler with higher product concentration. Compared to the commonly used salt gradient, a pH gradient elution can support similar product purity but higher yield at <50% pool volume, which was shown at large scale with an overall recovery of >95% (100). The process reliability of pH-conductivity hybrid gradient CEX with high-step purity and yield at multiple 2,000-liter runs was also reported (185). The SP Sepharose (strong) and the CM Sepharose (weak) cation exchangers (GE Healthcare) are commonly used.

HIC and ceramic hydroxyapatite chromatography can also serve as efficient methods to remove dimers and aggregates (68). However, HIC has relatively low yield and leads

to high salt concentration in the elution pools. So instead of bind-and-elution, HIC is used more in a flow-through mode to remove a large percentage of aggregates, in which slow flow rate is necessary to allow sufficient time for aggregates to bind to the resin. For ceramic hydroxyapatite chromatography, remaining technical issues include lot-to-lot variability, extractables, and the short resin half-life.

13.1.6. Virus Removal Filtration

Viral contamination is a risk to all biopharmaceutical products (including MAbs) derived from cell lines of human or animal origin (42, 129). Viral safety should be considered throughout the life of a biopharmaceutical manufacturing process, from process design to selection of source materials to setting process limits (51, 53, 54). Contamination of a product with endogenous viruses from cell banks or adventitious viruses from production processes can have serious clinical implications, so regulatory guidelines (25, 42, 54) mandate that therapeutic biological product manufacturers implement adequate technologies in their manufacturing processes to remove or inactivate known or adventitious contaminants based on a process-specific virus clearance strategy. At least two virus removal/inactivation steps are needed, one based on filtration and another on inactivation, which is typically incorporated between the earlier steps such as protein A and AEX, as described above. The entire purification process for clinical manufacturing must be validated to achieve a 16- to 20-log reduction of viral load using two (for early clinical phase) to four (for late clinical phase) different and representative viruses.

A statistically independent combination of methods (orthogonal approach) is required for removing enveloped and nonenveloped viruses, with the methods based on different physical principles of removal and inactivation and yet complementary to each other (160). Viral inactivation and filtration are specifically designed and dedicated steps that effectively clear viruses. Solvents, detergents, chemicals, low pH, etc., can be used for virus inactivation. Low-pH inactivation is demonstrated to be effective against enveloped viruses, and its effectiveness is highly dependent on time, temperature, and pH (15). Nanofiltration such as using 20-nm retentive filters has traditionally been accepted as a robust method for clearance of both large and small viruses (139, 164), despite the fact that it is the most expensive downstream step and needs a lot of optimization (74). However, the combined log reduction values of these steps rarely exceed 12 logs due to the limited sensitivity of virus assays, which means that chromatography adsorption must provide additional clearance to achieve a typical 16- to 20-log reduction requirement. This can be mainly achieved by AEX (about 4 to 6 logs) plus protein A (about 2 to 3 logs). The relatively new membrane chromatography technique is efficient in removing small nonenveloped viruses (188), meeting or exceeding the viral clearance performance of AEX (7, 129). Its disposable feature not only reduces capital costs, but also eliminates post-use cleaning, sterilization, validation, and risk of contamination carryover, thereby simplifying adsorptive virus clearance (46, 188).

Viral clearance studies are used to measure the relative safety of purification processes, and it is essential to ensure that the studies are carefully designed to exactly reflect the scale-down of the manufacturing conditions, or the worst-case scenarios if established, thus providing key data rather than becoming just a box to check on the way to licensure of a product (21, 167). A virus spiking trial needs to be performed to validate the efficiency of the purification

process steps (78, 164). Duplicate runs are needed (42). Depending on the feasibility and purpose, relevant/specific model viruses or nonspecific model viruses should be selected (54). For cell lines that express retroviral particles, such as CHO, NS0, and Sp2/0, two model viruses are used to assess the ability of downstream processes to clear virus (54). MMV or porcine parvovirus (PPV) can be used as a model of parvoviruses, which are a known contaminant of bioreactors and are relatively small and resistant to physical inactivation. MMV or PPV can be readily removed by a 20-nm filter (>4 logs in this one step). The other is a specific model of retroviruses for cells of murine origin, MuLV. Retrovirus-like particles theoretically pose safety concerns to humans because of their morphological and biochemical resemblance to tumorigenic retroviruses (33, 153). The target of clearance is 6 logs in excess of retroviral load in the unprocessed cell culture harvest broth, which is typically in the range of 10^5 to 10^9 virus-like particles/ml broth. For example, if there are 9 logs of counts in broth, a production process of 2-g/liter cell culture titer needs to achieve an 18-log reduction factor during purification to ensure no more than 10^{-6} viral counts per dose (54) for a typical antibody dosing of ~2 g. Higher titer or lower dosage can reduce the log reduction factor requirement.

13.1.7. Final Formulation—Final Dosage Concentration and Buffer Formulation Including Bioburden Reduction Filtration

After the antibody is purified out from the mixture, the “bulk” drug goes into final processing—formulation. The development of formulation buffer is discussed in the next section. Usually at this stage, the antibody solution from the virus removal filtration step is concentrated by UF, then exchanged into the desired formulation buffer by DF. The two operations are performed on the same UF/DF membrane filter with a molecular mass cutoff of 30 to 50 kDa, which retains the IgG molecules of about 150 kDa. The UF and DF steps can alternate based on an optimized scheme to minimize buffer consumption while avoiding product aggregation, until the desired final MAb concentration is reached, with the buffer thoroughly exchanged into that of the final formulation. While final concentrations are normally about 110 mg/ml (145), a robust, scalable UF/DF formulation process was developed which produced up to 183 mg/ml MAb as clinical study supplies (109). The formulated solution is then subject to the terminal sterile filtration using a 0.2- μ m membrane to give rise to the bulk or drug substance.

13.2. FORMULATION DEVELOPMENT AND FILL/FINISH FOR BIOPHARMACEUTICALS

Just as the physicochemical properties of an antibody make all the difference in how it is purified, they also determine what type of formulation will suit it best. One of the most challenging tasks of developing protein biopharmaceuticals such as MAbs is to deal with and overcome their inherent physical and chemical instabilities (147), which have the potential to alter the state of the molecule from a desired (native) to an undesirable form upon storage, compromising patient safety and drug efficacy. Formulation development is to overcome this inherent instability to changes in pH, osmolality, tonicity, pressure, and temperature, and it is a major area of biopharmaceutical development (144). Various factors can affect the decision on a formulation, including the reliability, cost, and availability of analytical methods; the availability of qualified excipients and stabilizers on the

market; methods and devices of delivery; product form, dosage frequency, and concentrations; patient preferences and behavior; biology of the disease; transportation and storage; packaging; manufacturing process; and considerations of legal, sales, and marketing issues (145).

By far the most common delivery method used in the biopharmaceutical industry is parenteral dosing, that is, liquid formulations for subcutaneous (SC) injection or intravenous (IV) drip, because of the assured bioavailability compared to oral route (70). Although an IV liquid formulation is most commonly used for toxicology and phase I studies, potential target indications and market competition often lead different dosage forms to be evaluated. For example, for non-life-threatening diseases that require systemic administration, the convenience of an SC formulation is preferred to an IV formulation. Similarly, for administration convenience and patient compliance, a stable liquid formulation is a better choice than a lyophilized product. Further, a higher product concentration is desirable if less frequent administration provides the same therapeutic effect, and in some cases such as SC administration it is a must because of the limit on the injection volume.

13.2.1. Preformulation

Preformulation is an initial development of formulation, which is an exploratory activity early in development that characterizes the antibody and its compatibility with potential excipients toward safe, stable, beneficial, and marketable product. For example, administration by the SC route requires that the MAb is available at high concentration (over 100 mg/ml) in the vial. Therefore, a concentration study in various buffers needs to be considered to investigate solubility behavior, concentration effect on viscosity, and increased potential for aggregation. These studies have the potential to strongly influence the target product profile as well as the design of clinical trials.

While there are numerous ways for a protein product to lose its stability, three are the most common: aggregation (physical), oxidation, and deamidation (chemical) (120). Physical degradation changes only the higher structures (secondary, tertiary, and quaternary) of a polypeptide, resulting in aggregation but not necessarily creating a brand-new molecule. Such degradation can also occur as adsorption, unfolding, and precipitation. Chemical degradation changes the primary structure of a protein, which is usually preceded by a causal physical process, typically unfolding, that makes available residues that are usually inaccessible for chemical reactions with their environment. Certain amino acids in protein molecules are susceptible to oxidation, and metal ions, high pH, fluorescent light, and hydrogen peroxide can all cause or aggravate oxidation, in addition to atmospheric O_2 itself. Deamidation leads to the hydrolysis of a side-chain amide on a polypeptide's glutamine or asparagine residue to yield a carboxylic acid, which is facilitated by elevated temperature and pH (73).

Several approaches have been identified to prevent or inhibit chemical degradation, including effective excipients, reducing agents, optimal pH, and lyophilization. Sucrose was shown to inhibit the conformation mobility of a serine protease, thus inhibiting oxidation (31). It was observed that addition of an antioxidant such as methionine thiosulfate significantly reduced the oxidation rate of an anti-HER2 antibody (96). The improved stability of a therapeutic protein was also demonstrated by pretreatment with a reducing agent (184). Most antibodies require a slightly acidic to neutral pH for maximum stability because

of their slightly basic isoelectric points (pH of approximately 8 to 9). For those protein products not sufficiently stable as aqueous solutions, the lyophilized formulation can be used. The key is to protect the protein from unfolding during the freezing and vacuum-drying stages (19). Thermodynamic stabilizers can be used to inhibit unfolding of a protein in the presence of low concentrations of denaturants (90). Sucrose and trehalose are the most commonly used excipients to serve as cryoprotectant and lyoprotectant. The former excludes water and protects proteins from freezing stress (147), while the latter substitutes for water and protects protein from drying stress (22). In addition, nonionic surfactants such as polysorbate (plant-derived) or Tween (animal-derived) can be employed to protect proteins against freeze-thaw and agitation-induced aggregation, primarily by competing with stress-induced soluble aggregates for interfaces, thus inhibiting subsequent transition to insoluble aggregates (20). Polysorbate 80 is also widely used for stabilizing antibody IgGs in liquid formulation because it prevents small aggregates from progressing (27) and can be used to reduce the detrimental surface adsorption at low protein concentrations. In addition, polysorbate 80 decreases the opalescence in a NaCl-containing formulation for MAbs (173). By far the most widely accepted methods of protein stabilization are additives and excipients, cryopreservation, and freeze-drying (12).

There are practical issues that need to be considered during formulation development (23). Chemicals used in a manufacturing process can contribute to product instabilities. For example, chloride ion in a low-pH formulation can corrode stainless steel storage tanks for buffers and/or products, thus compromising protein stability. Increase in ionic strength can result in higher viscosity and opalescence (173). High viscosity of a high-concentration MAb solution is difficult to scale because of poor recovery and instrument constraints. Formulations containing sodium phosphate can experience significant pH drop during lyophilization because of precipitation of Na_2HPO_4 upon ice crystallization. A citrate buffer in an SC dosage form may cause injection-site pain. A near neutral pH and isotonic formulation is preferred for SC dosage forms. New excipients require extensive toxicity studies. Finally, cost of certain excipients may be a factor; for example, trehalose is much more expensive than sucrose and may present supply issues.

13.2.2. Formulation Stability

Formulation development is primarily about stability and the mode of use of antibody. The fragile proteins need to be protected from denaturation and degradation until they can be delivered to their site of action in a patient's body. The antibody development process does not allow enough time to confirm stability requirements for a final formulation, which could take 2 years, before it is ready to apply for marketing. But testing of the structure and innate stability of the antibody using various analytical methods should begin as soon as a final formulation is decided, and the results should be updated frequently (59). Accelerated stability tests subject products to various stresses over a period of about 3 to 6 months, including a range of pH values, heat, light, freezing and thawing conditions, additives, and surface materials and interfaces (112, 161). The signs of degradation are observed and used to predict long-term storage behavior. Although accelerated tests are needed, real-time tests are the ultimate proof (110, 111). During stability studies, in addition to physical and chemical assays

to monitor the physicochemical properties of the protein, bioassays are used to evaluate antibody activity, identity, and critical pathways. If any of these parameters is changing with storage time, the formulation will need to be improved in order to meet the current market demand of 1 to 2 years of storage for most products. In general, formulation decisions are made primarily on product stability (shelf life), followed by convenience of use and cost-effectiveness.

Because of the extreme sensitivity of antibody stability to multiple physical and chemical factors as discussed above, in addition to the testing of purified bulk substance and drug product, testing the stability of process intermediates using various analytical methods should take place wherever there is potentially a storage period during a purification process. Physical and chemical assays are employed to monitor the physicochemical properties of IgG, such as molecular integrity, charge variation, aggregation, concentration, and pH in the solution. Microbiological assays are used to demonstrate the absence of microbial growth, which can otherwise introduce contaminants to the preparation, potentially changing the protein structure and even jeopardizing the safety profile of the product. If any of these parameters change with storage time, the in-process hold step will need to be redefined, either by shortening or eliminating the storage period or by improving the storage environment such as buffer formulation or temperature or container. A degraded or aggregated process intermediate cannot lead to a final drug product that meets the quality requirements.

13.2.3. Drug Delivery

How a biopharmaceutical is formulated may also depend on the intended mode of delivery. The most common delivery method used in the antibody/biopharmaceutical industry is parenteral dosing of liquid formulations (70). High-concentration formulation (>100 mg/ml) enables less than 1 ml per SC injection, for which gentler fill technology than traditional vial-fill is required to avoid sheared, precipitated, or aggregated product during the filling process. Lyophilization or UF/DF can be used to concentrate the formulation (109). For better patient comfort, convenience, and dosage compliance, other notable technologies under development include needle-free injection by means of high-pressure air or liquid that forces tiny droplets through the skin, allowing self-administration of medications without a hypodermic needle, and controlled delivery that makes it possible to control the duration (sustained delivery) and the site of action (targeted delivery) of a biopharmaceutical (12). The sustained delivery is achieved by a depot of drug created in the body to release the drug over a specified time, which can be implanted by emulsification, coacervation, extrusion, and polymerization; targeted delivery has been practiced for some time using the high specificity of MAbs and surgical implantation. Currently, needles and syringes—especially with the new trend toward prefilled syringe packaging—remain the most practical option for protein delivery (145).

13.2.4. Fill and Finish

Fill and finish is the actual process of dividing a biopharmaceutical bulk formulation into dosage forms for sale or clinical study use. The product container, the cap, the label, the packaging, the patient instruction, and the transportation are all part of filling and finishing a product. The operation is often at least partly automated, with aseptic conditions being the priority. Unit processes in manufacturing finished

dosage forms include compounding and mixing, filtration, filling, lyophilization, closing and sealing, sorting and inspection, labeling, and final packaging for distribution. Each of these steps faces challenges and must be controlled carefully to ensure quality of the relatively unstable and interactive biopharmaceuticals (1).

The protein nature of MAbs requires more care in handling and preservation than classical small-molecule pharmaceuticals, because proteins have limited stability in their liquid state. To preserve the bulk liquid therapeutics before fill so as to meet the current market demand of 1 to 2 years of storage for most products, the most effective method currently is freezing, which also adds flexibility to the manufacturing process. But the subsequent thawing operation stresses protein molecules, and each additional thaw reportedly increases degradation (174). Parameters such as processing time, temperature, pressure, solute distribution, and pH need to be carefully controlled, and the product must not change physicochemical characteristics nor lose bioactivity during freezing and thawing.

For protein products not sufficiently stable as aqueous solutions post-fill, lyophilized formulations are often used. A lyophilized biopharmaceutical drug maintains its potency over time, thus adding flexibility to the entire manufacturing operation and extending the shelf life of the drug product. About half of the biopharmaceuticals currently sold are shipped and stored in freeze-dried form at room temperature (145). To achieve this formulation, the protein needs to be protected from unfolding/aggregation during the freezing and the subsequent drying stage (2), and thermodynamic stabilizers can be used to inhibit the unfolding of a protein (90). As stated above, sucrose and trehalose are common excipients to serve as cryoprotectant and lyoprotectant, and polysorbate 80 can protect proteins against freeze-thaw and agitation-induced aggregation. Operationally, control considerations in a freezing process include minimizing freezing speed, reducing convection and cryoconcentration, and preventing mechanical stresses in the vessel. One recent trend is toward use of organic solvents such as ethanol for increased sublimation rates and improved product stability (145). For a thawing process, the important control factors include avoiding overheating, maximizing convection in liquid phase, preventing interaction among formulation components, and avoiding internal melting, which creates a negative-pressure cavity that can degrade proteins. The options for reconstitution of lyophilized biopharmaceuticals were reviewed recently (131).

As parenteral drugs, MAbs must be free of all microorganisms; therefore, they must be packaged aseptically in a class 100 clean room with strict limits on viable and particulate contamination, and with production personnel thoroughly gowned up to keep the drug from being exposed to human-borne contaminants (60). There are many considerations for aseptic filling of parenteral biopharmaceuticals, including the product's physical characteristics and its intended market, which determine the most appropriate facility, filling equipment, delivery system, and container-closure system (77, 158). An automated parenteral production line usually consists of a washer, a depyrogenation tunnel, and a filler (with companion check-weigher). The filled vials are stoppered and secured with an aluminum cap. The final product is inspected, labeled, boxed with patient insert information, and shipped. Lyophilized products are filled in liquid form and then freeze-dried before completing the packaging. Alternatives to vials include ampoules,

syringes, and cartridges. Recent trends in fill and finish include the development of barrier systems (123), which enclose the fill operation and thus reduce the chances of opportunistic contamination and the need for a clean room. Barrier isolators, which are gaining rapid acceptance by industry and regulatory authorities, have the major advantage of sterilizing equipment and enable sterile filling instead of the traditional aseptic filling, but are specific to the product and process used, difficult to clean, and complex to design. Blow-fill-seal production is an alternative approach that fills and seals protein drug solutions into plastic containers in a sterile enclosed area inside a machine, minimizing human intervention (88).

13.3. BIOANALYTICAL METHOD DEVELOPMENT AND QUALIFICATION

A broad variety of bioassays and analytical testing are required for a biopharmaceutical before it reaches the market. The relation between the kinds of results needed and the type of test that must be performed, as well as regulatory requirements and how to ensure consistency of results over time and at different locations, are topics of various surveys, reviews, and publications (132, 137, 157). The analytical methods, procedures, and instruments need to be validated to qualify the use (55, 56, 61, 93, 94). No company can develop and perform every kind of testing in-house, so there need to be strategies for deciding which tests to outsource.

13.3.1. Lot Release Testing

The development of complex biological materials such as MAbs as therapeutic agents requires comprehensive assessment with regard to regulatory guidelines. Reflecting the importance and complexity of MAb products, several statutory and guidance documents have been issued by the U.S. Food and Drug Administration (FDA) recommending approaches for characterization and lot release (47, 48, 53, 55). Generic test methods for MAbs cannot be recommended because the "critical quality attributes" that affect product potency and safety are product specific. However, a basic set of lot release test methods should be included for each individual MAb. The view generally accepted is to perform release tests on the quality attributes that are related to product performance (safety or efficacy) or stability (137), including aggregation and size, molecular weight, free sulfhydryl groups, heavy-chain glycosylation, C- and N-terminal heavy-chain heterogeneity, and fragments/IgG4 half molecules.

The most commonly used analytical characterization and lot release techniques for development of biopharmaceutical proteins are spectrophotometric, chromatographic, electrophoretic, and mass spectrometric (113), although the current preference is for assays easier to perform and control than mass spectrometry. For MAb products, the following test methods often need to be developed as the analytical tools for characterization and lot release (119, 137): (i) identity (for product identification) by isoelectric focusing (IEF), capillary gel electrophoresis, specific binding, or peptide mapping (36); (ii) native size (for aggregates under native condition) by size exclusion chromatography, analytical centrifugation, and electrospray ionization mass spectrometry (ESI-MS); (iii) denatured size (for fragments/half molecules) by denaturing sodium dodecyl sulfate-polyacrylamide gel electrophoresis, size exclusion chromatography, and capillary gel electrophoresis; (iv) charge heterogeneity (for C-terminal lysine truncation and

other charge variation) by IEF and capillary IEF, IEC, and capillary zone electrophoresis; (v) N-terminal heavy-chain heterogeneity (for structure integrity) by peptide mapping, ESI-MS, enzyme digestion, and high-performance liquid chromatography (HPLC); (vi) heavy-chain glycosylation (for oligosaccharide pattern) by ESI-MS, enzyme digestion, and HPLC; (vii) free sulfhydryl groups (for antibody stability) by fluorescent technique (183); and (viii) potency (for functional capability or biological effect) by cell- or animal-based bioassays, enzymatic assays, and binding assays. In addition to the product itself, process-specific analytical tools need to be established and validated to ensure that impurities introduced during production of antibodies are eliminated to the desired extent, for example, components added to the medium such as methotrexate for the dihydrofolate reductase expression system or methionine sulfoximine for the glutamine synthetase expression system, insulin, transferrin, etc.; protein A leached from the resin; and host cell DNA and proteins (157). Immunological and enzymatic methods are widely used in the detection of biological impurities due to their increased sensitivity and specificity over analytical methods (e.g., HPLC).

During release, stability, and formulation studies, cell-based biological assays are a critical and ubiquitous component of MAb testing, because the product's biological function, or potency, is a quality issue. From candidate selection and product release to product stability assessment and process change proposal, as well as during pharmacokinetics/pharmacodynamics (PK/PD) evaluation and drug response measurement, cell-based bioassays for functional and binding measurements are required. Since binding assay results do not necessarily correlate with functional assay results, the correlation of a binding assay with a cellular/functional end point must be validated before it can be used for lot release (137). Despite the fact that it is only in clinical trials that the clinical potency is determined and the dose range defined, regulatory guidelines state that "a correlation between the expected clinical response and the activity in biological assay should be established" (55). Thus, there needs to be an understanding of the mechanism of action of the product. It is not always possible to completely understand the mechanism, in which case more than one potency assay may be necessary. It is also often the case that *in vivo* assays are established later in the product development cycle when the "go" status has been reached, so at early stages only the binding assay is available for simple quantification of materials and for pharmacokinetics analyses. The various practical aspects of potency assay development have been reviewed (137). The current industry status and trends on bioassays are summarized in a recent survey (132). It should be pointed out that the complexity of the materials and procedures involved in the biological assays results in significantly increased variability as compared to analytical methods, and bioassays are often difficult to develop for use in lot release.

13.3.2. Glycosylation Analysis

Among the many characteristics of MAbs, glycosylation is particularly critical and highly sensitive to upstream process variations. A detailed description of the glycol structure features is increasingly part of the expected content of a New Drug Application or comparability protocol (61, 114). Glycosylation of MAbs is important not only for their biological function (11, 14, 83, 101) but also for pharmacokinetics (37). Because the biosynthesis of glycans does not follow a genetic "code" like protein biosynthesis does, many variations are possible, thus leading to glycan heterogeneity.

The biosynthesis of glycoproteins in mammalian cells and their characterization are well documented in literature (114). Due to the sensitivity of MAb glycosylation profiles to host cell enzymatic systems and bioreactor conditions (124, 148), selection of host cells and culture conditions must consider the requirement for stably producing each specific glycosylation pattern. Appropriate analytical tools must therefore be developed for in-process monitoring to determine any changes due to culture conditions. A high-throughput analysis of the N-glycans of NS0 cell-secreted antibodies is described (29). Peptide mapping, HPLC, CEX, IEF, capillary electrophoresis oligosaccharide mapping, nuclear magnetic resonance, various types of MS, and specific potency assays can all be used to detect glycol variants. A combination of tandem MS, methylation analysis, and exoglycosidase digestion was employed to characterize the oligosaccharide structures of Campath IgG1 from CHO and NS0 (152). A combination of tryptic digestion, HPLC with fluorescence detection, and MS analysis was used to characterize N-linked oligosaccharides of MAbs (91, 107).

13.3.3. Assay Development and Validation

When developing a new assay method for a new antibody/biopharmaceutical product, optimizing an existing method for an existing product, or changing a release method for a licensed product, many validation elements should be considered (56, 57, 61). The development and optimization process can improve an analytical method, but validation does not. Validation is the final proof that regulations and expectations are met. A list of regulations and guidance governing analytical method development and validation are provided by Kanarek (87). The minimum requirements for the development and validation of a new method are summarized in ICH Q2(R1) (61), and method validation approaches can be found in recently published literature (87, 95). Current GMP regulations also require analytical instruments to be qualified to demonstrate suitability for the intended use (57, 166). Similar to analytical method validation, analytical instrument qualification is to ensure the quality of each analysis before tests are conducted, which includes qualifications on design, installation, operation, and performance (10). A standardized DQ (Design Qualification), IQ (Installation Qualification), OQ (Operation Qualification), and PQ (Performance Qualification) approach was discussed (178).

Many new analytical technologies are now available for development of biopharmaceuticals in general and MAbs in particular (108, 119, 137), resulting in shorter testing times, increased throughput, greater ease of use, and improved sensitivity, selectivity, and precision. But changing biological assays, such as impurity testing by enzyme-linked immunosorbent assay, to automated or more sensitive ones requires extra care, because any bias in results must be reflected in the release specifications (55). In-process and product specifications should reflect production process consistency and analytical capabilities, unless otherwise dictated by regulation (55). Current GMP guidelines state that GMP documentation and the detail of validation activities should increase as the production process progresses (58). Testing upstream stages may actually be more critical than many final container release tests because it provides evidence of cell culture quality and the efficiency of impurity removal, despite the fact that the tests are more uncertain and variable. Final container testing attests that active and inactive formulation components remain at predicted levels with little variability. The analytical methods should detect

lot-to-lot variations, while whether the measurements are extremely accurate (100% recovery) is not as important.

13.4. GMP MANUFACTURING OF BIOPHARMACEUTICALS FROM MAMMALIAN CELL CULTURE SYSTEMS

Having developed a robust and productive cell culture process, a reproducible and high-yielding purification method, and reliable analytical tests for manufacturing controlled lots to be used for clinical trials and eventually for commercial sale, successful implementation of large-scale manufacturing in compliance with cGMP guidelines becomes the ultimate test for biopharmaceutical companies. Some of the cGMP manufacturing concepts have been introduced in the above sections and in the previous chapter. Additional regulatory compliance requirements for cGMP manufacturing are included in this section.

The goals of cGMP can be summarized as (143): protect the product from contamination; prevent mix-ups; know what you are to do before you do it; document what really happens; strive for consistency and control; have an independent group make the final decisions; and solve problems, learn from mistakes, monitor, and continuously improve. It should be pointed out that the regulatory requirements of the FDA and European Medicines Evaluation Agency (EMA) can differ, with the FDA focusing on process and the EMA on results (175). For investigational new drugs, the FDA issued "Guidance for industry: cGMP for phase 1 investigational drugs" (cGMP1) (65), whose EMA counterpart is "Good automated manufacturing practices 5" (GAMP 5) (79). Differences can be reflected in procedures, facilities, and release requirements, etc. For example, different clean-room settings are expected for fill/finish. It is important to reconcile the guidelines from both agencies, to understand the legal framework, and thus to implement corresponding strategies under the new European Union GMP environment for investigational medicinal products (117).

13.4.1. Characteristics of Desired Manufacturing Processes

Most antibody therapy requires multiple doses at dosages 10 to 100 times greater than those for successful recombinant protein drugs, such as erythropoietin and human growth hormone (126); thus, large amounts of pure product are needed, which requires highly productive and consistent manufacturing processes derived from optimization and validation. On the other hand, most biopharmaceuticals that enter development will fail to make it to the market, so the high cost and resource commitment of a thorough process development effort for a specific drug candidate is difficult to justify until the risk of failure has been decreased by successful results in early-stage clinical trials. Furthermore, speed to market is critical to quickly deliver health benefit to patients and achieve business success. Therefore, for early-stage clinical studies (phase I and phase IIa), a standardized platform process is usually employed despite its relatively low productivity and relatively high variability. Only when the product candidate is proven to be safe and the initial therapeutic efficacy is demonstrated is the process individually optimized and validated to become high-yielding, robust, and economical, suitable to late-phase clinical studies and commercialization. It is important to demonstrate through analytical, nonclinical, and even clinical comparability studies that the manufacturing process changes will not have an adverse effect on the quality, safety, and efficacy of the drug product (62).

It is critical for a biopharmaceutical company to determine what constitutes a good manufacturing process and factor those attributes into the early development platform process, which is much simpler and more effective than trying to change an approved, validated commercial process. Characteristics of a good antibody manufacturing process are twofold: product specific and generic. The former includes maximum yield, high purity, desired log of viral clearance, expected bulk product concentration, adequate product stability, low production cost, sufficient campaign delivery, and adherence to manufacturing schedule. The latter includes safety, compliance, plant capacity, ease of operation, production cost, process characterization/validation, and robustness (179). In general terms, a good manufacturing process should have a safe working environment that minimizes personnel exposure to hazardous chemicals, process waste or by-products, and dangerous working conditions. It should be in compliance with regulatory guidelines on quality (67), which requires the process running as designed, with product specifications guarding against deviations from normal practice. It should maximize plant capacity, and thus productivity, by using fewer steps and/or tanks and/or fewer buffers, but still achieving higher yield and higher success rates. Its operation should use simple and reliable process equipment and solution preparation. The manufacturing process should be cost-effective based on a combined consideration of raw materials, utilities, labor, and facility, with a high batch success rate. A key feature of a good manufacturing process is adequate process characterization and validation, which is required by cGMP regulations (50, 66). Critical process parameters are identified by process characterization, and then the acceptable ranges are validated, before filing of a Biologics License Application. Finally, process robustness is the most important consideration when deciding whether it is a good manufacturing process, which reflects the relative insensitivity to small changes in process parameters or conditions and the simplicity and reliability in operation.

13.4.2. Process Validation

According to the FDA, process validation is "establishing documented evidence which provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality characteristics" (50). This is required by worldwide regulatory authorities, because validation helps to provide a better understanding of procedures and processes, thus making them more controllable for consistent product quality. It also helps prevent costly problems for companies.

Validation begins in process development, continues through clinical trials, and resides in the final manufacturing process (125). In the development stage, statistically designed experimentation and high-throughput methodologies may be employed to high thresholds for optimization in relatively short timelines and using small amounts of starting material (140). It is necessary to have validated analytical tools available to assess any impact on product yield and quality (95). Changes to a process resulting from these investigations must be exemplified in representative systems, and any impact on downstream processing addressed early. Prior to transferring a process to a cGMP production facility, it is vital to demonstrate scalability using pilot-scale versions of the production equipment. Developing a sound process validation strategy early in clinical studies is critical to the success of a validation program (49) and is consistent with the FDA's Quality by Design initiative (63).

MAB manufacturers prepare written validation plans or protocols that specify procedures, tests, and necessary data and analyses. That includes in-process monitoring of important process variables. Test protocols specify a number of process runs to demonstrate reproducibility and variability. All variables cannot be challenged to their extremes, but those that affect product quality are subjected to stressed conditions to demonstrate process robustness (143). The first step in process validation is process characterization, including process, controls, variables, changes, equipment, and assays; performance qualification comes next to ensure the process performs as designed, with process robustness demonstrated at lab or pilot scale; the final phase of validation requires successful completion of several consecutive manufacturing lots that are properly documented following a validation protocol (125).

Although the use of disposables for biopharmaceutical manufacturing may reduce validation efforts, especially in cleaning validation, it does not eliminate them, because there may still be many validation-related issues, such as raw material identity and consistency, leachables and extractables, interactions between antibodies and bag/tubing materials, stability, installation and operation qualification, process validation, disposal, and even cleaning and sanitization (159). Even for using disposable biocontainers for sterile liquid transportation, the system needs to be evaluated and validated (121).

13.4.3. Raw Materials for GMP Manufacturing

In each of upstream, downstream, and formulation steps, biopharmaceutical products come in contact with a variety of raw materials (RMs), starting with culture media for production; followed by filters, buffers, and resins for purification; and finally excipients such as sugars, salts, amino acids, and surfactants for final drug formulation. To illustrate the many considerations in cGMP manufacturing, the RM aspect is discussed here.

An RM is a component that GMP regulation refers as “any ingredient intended for use in the manufacture of a drug product, including those that may not appear in the drug product” (64). The scope of RMs thus includes chemicals, biological materials, liquids, solids—anything that contacts the product during the manufacturing process, including all inactive ingredients contained in final formulations (150). The biopharmaceutical industry uses compendial RMs, which are those that have monographs in major compendia. The grade for an RM can be USP (United States Pharmacopoeia) or NF (National Formulary). For the worldwide market, compliance with multinational regulatory rules is required; thus, multicompendial grades (MC) are needed, or EP (European Pharmacopoeia) or JP (Japanese Pharmacopoeia) specifically.

RM selection, testing, and control strategies form an important part of biopharmaceutical manufacturing tasks. It is critical to understand the relationship among RMs, process design, process settings, and end-product results (106), because biological product characteristics are defined by their production processes, which are affected by the RM quality. Therefore, the primary objective during RM selection and evaluation is quality. Since manufacturing processes employ a variety of RMs that can vary widely in quality (84), an important task is to develop methodologies and strategies that take this variation into account for manufacturing a biopharmaceutical product in a consistent manner.

In the manufacture under cGMP guidelines, RMs need to be characterized and released to ensure that they meet predefined specifications on their quality. Characterization is an important check of the physical, chemical, and biological attributes of an RM, while release ensures that

the RM is suitable for its intended use (136, 151). The guidelines for release (40, 58) govern from the time an RM is procured until it is finally consumed in a biopharmaceutical manufacturing process.

As an example (9), a vendor-made cell culture medium, treated as a single RM, can be characterized and qualified through in-process testing based on established release criteria. The quality attributes include identity, purity, suitability, and traceability. The need for traceability can be exemplified by the requirement in EMEA guidelines (41) that the use of any animal-derived RMs should be justified based on the source animals and their geographical origin, the nature of the animal material, and the production process(es) and the quality assurance system. Properties of a medium that need to be checked include chemical (grade, potency, purity, impurity profiles, etc.), physical (appearance, identity, etc.), physiochemical (pH, osmolality, etc.), and biological (functional capacity in supporting growth and production, etc.). In addition, qualification tests on sterility, endotoxin, and mycoplasma need to be performed to demonstrate lack of bioburden. For liquid media, release criteria from vendors typically are appearance, pH, osmolality, sterility, endotoxin, and in some cases, growth promotion. For powder media, release criteria can also include moisture. Additional quality tests such as measurement of trace elements or heavy metals may also be performed. The test results are supplied on the vendor's Certificate of Analysis.

Upon receipt of the medium from a vendor, most biopharmaceutical manufacturers would repeat some or all of the tests. Assays on pH, osmolality, sterility, and endotoxin are standardized procedures that are well established in the industry, and can also be contracted out to specialized test labs. In addition, according to 21 CFR, Part 211 (64), identity must be confirmed. This can be done by spectroscopy like infrared or nuclear magnetic resonance to see if the RM matches the label claim based on established fingerprints of functional groups. But most of all, the medium needs to be able to support cell growth. A “Pass” or “Acceptable for Use” release criterion by the vendor does not always ensure that the medium can meet the customer's specific process requirements. Growth promotion testing of media is considered unique and needs to be performed by the user (customer) itself, since frequently the criteria for release by vendors do not match the customer's requirements, for the following reasons: (i) the vendor usually does not possess the actual production cell line for real performance evaluation; (ii) the vendor cannot test the medium matrix effect because the customer may supplement additional components to the medium at use; (iii) there may be container effects, such as cholesterol/lipid depletion during medium storage in plastic bags (85, 176); (iv) filtration prior to use in a bioreactor vessel may retain filter-extractable substances; (v) there can be an impact on cell culture performance that can only be detected by a sensitive cell line and when carryover is completely eliminated; and finally, (vi) in-house growth promotion testing at small scale can better take scale-up factors into consideration. Case studies were described to illustrate the development and application of growth promotion testing, along with the influencing factors (9).

13.4.4. Operation and Release

Standard, fixed manufacturing remains a good investment for high-demand drugs. But modular manufacturing facilities let companies easily change and optimize operations and floor space as needs evolve and technology improves. A current trend is to use multiple production bioreactors in a cell culture facility, basing the size and quantity of production

bioreactors on the forecasted annual demand of product, the titer that can be achieved, the bioreactor success rate, and overall recovery and purification yields. Batch processing makes chromatography columns sit idle at times. Staggering batches could increase throughput and relieve bottlenecks by approximating continuous processing. A flexible facility can process more production campaigns, handle a wide range of products and process yields, and ultimately increase the facility output dramatically. Also, productivity improvements can be gained by using smaller equipment or the similar-size equipment in a more time-efficient manner (104).

In addition to widely used disposable bioreactors, single-use apparatuses like filters, tubings, bags, mixing systems, and aseptic connectors can now be incorporated in every process step. Single-use technologies such as noninvasive sensors (127), fully disposable cross-flow cassettes or systems for cell harvest, concentration, and DF, and disposable membrane chromatography capsules have proven effective and cost- and time-efficient for certain steps, replacing the traditional packed-bed chromatography in flow-through operations, including polishing for removal of viruses and contaminants (69, 189). Closed, sterile mixing bags are used for column eluate collection, dilution, titration, and viral inactivation. The single-use disposable process has also been integrated into the critical aseptic processing (fill) operations (17). One application increasing in use is transportation of sterile liquids (121). Single-use systems can be scaled up faster than their stainless steel counterparts and offer process flexibility every step of the way because they eliminate cleaning, sterilization, and their validations; reduce use of caustic chemicals and detergents as well as consumption of water for injection; allow efficient use of space; minimize cross-contamination; reduce downtime associated with stainless steel assembly, labor, cleaning-in-place, and sterilizing-in-place; provide the ability and flexibility to increase production capacity; and decrease capital investment (18). The growth in use of disposables will be a function of economics, which is justified in biopharmaceutical manufacturing (98, 102). Phase I and II production operations can use disposable manufacturing to increase flexibility and avoid tying up capital in stainless steel (32). However, completely disposable manufacturing plants for the large-scale commercial production of specific molecules is thought unlikely to become a reality because of the natural technology limitations (169).

Release testing is a major aspect of biopharmaceutical manufacturing, particularly viral safety (42, 51, 53, 54). The cell banks, unprocessed bulk, final bulk, and finished product should all be characterized and tested before being released for use. According to regulatory guidelines (42, 54), the viral safety of an investigational medicinal product should be ensured by three complementary approaches involving (i) selecting and testing cell lines and other RMs of human or animal origin for viral contaminants, (ii) assessing the capacity of downstream processing to clear infectious viruses, and (iii) testing the product at appropriate steps for contaminating viruses. To fulfill these requirements, Master Cell Bank/Working Cell Bank and all biologically originated RMs should be tested for viral safety; the purification process needs to be validated for virus clearance; and the unprocessed bulk materials need to be evaluated for the presence of adventitious viruses and the count of retroviral particles.

13.4.5. Production Cost

Mammalian cell culture on the industrial scale is not to be taken lightly. It involves expensive growth media, complicated purification processes, and expensive cell line characterization and documentation. In addition, the cost and startup times for large-scale protein production facilities

are substantial, typically ranging from \$500 million to \$1 billion and taking about 3 to 5 years to achieve full regulatory approval (3). Therefore, biopharmaceuticals such as MABs are among the most expensive drugs, as the annual cost per cancer patient can reach \$35,000 (44), and final products from mammalian cell culture may cost \$500 to \$5,000 per gram (146), of which about half is due to purification and the other half is shared by cell culture and quality control/quality assurance. Despite the attractive returns, potential losses in revenue due to product approval delay have made companies focus more on speed to market rather than on improving process economics, and the competition and pressure will force MAB therapeutics to increasingly depend on economic factors (116). As a result, production costs and capacity use are becoming critical factors for the industry (45, 86).

The cost structure of manufactured lots depends on process time and productivity. To shorten the time, recent technologies include using perfusion cell cultures to amplify dihydrofolate reductase-based expression cell lines by incrementally increasing methotrexate in the perfusion medium for the faster generation of stable and high-productivity clones, and performing perfusion processes in single-use bioreactors to prepare cell banks at high density, which minimizes the inoculation time from vial thaw to seed bioreactor, leading to cost-effective facility utilization (5). In addition, all phases of cell line development have been integrated using a single medium—the production medium—thus reducing the cell culture development time and minimizing intermittent adaptation processes, which saves both time and cost (5). To enhance productivity, a perfusion process with compact packed-bed bioreactors achieved reported CHO cell densities of $\sim 250 \times 10^6/\text{ml}$ and as high as 31 g/liter of bed-volume MAB productivity at development scale (4). Another example used perfusion-fed batch technology to enable both high cell density and antibody concentration (~ 25 g/liter) in low-volume cell culture medium, while integrating recovery operations (122). These high titers minimize equipment sizes and processing volumes. The assembly of individual process units becomes easy and flexible because of the application of single-use systems, which can lead to significant cost reduction in upstream and recovery unit operations. For downstream processing, practically feasible approaches are also emerging to control economics and reduce purification cost, which has been the major cost driver for MAB manufacturing (6, 30). It is claimed that the future of therapeutic MABs lies in the development of economically feasible downstream processing (44).

Outsourcing of biopharmaceutical product manufacturing has grown significantly in the past few years, mainly because of the increase in the number of biopharmaceuticals being developed and the availability of highly qualified contract manufacturing organizations (CMOs) (149, 162). Such a transformation is gradually taking place in the biopharmaceutical industry, as exemplified by the fact that the total number of related articles published in 2005 is more than in the entire decade of the 1990s (120). Before 1995, companies were required to manufacture phase II clinical materials at the final commercial scale. In 1995 the FDA authorized the use of pilot facilities, allowing companies to make clinical materials at smaller scale or license those smaller GMP facilities later for commercial manufacturing (52). This incurred less financial risk for companies that do not have the capacity, capability, or in-house expertise to manufacture the clinical products in the event of phase II failure, as they did not have to construct expensive large-scale facilities. A sound Chemistry, Manufacturing and Control (CMC) strategic plan is the key to the selection of the right CMO (149), and well-executed technical transfer of manufacturing processes

to CMOs leads to the success of custom manufacturing (154). It should be pointed out that a change in production scale and/or site is considered a change in manufacturing process, so analytical, nonclinical, and even clinical studies are needed to demonstrate the comparability in quality, safety, and efficacy of the drug product (62).

Mammalian cell culture requires more testing than microbial fermentation systems. Generally the more advanced the bioactive entity, the greater the problem in paying for discovery, development, scale-up, facilities, regulatory compliance, and overall investment. These economic aspects of the biotechnology industry are described in detail in an excellent article in the last edition of this manual (130). A recent review discussed the key process economic drivers and the impact of scale and titer on trade-offs in antibody purification processes (44). To address these two critical factors, the industry is looking to improve the overall downstream processing yield and reduce the batch duration by using platform processes based on chromatography steps without intermediate buffer exchange steps, to increase capacity by improving resins to allow increased throughput over shorter times, and to lower buffer demands and validation cost using new technologies such as membrane chromatography. Overall assay development and validation for biomolecular analysis can cost around \$1.5 million—about \$150,000 for three immunological assays, about \$1 million for maybe a dozen chemical/biochemical assays, and almost \$0.5 million for just three bioassays (143). The cost of one lot of MAb product release assays can be \$50,000 to \$100,000, and that for systematic stability testing \$250,000 to \$500,000. As for the preclinical development, the overall cost estimate 10 years ago for developing a protein molecule into the clinical phase was already about \$1.7 million to \$2.7 million (170).

13.5. SUMMARY

The dramatic advancement in mammalian cell line and cell culture development has shifted the biopharmaceutical manufacturing bottleneck to downstream processing. In response, the industry is moving toward using current purification capacity more efficiently by improved operations and new technologies such as membrane chromatography and disposable apparatuses, and toward using platform purification approaches until late phase for products such as MAbs. However, the first step using protein A affinity resin remains rate limiting due to its low capacity and high cost despite great purification. Formulation is critical to the stability and application of therapeutic proteins, and its development remains mostly the combination of art and science. Fill and finish of these products require more care than classical small-molecule drugs because of their limited stability in liquid and their parenteral administration. Modern bioanalytical tools have been established to characterize and release biopharmaceuticals, and the methods need to be validated. Manufacture of biopharmaceutical is governed by various cGMP regulations, requiring validation of process, qualification/release of all RMs, and thorough testing/release of cell banks and products to ensure safety and potency. Costs are high for production using mammalian cell systems due to expensive facilities, equipment, RMs, testing, validation, etc. Alternative operation approaches are emerging, including incorporation of more single-use devices and outsourcing.

Plant Cell Culture

NANCY L. PAIVA

14

Plant cell culture has found wide applications ranging from studies on basic plant biochemistry and molecular biology to mass propagation and genetic engineering of crop species. The media, conditions, culture vessels, and other critical parameters vary widely depending on the intended use of the culture. This chapter covers the basic requirements for common procedures in plant cell culture. For work with a specific species, it is recommended that one survey the literature to see if procedures and media for the chosen species or a close relative have already been developed, since optimum conditions can be species or genus dependent. Several books and reviews containing detailed protocols have been published (2, 13, 18, 21, 28, 36, 38, 41, 46, 48, 50, 52, 53, 55), and several journals are dedicated to reporting the latest breakthroughs in plant tissue culture.

In general, plant tissue culture begins with the initiation of callus cultures, i.e., dedifferentiated masses of rapidly dividing cell cultures, on solid, agar-based nutrient media. The callus is generated by exposing sterile pieces of plant tissue to plant growth regulators. Normally, cell division in an intact plant is restricted to various meristematic regions (for example, root and shoot tip meristems) by the plant regulating its natural hormone distribution. The plant growth regulators are either natural plant hormones or synthetic analogs that bind to receptors in the plant's cells, causing all cells to resume division and growth.

Callus cultures can be maintained indefinitely by transferring clumps of cells to fresh agar media at regular intervals. Alternatively, callus pieces can be placed in shake flasks containing liquid media to eventually form suspension cultures. These grow faster than callus cultures, probably due to better nutrient exchange with the medium. Plant cell suspensions consist of some single cells and many clumps of a few to hundreds of cells; the size of the clumps depends upon a number of factors including the species, the medium, and the length of time since the culture was initiated. Suspension cultures can be used as a uniform, year-round source of plant cells for biochemical and plant physiological studies or as a source of valuable plant secondary metabolites following appropriate treatments.

The callus cultures can also be allowed to differentiate (regenerate) back into plants; this process is often accelerated by the omission of or changes in the types of plant growth regulators. Each piece of callus can give rise to one to hundreds of plantlets, each with the same genome as

the parent, giving rise to the industry of micropropagation. Either early or late in the callus stage, foreign DNA can be introduced into the dividing plant cells. If the cells are then allowed to regenerate, a portion of the plantlets will be transgenic and can be selected for in a number of ways. At one time, the main way of introducing foreign DNA and organelles into plant cells involved the production of protoplasts (wall-less plant cells released by the action of cellulases and pectinases). Currently, several methods of DNA delivery are employed, including delivery by the "tamed" plant pathogen *Agrobacterium tumefaciens* or delivery by direct shooting of DNA-coated particles into the cells.

In the last 2 decades, transformation of important crop plant species such as corn, soybean, cotton, alfalfa, and wheat has become increasingly routine. Transgenic soybean, corn, and cotton varieties are now being planted on more than 50 to 90% of the farmland in the United States dedicated to those crops, and global use of transgenic crops is increasing rapidly. Transgenic plants and cell cultures are also used widely in reverse genetics experiments to determine the function of genes discovered in large-scale plant genome sequencing and mutational studies. Given good sterile technique and some patience for the comparatively slow growth rates, much can be accomplished today with plant cell culture.

14.1. CULTURE MEDIA

The composition of a plant cell culture medium resembles that of an all-purpose plant fertilizer, with the addition of a carbon source, since most cultures cannot photosynthesize enough sugars for growth, and plant growth regulators to stimulate cell growth (14, 18, 20, 33, 45, 52, 53, 55). Most plant cell lines can be cultured in completely defined media, although for some applications complex ingredients such as coconut milk or yeast extract were used in some early formulations and are still used today. Compositions of two of the most commonly used media are shown in Table 1. Murashige and Skoog medium (MS) (33) was one of the first developed for the growth of plant cells, using tobacco as the test species; it is still used today for the growth of callus and suspension cultures, as well as the growth of axenic cultures of plants. Gamborg's B5 medium (B5) (20) was an adaptation of MS, optimized for the growth of soybean

TABLE 1 Composition of common plant cell culture media

Component	Concn in:			
	MS		B5	
	mM	mg/liter	mM	mg/liter
Macronutrients				
NH ₄ NO ₃	20.6	1,650		
KNO ₃	18.8	1,900	25	2,500
CaCl ₂ ·2H ₂ O	3.0	440	1.0	150

Thiamine·HCl	0.0003	0.1	0.0300	10.0
Glycine	0.0005	2.0		
Carbon source				
Sucrose		30 g/liter		20 g/liter
pH		5.8		5.5

cells, and is used for many species. There is some confusion in the terminology used in the literature, but generally a medium is defined by its formulation of inorganic salts and organic compounds (the macro- and micronutrients), often excluding the major carbon sources (usually sucrose). Some authors include either the carbon source or growth regulators or both in their definitions, so it is important to check formulations in the literature carefully.

14.1.1. Macronutrients

The macronutrients provide the sources of N, P, K, S, and Ca, all required for healthy plant growth. The Na and Cl included as counterions are not essential; MS medium contains no Na source other than a trace amount included with the micronutrients, and studies have indicated that plants can synthesize organic anions to take the place of chloride ions as needed. Na, K, and Cl ions can be tolerated at levels up to 50 to 60 mM and can be used as counterions for additives or for pH adjustment without concern. Nitrogen is mainly provided as nitrate, although some media contain both ammonium and nitrate. Utilization of ammonium causes the culture pH to

drop, while utilization of nitrate causes the pH to rise. Some species have a requirement for ammonium or greatly benefit from the inclusion of ammonium or glutamine, but high concentrations of ammonium can be toxic either directly or by causing extremely low pH shifts. Phosphate salts provide both a source of P and the majority of the buffer capacity of the media.

14.1.2. Micronutrients

The micronutrients are sources of various trace elements required for growth. These are similar to those found in microbial defined media, with the addition of iodide. Studies have indicated that iodide is not essential, but greatly stimulates cell growth. Iron is always added in a chelated form, either as an EDTA salt or as agricultural chelates (e.g., Sequestrene 330 Fe [Novartis Crop Protection, Inc., Greensboro, NC]).

14.1.3. Carbon Sources

The most common carbon source is sucrose, generally in the range of 20 to 30 g/liter; the original formulation for MS

called for 30 g/liter, while B5 called for 20 g/liter. Glucose is used less often, and fructose only occasionally. In many cultures, much of the sucrose is rapidly taken up by the cells in the first 1 or 2 days of culture and converted to starch granules inside the cells. If different carbon sources are to be tested for growth, one must take into account that the cells previously cultured on sucrose may have substantial starch reserves, allowing growth for several days. Cultures of other species often hydrolyze the sucrose to fructose and glucose and utilize the glucose first and then the fructose. Very high sugar concentrations (40 to 100 g/liter) have been used in specialized secondary-metabolite production media (21, 23, 24, 28, 36) and to adjust the osmotic potential of the media in short-term treatments for regeneration (2, 18).

14.1.4. Vitamins

Although intact, soil-grown plants normally synthesize all of the vitamins required for growth, vitamins are generally added to all plant culture media. Very early work indicated an absolute requirement for thiamine (vitamin B₁) in the growth of tomato cells (56), but this has not been determined for all species. Pyridoxine, nicotinic acid, and *myo*-inositol have each been shown to increase the growth of certain species and should also be included, especially when establishing new callus cultures. In many cases, however, these may not be required for growth, and some species have been reported to be unable to take up exogenous *myo*-inositol. All of the common vitamins listed here (thiamine, pyridoxine, nicotinic acid, and *myo*-inositol) are sufficiently stable during autoclaving at common medium pH values. Other vitamins have been added (1 mg/liter or less) in some instances, especially when cells or protoplasts are cultured at very low densities (21, 55); these include biotin, pantothenic acid, folic acid, choline chloride, *p*-aminobenzoic acid, riboflavin, vitamin B₁₂, and ascorbic acid. Ascorbic acid and cysteine-HCl are often added at very high concentrations (25 to 100 mg/liter) as antioxidants to prevent browning of cultures (21, 52).

14.1.5. pH

Most cell culture media are adjusted to pH 5.5 to 5.8 before autoclaving. Following inoculation, the cells may rapidly shift the pH of the media by the release of stored ions or by the uptake and utilization of nutrients such as ammonium. After a week or more of growth, suspension cell culture media may exceed pH 6.0. Rapid alkalization of the medium is also common after elicitation (see below), with values reaching as high as pH 7.0.

14.1.6. Plant Growth Regulators

Plant growth regulators include both the naturally occurring plant hormones (phytohormones) and synthetic compounds, most of which are structural analogs of the natural hormones and bind to the same receptors. Commonly used regulators are listed in Table 2, along with their abbreviations. One class of regulators are called auxins, which cause plant cells to grow, the naturally occurring plant auxin being indoleacetic acid (IAA). IAA is unstable in solution and is easily oxidized and conjugated to inactive forms by plant cells. However, IAA and the slightly more stable indolebutyric acid (IBA) are still used when low doses or short pulses of hormone are needed, as in certain regeneration systems or in rooting micropropagated plants or cuttings. Naphthaleneacetic acid (NAA) and 2,4-dichlorophenoxyacetic acid (2,4-D) are the most frequently used auxins. 2,4-D is more potent than NAA, followed by IBA and then IAA. IAA and IBA must be added after autoclaving, and the media must be used immediately thereafter; stock solutions should be frozen or made weekly and refrigerated. 2,4-D and NAA can be added before autoclaving and will not break down in the media during storage; stock solutions can be stored indefinitely at 4°C. Many callus cultures can grow with auxins alone; the original formulation for B5 contained 1 ppm of 2,4-D (i.e., 1 mg/liter, or 4.5 μM).

A second class of regulators, the cytokinins, promote cell division and are sometimes required for culture initiation

TABLE 2 Growth regulators and additives commonly used in plant tissue cultures

Class of additives	Compound name	Abbreviation(s)
Auxins	Indole-3-acetic acid	IAA
	Indole-3-butyric acid	IBA
	1-Naphthaleneacetic acid	NAA
	(2,4-Dichlorophenoxy)acetic acid	2,4-D
	(2,4,5-Dichlorophenoxy)acetic acid	2,4,5-T
	(<i>para</i> - or 4-Chlorophenoxy)acetic acid	PCPA or CPA
	Picloram (4-amino-3,5,6-trichloropicolinic acid)	PIC
	2-Naphthoxyacetic acid	NOA
Cytokinins	6-Benzylaminopurine	BA or BAP
	Zeatin	ZEA
	Kinetin (6-furfurylaminopurine)	KIN
	(2-Isopentenyl)adenine	2iP
	Adenine	ADE
Other hormones	Gibberellic acid (gibberellin A3)	GA or GA3
	Absciscic acid	ABA
Other additives	Casein hydrolysate (NZ Amine)	CH or C
	Coconut water	CW
	Ethylenediaminetetraacetic acid	EDTA

or long-term growth. Cytokinins are often added to induce shoot initiation during plant regeneration from callus (18), at which time the auxins may be decreased or omitted from the medium. The first naturally occurring cytokinin to be identified was zeatin, a purine derivative (22). Zeatin is occasionally used in culture media, but the most common cytokinins in use today are kinetin (6-furfurylamino-purine) and 6-benzylamino-purine (also known as N6-benzyladenine); adenine and adenosine can also have cytokinin activity, particularly at high levels. Most cytokinins, except for zeatin and its derivatives, can be sterilized by autoclaving.

Gibberellins (usually GA3, gibberellic acid) and abscisic acid are sometimes used to stimulate embryo or shoot development (2, 18). Other plant growth regulators such as the recently discovered brassinosteroids are still being evaluated in culture systems.

Auxins and cytokinins are used in the range of 1 to 50 μM . Most plant growth regulators can be dissolved in a small volume of reagent-grade ethanol and then diluted in warm water to the final stock concentration; the ethanol will evaporate during autoclaving. Alternatively, NaOH is used to dissolve most auxins and HCl can be used to dissolve cytokinins, but these should be kept to a minimum to avoid altering the pH of the media.

14.1.7. Other Additives

Complex ingredients such as coconut milk, yeast extract, fruit juices, and casein hydrolysates (such as NZ Amine) were used in many early culture experiments and are still used today. They provide plant growth regulators, vitamins, and amino acids that can enhance plant cell growth rates and survival of some cultures. However, they are expensive, sometimes variable in quality, and sometimes detrimental, such as when yeast extract induces stress responses in dilute cell suspensions.

Mannitol, sorbitol, or combinations of these two sugar alcohols are routinely added as an osmoticum (i.e., a supplemental agent increasing osmolarity). A concentration of 100 g/liter (0.6 M) sugar alcohol is used in most media for the isolation of plant protoplasts, to prevent the cells from bursting once the rigid cellulose cell walls are removed (55). The addition of 0.2 to 0.5 M total osmoticum (300 to 900 mOsm/kg of H_2O , added as an equimolar mixture of sorbitol and mannitol) to the culture medium increases the number of transformants produced by bombardment techniques (43).

Organic acids such as citric, fumaric, malic, or succinic acids, or synthetic buffers such as Tris, morpholineethanesulfonic acid (MES), or HEPES, have been used to help maintain culture pH, especially when ammonium salts are used as the nitrogen source (21). Neutralized activated charcoal is occasionally added to young regenerating cultures to remove toxic phenolics released by the stressed plant cells, or to help remove plant growth regulators introduced at an earlier stage. Silver thiosulfate serves as an ethylene biosynthesis inhibitor, preventing this gaseous plant hormone from accumulating to detrimental concentrations.

"Nurse" medium or "conditioned" medium is the liquid medium removed from a suspension of fast-growing cells. It contains uncharacterized growth factors released by growing cells, or it may be depleted of growth-inhibiting substances, such as high levels of ammonium ions. Conditioned medium is usually removed aseptically from a culture and never autoclaved. A nurse culture or "feeder" layer is usually a thin layer of fine, fast-growing cells spread on the agar surface and covered with a moist sterile filter paper.

Conditioned media and nurse cultures are sometimes used in the culture of regenerating protoplasts, single cells, or very dilute cell suspensions (29, 49). The nurse media or cultures are often not from the same species as the species of interest; e.g., a tobacco cell culture may be used as the nurse culture for carrot cells.

14.2. MEDIUM PREPARATION

Only high-purity (reagent-grade) chemicals should be used for plant cell culture, especially when new cultures are being initiated or sensitive cell lines are being used. Water should be double-distilled (glass stills preferred) or deionized, such as 18 M Ω water produced by MilliQ devices (Millipore, Bedford, MA). Glassware must be free of residual detergents. If glassware is cleaned with chromic acid (or any solution containing heavy metal ions), it must be treated with EDTA or another chelator to remove all traces of chromium, since some cultures are very sensitive. In fermentors or bioreactors, all parts in contact with the medium must be made of high-quality stainless steel, glass, or plastic for work with sensitive cell lines. In studies with opium poppy cells (*Papaver somniferum*), the use of bioreactors containing even a small amount of silver solder or brass screws results in the browning and death of the cultures, while periwinkle (*Catharanthus roseus*) and tobacco (*Nicotiana glauca*) cells grow well (personal observation).

The options for gelling agents for plate cultures include bacteriological-grade agar (such as Bacto Agar [Difco, Detroit, MI]), Noble agar (agar reduced in ionic impurities [Difco]), tissue culture-grade Phytagar (specially prepared agar [Gibco-BRL, Gaithersburg, MD]), agarose (highly purified agar), and Phytigel (Gellan gum agar substitute [Sigma, St. Louis, MO] or Gelrite [Merck/Kelco Division, San Diego, CA]). For routine work, our laboratory prefers Phytagar at 0.6 to 0.8% or agarose at 0.55%, although many cultures can tolerate the impurities in bacteriological agar. Carrageenan (vegetable gelatin) and calcium alginate have been used for cell immobilization, particularly in bioreactor studies.

A number of strategies have been used to handle medium preparation. One traditional method is to prepare four liquid stock solutions, containing (i) the five or six macroelements (20 \times stock), (ii) the microelements omitting the iron source (200 \times), (iii) the iron chelate (200 \times), and (iv) the vitamins (200 to 1,000 \times). The first three are stored at 4 $^{\circ}\text{C}$, while the vitamins are stored frozen. The carbon source is added as a solid. If hormones are to be included (Table 2), heat-stable hormones are predissolved and added as a 200 to 1,000 \times stock; otherwise, they are filter sterilized and added after autoclaving. Agar, if required, is added after pH adjustment. The use of multiple concentrated stocks of N and P sources make medium variations easier.

Once an acceptable medium is identified and large quantities are needed, a convenient practice is to prepare a 10 \times concentrated stock and freeze it in appropriately sized aliquots. An example of this strategy for the preparation of an SH stock (supplemented with three growth regulators and 30 g/liter of sucrose for use with alfalfa cell cultures [2, 14, 45]) is provided in Table 3. A 4-liter volume of 10 \times concentrate, including three growth regulators but excluding sucrose, is dissolved, distributed into plastic Whirlpak bags (Nasco, Grand Prairie, TX) in 100-ml aliquots, and frozen at -20°C or lower. To prepare the medium, one bag of concentrate is thawed for every liter of liquid or agar needed, and the contents of the bag are transferred with rinsing to a large flask or beaker and dissolved by stirring

TABLE 3 Preparation of SH frozen stock^a

Medium component	Concn (mM) in final medium	Amt (g/40 liters) per batch of 10× stock
KNO ₃	25.0	101.0
MgSO ₄ ·7H ₂ O	1.5	14.8
NH ₄ H ₂ PO ₄	2.5	11.6
CaCl ₂ ·2H ₂ O	1.5	8.8
<i>myo</i> -Inositol	5.0	40.0
MnSO ₄	0.059	0.358
H ₃ BO ₃	0.13	0.200
ZnSO ₄ ·7H ₂ O	0.0035	0.040
KI	0.0060	0.040
CuSO ₄ ·5H ₂ O	0.0008	0.008
FeSO ₄ ·7H ₂ O	0.0054	0.600
Na ₂ EDTA	0.0054	0.800
Thiamine·HCl	0.0150	0.200
Nicotinic acid	0.0410	0.200
Pyridoxine·HCl	0.0024	0.020

^aFor 10× concentrate without sugar or pH adjustment. The method is as follows.

1. Dissolve all of the above solids in 2.5 liters of distilled H₂O.
2. Add 8 ml of Mo/Co microstock: 50 mg of Na₂MoO₄ and 50 mg of CoCl₂·6H₂O dissolved together in 100 ml. (Store at 4°C.)
3. Add 20 ml of kinetin stock: 43 mg/200 ml.
4. Add 80 ml of 2,4-D stock: 225 mg/liter.
5. Add 400 ml of PCPA stock: 186.6 mg/liter.
6. Adjust volume to 4 liters. Mix well. Divide into 100-ml lots in Whirlpak bags. Store at -20 to -40°C.

Note: each 100-ml bag is equivalent to 1 liter of SH medium. To use, thaw 1 bag/liter needed, add 30 g of sucrose per liter, adjust volume, and titrate to pH 5.7 with 1 N NaOH. For plates, add 8 g of agar per liter.

for 30 to 60 min at room temperature. Sucrose (30 g/liter) is added, the pH is adjusted to 5.7, and the medium is distributed into flasks (with or without agar) for autoclaving. We find it advantageous to add the sugar at the time the concentrate is thawed for use, because otherwise the stock would contain 30% sucrose, which is difficult to dissolve, distribute, and freeze. The pH of the stock is slightly acidic and should not be adjusted prior to freezing. A slight precipitate may form in the bags during freezing, but this will redissolve with extended stirring.

A few companies produce a variety of premixed plant cell culture media. Usually, the medium is divided into "basal salts" (the macro- and micronutrients), sold as a dried powder, and vitamins, sold separately as a solution. These components may also be sold as a combined dried powder ("basal salts with minimal organics"), with or without sugar included. The medium is usually dispensed into preweighed packets such that each makes 1 to 10 liters of medium; one can also purchase a jar of well-blended powder that makes 50 liters and weigh the powder as needed. Plant growth regulators and agar are rarely included. Due to inconsistencies in formulations and terminology in the literature, manufacturers usually provide very detailed tables of their formulations; one manufacturer supplied 15 variations of MS salts. If one is careful to select the correct preparation and labor is limited, these commercial powders offer a slightly expensive but reliable option.

For many liquid media including MS, a small amount of white precipitate may be visible in shake flasks, especially after extended autoclaving or storage. For routine culture maintenance, this medium will work well, since the

precipitate will gradually be used by the cells. Media should be autoclaved at 121°C for a minimum of 15 min for small volumes and for longer times for larger volumes or thick-walled vessels. The required times may need to be evaluated on-site; 30 min for 500 ml of agar or 1 h for a 2-liter bioreactor vessel is not unusual (6).

14.3. FACILITIES

Successful plant cell culture requires extremely close attention to proper sterile technique and temperature control. The growth of plant cell cultures is relatively slow compared to common microbial cultures, necessitating very long culture times for experiments; a low level of contamination which would be outgrown and perhaps unnoticed in a bacterial culture would have time to overwhelm plant cultures. It may take months to establish a high-producing cell line or to regenerate transgenic plants from the original explants.

14.3.1. Sterile Transfer Facilities

Laminar-flow hoods are strongly recommended. An even flow of HEPA (high-efficiency particulate air) filter-sterilized air comes from the back of the hood, protecting the cultures when the vessels are opened. Unlike primary animal cell cultures, no biohazard containment of the cultures is required. Some laboratories use containment hoods when introducing microbes into plant cell cultures, such as during genetic transformation or inoculation with plant pathogens. Each hood should be equipped with a natural gas outlet for a Bunsen burner and lighting (usually

overhead). A UV germicidal lamp is strongly recommended for use in decontaminating the hood work surface after the HEPA filter is replaced, if the hood is switched off for more than 30 min, or if the hood is accidentally contaminated. A selection of stainless steel forceps, spatulas, and scalpels with replaceable blades are required for culture initiation, callus subculture, and transformation and regeneration. For quantitative transfers, an electronic (digital) top-loading balance (400-g to 4-kg capacity) with auto-tare feature is essential.

14.3.2. Temperature

Most cell cultures grow well only in a narrow temperature range. The most common growth temperature is 25°C. Some plant species, especially heat-tolerant plants such as tobacco or *C. roseus*, can continue to grow at temperatures of 30°C and above, while heat-sensitive cultures like opium poppy will cease to grow above 27°C and will die at higher temperatures.

Cyclic temperature changes may occur during the day-night cycles used for some culture procedures. Localized heating of shelves occurs during the day, and they then cool during the night. Although not directly lethal to cultures, this contributes to the formation of condensation inside the lids of petri dishes and other culture vessels, which can dry out the cultures or contribute to contamination. Very careful room design and high airflows can reduce these temperature fluctuations, but these features may add to the cost of culture rooms. Stacking an uninoculated petri dish containing water agar on top of the important cultures will greatly reduce condensation yet still allow sufficient light for regeneration.

14.3.3. Light

Callus and shake flask cultures generally do not require light for growth. Usually they are grown in dark rooms, equipped with lights which are turned on when inspecting or subculturing the cultures. Absolute darkness is not usually required. High light intensities or low levels of continuous illumination can cause cultures to turn green (form small numbers of chloroplasts) or brown (accumulate polymerized phenolics). Enough light to induce either color change can be sufficient to inhibit secondary-metabolite accumulation, and browning may greatly slow the growth of cultures. If callus and shake flasks must be incubated in lighted rooms (such as rooms shared with regenerating cultures or aseptically grown plants), they can be shielded with foil or boxes.

For regeneration, cool white fluorescent lights are recommended. Interspersing incandescent bulbs will greatly increase the quality of the light, providing a spectrum close to that of sunlight. Lights are generally suspended 12 to 14 in. above the culture vessels. Sufficient distance must be maintained between the lights and vessels to allow cooler air to circulate and avoid overheating the plates. Wire shelving, positioned a few inches from the culture room walls, is often preferred, providing good air circulation at a reasonable cost. The shelves can be partially covered with aluminum foil or Plexiglas to provide a more stable, easily cleaned surface. If several layers of closely lit shelves are used, heat from a lower shelf may warm the shelf above; plates can be partially insulated by placing them on foil-covered sheets of styrofoam, or lights should be suspended by chains to allow heat dissipation.

Too much light can actually be detrimental to culture growth and regeneration. One indication of a high light

level is the accumulation of anthocyanins (red to purple pigments) in callus or differentiated tissues. Continuous light is sometimes detrimental to whole-plant growth and is rarely used in plant cell cultures. The use of household timers is adequate for generating day-night cycles (16 to 18 h of light, 6 to 8 h of dark). One exception is the culture of photoautotrophic cells, which require high-intensity and high-quality light to enable the cells to photosynthesize sufficient sugars from CO₂ (36).

14.3.4. Aeration

Under most conditions, shake flask cultures of plant cell suspension have a lower volumetric oxygen demand than do microbial cultures. The respiration rates (Q_{O_2}) reported for plant cell cultures range from 0.2 to 3.6 mmol of O₂/h/g (dry weight), compared with 2 to 16 mmol/h/g for *Escherichia coli*, 39 to 570 mmol/h/g for *Bacillus* spp., and 1.9 to 2.8 mmol/h/g for *Saccharomyces* spp. (48). Shaker speeds (100 to 150 rpm with a 1-in. throw) are generally lower than those used for microbial cultures, and the fill ratios in the flasks (volume of medium/volume of flask generally 0.2 to 0.4) are generally higher. Baffled flasks are rarely used to increase aeration but are occasionally used for breaking up clumps of cells, especially when a suspension is first being initiated.

Generally, shake flask cultures can be removed from a shaker for subculturing and observation for 1 h or more without killing the cells. However, this procedure will affect the growth rate and can affect the ability of the culture to produce secondary metabolites. High oxygen demands have been reported immediately following elicitation (see below), since a short-term burst of O₂ utilization occurs as a result of activation of many defense processes. If elicitation is used to induce secondary-metabolite accumulation, one should prevent even brief interruptions in aeration of shake flask cultures, and it may be necessary to increase the aeration of production bioreactors.

A wide variety of closures have been used for shake flask cultures. Traditional cotton plugs in Erlenmeyer flasks can work well, particularly if the cotton plugs "mushroom" over the rim of the flask, keeping it free of microbial contamination. Since the cultures may be on the shakers for weeks, particulates in the culture room air will tend to collect around the rim if unprotected, making it impossible to open the flask for subculture without contamination. A preferred option is straight-walled Delong-style flasks with metal culture tube closures; a small piece of folded cheesecloth or gauze is placed in the top of the closure to act as a sterile filter, and the prongs on the closures hold it securely on the flask. These caps have the advantage of providing the same sterility barrier and good aeration as cotton plugs while covering the rim and upper edge of the flasks. Any dust from the shaker rooms or media storage areas can be easily removed by a brief flaming before the flask is opened.

Petri dishes containing agar media and callus cultures or regenerating plants are incubated agar side down, not inverted like microbial cultures. Plates are always sealed with Parafilm or porous medical tape (such as Urgopore tape [Karlan Research Products Co., Santa Rosa, CA]) or can be placed inside a sterilized box or new plastic self-sealing freezer bag for short-term incubation. Otherwise, contaminants will enter the plate during the long cultures or the agar media will dehydrate.

Closures on culture vessels must not only allow oxygen and CO₂ to pass but, in sensitive species, must also allow ethylene and other volatiles to escape. Ethylene, a gas, is a

plant hormone often released by plant cells in response to wounding and infection or during senescence. It can have a number of effects on axenically grown plants and cell cultures (18). In very sensitive species, such as *Arabidopsis* and potato, the addition of ethylene biosynthesis inhibitors such as silver ions (as silver thiosulfate) greatly increases the yield of regenerated transgenic plants. Without these, the wounded tissue produces enough ethylene to inhibit the development or lead to browning and death of nonwounded cells.

Dedicated growth rooms provide the most efficient and flexible use of space. Commercial growth chambers equipped with lights, temperature control, and (optional) humidity control are available; several growth chambers allow many different conditions to be maintained, which may be important if diverse species are to be cultivated. For important cultures, it is recommended that several separate cultures be maintained, preferably in separate culture rooms or incubators. Temperature recorders are strongly recommended to diagnose possible problems in temperature control. Motion sensors and temperature monitors with audible alarms can also be employed to minimize the damage caused by heating and cooling and by shaker equipment breakdowns. Even brief overheating to 35°C or more can greatly reduce regeneration and secondary-metabolite production if it occurs at critical times, while regenerated plantlets are relatively resistant. Long-term exposures (hours) to high temperatures can stop the growth or rapidly kill suspension cultures.

14.4. CULTURE INITIATION

Rapidly growing plant tissues are generally best for rapidly producing callus cultures, although any living plant cell can in theory be induced to divide. While authors often indicate the plant organ from which a callus was derived (i.e., root, leaf, or hypocotyl), after several generations the cultures are fully dedifferentiated and there is little evidence that the original tissue source influences the behavior of the culture, such as the products it will accumulate. In contrast, for short-term cultures such as for transformation and quick regeneration, the explant source can be critical; for wheat and some recalcitrant legumes, immature seeds or cotyledonary nodes will produce easily regenerable callus while leaf or root callus cultures will not.

14.4.1. Sterile Explants

There are two basic sources for obtaining surface-sterilized plant tissues. One is to surface-sterilize seeds, which are dormant with tough, dry seed coats and can therefore tolerate very harsh sterilization conditions. The seeds are then germinated under sterile conditions, and the various tissues are placed on callus-inducing media. The other is to surface-sterilize undamaged tissue from a growing plant, which may be the only option for vegetatively propagated species or tree species that are slow to set seed. The same sterilization strategies can be used in each case. Most commonly, a brief ethanol wash serves to remove and kill spores and bacteria on the plant surface and to thoroughly wet the tissue; it is followed by a hypochlorite soak to kill any remaining microbes.

14.4.1.1. Seeds

The following protocol works well for soybeans and other medium-sized to large seeds. The seeds are placed in a clean plastic petri dish (25 × 100 mm preferred) or beaker and covered with 70% ethanol for 5 min. The dish is stirred or

gently swirled occasionally to ensure that the ethanol contacts all the seed surfaces. The seeds are transferred using a sterile (flamed) spoon-shaped spatula to a sterile dish with enough bleach solution (20% Chlorox in distilled water with 1 drop of Tween 20 or 2 drops of 10% sodium dodecyl sulfate solution per 100 ml; equivalent to 1% sodium hypochlorite [final concentration]) to cover the seeds. They are soaked for 15 to 20 min with periodic stirring. Any cracked, floating, or noticeably damaged seeds are removed. The seeds may begin to swell during this time. The seeds are transferred with a sterile spatula to a sterile dish containing sterile distilled water and are rinsed two or three more times by transferring to new dishes of sterile water. They are then transferred to sugar-water agar plates (5 g of sucrose and 8 g of Phytagar/liter; 50 ml/25-mm-deep plate) and sealed with Parafilm. If possible, the seeds are spread out so they do not touch each other, using several plates, so that any unsterilized seeds will not contaminate clean seeds. The seeds are incubated at approximately 25°C.

Germinating the seeds on media containing sugar or other nutrients helps locate contaminants by stimulating their growth on the agar surface. Seeds may also be germinated on damp filter paper or cotton. Tiny seeds, such as those of tobacco, lettuce, and *Arabidopsis* spp., may be more easily sterilized by being treated in sterile 1.5-ml plastic snap-cap tubes, briefly centrifuging them to the bottom of the tubes to remove solutions. The seeds can be transferred to new tubes by being suspended and pipetted. To make tiny seeds easier to distribute, after sterilization they can be suspended in a viscous 0.1% agarose solution and dripped onto the agar surface. If a special treatment is recommended prior to planting in soil, the same treatment should be applied before sterilization. For example, some species require extended cold treatments, exposure to light, or scarification (scratching the seed surface with sandpaper or nicking the seed coat with a razor blade).

14.4.1.2. Leaves

Young leaves, free of insect and microbial damage, should be selected. They are rinsed with distilled water to remove dirt and kept in a moist container to prevent wilting. For leaves that are thick or have a thick waxy cuticle, the above seed sterilization protocol should work well. For very thin leaves or for delicate leaves such as those grown in a very humid environment, less harsh conditions may be required. For example, for tender alfalfa leaves, the ethanol concentration may be reduced to 50% and the exposure time to 1 to 2 min to avoid killing the leaf cells.

14.4.1.3. Other Tissues

Depending upon the species and environment, other plant parts may be available. For species that make tubers or rhizomes, these organs should be first scrubbed free of soil and may be surface-sterilized, peeled, then sterilized briefly again. Young stems and petioles are often more resistant to damage during sterilization than are leaves.

Other sterilizing agents have been used, such as HgCl₂ or antibiotics, especially for seeds that have a natural bacterial population under their seed coats. A procedure using chlorine gas is sometimes recommended for dry seeds such as soybeans. The seeds are placed in a dish in a larger, sealable glass container such as a desiccator, together with a beaker containing bleach. The bleach is acidified (3 to 5 ml of concentrated HCl per 100 ml of Chlorox), which releases chlorine gas, and the container is quickly sealed. After 6 h to overnight, the container is opened and the

seeds are rinsed with sterile water and transferred to plates for germination. Procedures have also recommended acidifying the bleach solution in the leaf and seed procedures described above to cause less damage to the tissues and to “activate” the chlorine. Any procedures in which bleach and acid are mixed should be carried out in a chemical fume hood, not a sterile transfer hood, due to human toxicity of the chlorine gas.

14.4.2. Callus Culture Initiation

Once surface-sterilized seedlings or explants are available, these are cut into small pieces (0.5- to 1-cm segments or squares) with a sterile scalpel and placed on callus-inducing media. Hypocotyl and root segments are most commonly used. The edges of leaves and any cut surface that was exposed to bleach should be trimmed away and discarded, since these will not yield callus. The tissues will increase in size and should show visible callus formation within 1 month. Some tissues, such as older leaf and stem segments, may show callus development only at the cut edges, while younger tissues, such as roots, hypocotyls, and very young leaves, may completely dedifferentiate. If tissues curl and lose contact with the medium, they should be cut and pushed gently into the agar surface.

Much time can be saved by consulting the literature and finding medium formulations that have been previously developed for the species of interest (2, 18, 21, 52). If this information is not available, one should try media that have been successful with closely related species or try a number of different basal salt and hormone combinations. MS and B5 salts with 1 mg of 2,4-D per liter and SH medium with the two auxins and one cytokinin described above (Table 3) provide a wide range of media for dicots. While callus may form on several media, the texture and growth rate may vary greatly. For example, peanut callus on B5 salts with 1 mg of 2,4-D per liter is very soft and friable, while the callus after several subcultures on SH medium (Table 3) is extremely dense and hard. Monocots often require very high concentrations of auxins (up to 20 mg of 2,4-D per liter) for callus initiation but require reduced levels for extended rapid callus growth (2). If a particular cultivar or variety of a species is not required, several should be tried, since callus formation may vary with the genotype. Several plates of each type should be initiated, due to variations in callus formation response between individual explants and to allow for possible losses to contamination.

The callus should be subcultured every 2 weeks to 1 month by simply moving clumps of rapidly dividing cells to fresh plates with a cooled, sterilized spatula. During the first transfers, it may be beneficial to cut any remaining intact explants to expose fresh tissue to the medium, or to break up large callus pieces. If sufficient material is available, the softest, most friable calli should be selected for subculturing.

14.4.3. Suspension Culture Initiation

Suspension cultures are initiated by inoculating liquid media in shake flasks with callus clumps. Approximately 1 to 2 in³ of callus (5 to 15 g [fresh weight]) should be suspended in 50 ml of medium. Generally, the same medium used for callus culture is used for suspension cultures. Large clumps can be gently broken or cut into smaller pieces. Softer, friable, rapidly growing callus works best, since it will more quickly disperse into a fine suspension, whereas hard callus clumps may simply enlarge without dispersing. If only a small amount of callus is available, less medium should be used, since high liquid-to-cell ratios may inhibit growth.

The growth rate of suspension cultures will gradually increase as faster-growing cells take over the culture. Initially, growth may be slow, and it may take weeks for the culture to double or triple in biomass. At this time, the culture should be divided into two new medium flasks. This is often accomplished by simply swirling the culture and pouring cells and old medium into the new flasks. If the major cell aggregates are white but the medium is brown and contains much cell debris, it may be beneficial to pour off the old medium and transfer the cells with a spatula. As the growth rate increases, the cultures will have to be divided more frequently. Also, the aggregate size should decrease, and the ratio of old culture to new medium can be reduced.

A portion of the original callus should be reserved and subcultured. If the initial suspension does not grow well, after additional months of subculturing a callus that was too hard to form good suspensions may improve in texture and can be tried again. After a good suspension culture is established, a portion of the cells may be returned to agar to form a callus culture again; this callus will usually grow faster than the original. If the shaker stops and/or the shaker room overheats, suspension cultures can be killed or may lose desirable properties such as the ability to produce secondary metabolites; healthy callus cultures serve as a backup in case such problems arise.

14.4.4. Bioreactors and Scale-Up

The same principles regarding scale-up that apply to microbial or mammalian cell cultures also apply to the scale-up of plant cell cultures (9, 13, 27, 28, 34, 36, 48). Because aeration is usually not limiting for growth in shake flasks, scale-up to larger shake flasks (up to 4 liters) is often easily accomplished for biomass production, keeping the ratio of medium volume to flask volume constant.

Plant cell suspension cultures have been grown successfully in a wide range of bioreactor designs, but there are two important design considerations. First, plant cells tend to be very shear sensitive, and impeller damage can greatly impair the growth of a culture. Strategies to decrease impeller damage include decreasing the angle of the impeller, changing to a marine-style impeller, or using airlift fermentors. By manipulating the hormones or medium components, the culture may be induced to form larger aggregates, which can be less shear sensitive. Second, the cultures can be very heterogeneous. Large cell aggregates tend to settle to the bottom of the reactor vessels, while small aggregates may be carried out of the medium to stick to the reactor walls or float on foam, forming a “meringue” layer above the useful area of the reactor.

To reduce the problems of shear and cell floating or settling, many immobilization matrices have been tested. Cells have been embedded in beads of calcium alginate and carrageenan or entrapped in porous matrices such as foam rubber or polyester fabric (13, 29, 48). For cells that release products into the medium or carry out biotransformation reactions, immobilization allows the cells to be recycled. Unfortunately, new problems arise, such as decreased mass transfer to and from the cells and decreased volumetric productivity of the bioreactor, plus the added cost associated with immobilization.

Plant cell suspension cultures have been grown in industrial-scale fermentors. An extremely fast-growing cell line of tobacco (TBY-2) was grown in a 369-liter, then a 1,500-liter, and finally a specially designed 20,000-liter culture tank (27, 34). For the commercial production of shikonin, cells are first cultured in a 250-liter fermentor in a growth

medium and then transferred to a production medium in a 750-liter fermentor (9).

14.5. GROWTH QUANTITATION

Many methods have been used to estimate the growth of plant cell cultures both directly and indirectly. The method chosen will depend on the requirements for maintaining the sterility of the culture and the speed and accuracy of the measurement. One must keep in mind that the doubling time for most plant cell cultures exceeds 12 h and that a typical culture experiment will continue for 1 to 4 weeks.

14.5.1. Fresh Weight

The growth of callus cultures can be measured by simply moving the callus mass to a preweighed sterile container and measuring the weight of the callus at regular intervals. The new agar medium plates can be weighed before and after inoculation at each subculture.

Cells can be collected from suspension cultures by filtration using Miracloth (CalBiochem, San Diego, CA), nylon mesh filters (40- to 200- μm mesh), or sintered glass filters. Filter paper may also be used, but it may clog quickly due to the abundant cell debris or polysaccharides present in most cultures. Due to their extremely high water content, the cells will quickly become too dry, so the length of time the vacuum is applied should be closely monitored, either by timing the filtration or by stopping it as soon as the liquid stops dripping from the filter. The weight of cells collected in this manner is often referred to as "filtered fresh weight."

An alternative measurement is "wet fresh weight" or "drained fresh wet." By placing a pipette loosely against the bottom of a flask, much of the liquid medium can be withdrawn from a suspension culture while the majority of the cells will remain in the flask. The cell mass will retain a high percentage of medium (often about 50%), but this percentage will be fairly constant if the cell aggregate size remains constant. The wet fresh weight is calculated by subtracting the weight of the culture flask. This procedure can be carried out aseptically with cotton-plugged pipettes, preweighed flasks, and a clean top-loading digital balance in a laminar-flow transfer hood. These cells can then be weighed into new culture flasks, giving fairly reproducible inoculum levels without risking damage to the cells by filtering them dry. This measurement has also been adapted to immobilized cells, for which the weight of the medium-soaked immobilization matrix is subtracted from the weight of the inoculated, drained matrix.

14.5.2. Dry Weight

Collected fresh cells can be dried on preweighed filters or dishes to obtain the dry weight. Due to their high water content, the dry weight can be as low as 1 to 2% of the fresh weight. Cells should be dried at low temperatures (55 to 65°C), preferably either under vacuum or in a convection oven, to avoid being caramelized. Filter-collected cells should be washed briefly with distilled water to remove medium solids before being dried. Cells that are drained but not filtered can also be dried for a relative comparison of biomass, but the solids in the medium retained by the cells will contribute greatly to the dry weight. If a more accurate estimate of the dry weight is needed, the percentage of the wet fresh weight contributed by the medium, multiplied by the solids content (largely the dissolved sugars), can be subtracted from the dry weight (29).

Increases in dry weight can be misleading, particularly soon after cells are subcultured. Cell cultures of many species will quickly absorb the sugars from the medium and convert them to starch granules inside the cells. This starch reserve will then be slowly utilized during the growth of the culture. If a growth curve of the culture is determined, starch formation will cause the dry weight to increase dramatically for 1 to 2 days and then to decrease slowly, while the fresh weight is still increasing. (The presence of starch granules can be confirmed by examining cells under a high-power microscope; starch granules will polarize light and will stain blue with 1% iodine solution.) Thus, for initial studies, researchers will often monitor more than one parameter and then determine which is the best indicator of growth for the particular culture. Some cell lines will also concentrate and store substantial amounts of phosphate. Each new cell line must be evaluated for starch and phosphate accumulation, since some cell lines will accumulate neither, both, or only one or of these substances.

14.5.3. Packed Cell Volume

Cell suspensions can be transferred to calibrated conical screw-cap tubes and gently centrifuged at 200 to 500 $\times g$ for 10 min. The volume of cells and medium can be read directly from the tube.

14.5.4. Indirect Measurements

In some instances, the entire cell mass cannot be harvested. For example, in long-term bioreactor experiments or immobilized-cell culture systems, only a small sample of the culture or medium may be obtained. If the suspension is homogeneous and a representative sample can be obtained, any of the above methods can be used to estimate the entire contents of a bioreactor. At other times, the biomass can be estimated indirectly by monitoring the consumption of nutrients. A correlation coefficient will have to be established for each cell line, usually from small-scale shake flask experiments. If the culture does not accumulate starch, the growth of the culture can be correlated with the disappearance of sugars from the medium. If sucrose is the carbon source, many cultures will release invertase, which hydrolyzes sucrose to fructose and glucose, and utilize the glucose before the fructose. In such cases, the combination of all three carbohydrates must be monitored by a method such as ion-exchange high-pressure liquid chromatography with refractive index detection. If glucose is used as the sole carbon source, a simple reducing sugar assay may be sufficient. If the culture does not accumulate phosphate reserves (immediately depleting the medium of phosphate), phosphate uptake can be correlated with growth by using either colorimetric or chromatographic detection.

Nitrate is the major nitrogen source in most cell culture media. Very few cultures accumulate and store nitrate, and therefore depletion of nitrate from the medium is often well correlated with the growth of the culture. Several methods of nitrate quantitation have been developed, including colorimetric methods, high-pressure liquid chromatography, and capillary electrophoresis. Since nitrate (NO_3^-) is also the highest-molarity ion (40 mM in MS and 25 mM in B5), it is the major source of conductivity in the medium. It is often possible to correlate a decrease in conductivity with cell growth (14). For some experiments, the exact biomass is not required. For example, if the same inoculation and culture regimen is used each time, a certain conductivity value can be simply correlated with the correct time for harvest or elicitation.

An example of a typical plant suspension cell culture growth curve and the corresponding pattern of sugar hydrolysis and consumption in shake flasks is given in Fig. 1. The poppy cell line used in this experiment does not accumulate starch, and the total sugar consumption closely parallels the increases of dry and fresh weight. Depletion of free carbohydrates in the medium also correlated well with the end of the growth phase.

14.5.5. Viability Assays

At times, the percentage of live cells in a culture must be determined. This is often needed when cells have been subjected to harsh treatments as part of an experiment, such

as heat shock, chemical or pathogen addition, or freezing during the development of cryopreservation conditions. It is also useful when cells have been unintentionally stressed such as during a culture room malfunction. Callus cultures can be dead but not brown or collapse for months.

Several assays have been used, depending on the equipment available and the texture of the tissue. The best assay for viability is to subculture the cells and watch for a visible increase in cell mass. Unfortunately, this may take several days or weeks. Assays in which the stain (such as fluorescein diacetate [FDA] or triphenyltetrazolium chloride [TTC]) is meant to be taken up only by living cells are known to sometimes give false-positive results with cells that no longer divide.

14.5.5.1. Cytoplasmic Streaming

A quick estimate of viability can be made by examining individual cells under a high-power microscope. The cytoplasm and some organelles can be seen circulating inside live cells. This procedure works well for fine cell suspensions but not for large aggregates or regenerating embryos and plantlets. If a researcher is unfamiliar with this phenomenon, both positive and negative controls (a sample of a known well-growing culture and a heat- or freezing-killed sample, respectively) should be used. False-positive results can come from mistaking Brownian motion for cytoplasmic streaming.

14.5.5.2. FDA Staining

The diester FDA will not fluoresce. However, it can pass through the plant cell membrane, whereas esterases will remove the acetate groups. The charged product molecule is unable to leave the intact cell, due to a pH gradient, and fluoresces strongly. Only live cells should emit fluorescence, since dead cells will leak the stain or will not have active esterases. A 0.5% stock solution of FDA in anhydrous acetone can be stored at -20°C indefinitely. When needed, the stock is diluted 50-fold (final concentration, 0.01%) in ice-cold culture medium. One drop of FDA solution is mixed with one drop of culture on a microscope slide, covered with a coverslip, and monitored for 5 to 30 min. The slide is observed under a microscope with a UV/fluorescence attachment (excitation filter, 450 to 490 nm; barrier filter, 520 nm). If relevant, the total number of fluorescing cells can be counted and divided by the total number of cells (counted under visible light) to calculate the percent viability (55).

14.5.5.3. Evans Blue Staining

The blue stain is able to enter dead cells but cannot penetrate intact cell membranes. A solution of Evans blue (5 mg/ml) in culture medium is prepared. The cells are mixed with stain solution and incubated for 5 min, and then live (colorless) versus dead (blue) cells are counted under a microscope with bright-field illumination (57).

14.5.5.4. TTC Reaction

Viable cells will reduce TTC to a pink formazan product, which can diffuse out of the cells and into the reaction medium. Viability can be assessed visually or quantitatively in a spectrophotometer. This procedure can be used for both fine and coarse cells and callus, as well as whole embryos or leaf pieces (4). A 0.6% solution of TTC in 0.5 M phosphate buffer (pH 7.0) is prepared. The tissue (100 mg of cells or plant tissue/3 ml of solution) is suspended and incubated overnight (15 h) at 30°C . The TTC solution is removed, the cells are washed with distilled water, and 7 ml of 95% ethanol is added. The mixture is incubated at 80°C for

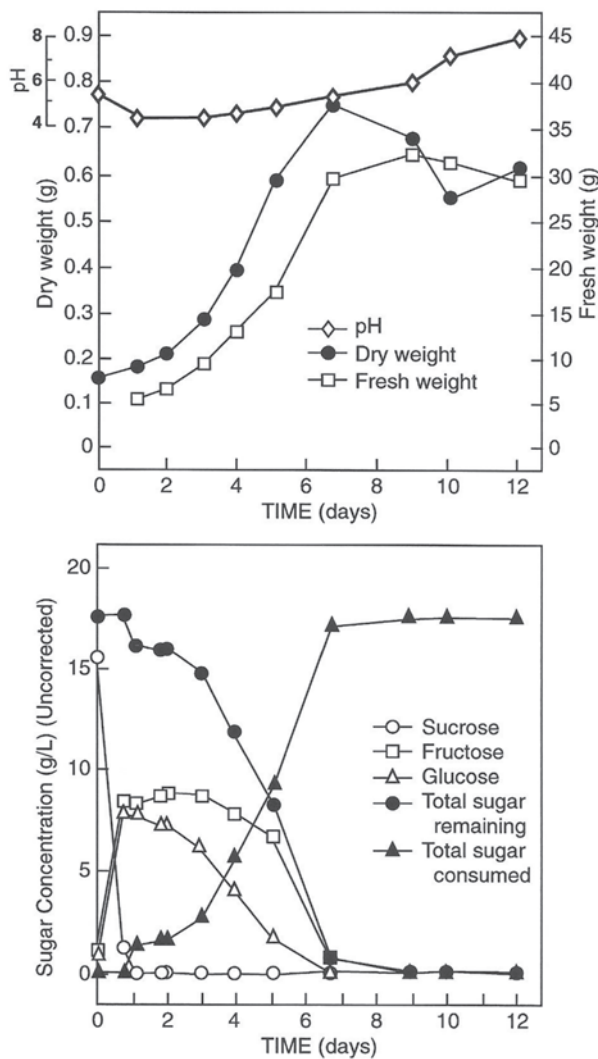

FIGURE 1 Growth of opium poppy cell suspension cultures in 250-ml shake flasks. The inoculum (*Papaver somniferum* L. cv. Marianne, PBI 2009) (29) was 10 g (wet fresh weight) (13% [wt/vol]) per 75 ml of medium per 250-ml flask. Cells were cultured at 25°C and 150 rpm. The medium was 1B5C (B5 salts supplemented with 20 g of sucrose per liter, 1 mg of 2,4-D per ml, and 1 g of casein [NZ-Amine] per liter; pH 5.5). The initial sucrose level was less than 20 g/liter, due to dilution by sucrose-depleted medium in the inoculum.

5 min. The extract is cooled to room temperature, and the volume is adjusted to 10 ml with 95% ethanol. The absorbance at 530 nm is measured.

14.5.5.5. Phenostrafanin Staining

Dead cells will be stained red with phenostrafanin, but the dye cannot penetrate living cells, similar to Evans blue. A 0.1% solution dissolved in culture medium is used, and the cells are observed under bright-field microscopy (14).

14.6. SECONDARY-METABOLITE PRODUCTION

One application of plant cell cultures is the study of plant secondary-metabolite biosynthesis and the commercial production of such valuable natural products. Plant secondary products have been used for centuries in human medicine, such as codeine and morphine (painkillers) from opium poppy (*P. somniferum*) latex, atropine and scopolamine (neuroregulatory), quinine (antimalarial) from *Chinchona* sp., and diosgenin and digoxin (cardioactive) from the foxglove plant (*Digitalis* sp.). Modern bioactivity-guided screens have identified a range of new important compounds, especially the anticancer compounds vincristine and vinblastine from periwinkle (*C. roseus*), Taxol from the yew tree (*Taxus* sp.), and camptothecin (*Camptotheca acuminata*). Some medicinal plant parts are consumed whole or as a complex extract, such as ginseng root. There are also valuable food ingredients including coloring agents such as anthocyanins from many species and flavor extracts such as vanilla from the vanilla bean (a species of orchid). Fragrant oils such as mint, rose, and jasmine have always commanded high prices in the perfume industry. Some plant extracts are used as pesticides in organic gardening, including rotenone from tropical legumes, pyrethrins from the flowers of the pyrethrum daisy (*Chrysanthemum coccineum* and other species), and azadirachtin from the neem tree (*Azadirachta indica*).

Many studies have investigated the production of these and hundreds of other secondary metabolites in plant tissue culture (9, 13, 14, 21, 23, 28, 36, 38, 46, 48, 50, 51, 53). In some cases, cell cultures provide a source of homogeneous, highly active cells, ideal for studying the biosynthetic pathways by labeled-precursor feeding, enzyme purification, and cloning of the genes encoding pathway enzymes. Other studies have focused on increasing the productivity of cultures, with a goal of profitably producing these metabolites. Many of the above products are currently produced by growing the plants, often in tropical regions, and harvesting and processing the appropriate parts. This means that production is subject to seasonal and environmental variation, disease, competition with other crops and land uses, and political pressures such as environmental concerns or international embargoes. The growth of the source plant may be slow, such as yew trees (for Taxol) or ginseng roots. Occasionally, cell cultures make high levels of one or a few compounds, which would not normally accumulate in the intact plant, decreasing downstream purification costs. For example, elicited *P. somniferum* cultures produce very high levels of sanguinarine and few other trace alkaloids, while the most competitive whole-plant system (*Macleaya cordata*) accumulates more sanguinarine but only as a complex mixture with other undesirable alkaloids, adding several expensive chromatographic steps to the purification.

In some cases, plant tissue cultures might appear to be an economical source of metabolites. Unfortunately, due to

their slow growth and often low volumetric productivity, only extremely valuable compounds may be profitably produced; one analysis estimated that a product must be worth over \$1,000 per kg, given average productivities and growth rates (50). Cell cultures are also often capable of degrading the desired products, and cell lines can suddenly lose their productivity, making industrial production difficult. Many strategies have been used to improve production, including selecting for higher-producing cell lines, developing production media, and inducing production by elicitation.

14.6.1. Constitutive Production and Strain Improvement

In certain species, media that allow good growth of the cultures will also allow good accumulation of secondary metabolites. In general, compounds that accumulate in root tissues or throughout all organs of a plant have been most easily produced at high levels in fully dedifferentiated cell cultures. This may in part be due to the lack of light or the hormone regimes; it is often said that cell culture metabolism most closely resembles that of plant roots.

Production can vary greatly among cultures of the same species. When initiating cell cultures for secondary-metabolite production, many separate cultures should be initiated from individual seedlings, and plants or seedlings should be obtained from as many sources (companies, botanical gardens, and research laboratories) as possible. These should be evaluated separately to determine if there is a variation in production between individuals, cultivars, varieties, or other genotype designations.

In some cases, product accumulation decreases either rapidly or gradually as the culture is subcultured, possibly due to natural selection for faster-growing cells, especially in suspension (12, 15). This natural variation can also be used advantageously, in that occasionally a subpopulation of highly producing cells can be selected. Visual selection was successfully applied to the production of shikonin, a red alkaloid pigment with antibacterial activity. For initial rounds of selection, portions of callus which were darker red were picked by hand and subcultured separately; for later rounds of selection, quantitative chemical analysis was used (9). Fluorescence microscopy was employed to select cell lines with high berberine production. The berberine content was increased from approximately 5% in unselected cells to 13.2% in a selected line (44).

14.6.2. Production Media

Many cell lines will accumulate only low levels of secondary metabolites in standard growth media, but production can be increased severalfold by altering one or more medium components. A wide range of production media have been developed, and a few trends have been established. In general, the growth of the culture may slow or stop completely. Production media often contain lower levels of growth regulators or none at all, or they contain weaker auxins such as NAA or IBA instead of 2,4-D. For anthocyanins (colored phenolic compounds), limiting the growth of the culture by restricting either the nitrate or phosphate supply while simultaneously providing very high concentrations of sugars has greatly improved production. Increasing the sucrose concentration from 20 to 80 g/liter and decreasing the nitrate concentration from 25 to 2.5 mM in B5 increases anthocyanin accumulation 10-fold (24), while phosphate limitation together with a high sucrose concentration is also successful (60). In the production of alkaloids (nitrogen-containing compounds), low phosphate levels are

beneficial, but high nitrate levels increase accumulation in some cases and are inhibitory in others.

In many cases, fully dedifferentiated tissue cultures will not accumulate the same valuable product as the parent plant or will accumulate only small amounts, sometimes only when cells are allowed to differentiate back into shoots or roots (58). For example, thiophenes are light-activated insecticidal and antimicrobial compounds that are highly toxic to both plant pests and host plant cells; they are accumulated only in specialized veins running longitudinally inside the roots (28). For unknown reasons, opium alkaloids accumulate only in specialized lactifers in the above-ground portions of plants, and production in tissue culture has been associated only with redifferentiation into shoots (30). Similar observations have been made for the famous anticancer compounds vincristine and vinblastine from *C. roseus*. These molecules are heterodimers derived from the indole alkaloids catharanthine and vindoline. While high levels of catharanthine (5 to 20 times that in the plant) accumulate, no significant levels of vindoline, vincristine, or vinblastine have been reported in homogeneous cell cultures, despite the fact that this has been one of the most thoroughly investigated systems (5). One of the enzymes in vindoline biosynthesis is light activated, while another may require the differentiation of functional chloroplasts, which are absent under standard cell culture conditions.

14.6.3. Elicitation

Many economically valuable plant secondary metabolites serve as defense compounds for the producing species, protecting them against attacks by insect herbivores and microbial pathogens. Some of these compounds are absent or present only at very low levels in healthy tissues, but they accumulate to very high levels in a narrow zone surrounding the site of microbial infections; these are referred to as phytoalexins (from the Greek for “plant warding-off agents”). In 1981, it was observed that contamination of a plant callus culture by a fungus resulted in the accumulation of a pigmented antifungal alkaloid (47). Later, it was determined that live fungus was not required to cause the response but that either autoclaved fungal culture filtrates or a number of purified compounds could “elicit” phytoalexin production and other defense responses, in both callus and suspension cultures. The process was referred to as “elicitation,” because the regulatory mechanisms involved were not known at the time; it has subsequently been shown that in most cases, the increase in the production of secondary metabolites is the result of an increase in the transcription of the genes encoding the corresponding biosynthetic pathway enzymes.

Elicitors are classed as biotic or abiotic. Abiotic elicitors include heavy metals such as copper or mercury salts, and UV light. Biotic elicitors include many components of fungal cell walls (chitin, chitosan, β -glucan, peptidoglycans, and arachidonic acid), compounds excreted by plant pathogens (cellulase, ribonuclease, pectinase, antibiotics, various sugar polymers, and proteins), and compounds released from plant cell walls during degradation by plant pathogens (pectin fragments) (11). The type of elicitor that is most effective in inducing secondary metabolism in a particular plant cell culture varies widely. The elicitor does not have to be derived from a pathogen of the source plant. In general, members of the same plant genus will respond well to the same elicitors but members of the same family may not. For example, cultures of several legume species (alfalfa, soybean, and green bean) are highly elicited by a crude β -glucan derived from *Saccharomyces cerevisiae* (28,

47) but are unresponsive to chitin. Solanaceous species (tobacco, potato, and tomato) are all elicited by cellulases, arachidonic acid, and β -glucans, but while two members of the poppy family, *P. somniferum* and *Eschscholtzia californica*, are both elicited by β -glucans, only the former is responsive to chitin hydrolysates (29, 34).

In the *Eschscholtzia* system, in which elicitation was first studied, the control cultures accumulate a low level of one alkaloid. Following addition of the elicitor, the level of this alkaloid increases and five related alkaloids appear; the total benzophenanthridine alkaloid content of suspension cultures increases more than 20-fold compared to that in unelicited cultures (34). In some cultures, such as soybean and green bean, no pterocarpan phytoalexins are present before elicitor addition but reach maximum levels (16, 19) within 24 to 48 h after elicitation. In an attempt to use elicitation to stimulate the accumulation of opium (morphinan) alkaloids in *P. somniferum* cultures, the authors were surprised to induce instead the accumulation of sanguinarine, a member of a different (benzophenanthridine) class of alkaloids but one which is also inducible by pathogen attack on poppy plants (17).

The optimal time for addition of the elicitor is usually in the middle to late growth phase of the culture, often 3 to 7 days after subculture. Elicitor addition before or after this time results in little or no response from the plant cells. The optimal time may shift; for example, as a cell suspension is repeatedly subcultured and the net growth rate increases, the optimal time will become earlier by as much as 2 or 3 days. Elicitors are often effective when added to standard growth media, although combining a production medium with elicitation may result in even higher production levels (8). Many elicitors cause a browning of the cell cultures and may result in the death of a high percentage of the cells.

The first secondary metabolite commercially produced by plant cell cultures was shikonin, a pigmented antibacterial alkaloid that was normally extracted from the older (3- to 7-year-old) roots of *Lithospermum erythrorhizon*. By using a combination of strain selection and production medium, the investigators found that the cultures could accumulate 12% dry weight of shikonin, versus 1 to 2% in older roots (9). While other products have come close to commercialization, in general, producers have defaulted to using field-grown plants as the source. The most recent promising candidate for tissue culture production is Taxol, due to its high value and environmental concerns regarding harvesting of wild trees. While plantation production and semisynthetic methods are currently the favored production routes, recent manipulations in explant sources and culture conditions have resulted in the accumulation of Taxol in plant cell cultures at levels several times higher than that found in the tree bark (25).

14.7. REGENERATION

Even individual plant cells or protoplasts, if cultured properly, can regenerate into fully developed, fertile plants. This property is referred to as “totipotency” and was first demonstrated in plants in 1965 (18). In current applications, small explants (rather than individual cells) are first induced to form calli, which are then induced to regenerate into a number of plants. There are two modes of regeneration, organogenesis and somatic embryogenesis.

In organogenesis, leaf explants, callus cultures, or suspension cultures differentiate directly to form shoots, which can then be induced to form roots. Generally the procedures involve induction of rapid cell division and/or callus formation on media containing high auxin levels, followed

by a medium containing low auxin and high cytokinin levels to induce shoot formation. For example, for tobacco, young leaves are surface-sterilized, cut into 1-cm squares, and placed onto MS agar containing 4.5 μM 2,4-D and 30 g of sucrose per liter for 2 to 4 weeks to induce callus formation. The explants are then transferred to MS agar supplemented with 5 μM 6-benzylaminopurine and placed under lights; shoots appear within a few weeks. Young shoots are cut off with a scalpel and rooted in MS with 30 g of sucrose per liter without hormones. Organogenesis is easily accomplished for most solanaceous species (tobacco, tomato, potato, petunia, etc.) and has been reported for many dicot species but is rarer among monocots.

In somatic embryogenesis, embryos or embryolike structures are produced from somatic cells, as opposed to the maturation of zygotic cells in plant flowers. Somatic embryogenesis was first demonstrated for carrot cultures in 1964 but has since been demonstrated for many species, both dicots and monocots. For carrot (18, 55), callus cultures are simply initiated on MS agar supplemented with 4.5 μM 2,4-D and 30 g of sucrose per liter for 1 month; then a fine, rapidly growing suspension is initiated in the same medium without agar. After 2 to 4 weeks, the cells are washed with the same medium without 2,4-D and incubated in the dark to induce embryo formation. Embryos appear after 8 to 10 days and continue to increase in size for 2 weeks. The embryos are then transferred to MS agar medium (with sucrose and no hormones) for plantlet formation; this last step is referred to as conversion or germination of the embryos. In some systems, many embryos are formed but not all of them will germinate. The addition of abscisic acid may aid in the development of normal embryos, and supplementation of the medium with proline and glutamine can greatly increase embryogenesis.

14.8. MICROPROPAGATION

In both organogenesis and somatic embryogenesis systems, hundreds of plantlets can be generated from a single explant. This is one method by which plants can be multiplied for commercial purposes. Another method is simply establishing sterile shoot cultures of plants, from which axenic cuttings are made and rooted in culture; cuttings can be made at any time of the year and will usually grow more quickly under plant tissue conditions than in the field. Either method is referred to as micropropagation. Many houseplants and ornamentals are propagated in this manner, allowing producers to introduce new varieties in a short time. Crop species such as blueberries, strawberries, garlic, and potatoes are also propagated by micropropagation to produce virus-free plants. The regeneration step can also be used to induce secondary-metabolite accumulation (see the section on production media, above).

14.9. TRANSFORMATION

Genetic transformation of plant cells, and their subsequent regeneration into transgenic plants, was first accomplished in the early 1980s for tobacco and is now routine for many species. Important crop species such as corn, wheat, rice, and soybean, which were deemed impossible to transform or regenerate only a few years ago, are now routinely manipulated. Usually, breakthroughs in transformation protocols of so-called recalcitrant species are first made with a highly regenerable cultivar. This transformed cultivar can then be crossed with elite high-producing cultivars to introduce the transgene into a number of plant lines.

In very early versions of plant transformation protocols, foreign DNA was introduced into plant protoplasts (plant cells treated with cellulase and other digestive enzymes to remove the cellulose cell walls) by using electroporation or polyethylene glycol (39). Since many plants are regenerated from protoplasts only with great difficulty, this method has not been widely applied. Most plant transformation has been carried out by *A. tumefaciens*-mediated DNA delivery (41). Wild-type *A. tumefaciens* causes crown gall disease by transferring a segment of plasmid DNA (called the T-DNA, for transfer DNA) containing bacterial genes encoding auxin biosynthesis and other pathways into wounded plants, which in turn cause dedifferentiated callus tumors to form, releasing nutrients to the surrounding *A. tumefaciens* organisms in the soil. *A. tumefaciens* strains have been modified (disarmed) such that the auxin biosynthetic genes have been deleted so they can no longer cause disease but the strains still contain the *vir* genes required for T-DNA transfer. Foreign genes of interest, including a selectable marker, are inserted into binary vectors, such that the foreign genes are between the ends of the T-DNA region. When in contact with cultivated plant cells, usually at the beginning of the callus induction phase of either organogenesis or somatic embryogenesis, the disarmed *A. tumefaciens* strain transfers the foreign gene construct. Selection pressure is applied (usually an antibiotic or herbicide in the medium), so that the only cells that are able to grow are those that received the foreign T-DNA (including the selectable marker, usually a drug resistance or herbicide resistance gene). The *A. tumefaciens* strain is then killed by antibiotics (such as penicillin derivatives) that do not act against plant cells. The surviving transformed plant cells are then induced to regenerate into transgenic plants.

A. tumefaciens-mediated transformation has been used for many dicot species but has been less effective with monocots. A more recently developed DNA delivery system is called particle bombardment or the biolistic approach (42, 43). Early versions of biolistic equipment used the explosive force of gunpowder to propel the 1- μm tungsten or gold particles, coated with the desired foreign gene construct. The current version of the equipment (patented by Dupont but marketed through Bio-Rad [Hercules, CA]) uses high-pressure helium gas and calibrated membranes (rupture disks) as a safer and more reproducible driving force. Transgenic plants have been produced by "shooting" leaf explants, embryogenic suspensions, or young embryos followed by applying drug or herbicide selection pressures, as described for the *A. tumefaciens* system, and then by regeneration. The biolistic approach was the first system to allow routine transformation of many monocot species such as corn, wheat (54), and rice (1), but it is also popular for dicot transformation (42).

Plant transformation and regeneration have resulted in the release and marketing of many genetically engineered plants, worth billions of dollars annually, and their use and the available genotypes are increasing rapidly. Transgenic soybeans have been the most widely adopted, with herbicide-tolerant transgenic soybeans being planted on over 90% of the U.S. and over 50% of the worldwide soybean farmland in 2008, based on U.S. Department of Agriculture public reports. Glyphosate-resistant (or Round-Up Ready, from Monsanto Co. [St. Louis, MO]) soybeans are engineered to be resistant to the herbicide glyphosate (an inhibitor of aromatic amino acid synthesis), which is highly toxic to most plants but relatively harmless to people and animals and which is rapidly destroyed in the environment. Farmers using

these varieties achieve much better weed suppression with fewer herbicide applications and can adopt “no till” planting strategies, which further reduce fuel consumption and soil erosion. Over 80% of U.S. cotton and corn planted in 2008 contained either herbicide tolerance (resistant to glyphosate, bialaphos, or acetolactate synthase-inhibiting herbicides), insect tolerance, or both types of transgenes. The most common method of conferring insect resistance is the expression of the insecticidal *Bacillus thuringiensis* (Bt) toxin protein; this protein only kills lepidopteran insect pests that eat the transgenic tissues, thus sparing beneficial and nontarget insects. Some products have been developed but are not being marketed, such as ripening-delayed tomatoes and transgenic wheat, due to lack of consumer acceptance or fear of import bans from countries outside the United States.

Many more transgenic plant products are under development, including plants with altered nutritional properties (e.g., high-lysine corn, increased vitamins, or improved protein quality), fatty acid or oil content (for nutritional, industrial, or fuel applications), and secondary-metabolite accumulation. Studies have indicated that consumption of certain plant secondary metabolites such as isoflavonoids, anthocyanins, resveratrol, lignans, and carotenoids may help reduce the incidence of human ailments such as cancer, heart disease, osteoporosis, and sight loss. Genes from the biosynthetic pathways of these so-called nutraceuticals have been cloned and overexpressed in transgenic plants either to increase their levels in native hosts or to introduce them into more widely consumed foods (32, 37). Several researchers joined forces to develop “golden rice,” a carotenoid-accumulating transgenic rice containing multiple foreign genes, to provide a cheap source of dietary vitamin A for tropical developing countries with high levels of childhood blindness (caused by vitamin A deficiency) (61). In the case of soybean oil, researchers have introduced constructs expressing plant and microbial enzymes to increase the overall fatty acid unsaturation level or to introduce desirable omega-3 and omega-6 fatty acids (7, 10). Since transformation and regeneration of soybean relies on somatic embryogenesis, and the oil profiles in transgenic somatic embryos in tissue culture closely predict those that will accumulate in developing soybean embryos in pods in the field, companies are able to test many transformation constructs quickly by analyzing embryos from early-in-transformation cultures, without waiting several months for transgenic plants to set viable seed (7).

Plant tissue culture and plant transformation are becoming routine tools in both basic research and applied crop development projects and have yielded many important discoveries. Early plant studies were supported by the floral industry, and in the process of trying to overexpress anthocyanin pigment-related genes in an attempt to produce darker-red petunia flowers, the studies found that some transgenic plants produced only white flowers (35). Later studies with plant RNA viruses demonstrated that transgenic plants overexpressing certain viral RNAs were resistant to infection by the same virus (31, 40). Years later, additional work analyzing these perplexing results led to the widely applied tools of posttranscriptional gene silencing or RNA interference, now used in the plant, animal, and microbial fields. In recent years, RNA interference has become a quick way to knock out a specific gene in both whole plants and tissue cultures, producing the same phenotype as if the gene had been deleted or suppressed. One can then attempt to determine the role of the targeted gene in plants. Now that the genomes or large cDNA

pools from several plant species have been sequenced, the demand has increased for quick plant transformation and efficient culture methods for screening transformed cells to identify and characterize new genes.

Plant transformation itself has become a highly developed mutagenesis and gene discovery tool. When foreign DNA (often referred to as T-DNA) is introduced into a plant cell, it is integrated into chromosomes at one or more seemingly random sites. It may insert into intergenic spaces with no additional phenotype, but it may also disrupt coding or regulatory regions of endogenous genes; such T-DNA-tagged populations of model plant species have yielded many useful mutants, and the altered gene is easily recovered and sequenced using the foreign gene sequences as a marker (59). A variation on this is “activation tagging,” wherein the introduced DNA bears strong promoters (to activate the expression of nearby endogenous genes after insertion) or easily detected marker genes (to be activated by nearby endogenous genes after insertion) (3, 26).

In closing, plant tissue culture began in the early 1900s primarily as basic laboratory experiments and a means to readily propagate expensive tropical houseplants. While the media and growth conditions still vary widely depending on which of the thousands of plant species are being cultured and the purpose of the culture (e.g., biochemical analysis, regeneration, transformation), the principles behind their selection are well understood. In the past 25 years, plant tissue culture has become a major tool in plant biochemistry, plant gene discovery and functional analysis, and plant genetic modification, with a huge economic impact on agriculture and human nutrition worldwide.

Insect Cell Culture

SPIROS N. AGATHOS

15

15.1. INTRODUCTION

Insect cells were first isolated and put into culture in the form of continuous cell lines in the late 1950s and early 1960s for the study of insect metabolism and physiology but also for the *in vitro* synthesis of baculoviruses (a group of viruses that infect invertebrates) as biological control agents against insect pests. However, insect cell culture received a major boost when the genetic manipulation of baculoviruses in the early 1980s made it possible to use them as vectors for the production of recombinant proteins. Today the *in vitro* cultivation of insect cells coupled with infection with baculovirus vectors (the insect cell-baculovirus expression vector system, or IC-BEVS) constitutes a major biomanufacturing platform for the commercial production of occluded viruses as biopesticides and of recombinant proteins as human and animal vaccines and therapeutics. This is the result of a combination of advantages of both the cell culture component and the vectors ensuring the transfer of heterologous genes: the culture of insect cells *in vitro* is now mastered to a similar extent as mammalian cell culture, and the application of baculoviruses as vectors for recombinant protein production or for manufacturing of viral biopesticides is safe and readily amenable to scale-up (1, 36, 60). The IC-BEVS is a highly versatile system because it can express gene products of practically any origin (from bacteria to human tissue), and in contrast to most industrial mammalian cell culture systems, it is based on engineering only the vector and not the host cell line. As a result, the development time needed to progress from gene cloning to protein overproduction is much shorter (weeks instead of months). Compared to other biomanufacturing platforms, the IC-BEVS offers other significant advantages, including typically high product titers, a range of posttranslational modifications, and the possibility to express multimeric proteins or even several distinct proteins using the same vector. The ready adaptation of insect cells to suspension culture and the continuous improvement of cell culture media and additives (3) are contributing to reliable and robust scale-up practices for commercial applications.

15.2. CELL GROWTH

15.2.1. Characteristics of Cell Lines

Several hundreds of insect cell lines have been established from more than 100 different species encompassing seven

orders and originate from eggs or adult tissues like ovaries, imaginal disks, midgut, etc. (50). The IC-BEVS makes use mostly of lepidopteran cell lines, in particular from *Bombyx mori* (silkworm), *Mamestra brassicae*, *Spodoptera frugiperda* (fall army worm), and *Trichoplusia ni* (cabbage looper). Among them, Sf-9 and Sf-21, isolated from *S. frugiperda*, and Tn-368 and BTI-TN-5B1-4, isolated from *T. ni*, are the cell lines most commonly used in industrial applications. These cell lines are very susceptible to infection by *Autographa californica* multiple nucleopolyhedrosis virus (AcMNPV) and other baculoviruses that form the basis for the construction of vectors in the IC-BEVS. A detailed, comprehensive, and up-to-date reference on all the techniques and methodologies involving the use of insect cell culture and baculoviruses for research and industrial applications is given by Murhammer (55).

The first line to be intensively used in research and technological applications was Sf-21, isolated from ovarian tissues of *S. frugiperda*. The Sf-9 cell line, derived from Sf-21 (68), remains probably the most widely used of all insect cell lines, thanks to its improved growth and high susceptibility to baculovirus infection, leading to excellent viral particle and protein yields. Tn-368 was obtained from ovarian tissues of *T. ni*, and BTI-TN-5B1-4 is a clone of the embryonic Tn-5 cell line isolated from *T. ni* (31). BTI-TN-5B1-4, patented by Granados (30), has been commercialized under the name High Five™ (Invitrogen, Carlsbad, CA) because of its superior capacity for secreted glycoprotein production compared to Sf cell lines (20, 66) and now rivals Sf-9 as the most popular cell line for heterologous gene expression. Conversely, the Sf-9 cell line is used more frequently for extracellular virus production (e.g., biopesticides) because of its higher yield of assembled viral particles. A genetically modified Sf cell line commercialized under the name Mimic™ Sf-9 (Invitrogen) is used for the stable expression of complex glycosylated heterologous proteins and is the same as the SfSWT-1 cell line developed by the group of Jarvis (32).

The Sf lines are adapted to suspension cultivation and are easily detached from T-flask (or other recipient) surfaces by gentle agitation without trypsinization (57). Tn lines were originally anchorage dependent, but today they are fully adapted to suspension cultivation. Moreover, upon microcarrier cultivation, High Five cells are more easily detached than Sf-9 cells (34). Among Sf lines, Sf-21 cells

are more fragile than Sf-9; less tolerant to osmotic, pH, and shear stress than Sf-9; and have a lower growth rate (57). High Five cells are more robust to shear stress and osmotic shocks than Sf-9 (42), although Sf-9 cells are more resistant to thermal shock (28). High Five cells (15 μm) are larger and have higher protein content than Sf-9 cells (13 μm), and they have wider cell size distribution than Sf-9 cells (J. C. Drugmand, Y. J. Schneider, and S. N. Agathos, unpublished data). However, the cell size depends on medium osmolarity, shear stress, and cell state (viable, apoptotic, etc.) (58). In general, Sf and Tn cells are bigger when infected (49). Maximal cell densities in serum-free batch culture can reach up to 9.6×10^6 cells/ml with High Five cells in YPR medium (Drugmand et al., unpublished) and 8.1×10^6 cells/ml with Sf-9 cells (63) in Sf900-II medium. Insect cell lines can grow over long-term passaging, which, however, can give rise to morphological and physiological changes: decrease of productivity, increase of growth rate and cell diameter (22), and lower susceptibility to growth enhancement by conditioned medium (11, 12). Finally, the tendency of baculovirus-infected cultured insect cells toward production of defective interfering particles ("passage effect") increases with higher cell passage number (43, 61). It is recommended to renew the working subcultivation after 30 passages (60).

The industrially and biotechnologically important cell lines of *S. frugiperda* and *T. ni* grow in the typical pattern of other animal cells in vitro. Following a short lag phase, the cells grow exponentially with doubling times between 18 and 30 h. Starting from seeding densities of 2 to 4×10^5 cells/ml, maximal cell densities between 5 and 10×10^6 cells/ml for Sf-9 and High Five cells are typically obtained on day 5 to 7 postinoculation in batch shake flask culture and in suspension bioreactors, depending on the medium formulation and the passage number of the inoculum. These values can easily increase by 100% or more in cases of fed-batch culture, especially when medium replacement or specific nutrient supplementation is practiced (36). The optimal temperature of insect cell cultivation is 27 to 28°C and it does not require sparging of CO₂. The optimal pH for the growth of most insect cells in culture lies between 6.2 and 6.3, somewhat more acidic compared to the growth pH required by cultured mammalian cells.

The biotechnological exploitation of cultured insect cells is based on their infection either with a recombinant baculovirus to produce a recombinant protein or with a baculovirus (mostly wild-type but also recombinant) to produce biopesticides in the form of budded virus. The production of the recombinant protein or of the viral particles occurs late in the infection phase, when the infected cells are lysed due to the pathogenic effect of the baculovirus. Thus the IC-BEVS production platform is a lytic system and the formation of the viral or protein product is transient, as a new batch of insect cells must be grown and infected for a new cycle of production.

15.2.2. Insect Cell Culture Media Development

Insect cell media contain the same basal ingredients as mammalian cell media (carbohydrates, amino acids, and salts) but at concentrations adapted to insect cell metabolism. In contrast to mammalian media, they are supplemented with specific additives such as a lipid mixture to supply lipids that insect cells are unable to synthesize. Other ingredients added include the shear-protective agent Pluronic® F-68 (Sigma-Aldrich, St. Louis, MO) (typically at 0.1 to 0.2% [wt/vol]) and antifoam for agitated and sparged reactor cultivation.

Insect cells have been cultured for decades in noncommercial basal media, such as Grace's, TNM-FH, TC-100, or IPL-41, that have been supplemented with 5 to 20% fetal bovine serum. In the last decade serum-free media have become dominant in insect cell culture in order to overcome the drawbacks of serum (cost, lot-to-lot variability, potential adventitious agents or contaminants, interference with product purification, etc.). Serum-free media are formulated from the above basal media (typically IPL-41 or TNM-FH) upon supplementation with yeastolate (ultrafiltered yeast extract), a lipid mixture emulsified in Pluronic F-68 (51) and other, mostly proprietary complements. Commercial serum- and protein-free media, including BD BaculoGold Max-XP (BD Biosciences, Franklin Lakes, NJ), ESF 921 (Expression Systems, Woodland, CA), EX-CELL® 405 and 420 (Sigma-Aldrich, St. Louis, MO), Express Five® and Sf900III™ (Invitrogen), HyClone SFX-Insect™ (Thermo Scientific, Logan, UT), and Insect-XPRESS™ (Cambrex Bio Science, Walkersville, MD), are used routinely for insect cell cultivation. These media, although able to support high cell densities and recombinant protein titers, are typically expensive, cell line specific, and of proprietary composition. A comprehensive listing of most serum-free media currently available for insect cell culture has been compiled by Agathos (3). A dominant feature of medium design today in response to stringent regulations is the elimination of animal-derived components. Thus, supplements designed to replace serum and other animal-derived ingredients are protein hydrolysates (peptones) of plant or microbial origin. Hydrolysates may have a nutritional role if basal media with lower amino acid content or no amino acids are used, but mostly they are assumed to perform many serum functions (protection from oxidative stress, shear damage, or apoptosis, etc.), as shown by the use of yeastolate, which moreover facilitates the purification of the recombinant proteins produced in the IC-BEVS (3, 36).

In addition to their high cost, the lack of information on the detailed composition of commercial serum-free media can also limit their attractiveness for specific biotechnological applications. Hence, there is a need for formulating serum-free media based on a rational assessment of the metabolic requirements of the lepidopteran cells during both the growth and production phases. The development of low-cost, in-house serum- and protein-free media can be based on empirical, statistical, or advanced genetic algorithm approaches (3).

A typical empirical path toward formulating an in-house, cost-effective medium starts with a basal medium requiring serum supplementation, such as IPL-41 (72), which has a simple composition and is easy to filter. Levels of glucose and of glutamine are fixed first, according to the requirements of the cell line to be cultured. Next, the lipid mixture emulsified in Pluronic F-68 (51). Alternatively, if the level of Pluronic F-68 is to be varied, the lipid mixture (1,000 \times , liquid; Sigma-Aldrich) can be mixed directly with Pluronic F-68 (10% solution; Sigma-Aldrich or Invitrogen). Serum and amino acids are replaced with hydrolysates (or, alternatively, with different defined peptides and vitamins). All components of the serum-free medium under development are mixed together, followed by filtration through a 0.2- μm filter. Each component is tested by individual titration to determine its optimal level of supplementation. For this, criteria of growth rate, viability, and growth extent (maximal or final cell density) are used for the growth phase, and growth extent, viability, and product virus or protein titer for the infection (production) phase. The last steps after

serum substitution must be repeated as different components are added, in order to exclude combinations that have an adverse effect on growth and/or production.

A statistical approach involves factorial experimental design, which enables the rational formulation of media through screening of many ingredients at the same time while keeping the number of experimental runs required low and manageable (54). This approach can result in great time and cost savings. Ikononou et al. (33) used a 2^{7-4} fractional factorial experiment for the screening of seven different hydrolysates and a subsequent 2^2 full factorial experiment for the optimization of the concentrations of the two selected hydrolysates (yeastolate and Primatone RL). This led to the formulation of the serum-free medium YPR, which performed equally well with commercial serum-free media costing 10- to 20-fold more (33). A variation of this serum-free medium that we have found to perform equally well and to be as cost-effective is given in Table 1. Designated YSD, this versatile serum-free medium is an evolution of YPR to which a low level of dextran has been added and in which Primatone RL, a meat hydrolysate, has been replaced by soy protein hydrolysate to ensure that the medium is free of animal-derived components.

In contrast to factorial experiments, which use only a small number of levels, genetic algorithms may enable the comprehensive optimization of insect cell media and cultivation conditions because they allow the screening of a wide variety of components and each of them at a wide range of concentrations. For instance, in the case of a fed-batch culture of *Helicoverpa zea* insect cells, a feed was developed from 11 different medium components, each used at a range of up to 31 concentrations. The feed was then optimized within four sets of 20 experiments (52).

15.2.3. Small-Scale Culture

Small bench-scale culture involves volumes ranging from a total of a few milliliters in wells of multiple-well plates or

TABLE 1 Formulation of YSD, a generic all-purpose serum-free medium for insect cell culture

Component	Content	Supplier(s)
Basal IPL medium ^a		HyClone
Glucose supplement ^b	41 mM	
Glutamine supplement ^c	3.5 mM	
NaHCO ₃	4 mM	
Pluronic® F-68	0.1% (vol/vol)	Sigma-Aldrich
Lipid mixture for insect cell culture	0.25% (vol/vol)	Sigma-Aldrich
Dextran 67 kDa	0.1% (wt/vol)	Sigma-Aldrich
Yeastolate	6 g/liter	Sigma-Aldrich
Soy hydrolysate	5 g/liter	DMV International Nutritionals (SE 50 MAF), Kerry Bio- Science (HySoy)

^aPreparation in Milli-Q® water (Millipore), pH 6.2 to 6.3.

^bFinal glucose concentration, 55 mM.

^cFinal glutamine concentration, 10 mM. For certain applications a higher supplementation with free glutamine may be needed (final concentration, 15 to 17 mM).

T-flasks for adherent culture to shake flasks or spinners up to 250 ml for suspension culture. The equipment required is limited to an incubator and an orbital shaker. All addition and removal of medium should be done in a biological safety cabinet or laminar-flow hood by using aseptic conditions and scrupulously sterilized equipment. The incubator is held at an optimal temperature of $27 \pm 0.5^\circ\text{C}$ for Sf-9, Sf-21, and High Five cells, which, moreover, do not need CO₂, since most media are buffered.

Most types of insect cells tend to clump and lose viability when they are transferred abruptly to suspension from monolayer culture or to serum-free from serum-supplemented medium. It is recommended that one adapt the cells to suspension culture before attempting to grow them in serum-free medium. The increased sensitivity of the cells in serum-free culture requires reduced use or total elimination of antibiotics, avoidance of trypsinization for dislodging adherent cells from culture vessels, and consistent cryopreservation (freezing) and recovery (thawing) procedures. Cells propagated in serum-free medium are also more fragile than cells grown in serum-containing medium. Therefore, upon subculturing, insect cells grown in serum-free medium must be separated by low-speed centrifugation. Dislodging of adherent cells from culture vessels should be done with mild tapping or shaking or with a gentle stream of medium.

For routine monolayer culture in polystyrene T-flasks, dishes, or multiwell plates, cells are inoculated at 2 to 5×10^5 cells/ml (e.g., 0.8 to 2×10^6 cells/25-cm² T-flask). The recipient container is incubated at $27 \pm 0.5^\circ\text{C}$ for 3 days, whereupon spent supernatant medium is removed from the monolayer and the culture is refed with fresh medium gently introduced to the side of the recipient container. Subculturing to the next passage is done when the monolayer reaches 90 to 100% confluency. Exponential growth can be maintained by splitting cells at a 1:5 dilution. After about 30 passages (2 to 3 months in culture) and after increased doubling times (>28 h) have been reached, insect cells tend to lose their viability and it is time to thaw new cell cryovials to initiate new monolayer cultures.

Cell viability should be monitored at each passage and should exceed 90%. Most insect cell lines do not adhere to monolayer substrata (e.g., T-flasks, dishes) as strongly as do anchorage-dependent mammalian cell lines. In the case of High Five cells, which have already been adapted to suspension in many laboratories, an occasional tendency toward adhering to substratum and clumping can be counteracted by addition of heparin or dextran sulfate (20a) in order to obtain single-cell suspensions. This is not necessary when an already suspension-adapted cell line is obtained from a commercial supplier (e.g., High Five cells from Invitrogen have been adapted to grow individually in suspension). Thus, monolayer cultures of all types of lepidopteran cells can be used to initiate suspension cultures.

A typical protocol of adaptation requires six to eight confluent 25-cm² T-flasks to start a 30-ml suspension culture (or six to ten 75-cm² T-flasks to start a 100-ml suspension). After cells are dissociated from the bottom of the flasks with a gentle stream of medium or by a sharp shaking motion, the suspensions from the various T-flasks are pooled into a shake flask or spinner and the cells counted. Fresh medium is added to the cell suspension to reach 2 to 5×10^5 cells/ml. The shake flasks are incubated on the shaker at 90 to 100 rpm and the spinners are operated at a stirring rate of 40 to 60 rpm in an incubator (or constant-temperature room) at $27 \pm 0.5^\circ\text{C}$. Subculturing into fresh medium is done when the viable cell count reaches 1 to 2×10^6 cells/ml,

and the stirring or shaking speed is increased by increments of 5 rpm as long as viability is maintained above 90%. This last step is repeated until a constant agitation speed of 90 rpm for spinner flasks or 130 rpm for shake flasks is reached and a consistent viability above 90% is maintained. Further subculturing from this point can be done at 0.3 to 1×10^6 cells/ml (i.e., every 1 to 3 days). If cell clumping is observed, the larger cell aggregates can be left to settle and only single cells and small clumps are selected from the upper third of the suspension for subsequent subculture. In a final step, a sufficient quantity of cells fully adapted to suspension culture should be frozen into cell banks to initiate future suspension cultures.

Erlenmeyer shake flask culture is by far the easiest way to grow *S. frugiperda* and *T. ni* insect cells in suspension. The most common configurations are 100-ml (working volume, 30 to 40 ml) or 250-ml (working volume, 80 to 100 ml) flasks. Loosening the cap approximately one quarter turn enables unhampered aeration to the cells, which can grow at their maximum specific growth rate. In a representative sequence of operations, the desired number of 250-ml shake flasks is inoculated with 80 to 100 ml of medium containing 3×10^5 viable cells/ml at a viability of at least 90%. The flasks are placed on an orbital shaker agitated at 125 to 140 rpm (depending on the cell line and the medium) and maintained in an environment of $27 \pm 0.5^\circ\text{C}$. When the culture reaches 1 to 3×10^6 viable cells/ml, the shake flask contents are split to subculture the cells to about 3×10^5 viable cells/ml into similar-size shake flasks with fresh medium. The subculturing should be done when the cells are in mid-exponential growth and at maximum viability (i.e., above 90%). Every 3 weeks, cultures are centrifuged (100 to $200 \times g$ for 5 min) and the cell pellet is resuspended into fresh medium to reduce cell debris and toxic by-product accumulation.

Spinner culture is less common than shake flask culture but better simulates the environment of a stirred bioreactor for eventual scale-up. A spinner flask with a vertical impeller is preferred over that with a hanging stir bar because it supplies better aeration. The liquid culture volume in a spinner should not exceed one-half the graduated volume of the vessel, to ensure proper aeration (e.g., a 500-ml spinner should contain no more than 250 ml of culture fluid). A minimum volume should also be respected, so the impeller stays submerged (e.g., 200 ml for a 500-ml spinner). In a spinner culture protocol for *S. frugiperda*, exponential-phase monolayer culture cells can be inoculated at a cell density of 0.3 to 1×10^6 viable cells/ml (four or five confluent 75-cm² T-flasks can supply this biomass for a 100-ml culture). Each spinner is incubated at $27 \pm 0.5^\circ\text{C}$ with constant stirring at 75 to 90 rpm. The top of the impeller should be slightly above the medium surface to provide additional aeration, and the sidearm caps of the vessels are kept loose to equilibrate the headspace with the atmosphere. When the cells reach a density of 2 to 3×10^6 viable cells/ml (i.e., once every 1 to 3 days), a sufficient quantity of fresh medium is added to the spinner(s) to bring the cell density back to 10^6 cells/ml. Alternatively, new, sterile spinners containing fresh medium can be reseeded to about 3×10^5 cells/ml from a growing suspension culture. As in all growth protocols, insect cells should be monitored daily for density and viability.

Growing shake flask or spinner cultures of sufficient volume and good physiological characteristics (in mid-exponential phase and with $>90\%$ viability) can be used for maintenance culture or for inoculating a higher-scale vessel, e.g., a stirred Celligen™ bioreactor (New Brunswick Scientific, Edison, NJ).

15.2.4. Large-Scale Culture

The capacity of insect cells to grow in suspension and the wide availability of serum-free media and additives, including hydrodynamic shear-protective agents, together with the vast prior experience using mammalian cells in biotechnological applications, have opened the way for the development of reliable and efficient large-scale insect cell culture processes. The successful scale-up from spinners or shake flasks of a few hundred milliliters to a large bioreactor of several hundred liters is done in steps, passing through progressively larger vessels. Scale-up requires a good understanding and control of fundamental process parameters, such as adequate oxygen delivery, good mixing, and appropriate modes of feeding, i.e., parameters whose consequences are crucial for optimal cell growth and efficient baculovirus infection. For instance, the crucial phenomena of insect cell damage in an aerated and stirred bioreactor can be assessed and mitigated by understanding and controlling the complex interplay among the aeration rate through the orifices of a sparger, the agitation rate with a mechanical impeller, and the existence (and extent) of gas-liquid interface for air bubble bursting and its control by additives such as Pluronic F-68 (14).

Generally speaking, the culture conditions allowing the attainment of high cell densities in the growth phase are different from conditions compatible with high production during the infection phase. Although the pH, temperature, dissolved oxygen (DO), and medium conditions to sustain high cell densities are well established, the corresponding parameters favoring an optimal outcome of the infection process and hence high recombinant protein productivity are less well documented. In addition to these, productivity of infected cells depends upon several more factors such as virus construction (62), number of passages of the virus (45), cell density at infection (CDI), multiplicity of infection (MOI) (16), "culture age" (36), cell state (73), and state of medium depletion (37). An important phenomenon underlying the distinct optima between the conditions for growth and the conditions for efficient virus infection and productivity is the "cell density effect," i.e., the consistently observed drop in cell-specific productivity when CDI exceeds a certain value (36). Its consequences and practices aiming at overcoming it are discussed below.

15.2.4.1. Selection of Bioreactors

A number of bioreactor systems have been investigated and proven their merits in terms of robustness and scalability (2, 36, 60). The selection of a production-scale bioreactor system from the point of view of design (stirred-tank, airlift, packed-bed, or Wave) and from that of cultivation mode (batch, fed-batch, or continuous perfusion) should be guided by considerations of product titer, overall productivity, and product quality. Although in the 1990s there was a tendency to experiment with a wide variety of bioreactor designs including prototypes, the last few years have seen a reaffirmation of the selection of mainstream reactors, mostly of the stirred-tank type. For instance, a side-by-side comparison of the bioprocess behavior of Sf-9 cells in an 8-liter stirred-tank reactor and in a 6-liter airlift reactor showed similar growth characteristics and productivity of a recombinant kinase (65). The flexibility and wide availability of stirred-tank reactors make them more attractive than airlifts, despite the latter's recognized potential for adequate oxygen transfer rates with low and homogeneously distributed shear compared to conventional stirred vessels. At several hundred liters, airlift scale-up rules impose a constant height-to-circumference ratio that can result in very tall, customized

vessels. In contrast, stirred-tank fermentors widely used in microbial applications can be readily retrofitted with low-shear impellers (e.g., marine propellers or hydrofoils) and adapted spargers for mammalian and insect cell cultivation.

Packed-bed reactors make use of a cell immobilization matrix (nonwoven fibers, foamy polymeric materials, and macroporous microcarriers) compactly loaded into a retention basket within the vessel (29). The main advantage of the fixed bed is its ability to retain the cells and perfuse the medium across the reactor under low shear stress. In this design, high cell densities can be reached in small bioreactors, potentially leading to high productivity if the cell density effect can be managed. However, the density of the immobilized cells in the bed is difficult to estimate, cell distribution inside the matrix can be heterogeneous, and problems of oxygen limitation with gas exchange and metabolic by-product accumulation are possible. In addition, the packed cells must remain viable and productive for prolonged periods during the culture. Although insect cell immobilization studies have some promise, as seen with microcarriers in a stirred reactor (34), insect cell cultivation in packed-bed reactors (5, 17, 18, 74) seems potentially more attractive for constitutive rather than transient protein production.

The Wave bioreactor was conceived for the suspension culture of shear-sensitive animal cells without the need for protective additives like Pluronic F-68 and is part of the current trend toward single-use biomanufacturing systems (67). It consists of disposable, presterilized polyethylene bags (from 1 to 1,000 liters with working volumes from 100 ml to 500 liters) placed on a rocking platform. The bags are filled with medium and cells and the rest of the chamber is inflated with air (67). The rocking motion of the platform generates waves, which enable good oxygen transfer and mixing. A 20-liter Wave bioreactor was used in a side-by-side comparison with a stirred vessel for the production of a secreted adhesion molecule (intercellular adhesion molecule-1) by baculovirus-infected Sf-9 cells (71). Similar product yields were obtained in both the Wave bioreactor and the stirred-tank reactor, but operational costs were 40% lower for the disposable bioreactor. The Wave reactor is well adapted to the fed-batch mode of operation. On the other hand, despite generating a constantly renewed liquid-gas interface, oxygen may be limiting at high-density infections where oxygen uptake rate (OUR) increases transiently after infection (2). The introduction of a floating filter and a perfusion control system in the Wave bioreactor (56) has opened the way to its use in insect cell perfusion culture. In recent versions of this system it is possible to fit DO and pH probes and to connect sample, input, and exit lines to a variety of analyzers for online monitoring (41).

15.2.4.2. Batch, Fed-Batch, and Continuous Culture

Batch culture remains the most common method for large-scale IC-BEVS processing because of its inherent simplicity and flexibility in bioreactor equipment. In a typical protocol adapted from Elias et al. (27), the batch bioreactor is inoculated at a density of between 3 and 5×10^6 cells/ml by pooling cells from exponentially growing smaller-scale cultures (see section 15.2.3). The volume of the inoculum should represent approximately 10% of the working volume. Cells are grown to 2 to 3×10^6 cells/ml (a CDI that is considered safe for infection, i.e., is not linked to a cell density effect) and are then infected by adding the baculovirus stock. If a synchronous infection is desired in the interest of fast and abundant production, an MOI of 5 to 10 is appropriate. This ensures that a growth cessation due to

the baculovirus vector's cytopathic effect on the cells will occur at about 24 h postinfection and the production of the recombinant protein will increase after that time. Based on the definition of MOI as the ratio of PFU per cell at the time of infection, the volume of baculovirus stock, V_b , is given by the equation

$$V_b = \frac{X \times V \times \text{MOI} \times 10^3}{P} \quad (1)$$

where X is the viable cell density (cells/ml), V is the working bioreactor volume (liters), MOI is the target multiplicity of infection (PFU/cell), and P is the baculovirus stock titer. However, as a rule, the volume of virus stock added should not be much higher than 2% of the total culture volume.

A close monitoring of the growth and infection phases by a combination of offline and online techniques such as OUR (see section 15.4) will allow the determination of the best time for harvesting, which, depending on the protein, may be between 36 and 72 h postinfection.

Fed-batch cultivation is today perhaps the most robust bioreactor operation mode, and its success seems to be linked in large measure to its capacity to overcome the cell density effect, which depends on the CDI. This effect represents a consistent reduction of the specific productivity when the cell concentration at infection is above 3 to 4×10^6 Sf-9 cells/ml or above 5 to 6×10^6 High Five cells/ml (26). This is thought to be due to nutrient depletion in the medium during infection, although its understanding remains incomplete. For instance, it has been shown that the drop in productivity of Sf-9 cells occurs prior to nutrient depletion (23). Complete medium replenishment or selected feeding of nutrients counteracts the cell density effect (as reviewed in reference 36), lending support to nutrient depletion as at least one causative factor. Generally, infection is more rapid at high cell density and high MOI, but the temporary burst in metabolic activity may not be sustainable in the absence of fresh nutrients. Cell productivity is also affected by the physiological state of the cells (e.g., apoptotic cells are less productive than exponentially growing cells). Finally, the effect of the time of infection (TOI; also known as culture age), i.e., the duration of the culture from inoculation to infection, depends directly on the specific growth rate of cells, on the inoculation cell density, and on the target CDI. Hence, as stated above in the batch culture protocol, infections that aim to reach high recombinant protein production must be as synchronized as possible and applied when the cells are highly viable in exponential phase, and at that point, medium depletion must be compensated with appropriate nutrient feeding.

Due to the depletion of medium ingredients and the density effect, infection of simple batch cultures is not optimal for high protein production levels. An initial approach to counteract this problem has been the total or partial medium replacement at the time of infection. Medium replacement can be applied before or shortly after the infection and has been found to be efficient for recovering high specific production at high cell density (reviewed in reference 36). Moreover, the use of a cell retention (or centrifugation) system to separate the cells from the exhausted media could serve to concentrate the cells (37). Partial medium replacement is less costly and allows the retention of potential growth-promoting factors secreted by the cells (11, 12, 24, 36a). Complete medium replacement, originally proposed in the early 1990s (47), helps to obtain high production with Sf-9 cells. Today, however, this solution is considered neither economical nor practical for large-scale applications.

Fed-batch operation involves essentially the intermittent addition of nutrients to a batch culture. It enables increased cell density and productivity without medium depletion. It is easier and cheaper to implement than perfusion and avoids exposure of the cells to high shear stress in a cell retention device. However, it requires knowledge of physiological requirements of the cells. Moreover, in fed-batch mode, accumulation of by-products may be considerable. Nevertheless, the low sensitivity of insect cells to by-product accumulation, to osmolarity increases, and to pH variation has made them a better candidate for fed-batch processing than mammalian cells. Fed-batch cultivation of insect cells has been studied intensively in the last several years, especially in the context of increasing both the cell density and the production yield using serum-free media and a suite of feeding strategies. Bédard et al. (6) demonstrated that Sf cells needed a single-pulse addition of yeastolate and amino acid mixture as supplement. Incidentally, the use of a richer supplement consisting of glucose, tyrosine, vitamins, iron, and a trace metal solution led to very high densities of Sf-9 cells (30×10^6 cells/ml) (7). In a report from the same group, (semi)continuous addition was better than single-pulse addition for achieving high cell densities of Sf-9 cells (26). The highest cell density reported with lepidopteran cells in fed-batch culture was 52×10^6 cells/ml using Sf-9 cells, but the cell density effect resulted in unsuccessful infection at such a cell density (26). The highest reported Sf-9 CDIs sustaining high production were 11.5×10^6 cells/ml (7), 12×10^6 cells/ml (15), and 17×10^6 cells/ml (26). There is less published information on the fed-batch cultivation of *T. ni* cells. Infection of High Five cells at a density of 3.8×10^6 cells/ml attained in serum-supplemented fed-batch culture allowed a modest production of β -galactosidase (75). In another report, a serum-free fed-batch strategy was developed based on culture pH as an indicator of a metabolic switch linked to the requirements of High Five cells for glucose and glutamine (70).

A protocol adapted from the developers of high-cell-density culture using fed-batch methodology (27) involves a start-up phase of batch cultivation of Sf-9 cells followed by additions of concentrated nutrient solutions together with close on-line monitoring and control of the integral process. In this sequence, the baculovirus infection is done routinely at cell densities of 10×10^6 cells/ml. The initial batch is inoculated at a density of 3 to 5×10^6 cells/ml with an exponentially growing culture of Sf-9 cells. The nutrient concentrate, which includes glucose, amino acids, yeastolate, lipids, vitamins, and trace metals (6, 7, 26), is added at 10% (vol/vol) to the culture volume at 24-h intervals and the working volume of the culture is maintained constant by removing an equivalent volume of mixed liquor between two consecutive feeds of nutrient concentrate. Finally, the culture is infected when the cell density reaches 10×10^6 cells/ml. As the cell density is progressively increasing, it is important to ensure adequate oxygenation of the culture by using an appropriate airflow rate or, if need be, an O₂-enriched gas mixture. The efficiency of oxygen supply can be checked by monitoring the DO concentration, which should not be allowed to drop below 20% air saturation. Both oxygen supply and nutrient adequacy should be checked throughout both the growth and the infection phases. As suggested in the batch culture protocol above, an MOI of 5 to 10 is also recommended here for synchronous infection. However, if a lower MOI is chosen based on small-scale trials because of better and prolonged product formation, the asynchronous infection will enable significant postinfection growth that will contribute to oxygen and nutrient consumption. Therefore, these substrates should be carefully monitored, and if need be, the feeding

strategy should be adapted in a manner ensuring that there is no nutritional limitation during the infection phase, since this may compromise the final production level.

Continuous culture involving the steady-state feed of sterile medium and replacement of culture liquor without insect cell retention has not been used much for production of baculovirus or recombinant protein because the continuous withdrawal of the culture from the continuous stirred-tank reactor (CSTR) causes the dilution of cells and product (25). Moreover, the two distinct phases of the production process (growth and infection) are not easily implemented in a continuous mode in the same reactor due to the transient, lytic nature of BEVS. Thus, continuous operation in a reactor cascade has been proposed, consisting of two (or more) CSTRs in series, where the first is used for cell growth and the next for infection (77). A key limitation in this configuration is the accumulation of defective virus (69).

In contrast to classical CSTR operation, continuous perfusion culture in a reactor equipped with a cell retention system is better adapted to insect cell propagation because, just as in the case of fed-batch operation, it allows increase in the cell density (16). Among the many cell retention systems available, perfusion culture of insect cells makes use of membrane-based modules (internal or external). The lepidopteran cells cultivated in perfusion are reported to attain very high cell densities and production levels. For example, when cultivated in perfusion, Sf-21 cells were found to reach 55×10^6 cells/ml (21), while Sf-9 cells attained 30×10^6 cells/ml (13), and about 500 mg/ml of a recombinant protein was obtained with High Five cells (16).

15.3. BACULOVIRUS INFECTION

15.3.1. Recombinant Baculovirus Vector Generation

Recombinant AcMNPV is generated by cotransfecting into insect cells the linearized AcMNPV genome with a transfer plasmid carrying the gene of interest in an expression cassette controlled by a late viral promoter such as that of the polyhedrin (*polh*) gene or of the *p10* gene. Following recombination of the expression cassette into the AcMNPV genome, the recombinant virus is amplified in an insect cell host and used for productive infections (62). The replacement of either of the above nonessential genes (*polh*, *p10*) with the foreign gene of choice and the very strong promoter control allow the production of recombinant protein at very high yield (53, 68). Owing to continuous improvements in recent years to the flexibility and efficiency of baculovirus vector-based expression, this system is now adapted for simultaneous expression of several foreign genes using a single recombinant baculovirus (76). The recombinant viruses produced using these transfer vectors have facilitated the study of complex protein assembly, by coexpressing protein subunits in the same host cells. Coinfection with several recombinant viruses is also possible to express different genes (44, 64). The incorporation of the recombinant expression cassette into the AcMNPV genome by site- and orientation-specific Tn7-mediated transposition has improved and simplified the selection procedure for amplified recombinant baculovirus (4). In addition, recombinant protein yield is significantly enhanced by the deletion of the genes coding for the baculoviral enzymes chitinase (*chiA*) and v-cathepsin (V-CATH), which are involved in insect cell host lysis when the cytopathic effect takes hold (40). The above improvements have been combined in a

baculovirus expression system named MultiBac, which is used mainly for the expression of heterologous multiprotein complexes (8, 10). Many of the components and reagents needed for the generation of recombinant baculovirus vectors are now commercially available in the form of kits (e.g., from Invitrogen).

15.3.2. Vector Amplification and Viral Titration

Depending on the amount of viral stock required, the baculovirus vector can be amplified in monolayer cultures, shake flasks, or bioreactors, typically using a routine protocol of small-scale culture (see section 15.2.3). Although *S. frugiperda* and *T. ni* cells, in addition to several other lepidopteran cell lines, are readily susceptible to infection by wild-type and recombinant AcMNPV baculovirus, the general tendency in practice is to use Sf-9 or Sf-21 cell cultures for routine production of baculovirus stock. It has been observed repeatedly that despite its capacity for overexpression of recombinant proteins (especially secreted ones) *T. ni* is less prolific than *S. frugiperda* in the production of extracellular virus. A low MOI of about 0.1 should be used for viral stock production to ensure the purity of the stock and prevent mutant accumulation. Usually a series of amplification steps are carried out until the viral stocks reach 1×10^8 or 1×10^9 PFU/ml. Adding 5 to 10% serum can enhance the stability of baculoviruses stored at 4°C (used as a working viral stock), but cryopreservation of the viral stock at -85°C is also possible without loss of stability for several months (master viral stocks).

An accurate baculovirus titer (in terms of PFU/ml) is essential to determine the strength of the stock for future infections. This effective concentration of infective particles can be obtained upon infection of insect cells in standardized laboratory assays, usually in culture dishes and multiwell plates. The most commonly used methodologies for baculovirus titration are the plaque assay and end-point dilution (57). The plaque assay is carried out on tissue culture-treated dishes and involves the infection of a monolayer of insect cells with a low concentration of virus, followed by an agarose medium overlay. When the infection is complete, a virus plaque (i.e., an isolated region of infected cells) is identified by visual inspection, and an agarose plug is removed at the corresponding plaque location for generating viral stocks. With the end-point dilution method, the culture medium is serially diluted to the point at which any infection event is expected to result from a single infectious viral particle. The direct visual identification of positive wells (i.e., wells containing cells infected by the baculovirus) is difficult for recombinant baculovirus vectors lacking the polyhedrin gene. Because of the exacting and time-consuming nature of both the end-point dilution and plaque assay methods, a number of alternative techniques for determining the viral titer have been proposed. Thermo Scientific has commercialized a kit containing the necessary ingredients for plaque assay, shortening the time of preparation (HyQ BEVS plaKit). Clontech (Mountain View, CA), Expression Systems, and Merck Biosciences (Darmstadt, Germany) offer quick and efficient enzyme-linked immunosorbent assay kits for titrating the virus based on the detection of the gp64 viral capsid protein with a monoclonal antibody. Finally, viral titration can also be accomplished through the detection of green fluorescent protein, whose gene is incorporated in the virus genome and coexpressed together with the recombinant protein of choice (19).

15.3.3. Infection of Insect Cell Cultures

Important considerations involved in the process of infecting an insect cell culture with a baculovirus are the cell line to use, the timing of the infection, the cell density at which the cells should be infected (CDI), the MOI to apply, and the time at which to harvest the product.

15.3.3.1. Cell Line Selection

The choice of insect cell line for use in the IC-BEVS biomanufacturing platform depends primarily on the product to be expressed. Lepidopteran insect cells are able to bring about eukaryotic posttranslational modification of heterologous proteins, such as N and O glycosylation, phosphorylation, fatty acid acylation, sialylation, α -amidation, N-terminal amidation, carboxymethylation, and isoprenylation (9, 32, 38, 39, 59). Moreover, baculovirus-infected insect cells are able to effect folding of heterologous proteins and peptide cleavage, although these recombinant proteins exhibit differences from their authentic counterparts. As a rule, Sf-21 and Sf-9 are the cell lines of choice for overproduction of whole viruses (e.g., as biopesticides) and also for the production of intracellular or periplasmic proteins, whereas High Five has been repeatedly demonstrated to overexpress many glycosylated and secreted proteins. Specifically, High Five cells are supposed to carry out better posttranslational modifications than Sf-9 cells, with a higher percentage of complex glycoforms and even some sialylation (38, 39).

15.3.3.2. TOI, CDI, and MOI

The fraction of the population of insect cells initially infected by the virus is a crucial factor affecting cell productivity. This fraction of the cell population is a function of the MOI, which corresponds to the number of infectious particles (PFU) divided by the number of cells, and follows a Poisson distribution given by equation 2. In this relationship, $p(r)$ is the probability of a cell being infected by r virus particles and MOI is expressed in PFU/cell (57).

$$p(r) = \frac{\text{MOI}^r \cdot \exp(-\text{MOI})}{r!} \quad (2)$$

The probability $p(r)$ is equivalent to the fraction of cells infected with r baculovirus particles at a given MOI. Since, according to equation 2, the fraction of uninfected cells (i.e., cells infected with $r = 0$ virus particles) at the given MOI would be $p(0) = \exp(-\text{MOI})$, then it follows that the fraction f of cells infected with at least 1 virus particle would be $f = 1 - p(0)$, i.e.:

$$f = 1 - \exp(-\text{MOI}) \quad (3)$$

Various reports have examined the combined effect of TOI and MOI on productivity. Infection using a high MOI (>1) implies that the infection is synchronized (i.e., all cells are infected at the same time), while with an MOI of <1 all cells are not simultaneously infected and several cycles of infection are required to infect the entire cell population. High MOI is thus predicted to lead to a short production period with high productivity (i.e., product concentration per unit time of process duration). On the other hand, in larger bioreactors infection at a high MOI would also imply a need for large volumes of virus stock (see equation 1). As seen previously (section 15.3.2), a low MOI is used for virus amplification and for applications where viral stocks are low (57). In addition, infections at low MOI and low CDI can be successful and cost-effective in cell lines like Sf-9 that are very prolific in extracellular virus production or when it has been empirically found that the accumulation of the product is not adversely affected

by a long infection phase. However, as a rule, asynchronous infections increase the time of harvest, lead to the production of defective viral particles, and expose the recombinant protein to proteases (2). Nonetheless, different opinions exist on this point. Some authors consider that an MOI between 1 and 20 leads to essentially similar levels of productivity (51), while others contend that an MOI close to 1 is better (2). Still others recommend an optimization of both the TOI and MOI in an effort to ensure that all cells are infected by the baculovirus and that there are sufficient concentrations of nutrients left for product (virus or recombinant protein) formation (73). Although previous attempts to predict the effect of MOI (and TOI) on recombinant protein production based on probabilistic mathematical simulations (46) have been borne out experimentally (73), the phenomena are complex and MOI optimization is not straightforward. In conclusion, MOI optimization depends on the virus, the cell line, the media/nutritional conditions, and the physiological state of the insect cells at the time of infection.

15.3.3.3. Time of Harvesting

The time of harvesting is an important consideration in the management of any biomanufacturing process involving IC-BEVS. The recombinant protein must be harvested before potential degradation by proteases that are secreted by the insect cells, which may occur during lysis and disintegration of the cells (35, 48). This is especially critical in the case of a secreted protein product. Therefore, as a general guideline, a protein product should be harvested when the cell viability falls below 80%.

15.4. QUANTITATIVE ASSESSMENT OF GROWTH AND INFECTION PHASE, AND PROCESS MONITORING

Insect cell growth is evaluated in terms of population doubling time, specific growth rate (μ), growth extent (maximal cell density or CDI), length of the stationary/decline phase, and viability. Infection at a given MOI is assessed by the time course of the postinfection cell density and viability and, most importantly, by the evaluation of the viral or recombinant protein titer. CDI, MOI, and time of harvesting must be optimized on an individual basis for different recombinant products, even though some general rules can be deduced (see section 15.3.3.2).

Cell growth and infection in insect cell culture are commonly monitored by counting total and viable cell numbers with a hemacytometer and using trypan blue staining/exclusion. A more accurate but more time-consuming alternative is the 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium bromide cell proliferation assay, which can be applied using a commercial kit (e.g., from the American Type Culture Collection [Manassas, VA]). Other less labor-intensive or invasive techniques are also possible for monitoring cell growth and infection, both offline and online (2). Offline measurements of growth make use of optical density or of a Coulter particle counter. Online monitoring of growth through respiratory activity is based on determinations of cellular OUR or CO₂ production rate using mass spectrometry or individual analyzers (O₂ paramagnetic analyzer or CO₂ infrared analyzer). Specific OUR can also be determined using a DO electrode. With proper calibration it is possible to monitor the infection phase via OUR because of the transient increase in oxygen consumption at the onset of infection. Epifluorescence microscopy of live and dead cells using fluorescence stains (Molecular Probes, Invitrogen) is

another technique for tracking the infection phase. Finally, protein production can be followed by a variety of assays, including fluorometric staining, Western blots, enzyme-linked immunosorbent assay, and enzyme activity.

15.5. PRODUCT RECOVERY

The recovery of the recombinant protein or viral product makes use of various well-established downstream processes that are commonly used in many biomanufacturing platforms (microbial fermentation, mammalian cell culture, etc.) but can vary widely as a function of the nature of the product (intracellular or extracellular protein, molecular size, state of ionization, hydrophobicity, etc.). The separation of the insect cells may be a prerequisite in the case of intracellular, periplasmic, or membrane-associated recombinant proteins. This cell recovery step and all associated operations should be carried out at 4°C. Insect cells can be recovered by centrifugation at low speeds (500 to 1,000 × g for 5 to 10 min) or by tangential flow membrane filtration, e.g., using a Pellicon tangential filtration unit (Millipore Corp., Billerica, MA) or a Filtron membrane unit (Pall Corp., East Hills, NY). An alternative possibility is cross-flow microfiltration using hollow-fiber cartridges (GE Healthcare, Piscataway, NJ). The release of the intracellular or cell-associated protein may be aided by a prior cell lysis step (mechanical milling or using a detergent mix in buffer). In the case of a protein product secreted in the culture supernatant, the cells can be centrifuged at 1,500 × g for 10 min. If further processing is to be done several days after harvesting, the cell paste and supernatant must be stored at -80°C until the next phase of separation and purification. It is recommended that large volumes of supernatant be concentrated by ultrafiltration through an appropriate membrane cutoff before being frozen for further processing.

15.6. SUMMARY

The practice of insect cell culture is becoming more and more widespread as an essential component of the IC-BEVS, perhaps one of the most successful and far-reaching expression systems available today for the production of recombinant proteins and viral particles. In addition to its established applications in the production of ecological biopesticides and of recombinant proteins as diagnostics and veterinary vaccines, this technology platform is attracting increasing attention because of emerging applications in human health, including new-generation vaccines against human papillomavirus and influenza virus. Furthermore, in the era of proteomics, the IC-BEVS is an obvious choice for the ample and rapid expression of hitherto unknown or poorly understood proteins of interest in fundamental biological research or with potential applications in drug discovery, sustainable agriculture practice, etc. Therefore, the understanding of insect cell physiology *in vitro* and the constant improvement of insect cell culture techniques using some of the tools and concepts outlined above will ensure the industrial maturity of the IC-BEVS through further development of efficient, scalable, and safe production processes.

GENETICS, STRAIN IMPROVEMENT, AND RECOMBINANT PROTEINS

NUMEROUS DIVERSE MICROORGANISMS, INCLUDING CULTURED CELLS derived from multicellular organisms, are used in industry to produce products ranging from therapeutic proteins, enzymes, and biopolymers to antibiotics, pharmaceuticals, and biofuels. Almost without exception, the strains used in such bioprocesses have been genetically altered, either through mutagenesis and screening for higher titers or through strain engineering using modern technology. Since the previous edition of this manual was published in 1999, the genetic toolbox for most organisms has grown significantly. The chapters in this section describe contemporary methods and strategies for engineering and improving some of the most widely used industrial microorganisms. Each is focused on a particular taxonomic grouping that shares similar methods of genetic manipulation and culturing. Although it was not possible to cover the genetic manipulation of every industrial microorganism in this section, much can be found here that should apply more widely. The genetic manipulation of industrial microorganisms in the context of natural products was recently covered in “Complex enzymes in microbial natural product biosynthesis” (*Methods Enzymol.*, volumes 458 and 459, edited by D. A. Hopwood [Academic Press, 2009]). Also, the useful “Guide to Yeast Genetics and Molecular Cell Biology” was recently updated (*Methods Enzymol.*, volume 464, edited by J. Weissman, C. Guthrie, and G. R. Fink [Academic Press, 2009]).

In chapter 16, “Genetic Engineering of *Corynebacteria*,” Masato Ikeda and Seiki Takeno provide a historical context for the extensive work on the gram-positive genus *Corynebacterium*, which is most famous for its use in large-scale production of amino acids. The authors describe how genomics and other “-omics” technologies have been applied to strains derived from classical mutagenesis and screening programs, allowing the rational reconstruction of industrial production strains. They discuss many strategies for metabolic pathway engineering in corynebacteria and the methods used to apply those strategies.

In chapter 17, “Genetics of *Clostridium*,” Marite Bradshaw and Eric Johnson discuss the latest tools for genetic manipulation of this gram-positive bacterial genus known for its many strictly anaerobic species. *Clostridium* is diverse and important in both industry and medicine, but has been relatively difficult to engineer. However, as this chapter attests, significant progress has been made during the past decade.

In chapter 18, “Genetic Manipulation of Myxobacteria,” Wesley P. Black and colleagues describe new genetic tools available for these fascinating gram-negative bacteria, which have been of interest to academia for the morphogenesis of complex, multicellular fruiting bodies. Myxobacteria are valuable to industry because they produce a wide diversity of novel biologically active compounds. This chapter describes many methods that

have been developed in the last decade, which hopefully will facilitate increased use of myxobacteria in biotechnology and drug discovery.

Michael Pyne and coworkers, in chapter 19, "Strain Improvement of *Escherichia coli* To Enhance Recombinant Protein Production," have focused on the latest developments for achieving high-level production of heterologous proteins from *E. coli*. They discuss the construction of host/vector systems and the various strategies for achieving efficient transcription and translation, as well as high cell densities. They describe strategies for overcoming many of the obstacles encountered at the different stages of a bioprocess (e.g., expression vector construction, strain engineering, cell cultivation, and downstream processing), thereby improving recovery or activity of the recombinant protein. Because there is a plethora of protocols for genetic manipulation of *E. coli*, this chapter takes a higher-elevation view of the major technical issues.

Chapter 20, "Genetic Engineering Tools for *Saccharomyces cerevisiae*" by Verena Siewers and coworkers, describes both new and established methods used to engineer this powerful and versatile cell factory. The authors focus on those methods for gene deletion, promoter replacement, heterologous gene expression, etc., that can be applied in high-throughput mode to allow the engineering of complex metabolic pathways, where it is necessary to interrogate the expression of several interacting genes in combinatorial fashion to maximize yield.

In "Protein Expression in Nonconventional Yeasts" (chapter 21), Thomas W. Jeffries and James M. Cregg

discuss the advantages and disadvantages of yeasts, particularly species other than *S. cerevisiae*. They focus primarily on heterologous expression of single protein products, although the strategies also apply to metabolic pathway engineering, which requires the balanced expression of multiple proteins under complex regulatory conditions. Because transformation and expression techniques for non-*Saccharomyces* yeasts have been well covered in recent reviews, this chapter emphasizes more general features of expression systems in these yeasts.

Chapter 22, "Genetics, Genetic Manipulation, and Approaches to Strain Improvement of Filamentous Fungi" by Vera Meyer and colleagues, discusses the recently developed genetic tools for strain improvement and optimization of protein production in filamentous fungi. The authors focus mainly on *Aspergillus niger*, although most of the methods described should be applicable to other industrially important filamentous fungi.

Finally, in chapter 23, "Genetic Manipulations of Mammalian Cells for Protein Expression," Anne Kantardjieff and her coauthors provide a thorough discussion of the methods for both stable and transient expression of heterologous genes. Mammalian cells are handled industrially as though they were microorganisms, and they are used to produce biologically active proteins that, in many cases, would be difficult or impossible using any other system. In addition to presenting methods for engineering efficient heterologous gene expression, this chapter also discusses methods for engineering cell physiology to achieve optimum performance at scale.

Genetic Engineering of Corynebacteria

MASATO IKEDA AND SEIKI TAKENO

16

Corynebacteria are gram-positive, high-G+C-content microorganisms that inhabit diverse ecological niches, such as soil, sewage, manure, skin, vegetables, and fruits. The genus *Corynebacterium* formerly included a diverse collection of morphologically similar species, both pathogenic and nonpathogenic. However, modern phylogenetic approaches based on 16S ribosomal DNA (rDNA) sequence analysis have redefined the genus *Corynebacterium* and reclassified some of its former members. In the new phylogenetic classification system, the genus *Corynebacterium* belongs to the class *Actinobacteria*, the order *Actinomycetales*, the suborder *Corynebacterineae*, and the family *Corynebacteriaceae* (23). The suborder *Corynebacterineae* includes the genera *Mycobacterium*, *Nocardia*, and *Rhodococcus*, which are characterized by the presence of mycolic acids, long-chain α -alkyl, β -hydroxy fatty acids, in the cell wall (23).

The genus *Corynebacterium* includes some biotechnologically relevant species, like *Corynebacterium glutamicum*, *Corynebacterium ammoniagenes*, and *Corynebacterium efficiens*. *C. glutamicum* is an especially important industrial microorganism with an annual production of more than 2 million tons of amino acids (33). Due to its importance as an amino acid producer and potential producer of other commodity chemicals and heterologous proteins, *C. glutamicum* is also the best-investigated species of the genus. There is an extensive body of literature on the physiology, genetics, biochemistry, genomics, and metabolic engineering of *C. glutamicum*, including many patents, which emphasizes the commercial importance of this microbe (16, 23).

During the last decade, genomic and other “-omics” data have accumulated for *C. glutamicum*, profoundly affecting strain development methods and providing a global understanding of this microbe. Such work has revealed new regulatory networks and functions that had not previously been identified in this microbe. A novel methodology that merges genomics with classical strain improvement has been developed and used to rationally reconstruct classically derived production strains. This chapter describes the technology and provides strategies for molecular strain improvement using current genetic engineering tools, global analysis techniques, and genome-based engineering approaches, with particular emphasis on the industrially important *C. glutamicum*. The fundamental techniques and tools for genetic engineering have been omitted because they can be found in the 2nd edition of this book and many other publications (16, 23).

16.1. GENOME ANALYSIS

Several corynebacterial genomes have been entirely sequenced: *C. glutamicum* ATCC 13032 (35, 44), *C. glutamicum* R (134), *C. efficiens* YS-314 (82), *C. diphtheriae* NCTC 13129 (19), and *C. jeikeium* K411 (122). The two different genome sequences for *C. glutamicum* ATCC 13032 (BA000036 and BX927147) revealed a genome of 3.3 Mbp with a G+C content of 53.8% and approximately 3,000 predicted genes. Similarity searches have predicted the function of more than 60% of the genes.

The more thermotolerant glutamic acid-producing bacterium *C. efficiens* YS-314, which could potentially reduce cooling costs during fermentation, has a genome of 3.1 Mbp with a G+C content of 63.4%. Comparative genome sequence analysis between *C. glutamicum* and *C. efficiens* has revealed a rather high frequency of certain amino acid substitutions in *C. efficiens* (K to R, S to A or T, and I to V), which might play a significant role in its thermotolerance (82). Detailed features of the corynebacterial genomes and their comparative genomics have been reviewed (16, 23, 134).

16.2. GENOME ENGINEERING

16.2.1. Transposon Mutagenesis

Although the genome sequences of three *C. glutamicum* strains have been completely determined, a large number of the genes are still annotated as hypothetical proteins or proteins with unknown function. The role of each gene may be elucidated by phenotypic analyses following targeted gene disruption, but this approach is laborious, because each disruption requires the construction of a deletion vector and a transformation. On the other hand, transposon (Tn) mutagenesis can generate a mutant library composed of a large number of single-gene disruptants. One can screen for mutants with a desired phenotype and then identify which genes were disrupted.

The Tn mutagenesis experiments described below were performed using special Tn delivery vectors containing insertion sequences (ISs). These vectors cannot replicate in *C. glutamicum*, contain an antibiotic resistance gene between IS elements, and express a transposase gene. Identification of the disrupted gene is done by direct sequencing upstream and downstream of the Tn insertion or by using a standard plasmid rescue technique (121).

The Tn vector pCGL0040 has been used for in vivo mutagenesis of the *C. glutamicum* strain (1, 12). The vector contains a Tn5531 formed by two IS1207 sequences isolated from *C. glutamicum* subsp. *lactofermentum* ATCC 21086. The vector is used only for mutagenesis of *C. glutamicum* strains that lack IS1207 or close homologs in the chromosome, because homologous recombination will occur between the vector and the host chromosome. For this reason, the applicable strains are *C. efficiens* YS-314, *C. glutamicum* ATCC 14752, and *Corynebacterium* sp. strain 2262. Genes encoding the phosphoserine aminotransferase (SerC) and the phosphoserine phosphatase (SerB) were identified by analyzing the serine auxotrophs isolated from a Tn5531-mediated mutant library of ATCC 14752 (92). The threonine exporter gene (*thrE*) was also identified using the same Tn vector (108).

Several IS elements, including IS31831, IS14751, IS14999, and IS13655, have been isolated from *C. glutamicum* strains, and Tn vectors containing these ISs have been constructed (39, 124, 126, 127). In particular, the Tn vector miniTn31831 and its derivatives, which are based on IS31831 isolated from *C. glutamicum* ATCC 31831, have been proposed for high-throughput mutagenesis and used in a reduced genome project described later (115). Vector pCRA732, which is based on IS14751 isolated from *C. glutamicum* ATCC 14751, was also constructed (39). It has been suggested that the pCRA732-based mutagenesis is applicable to *C. glutamicum* strains R, ATCC 13058, ATCC 13761, ATCC 13826, ATCC 14020, ATCC 14306, ATCC 14752, ATCC 14999, ATCC 15455, and ATCC 15990, but not to type strain ATCC 13032, as in the case of pCGL0040. The transpositional activities of IS14999- and IS13655-based Tn vectors have been evaluated only in the *C. glutamicum* R strain (124, 126).

As a tool for the mutagenesis of *C. glutamicum* ATCC 13032, Tn vector pAT6100 has been constructed (121). The vector has an IS6100 sequence found in R-plasmids pCG4 of ATCC 31830 (46) and pTET3 of *C. glutamicum* LP-6 (121). The histidinol-phosphate phosphatase gene involved in histidine biosynthesis has been identified by analyzing the histidine-auxotrophic mutants from an ATCC 13032 Tn mutant library comprising about 10,000 independent clones (77).

16.2.2. Reduced Genome

It has been assumed that a strain with a minimal set of essential genes required for production and cell survival would serve as the preferable host in bioindustrial applications, because minimizing the genome should increase productivity by reducing the metabolic burden caused by maintenance and expression of unnecessary genes (65). Moreover, such a strain is expected to exhibit less regulation and, therefore, be an ideal platform for production (75). It is also thought that a minimal genome should result in decreased by-product outputs. Based on these points of view, the concept of a minimum genome factory, which is defined as an engineered strain with an optimal minimum gene set needed for the intended process, has been proposed and is being tested in several biotechnologically relevant microbes, including *Escherichia coli* (59, 75), *Bacillus subtilis* (2), and *C. glutamicum* (113).

In *C. glutamicum*, comparative genomic analysis between two *C. glutamicum* strains, R and ATCC 13032, revealed that 11 strain-specific islands are scattered in the genomes (116). Such strain-specific islands are thought to be composed of dispensable genes acquired by horizontal gene transfer (59). Thus, these islands were selected as

the first candidates for deletion. Individual excision experiments demonstrated that these 11 regions, comprising 233 open reading frames, are nonessential for cell growth under normal laboratory conditions, indicating that a total genomic region of 250 kb (7.5% of the *C. glutamicum* R genome) can be deleted (116).

The most common excision method is shown in Fig. 1. The Cre/*loxP* excision system is based on Cre recombinase and two 34-bp *loxP* sequences (116, 117). When two *loxP* sites are integrated in the same orientation in the genome, Cre recombinase catalyzes recombination at those sites, resulting in excision of the region between the two sites. The major disadvantage of this method is that one *loxP* site is left on the genome after the deletion, thereby interfering with subsequent rounds of excision. To remedy this, two improved methods have been proposed. One is based on I-SceI meganuclease and its cleavage site. In this case, the *loxP* site left on the genome is designed so that it is flanked by two foreign I-SceI cleavage sites and short regions of homology. When I-SceI meganuclease cleaves the chromosome at such sites, the segment containing the *loxP* site is released and the resultant broken chromosomal ends are subject to RecA-mediated repair by intramolecular recombination, leaving only a single copy of the short homology (114). The other method is based on *loxP* characteristics. Two mutant *loxP* sequences that contain different mutations can be subjected to Cre recombinase-mediated recombination, leaving a *loxP* sequence with both mutations in the chromosome. The double-mutated *loxP* site shows dramatically reduced binding affinity for Cre recombinase and therefore does not interfere with subsequent rounds of excision. The latter method was successfully applied to achieve a 190-kb reduction of the genome (5.7% of the *C. glutamicum* R genome) (113).

Recently, random segment deletion was performed in *C. glutamicum* using IS31831-based transposon vectors and the Cre/*loxP* system (125). The principle is that two *loxP* sites can be randomly inserted into the genome by using transposon vectors. The system is independent of prior knowledge about which genes are dispensable. A schematic diagram of the method appears in Fig. 2. Using this method, 331 genes were identified to be nonessential for growth under normal laboratory conditions by analyzing the growth properties of 42 random excision mutants, and a 394-kb region (11.9% of the *C. glutamicum* R genome) was deleted in total (125). To date, no studies have been performed to test the practical utility of *C. glutamicum* strains having a reduced genome.

16.3. POSTGENOMIC TECHNOLOGIES FOR COMPREHENSIVE ANALYSIS

Determining the whole genome sequence of *C. glutamicum* is aimed at gaining sufficient information to manipulate the metabolism or physiology on a global scale, eventually integrating the information for development of more efficient production strains. The sequenced and annotated genomic information alone, however, is not sufficient to achieve this goal. However, the genomic data enable powerful DNA array technologies and proteomics, which are currently undergoing rapid development in this microbe.

16.3.1. DNA Arrays for Transcriptomics

Techniques for the design, construction, and validation of DNA arrays for *C. glutamicum* have been established and include selected gene subsets (28, 69) and arrays that monitor virtually all of the predicted genes (78, 130). Recent articles on the use of DNA arrays for *C. glutamicum* research have already shown how the technologies can be

FIGURE 1 Cre/loxP-mediated deletion of the *C. glutamicum* genome. Boxes A and B are short segments of the *C. glutamicum* genome. These PCR-amplified segments are integrated into the genome by homologous recombination using two separate vectors. After integration, the Cre-containing plasmid is introduced into the recombinant cell in order to excise the target region. Km^r , kanamycin resistance gene; Sp^r , spectinomycin resistance gene.

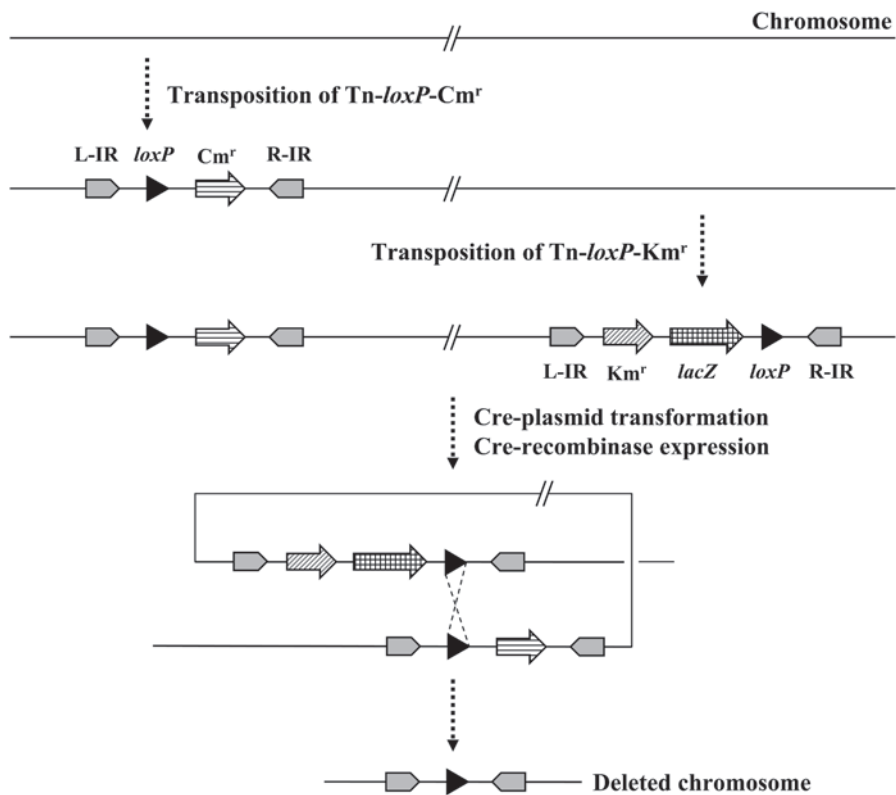

FIGURE 2 Random segment deletion of the *C. glutamicum* genome. Two IS31831-based transposon vectors are serially introduced into the *C. glutamicum* cell, randomly integrating two loxP sites into the genome, followed by Cre-mediated recombination. Cm^r , chloramphenicol resistance gene; L-IR, left inverted repeat; R-IR, right inverted repeat.

applied to study the metabolic and regulatory properties of this bacterium on a genomic scale (14, 26, 28, 78, 94, 107, 130). Importantly, previously unknown regulatory systems of central metabolism are being discovered, leading to the design of new metabolic engineering strategies. The array technologies can also be used to detect mutations that result in altered transcript levels. One example of using DNA arrays to map a spontaneous mutation in *C. glutamicum* was the characterization of a suppressor mutation in a pyruvate kinase-defective mutant (80).

Besides providing a basic understanding of the biology, these technologies can be used to engineer *C. glutamicum* strains toward improved production. For example, DNA arrays have been used to identify targets to improve valine production (63) or achieve higher productivity of pantothenate (31). Furthermore, the technologies can be used to identify which mutations confer beneficial traits for high-level production in strains from random mutagenesis and screening programs. This has been exemplified by the DNA array-based prediction of target genes for increased production of amino acids such as lysine, arginine, and citrulline (27, 34, 109).

16.3.2. Proteomics

Proteome analysis is also a powerful technology for understanding global regulatory networks by defining sets of coregulated proteins. The technology allows analysis of protein localization, quantification, and posttranslational modifications, which are not accessible by transcriptome analysis. Protocols for proteome analysis of *C. glutamicum* have been established, and high-resolution proteome reference maps have been developed for the cytoplasmic proteins (30, 67, 101), membrane proteins (102), phosphoproteins (9), and secreted proteins (30). Currently, proteomics is recognized as a promising tool for understanding both basic and applied aspects of this bacterium, including the global responses to various environmental conditions such as nitrogen limitation (107), heat shock (3), pH changes (5), and an excess amount of valine (63); the global effects of specific genetic modifications such as an H⁺-ATPase-defective mutation (66); and the comparative proteomic studies between an amino acid producer and a wild-type strain (103).

16.3.3. Toward Systems Biology

In addition to transcriptomics and proteomics, technologies for metabolomics (112) and fluxomics (133), combined with metabolic modeling (70), have been developed in *C. glutamicum*. Thus, systems biology is emerging for *C. glutamicum* (131). Very recently, a genome-scale model of the *C. glutamicum* metabolic network has been constructed, based on the annotated genome, available literature, and various “-omics” data (56). The constructed metabolic model consisted of 446 reactions and 411 metabolites, and the predicted metabolic fluxes during lysine production and growth under various conditions were highly consistent with experimental values. Such predictions of the metabolic state for maximum production yield can be used to guide strain engineering. This strategy is exemplified by the rational design of high-lysine-producing strains of *C. glutamicum* (7, 61, 131).

16.4. STRAIN IMPROVEMENT STRATEGIES

16.4.1. Overview

In the last 2 decades, metabolic engineering of *C. glutamicum* has seen rapid development. The targets of metabolic engineering have expanded beyond the core biosynthetic

pathways leading to products of interest and now include central metabolism, cofactor-regeneration systems, uptake and export systems, energy metabolism, global regulation, and stress responses. In short, strain development is beginning to achieve optimization of whole cellular systems. In addition, the product spectrum of this microbe has also expanded and metabolic engineering has been applied to the production of chemicals not naturally biosynthesized in *C. glutamicum* (e.g., cadaverine and poly-3-hydroxybutyrate) or amino acids that previously could not be produced cost-effectively from glucose (e.g., serine and methionine). Furthermore, strains are being engineered from the environmental point of view to utilize alternative feedstocks, such as whey, lignocellulose-derived xylose and arabinose, and glycerol, that do not compete with human food or energy sources.

16.4.2. General Strategies with Lysine Production as a Model

Exhaustive studies have been directed to metabolic engineering of *C. glutamicum* for lysine production, resulting in a large body of literature. Thus, lysine production is used here as a model to illustrate the overall strategies of rational strain improvement.

16.4.2.1. Fundamentals of Pathway Engineering

An essential first step for overproduction of lysine is the elimination of bottlenecks in the biosynthetic pathway from aspartic acid to lysine. This can be accomplished by mutations that reduce the expression or activity of homoserine dehydrogenase or desensitize aspartokinase to feedback inhibition by lysine (45, 93, 99, 105). These two modifications, when combined, appear to be synergistic for lysine production (86). *C. glutamicum* mutants with either or both modifications generally show lysine production yields of 10 to 30% from glucose (45, 86, 99). Overexpression of the dihydrodipicolinate synthase gene also can increase lysine production (20).

16.4.2.2. Strategies to Modify Central Metabolism

Once the core pathway is optimized, further gains can be made by increasing the precursor supply, in this case the pathways leading to aspartate. Several strategies have proved beneficial for this objective. Increasing carbon flux from pyruvate to oxaloacetate by overexpression of the pyruvate carboxylase gene or by deletion of the phosphoenolpyruvate carboxykinase gene resulted in significantly increased production of lysine (90, 91, 96). Increasing the availability of pyruvate by decreasing or abolishing pyruvate dehydrogenase activity can also improve lysine production (11, 106). As described later, disruption of malate:quinone oxidoreductase in the tricarboxylic acid cycle also has a beneficial effect, probably due to increased availability of oxaloacetate (74).

Although overexpression of key enzyme activities, as just discussed, can increase lysine production, this can be at the cost of reduced cell growth due to perturbation of the natural homeostatic mechanisms of the cell. This can be partially avoided by expressing additional activities that counterbalance the negative effect on growth. For example, a *C. glutamicum* lysine producer was recently engineered by compensating for the negative consequences of an overexpressed aspartate kinase by simultaneously increasing the pyruvate carboxylase anaplerotic activity that replenishes the tricarboxylic acid cycle intermediates (58).

16.4.2.3. Increased Availability of NADPH

Aside from pathway engineering to direct carbon toward lysine, the NADPH supply is crucial for efficient production of lysine because this cofactor is used either directly or indirectly at four steps in lysine biosynthesis. Augmentation of NADPH supply has been accomplished by engineering the redirection of carbon from glycolysis into the pentose phosphate pathway. Strategies have included disruption of the phosphoglucose isomerase gene (72), overexpression of the fructose 1,6-bisphosphatase gene (7) or the glucose 6-phosphate dehydrogenase gene (6), and introduction of a mutant allele of the 6-phosphogluconate dehydrogenase gene encoding an enzyme less sensitive to feedback inhibition (85). In addition, expression of the membrane-bound transhydrogenase genes from *E. coli* provided an alternative source of NADPH in *C. glutamicum* (42).

16.4.2.4. Engineering of Product Export

With the discovery of active export systems for several kinds of amino acids in *C. glutamicum*, this area has become another focus for further strain improvement. The exporters so far identified for *C. glutamicum* are LysE, which exports the basic amino acids lysine and arginine (128); ThrE, which exports threonine and serine (108); and BrnFE, which exports the branched-chain amino acids and methionine (49, 123). Recently, the NCgl1221 gene product, a mechanosensitive channel homolog, was identified as a possible glutamic acid exporter (79).

Sometimes the export step is critical for efficient amino acid production (17). Identification of the amino acid specificities of exporters, which generally have a limited capacity for amino acid efflux, has allowed the enhancement of efflux by increasing the dosage of genes encoding key exporters. It was revealed that overexpression of the *lysE* gene resulted in a fivefold enhancement of the excretion rate for lysine compared to the rate of the control strain (128). The functions of such exporters also can be transferred to heterologous bacterial species. For example, a mutant allele of the *C. glutamicum lysE* gene has been successfully used for improved lysine production in the methylotroph *Methylophilus methylotrophus* (25). Limited threonine production by *C. glutamicum* was also improved by heterologous expression of an *E. coli* threonine exporter (22).

16.4.2.5. Engineering of Respiratory Energy Efficiency

The supply of ATP is also critical to efficient amino acid production. Improving the efficiency of ATP synthesis is thus another strategy for increasing amino acid production. *C. glutamicum* possesses a branched respiratory chain with two terminal oxidases (13). One branch is composed of the cytochrome *bc₁-aa₃* supercomplex, which has a threefold-higher bioenergetic efficiency than the other cytochrome *bd* branch. Disruption of the inefficient cytochrome *bd* branch caused increased lysine production and, perhaps unexpectedly, no marked effect on growth or glucose consumption (43).

16.4.2.6. Other Potential Targets of Metabolic Engineering

16.4.2.6.1. Global Regulation

Amino acid biosynthesis in *C. glutamicum* is subject to both pathway-specific and global regulation (14, 60). Thus, global regulation is also important in strain improvement.

An interesting finding is that global induction of amino acid biosynthesis genes occurs in a classically derived industrial lysine producer (29). The *lysC* gene, encoding the key enzyme aspartokinase, is upregulated severalfold in this strain, even though a repression mechanism for lysine biosynthesis is not known in *C. glutamicum*. Although the genetic elements responsible for these changes remain to be elucidated, introduction of a mutant allele of the *leuC* gene into a defined lysine producer can trigger a stringent-like global response and thereby lead to a significant increase in lysine production (27). Recently, the use of DNA microarray technology and the genome sequence of *C. glutamicum* has identified a variety of global regulators. These include GlxR (53) and SugR (24), controlling carbon metabolism; AmtR (8), controlling nitrogen metabolism; PhoR (100), controlling phosphorus metabolism; McbR (94, 95) and SsuR (57), controlling sulfur metabolism; DtxR (132), controlling iron homeostasis; and FarR (26) and LtbR (15), controlling amino acid metabolism, all of which are potential targets of future metabolic engineering.

16.4.2.6.2. Stress Responses

In the industrial fermentation of *C. glutamicum*, cells must adapt to various suboptimal conditions due to the considerable heterogeneity within large-scale fermentors. The cells are assumed to possess a variety of mechanisms for adaptation to such conditions. For example, cells maintain the pH of their cytoplasm relative to the external environment. Although the mechanisms of pH homeostasis in *C. glutamicum* are not fully understood, it has been shown that a putative transporter of the cation diffusion facilitator family is responsible for alkaline pH homeostasis (118). Only limited studies have so far been conducted on other stress response proteins of *C. glutamicum*. Some examples include SigH (54) and WhcE (55), involved in heat and oxidative stress responses, and BetP (88), EctP (89), ProP (89), LcoP (110), MtrB (76), and MtrA (76), involved in osmotic stress response. These are potential targets for future engineering.

16.4.3. Metabolic Engineering for Serine Production

Serine is among the few amino acids where it has been difficult to engineer strains that give high production yields by fermentation on glucose. Classical mutagenesis and screening for a strain producing serine from glucose had not been successful. Recently, a systematic metabolic engineering strategy resulted in a *C. glutamicum* strain that accumulated considerable amounts of serine (92). In this case it was necessary to intervene at several points in the complicated metabolism of serine. Initial overexpression of serine biosynthesis genes coding for deregulated enzymes did not lead to significant serine accumulation, nor did the further deletion of the serine dehydratase gene, which catalyzes serine degradation to pyruvate. However, by reducing the *glyA*-encoded serine hydroxymethyltransferase (SHMT) activity, considerable serine accumulation was ultimately achieved. Since SHMT is essential for growth of *C. glutamicum* as the unique route leading to C₁ supply, a precise level of reduction of this enzyme activity was the key. This was first achieved by replacing the *glyA* promoter with the *tac* promoter, which caused *glyA* expression to be reduced in the absence of isopropyl-thio- β -D-galactopyranoside. However, this method of *glyA* control was unstable, with mutations in *lacI^q* restoring expression. To overcome this inconvenient

glyA expression control, a better physiological method was developed in which the strain was made auxotrophic for folate and SHMT activity could be controlled by the availability of 5,6,7,8-tetrahydrofolate. This resulted in serine accumulation to 345 mM in a 20-liter controlled fed-batch culture (111).

16.4.4. Metabolic Engineering for Methionine Production

As with serine, it has also been difficult to engineer strains that produce high yields of methionine. Recently, *C. glutamicum* was shown to possess both transsulfuration and direct sulfhydrylation pathways, in contrast to most microorganisms, including *E. coli*, which utilize only one of these two pathways (32, 64). Metabolic engineering to redirect carbon from the lysine pathway into the methionine pathway led to a *C. glutamicum* strain that produced 2.9 g/liter of methionine, together with 23.8 g/liter of lysine (87). In *C. glutamicum*, two regulatory genes relevant to methionine biosynthesis have been identified: *mcbR* (cg3253) and NCgl2640. Inactivation of either in wild-type *C. glutamicum* resulted in increased methionine production (71, 94, 95).

While progress has been made in creating improved methionine producers, the yields remain low compared with those attained for other amino acids. Metabolic pathway analysis has been used to evaluate the theoretical maximum yields of methionine production on the substrates glucose, sulfate, and ammonia in *C. glutamicum* and *E. coli*. The theoretical yield (mol-C methionine per mol-C glucose) of *C. glutamicum* was 0.49, while *E. coli* displayed a higher value of 0.52. This analysis also showed that introduction of the *E. coli* glycine cleavage system into *C. glutamicum* would increase the theoretical maximal methionine yield to 0.57 (62).

16.4.5. Engineering Production of Other Products

In the past decade, metabolic engineering approaches have been used to develop strains that produce chemicals not naturally biosynthesized in *C. glutamicum*. For example, cadaverine (1,5-diaminopentane), an expected raw material of polyamines, and poly-3-hydroxybutyrate, a biodegradable polyester, have received considerable research attention as alternatives to petroleum-derived chemicals. Production of cadaverine and poly-3-hydroxybutyrate by *C. glutamicum* has been achieved through heterologous expression of lysine decarboxylase from *E. coli* (73) and the poly-3-hydroxybutyrate biosynthetic pathway from *Ralstonia eutropha* (40), respectively. In the latter case, poly-3-hydroxybutyrate accumulation could be observed as granules in the cytoplasm of the cell. Not only gene dosage but also codon optimization of the poly-3-hydroxybutyrate biosynthetic genes has been shown to further improve the product content (41).

C. glutamicum also has potential for the production of organic acids such as lactic acid and succinic acid, which can serve as intermediates for the synthesis of a variety of chemicals and polymers. Since *C. glutamicum* is aerobic and does not grow under anaerobic conditions, little work has been done on anaerobic growth and fermentation. However, it was recently shown that this bacterium retains its primary metabolic capacity under growth-arrested anaerobic conditions (38), and production of lactic acid, succinic acid, and acetic acid from glucose was demonstrated (38). A significant increase of succinic acid production was obtained by deleting the *ldhA* gene for L-lactate dehydrogenase and overexpressing the endogenous *pyc* gene for

pyruvate carboxylase. The succinic acid yield of this strain was approximately 1.2 mol per mol of glucose.

More recently, it was shown that *C. glutamicum* can grow anaerobically by nitrate respiration (81, 119). In the presence of nitrate, lysine and arginine production occurred anaerobically, albeit at a very low level, indicating the potential of this bacterium for anaerobic amino acid production (119).

16.4.6. Engineering Feedstock Utilization

Presently, the primary feedstocks for industrial fermentations are sugars from agricultural crops. However, there is an increasing need to engineer the use of alternative raw materials, especially those that are not used for human food or energy supply. Wild-type *C. glutamicum* cannot utilize lactose, galactose, starch, xylose, arabinose, or glycerol for growth, but recently strains have been engineered that can. For example, by overexpressing both *lacYZ* from *Lactobacillus delbrueckii* subsp. *bulgaricus* and *galMKTE* from *Lactococcus lactis* subsp. *cremoris* in a lysine-producing strain of *C. glutamicum*, the strain was able to produce lysine at up to 2 g/liter when fed whey, which contains lactose and galactose (4). Another lysine-producing *C. glutamicum* strain expressing the α -amylase gene from *Streptomyces griseus* utilized soluble starch for lysine production, albeit at a lower efficiency than that obtained for glucose (104). More-efficient lysine production from soluble starch by *C. glutamicum* has been achieved by displaying the α -amylase from *Streptococcus bovis* on the cell surface. As the anchor protein, PgsA from *B. subtilis* was fused to the N terminus of α -amylase. A lysine producer displaying the fusion protein on its cell surface produced 6.04 g/liter of lysine with the conversion yield of 18.89% on starch. The titer and yield were higher than those obtained in glucose medium (120). This was the first study on a cell surface display system of *C. glutamicum*.

The use of lignocellulose as a feedstock is limited in part by poor catabolism of the xylose component. A xylose-utilizing *C. glutamicum* strain was engineered by expressing the *xylA* and *xylB* genes from *E. coli* on a high-copy plasmid. It is interesting that the *E. coli* *xylB* gene contributed to improved growth performance on xylose despite the existence of a functional *xylB* gene on the *C. glutamicum* wild-type genome. This engineered strain produced lactic acid and succinic acid from xylose anaerobically (48). As another example, heterologous expression of the *E. coli* arabinose-utilizing pathway in *C. glutamicum* gave a strain that was able to grow on arabinose, another component of lignocellulose (47).

Glycerol, the main by-product of biodiesel production, is also a potential carbon source in biotechnological processes. *C. glutamicum* was engineered to grow on glycerol by expressing the *E. coli* glycerol utilization genes, *glpF*, *glpK*, and *glpD*. This engineering allowed production of glutamate and lysine from glycerol with yields of 11% and 19% (grams of product per grams of glycerol), respectively (97).

16.5. GENOME-BASED STRAIN RECONSTRUCTION

The classical approach to strain improvement involves random mutagenesis and screening, but this technology cannot avoid accumulating detrimental or unnecessary mutations. Genome-based strain reconstruction is a technology that identifies the useful mutations in such strains through genome sequencing and then systematically and precisely

FIGURE 3 Methodology to create a minimally mutated strain. Useful mutations relevant to amino acid production are indicated (stars), together with unnecessary mutations (\times).

engineers those mutations into the wild-type genome, creating a strain with only the useful mutations (Fig. 3). Strains derived by this “reverse engineering” method are expected to be more robust, give higher fermentation yields in a shorter time, and resist stressful conditions. The technology is more fully described in the following sections.

16.5.1. Reverse Engineering of a Lysine Producer

Reconstruction of a *C. glutamicum* industrial lysine producer is carried out in the following way. (i) First, the genome sequences of the industrial lysine producers are compared with wild-type sequences to identify the mutational differences. (ii) The mutations are then sequentially introduced by allelic replacement into the wild-type genome (37). Mutations in the relevant terminal pathways are first introduced, followed by those in central metabolism, and finally genes involved in global regulation. (iii) Each strain is evaluated to determine the contribution of each mutation to production. When the mutation is beneficial, the resulting strain is used as the parent to introduce and evaluate further mutations. This iterative cycle makes it possible to generate a minimally mutated strain having only relevant mutations (27, 36, 74, 85, 86). It should be noted that the combination of mutations chosen for introduction and the host strain used at the beginning of the process can have a significant impact on the ultimate outcome. In the case of lysine fermentation, a key mutation, *lysC311*, that confers high-level lysine production on wild-type *C. glutamicum* was used to screen different wild-type strains of *C. glutamicum* to identify the best background to begin the process (84). Although this procedure is simple to describe, it is a challenge to execute in a meaningful time frame.

An industrial lysine producer that had undergone years of mutagenesis and screening was found to have more than 1,000 mutations accumulated in its genome (36). Among the mutations that resulted in increased production, two (*hom59* and *lysC311*) were identified in the terminal pathway to lysine (86), three (*pyc458*, *gnd361*, and *mgo224*) were identified in central metabolism (74, 85, 86), and one (*leuC456*) was identified that caused global induction of the amino acid-biosynthetic genes and thereby contributed to further increased production (27). Subsequent assembly of these six useful mutations in a robust wild-type strain was shown to substantially improve producer performance, resulting in a final titer of near 100 g/liter after only 30 h with 5-liter jar fermentor cultivation at a suboptimal temperature of 40°C (27, 36, 83).

16.5.2. Reengineering of an Arginine and Citrulline Producer

With accumulated knowledge of mutations relevant to production, it becomes possible to combine positive muta-

tions derived from different lines of classical producers in a single wild-type background. Such an advanced approach has recently led to an impressive result in the production of arginine and citrulline (*arg+cit*) by *C. glutamicum* (34). The final strain was generated according to the strategy described below.

The first step was to identify the most important mutation(s) causing *arg+cit* overproduction in wild-type *C. glutamicum*. Three independently derived industrial *arg+cit* producer strains were sequenced and compared to their natural ancestors. This identified a variety of mutations potentially associated with arginine biosynthesis. Five were located within *arg* operons (*argB26*, *argB31*, *argR123*, *argG92^{up}*, and *argG45*), and their relevance to *arg+cit* production was therefore examined in a wild-type background. Consequently, *argB26* and Δ *argR* (*argR123*-derived deletion mutation) were found to be the most important mutations. The second step was to screen for the wild-type background giving the best performance, as discussed for lysine production above. Thus, the two mutations, *argB26* and Δ *argR*, were introduced into six different *C. glutamicum* wild-type strains to generate isogenic mutants, which were then screened for their ability to produce *arg+cit* under suboptimal, 38°C conditions. This revealed that strain ATCC 13032 had the highest potential for *arg+cit* production at elevated temperatures. By combining those mutations in the best host, a robust producer was obtained, but its production was still only one-third of that of the best classically derived strain.

Thus, a third step was to identify what was limiting in the new strain by conducting transcriptome analyses. This revealed that the *arg* operon in the classically derived strain was much more highly expressed than it was in the new strain. From this analysis, *leuC456*, a mutation in an industrial lysine producer that provoked global induction of the amino acid-biosynthetic genes, including the *arg* operon, was thought to be a good target for engineering. When this mutation was introduced into the wild-type strain along with *argB26* and Δ *argR*, production was increased, but the strain also showed a growth defect. On the other hand, replacing the chromosomal *argB* with the heterologous *E. coli argB*, which is insensitive to arginine inhibition, increased production threefold without retarding growth, revealing that a prime target for engineering was the properties of the *argB* product.

Accordingly, the final step was to engineer the *argB* product, *N*-acetyl-L-glutamate kinase, so that it would not be feedback inhibited by arginine. To this end, in addition to *argB26*, the other *argB* mutation, *argB31*, was introduced into the new strain, causing more complete deregulation of the enzyme and resulting in dramatically increased production. This reconstructed strain, designated strain RBid, displayed enhanced performance, which is clearly reflected

FIGURE 4 Fermentation kinetics of the newly developed strain RBid at 38°C in 5-liter jar fermentor cultivation. For comparison, the profiles of the best classical producer, A-27, which was cultured under its optimal 30°C conditions, are shown as controls. ○, arg+cit of strain RBid; ●, growth of strain RBid; □, arg+cit of strain A-27; ■, growth of strain A-27.

in the differences in the fermentation profiles between strain RBid and the best classical producer (Fig. 4). Figure 5 summarizes this entire strain reconstruction process.

16.6. ENGINEERING FOR HETEROLOGOUS PROTEIN SECRETION

C. glutamicum is nonpathogenic and produces no hazardous toxins, and thus is also a potential host for protein production. Various bacterial proteins have been secreted by *C. glutamicum*, including a staphylococcal nuclease (68), a protease from *Dichelobacter nodosus* (10), subtilisin from *Bacillus* (10), and a fibronectin-binding protein from *Mycobacterium tuberculosis* (98). *C. glutamicum* has at least two advantages as a protein production host. First, no proteolytic activity is detected in its culture supernatants. Second, it naturally secretes only a limited number of extracellular proteins, thus facilitating downstream purification of secreted heterologous proteins. *C. glutamicum* may be a

favorable host for producing food enzymes and pharmaceutical proteins.

A recent notable example is secretion of the *Streptovercillium mobaraense* transglutaminase, a food enzyme, in an active form and in a significant amount by *C. glutamicum* (50). In this protein expression system, *C. glutamicum* can secrete the pro-transglutaminase efficiently by fusing the protein with a signal peptide derived from a cell surface protein of corynebacteria. When a subtilisin-like protease from *Streptomyces albogriseolus* is cosecreted, the pro-domain is processed by the protease to yield 142 mg/liter of active transglutaminase. It also has been demonstrated that the *C. glutamicum* protein expression system can be used to secrete a pharmaceutically important protein efficiently and in an active form, namely human epidermal growth factor (21). These successes relied on the signal peptide-dependent general secretion (Sec) pathway (18). However, heterologous proteins are often poorly secreted by the Sec pathway. Another food enzyme, *Chryseobacterium proteolyticum* protein-glutaminase, is an example where secretion by the Sec pathway failed. Very recently, this problem has been successfully overcome by using a second signal peptide dependent on the twin-arginine translocation (Tat) pathway (51). It has been shown that overexpression of TatABC, the components of the Tat pathway, significantly improves protein secretion in this organism (52).

Comprehensive screening of secretion signal sequences has been conducted in *C. glutamicum* R by using bioinformatic analysis and a high-throughput secretion assay, which identified a total of 108 candidate signal sequences that could secrete heterologous α -amylase in the organism (129). These secretion signals may be used for secretion of other heterologous proteins.

FIGURE 5 Schematic diagram of the creation of new strain RBid. Useful mutations identified in classical producers I-30, A-27, and D-77 are indicated (stars), together with unnecessary mutations (×).

16.7. CONCLUSIONS AND OUTLOOK

This chapter has discussed the technology and strategies for molecular strain improvement of corynebacteria, with special focus on the biotechnologically important *C. glutamicum*. The genetic engineering tools and global analysis techniques for this organism are well developed and have

been successfully applied. Understanding of the whole cellular metabolism of corynebacteria continues to improve. In parallel, in silico modeling and simulation approaches are being used to help identify new targets for further engineering and strain improvement. The power of such systems-level approaches will surely increase as modeling is combined with the ever-accumulating data from global analysis techniques such as transcriptomics, proteomics, metabolomics, and fluxomics. The rapid progress in genomic analysis technology and *C. glutamicum* genomics has already allowed the reengineering of classically derived industrial strains. The technology will continue to have an important impact on industrial fermentation.

C. glutamicum has a long history of classical strain improvement, providing many industrially useful strains. Now the beneficial mutations in these strains are being identified and are widely available to the amino acid industry. As a result, the conventional mutagenesis and screening approach is rapidly being replaced by the reengineering of strains using these identified mutations. The two examples of lysine and arg+cit production described herein will be a paradigm for future strain development in the fermentation industry.

Genetic Manipulation of *Clostridium*

MARITE BRADSHAW AND ERIC A. JOHNSON

17

17.1. INTRODUCTION

The clostridia have a rich history in medical and industrial microbiology (40, 77, 82, 166, 204, 233). Clostridia were probably first alluded to about 30 centuries ago in the writings of Hippocrates, who reported on wound infections in his *Epidemics III* (13). Pasteur noted in 1861 that the anaerobic butyric acid fermentation was due to a rod-shaped organism that he called *Vibrio butyrique*, which likely corresponds to *Clostridium butyricum*, the type species of the genus *Clostridium* (233). Throughout history, clostridia have also had positive properties and utilities in biotechnology, the chemical industry, and medicine (40, 77, 166, 204). Certain nonpathogenic clostridia have been used as a source of solvents, including butanol, as a precursor for butadiene for synthetic rubber, and acetone, used in the synthesis of munitions (39, 82, 230). Solventogenic and cellulosic clostridia are seeing a renewed interest as energy sources for production of solvents and for partial replacement of oil (39). Clostridia are a rich source of enzymes and vaccines, and are ecologically important in the degradation of various pesticides and xenobiotics (40, 77). A remarkable medical application is the development of clostridial toxins for the treatment of a myriad of neurological disorders (73, 185). The study of clostridia has had an important impact on the development of microbiological techniques, including the development of anaerobic media and methods for cultivation of anaerobes from the rumen, human intestine, and other anaerobic environments (77, 233). Despite the medical and industrial importance of this genus, the genetic manipulation of *Clostridium* is still relatively elemental, although considerable progress has been made since the second edition of this manual was published in 1999 (126).

The genus *Clostridium* is classified in the family *Clostridiaceae* of the phylum *Firmicutes* of *Bacteria* (35, 43, 208). The genus comprises a large and diverse group of at least 12 lineages of anaerobic and some aerotolerant gram-positive bacteria (26, 63). Most of the species are rod shaped and form endospores. Traditionally, the clostridia have been recognized to have common properties (35, 43, 208): (i) a gram-positive cell wall structure, (ii) formation of endospores, (iii) an anaerobic and fermentative metabolism, and (iv) the inability to reduce sulfate to sulfide. The genus *Clostridium* has a wide range of 21 to 54 mol% G+C content of DNA, supporting the heterogeneity of this group of bacteria.

Currently, clostridia are mainly classified on the basis of morphology and motility, spore formation, physiological properties including anaerobiosis and fermentative metabolism, phenotypic properties such as protein toxin formation, and rRNA gene sequence homologies. On the basis of sequencing of genes encoding 16S rRNA, 19 homology groups have been proposed (26). The type species, *Clostridium butyricum*, and most of the clinically important clostridia cluster within homology group I. The DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen, the German Collection of Microorganisms and Cell Cultures) has over 170 clostridial species listed in its collection. From the 16S rRNA gene sequence analyses, several species have been proposed as type species of new genera (209), including several nonsporulating genera. Although endospore formation is known to occur only in the low-mol% G+C branch of *Firmicutes*, it is a very complex developmental process and endospore formation requires more than 150 gene products, with at least 75 acting sequentially (211). Disruption of any of these genes could result in lack of sporulation, which may explain the relatedness of non-sporulating genera to *Clostridium* (149).

The genetic manipulation of clostridia is still in an early stage of development, but significant advances have been made in recent years, and this chapter emphasizes newly developed genetic methods and strategies. Considering the diversity of clostridial species that are important industrially and in medicine, it is not feasible to describe genetic protocols for all the various groups. Most genetic methods are described in detail in the literature, and the reader is referred to the pertinent sources cited in this chapter and in authoritative reviews. Furthermore, certain traditional methods of genetic manipulation, including transduction, protoplast formation and fusion, and chemical mutagenesis, have mainly been transcended by newer techniques, and these are described in earlier reviews (31, 110, 126, 133, 134, 219, 239, 240).

17.2. PHYSIOLOGY OF CLOSTRIDIUM RELATED TO GENETIC MANIPULATION

The clostridia have considerable diversity in metabolism and physiology (6, 58). Certain physiological properties of clostridia are integral for genetic manipulation and gene expression (6, 41, 79, 136). Most clostridia are strict

FIGURE 1 Characteristic spindle morphology of *C. botulinum* and presence of endospores. The photograph shows a phase-contrast visual micrograph (750 \times) of a culture of *C. botulinum* type A.

anaerobes and only grow in the absence of oxygen. Their manipulation requires anaerobic conditions such as the use of glove boxes, specialized culture tubes, and fermentors; reduced media; and other necessary conditions. Systems for manipulation of anaerobic organisms have been described (76). In addition, many clostridia tend to grow as mixed cultures with other anaerobes and facultative organisms, and strict attention is needed to affirm the purity of the culture under study or during culture growth and solvent, enzyme, or toxin production. Clostridia produce endospores, which are resistant to heat, radiation, drying, and chemicals. Spores can be visualized by phase-contrast microscopy (Fig. 1). Safe laboratory practices and special training of personnel are needed for the study of toxigenic species such as *Clostridium botulinum* and *Clostridium tetani*.

Clostridia are classified as proteolytic or saccharolytic depending on their preference for energy-yielding substrates. Many clostridial species are nutritionally demanding and are commonly isolated and grown in rich media (38, 63, 67, 81, 142). The optimal isolation of different species requires specialized media and conditions. The availability of defined media is useful for the isolation of certain classes of mutants such as auxotrophs (193). Chemically defined media have been described for several clostridia (80, 108, 179, 193, 228, 232). Media void of animal constituents have also been used for development of inocula for production of toxins for vaccines and other medicinal uses (48, 49). Rich media are commonly used for spore production (67, 196, 235) although spore production of certain clostridia has been obtained in defined media (179). For production of master cell banks and working cell banks for industrial processes, bacterial stocks should be prepared from mid-log cultures, particularly for processes where nonsporulating cultures are used (185). On the other hand, spore stocks are often valuable for maintaining physiological properties and preventing strain degeneration (89, 128).

17.3. NATIVE PLASMIDS, TRANSPOSONS, AND BACTERIOPHAGES

17.3.1. Native Plasmids

Several studies in the 1970s and 1980s showed that *Clostridium* spp. possess extrachromosomal plasmids (reviewed in reference 100). Most of the plasmids are considered cryptic, but plasmids carrying antibiotic resistance genes, bacteriocins, virulence factors, or genes for solvent production have been demonstrated (110, 175, 176). With the advent of new genetic tools, the function of some cryptic plasmids will be elucidated. Transferability of *Clostridium perfringens* plasmids was demonstrated in the 1970s (16). Plasmid states are also observed in pseudolysogenic phage cycles and as intermediates in transfer of conjugative transposons (19, 21). Native plasmids range in size from several thousand to several hundred thousand base pairs. The most extensively studied are *C. perfringens* plasmids, and this was the first *Clostridium* species that was found to carry conjugative plasmids (recently reviewed in reference 110).

Large plasmids (>50 kb) have also been found in several clostridia. Analysis of the large plasmids has lagged behind studies of gram-negative plasmids mostly due to difficulties encountered in purification and characterization of such large plasmids from clostridia (175). In the late 1980s large native clostridial plasmids encoding virulence genes were identified in neurotoxic clostridia. The gene encoding tetanus neurotoxin in *C. tetani* was discovered on an 84-kb plasmid in *C. tetani* (51). The *C. botulinum* serotype G neurotoxin gene cluster was also found on a 114-kb plasmid in *C. botulinum* (45, 243). In *C. botulinum* serotypes C and D the botulinum neurotoxin genes were determined to be located on pseudolysogenic bacteriophages, which may exist as a pseudolysogenic circular extrachromosomal state when not integrated into the chromosome (180).

Plasmid analyses using standard purification approaches did not initially identify these very large plasmids in clostridia. Large plasmids in clostridia were discovered using the pulsed-field gel electrophoresis (PFGE) method of total DNA preparations (27, 90, 122). PFGE analysis of nondigested preparations of total DNA from solvent-producing *Clostridium acetobutylicum* strain 824 identified an ~210-kb megaplasmid, pSOL1, that possesses genes for acetone and butanol production (27, 28). During sequencing it was established that the actual size of the plasmid is 192 kb and its nucleotide sequence was determined (147), and the role of the plasmid in *C. acetobutylicum* physiology and its relation to chromosomal genes have been studied (85, 153, 154). Katayama and coworkers (90) employed PFGE analysis of total DNA from different *C. perfringens* strains cleaved with the intron-encoded endonuclease I-CeuI from *Chlamydomonas eugametos*. This enzyme was shown to cleave only within the rRNA operons, and therefore this method was used to determine the localization of the virulence genes on extrachromosomal plasmids since I-CeuI only cuts chromosomal DNA. Based on these two approaches, the PFGE analysis has been used by several laboratories to identify large plasmids in *C. perfringens* (102, 138, 184) and *C. botulinum* (52, 122, 181). Virulence plasmids ranging in size from 47 to 270 kb have been identified in *C. botulinum* serotypes A, B, Ab, Ba, and Bf and in *C. tetani* (52, 122, 203). The presence of large plasmids in *C. botulinum* and *C. tetani* encoding neurotoxin genes has been confirmed by genomic sequencing (18, 203). Thus, large plasmids appear to be widely distributed in the clostridia, and it is anticipated that more will be discovered that encode metabolic and virulence properties.

The genetics, structure, and function of plasmids have been most extensively studied in *C. perfringens*. The nucleotide sequences of several *C. perfringens* plasmids have been

determined, including a 10.2-kb plasmid, pIP404 (53); a 54-kb plasmid, pCP13 (strain 13) (200); the 47-kb pCW3 (strain CW92) (9); the 75.3-kb pCPF5603 (strain F5603) (138); the 70.5-kb pCPF4969 (strain F4969) (138); 12.4- and 12.2-kb plasmids from strain SM101 (143); and the 64.7-kb pCT8533ext (strain NCTC 8533) (139).

Plasmid pIP404 is considered a paradigm plasmid in *C. perfringens* and has been extensively studied (176). The plasmid contains 10 open reading frames (ORFs), and several of the genes are involved in plasmid replication and maintenance, while others are associated with bacteriocin production. The pIP404 replicon has been used in construction of clostridial shuttle vectors (see section 17.6.2). Sequencing and diversity analysis of *C. perfringens* plasmids has revealed extensive similarities among antibiotic resistance plasmids (175), as well as within different toxin-encoding plasmids in *C. perfringens* types A, B, and D (184) and E strains (102, 138, 139, 184). Among conjugative antibiotic resistance plasmids, the 47-kb tetracycline resistance plasmid pCW3 has been studied in detail. The regions responsible for the conjugation and replication functions of pCW3 have been identified (9), and the role of the *tcp* (transfer clostridial plasmid) locus in the transfer of pCW3 has been confirmed (9, 156, 210, 213).

Interestingly, the replication region identified in pCW3 is conserved in all conjugative plasmids from *C. perfringens* (9). It appears that antibiotic resistance and toxin plasmids in *C. perfringens* share a common but poorly understood mechanism for plasmid transfer, and that the *C. perfringens tcp* locus is unique to this organism and differs from the transfer regions of conjugative plasmids from other gram-positive bacteria (9). Conjugal transfer of the toxin plasmids to normal flora *C. perfringens* strains possibly has given rise to pathogenic isolates and is implicated in disease dissemination (139, 210). These suggestions are based on the sequence similarities observed between different *C. perfringens* plasmids encoding antibiotic resistance and toxins, as well as the presence of the same *tcp* locus on these plasmids and mobile insertion sequence (IS) elements that carry different toxin genes on the plasmids or on the chromosomes in pathogenic *C. perfringens*. The pCPF5603 enterotoxin plasmid of *C. perfringens* is conjugative (69) and has extensive homologies to the epsilon-toxin-encoding plasmid in *C. perfringens* (139).

The plasmids found in proteolytic *C. botulinum* serotypes are highly related and contain large regions of homology (203). A 47-kb plasmid found in nonproteolytic type B *C. botulinum* strain 17B is unrelated to the proteolytic serotype plasmids (157). The only regions revealing homology between the plasmids from proteolytic and nonproteolytic strains are their BoNT gene clusters (157). In addition, the gene for C2 toxin has recently been identified on a 107-kb plasmid in *C. botulinum* serotype C (181). Although functional studies of the genes located on *C. botulinum* plasmids are not yet described, putative genes involved in conjugal transfer have been identified by genome annotation (see the Pathema website at <http://pathema.jcvi.org/cgi-bin/Clostridium/PathemaHomePage.cgi>). Our laboratory has recently demonstrated that certain of these plasmids are conjugative in *C. botulinum* (K.M. Marshall, M. Bradshaw, and E. A. Johnson, unpublished data). Identification of conjugative virulence plasmids and availability of sequences from 13 *C. botulinum* genomes including several large virulence plasmids should facilitate future studies of this pathogenic clostridial species.

17.3.2. Clostridial Transposons and IS Elements

Several transposable elements have been demonstrated in clostridia (114). Conjugative transposable elements have

been found in *C. perfringens* and *Clostridium difficile* (reviewed in references 4 and 114). Recently, a Tn5382-like transposon was demonstrated in a hospital isolate of *Clostridium bolteae*, a common inhabitant of the human intestine (37). Transposable elements carry antibiotic resistance determinants, particularly tetracycline and erythromycin. The Tc^r determinant of *C. perfringens* could be transferred to other *Clostridium* spp., including *C. difficile* (192), but the transconjugants were often unstable. Transposon Tn1549 has been shown to transfer vancomycin resistance from *Clostridium symbiosum* to *Enterococcus* in a mouse model (99).

IS elements, which possess only genes involved in their transposition, have been found in clostridia (15, 36, 61, 62, 70, 106, 109, 115, 203). These elements have been located not only on the chromosomes but also on plasmids and bacteriophages (115, 180, 181, 203). They mainly belong to the IS3, IS6, IS200, IS256, and IS481 families. In contrast to many other bacterial species such as *Escherichia coli*, IS elements appear to be present in relatively small numbers in clostridia, and many are truncated or contain deletions and are presumably nonfunctional. Active IS elements are likely involved in mobile gene transfer and recombination of chromosomal regions of certain clostridia, such as *C. difficile* (191), and in recombination of highly diverse loci such as the neurotoxin and flagellin gene clusters in *C. botulinum* (22, 36, 203). Interestingly, IS elements also appear to be involved in cellulose activity and associated microcrystalline cellulose degradation (245). The roles of transposons and IS elements warrant further study in clostridia in relation to gene movement, recombination, and metabolic activities, and for development of genetic tools.

17.3.3. Bacteriophages

Bacteriophages are present in many clostridia (3, 83, 148). The only group of *Clostridium* spp. that appear to lack phages are certain thermophiles (83). Phages are associated with toxin formation in *C. botulinum* types C and D, production of alpha-toxin by *Clostridium novyi* (44), and possibly sporulation of *C. perfringens* (244). Clostridial phages have also caused lytic infections of production strains, resulting in low yields of important industrial products such as acetone-butanol (84) and vaccines. Recently, bacteriophages from *C. botulinum* type C and *C. difficile* have been characterized at a molecular level (59, 71, 127, 180, 181).

Bacteriophages have not been routinely used for genetic analysis and manipulation by transduction in *Clostridium* spp. This is due in part to the unstable pseudolysogenic nature of many clostridial phages (4, 44), where the phage has a nonstable association with the chromosome and appears throughout much of its life cycle as an unstable element in the cytoplasm (78, 83). Phage manipulations have been hindered by practical aspects of working with the anaerobic clostridia (44, 83). However, more recent studies have demonstrated the ability to induce and assay for phage infection (59, 127). The development of transduction methods could have much utility in genetic analysis of *Clostridium* spp., but these methods require development.

17.4. DNA ISOLATION

17.4.1. Genomic DNA

Traditional protocols used for the preparation of clostridial genomic DNA consist of cell lysis with enzymes in the presence of detergents, followed by series of extractions with phenol and chloroform prior to precipitation of the nucleic

acids with ethanol or isopropanol. A detailed protocol using this approach has been published in the *Handbook on Clostridia* (31). However, in the past decade an increasing number of publications on clostridia have utilized various commercial DNA extraction kits for purification of genomic DNA. For example, researchers have used the MasterPure Gram-Positive DNA Purification Kit (Epicentre Biotechnologies, Madison, WI) for DNA isolation from *C. perfringens* (139) and *C. botulinum* (171); Qiagen DNeasy Minikit for gram-positive organisms (Qiagen, Valencia, CA) for *C. difficile* (121); InstaGene Matrix kit (Bio-Rad, Hercules, CA) for *C. perfringens* (33) and *C. difficile* (14); Puregene Genomic DNA Purification kit (Gentra Systems, Minneapolis, MN) for *C. acetobutylicum* (189); and High Pure PCR Template Preparation kit (Roche, Mannheim, Germany) for *Clostridium septicum* (145). Our laboratory uses the ChargeSwitch Genomic DNA Purification kit (Invitrogen, Carlsbad, CA) for *C. botulinum*. These kits allow purification of the genomic DNA in concentrations sufficient for different applications, as well as minimizing the time required and the use of caustic organic solvents. Prior treatment of bacterial cells with lysozyme at 37°C for 15 to 60 min has been included as a modification for some kits to achieve complete lysis of bacterial cells and thus increase DNA yield (31, 145; our laboratory, unpublished data).

For some PCR applications, crude cell lysates are prepared by resuspending bacterial cells in distilled water and boiling (29, 86) or heating them in a microwave oven (231). The protocol described below was used to prepare template DNA for the multiplex PCR of the *C. perfringens* toxin genotyping assay (231). Four or five *C. perfringens* colonies from the brain heart infusion plate are suspended in 200 µl of sterilized phosphate-buffered saline. The cell suspensions are microcentrifuged at 14,000 × *g* for 5 min, and the cell pellets are washed twice with phosphate-buffered saline and resuspended in 100 µl of PCR-grade H₂O. Microcentrifuge tubes containing washed *C. perfringens* cells are sealed with Parafilm and subjected to heating in a microwave (700 W) for a total of 20 min (administered as four separate 5-min heat treatments with 1-min cooling intervals) to induce bacterial lysis. The resultant lysates are cleared by microcentrifugation at 14,000 × *g* for 5 min, and 5 µl of each supernatant is used directly as template DNA in a multiplex PCR assay.

An automated method for the extraction of high-quality DNA from clostridial strains has been developed using the Nuclisens EasyMag bio-robot (Biomérieux, Marcy l'étoile, France) for testing the specimens of fat meat samples for contamination with *C. botulinum*, *Clostridium baratii*, and *C. butyricum* (47). According to the protocol, 25 or 50 g of meat samples (foie gras) were diluted 10-fold (wt/vol) in prerduced tryptone-yeast extract-glucose broth containing 200 µg/ml of D-cycloserine under a gas flow of N₂/H₂ (95:5 [vol/vol]) and then incubated anaerobically for 48 h at 37°C. After the enrichment step, the broth was collected from the extracts, a 2-ml aliquot was centrifuged at 9,000 × *g* for 5 min, and the supernatant was discarded. The cell pellet was mixed with 1 ml of the EasyMag lysis buffer (Biomérieux), and DNA extraction was performed with the Nuclisens EasyMag bio-robot following the instructions of the manufacturer. Extracted DNA (5 µl) was used in the PCR reactions.

17.4.2. Plasmid DNA

Protocols for isolation of plasmid DNA from clostridia are mainly based on the standard alkaline lysis method (182),

followed by extraction of nucleic acids from the lysates with phenol-chloroform and precipitation of plasmid DNA with ethanol or isopropanol. The lysis step of bacterial cells with lysozyme is recommended prior to the denaturation step (31, 126). Different commercial plasmid kits are also frequently used for plasmid isolation from clostridia, and preincubation of the cells with lysozyme is also strongly recommended (31).

A method for isolation of large plasmids (~50 kb) from *C. perfringens* has been developed (2). *C. perfringens* cells were cultured overnight on nutrient agar containing 5 µg/ml of tetracycline and then subcultured in 100 ml of Trypticase-peptone-glucose broth. Mid-log-phase cells were washed and suspended in 2 ml of 25% sucrose in 30 mM TES (Tris-hydrochloride buffer [pH 8.0] containing 5 mM EDTA and 50 mM NaCl). Then, 0.4 ml of a lysozyme solution (10 mg/ml in TES) was added and the cell suspension was incubated for 15 min at 37°C. This was followed by addition of 0.8 ml of 250 mM EDTA (pH 8.0), and incubation continued for an additional 5 min. Complete lysis of the cells was achieved by adding 0.5 ml of 10% (wt/vol) sodium dodecyl sulfate and incubating the preparation at 37°C for 5 min. The lysate was then treated with addition of 5 M NaCl solution to the viscous cell lysate with gentle mixing to a final concentration of 1 M. The lysates were stored at 4°C overnight and centrifuged at 17,000 × *g* for 30 min. This procedure removed essentially all chromosomal DNA and left plasmid DNA in the supernatant fluid. The resultant lysates were then subjected to cesium chloride-ethidium bromide density gradient centrifugation for 20 h. Plasmid bands were removed, dialyzed twice against 0.1 × TES, and stored at 4°C.

Routine methods for isolation of purified high-quality DNA from clostridial megaplasmids ranging in size between 100 and 300 kb are not available. The PFGE method of undigested total chromosomal samples has been employed for identification of these large plasmids (see section 17.3.1). The following protocol is routinely used in our laboratory for preparation of PFGE samples from clostridial strains. Bacterial cultures were grown anaerobically in anaerobic tubes in 10 ml of Trypticase-peptone-glucose-yeast extract medium until the optical density at 600 nm reached approximately 0.6. Bacterial cells were fixed with formaldehyde to inhibit DNase activity by injection of 1 ml of formaldehyde solution through the septum into the 10-ml bacterial cultures. The contents were mixed, the tubes were incubated on ice for 30 min, and cells were harvested by centrifugation. Cell pellets were washed twice with 10 ml of 0.85% NaCl solution; resuspended in 1.5 ml of solution containing 20 mM Tris-HCl (pH 8.0), 2 M NaCl, and 200 mM EDTA; and incubated for 10 min in a 50°C water bath. Equal volumes of the cell suspension and 1.5% InCert agarose (BioWhittaker Molecular Applications, Rockland, ME) prepared in distilled water were mixed, and the cell-agarose mixtures were loaded into plug-forming molds. The gel molds were chilled in a refrigerator for 15 min, and the agarose plugs were removed and incubated in 4 volumes of lysis buffer (10 mM Tris-HCl [pH 8.0], 1 M NaCl, 100 mM EDTA, 0.5% Brij 58, 0.2% deoxycholate, 0.5% sarcosyl, 100 µg/ml RNase A, 5 mg/ml lysozyme, and 40 U/ml mutanolysin) at 37°C for 12 h. The lysis buffer was removed, and the plugs were rinsed with 50 mM EDTA solution to remove lysozyme, RNase, and mutanolysin. Two volumes of proteinase K (PK) buffer (10 mM Tris-HCl [pH 8.0], 0.5 M EDTA, 1% sarcosyl, and 0.5 mg/ml proteinase K) were added, and the agarose plugs were incubated for 48 h with gentle agitation in a 50°C water bath. Following proteinase K treatment, the plugs

were washed with Tris-EDTA (TE) buffer and incubated for 2 h at 37°C, with shaking in TE buffer containing 1 mM phenylmethylsulfonyl fluoride to inactivate proteinase K. The agarose plugs were washed three times for 2 h each with 10 volumes of TE buffer to remove phenylmethylsulfonyl fluoride, then inserted into the agarose gel; the samples were separated using a clamped homogenous electric field system (CHEF-DRII [Bio-Rad, Hercules, CA]). Several methods for extraction of the plasmid DNA from the agarose gels following PFGE have been tried; however, the recovered DNA was significantly degraded during the extraction process and the yields decreased. More improved methods are necessary for isolation of these megaplasmids.

17.4.3. Bacteriophage DNA

Bacteriophages from *C. botulinum* type C, *C. difficile*, and *C. perfringens* have been investigated at the genomic level (59, 180, 244). In these studies, phage growth was induced by treatment of the bacterial cultures with mitomycin C or UV to induce lysis, and culture lysates were cleared by filtration or centrifugation. The cell-free supernatants were then treated with DNase and RNase and washed with NaCl solution, and phage particles were isolated by precipitation with polyethylene glycol followed by cesium chloride ultracentrifugation. The DNA from the phages can be isolated using DNA isolation kits available from various manufacturers following standard techniques (182). Another strategy for phage DNA isolation from *C. botulinum* type C strain was used by Sakaguchi and coworkers (180). These investigators prepared phage particles from the bacterial culture as described above, then embedded the phages into the agarose plugs, and after treatment with proteinase K and *N*-lauroylsarcosine at 50°C subjected the phage preparations to PFGE. The phage DNA migrating at the 186-kb position was recovered from the gel using a DNA extraction kit (Prep-A-Gene DNA purification kit [Bio-Rad]), and the DNA was sequenced.

17.5. GENE ISOLATION

17.5.1. Direct Cloning

The cloning and analysis of clostridial genes has led to several important discoveries of gene structure and function. The construction of clostridial gene banks began in the 1980s and generally used multicopy plasmids such as pBR322 and the pUC series (239, 240). The chromosomal DNA fragments were generally prepared by partial digestion of total chromosomal DNA with a frequently cutting restriction endonuclease, *Sau*3AI and/or *Mbo*I; both enzymes recognize the same GATC sequence, but *Sau*3AI cleaves methylated while *Mbo*I cleaves unmethylated sites (240). The resulting DNA fragments were separated through the agarose gels, and the fraction containing 4- to 10-kb fragments was eluted from the gels and ligated into *E. coli* cloning vectors. The average size of the inserts was ~4.5 to 5.0 kb. Therefore, 3,000 to 5,000 clones were necessary to cover the entire genome. For generation of larger insert libraries (20 to 40 kb), phage λ or cosmid vectors were employed (240). The screening of genome libraries by immunological methods and hybridization of clones with specific gene probes were used to isolate and further characterize different genes (reviewed in reference 240).

With the development of DNA amplification technologies, PCR methods are now routinely used for gene isolation and cloning. Amplification can be problematic in *Clostridium* due to the high % A+T of the coding regions

in some species. Generally, for amplification of random gene fragments, 20- to 25-mer primers can be designed from the gene regions containing 45 to 55% of the G-C bases. For amplification of the entire genes, which may contain very few G-C bases in their 5' and 3' regions, longer PCR primers (30- to 40-mers) are usually designed to ensure proper annealing to the target sequence without a need to use annealing temperatures that are too low in the amplification reactions. The PCR methods also permit addition of appropriate restriction sites during amplification of clostridial genes or their fragments to facilitate cloning into various commercial cloning vectors. The employment of PCR enzymes with high fidelity is strongly recommended to increase the accuracy of the amplified gene products. Generally, PCR reactions for amplification of clostridial genes are performed following the instructions of the enzyme manufacturers. For situations when the initial PCR conditions did not result in a desired product, investigators have optimized their reaction conditions, such as by increasing the purity of the target DNA, altering the stringency of the PCR, using longer primers or different enzymes, or other modifications. In our laboratory, we have observed that increasing the concentration of the dATP/dTTP twofold in the reaction mixes helps to achieve higher yields of the longer PCR products (>3 kb). Interestingly, in 1989 only ~50 genes from 15 different clostridial species were cloned and partially sequenced (239, 240). Currently there are 24,101 sequence entries in GenBank, containing different genes, gene fragments, and entire genomes from 40 clostridial species (see section 17.9).

17.5.2. DNA Transfer Techniques

Several different approaches have been used for introduction of DNA into *Clostridium* spp. Natural competence has not been reported in clostridia (31). The most commonly used approaches are electrotransformation (electroporation) and conjugation of vectors from *E. coli* or *Enterococcus faecalis* to *Clostridium*. Detailed protocols for DNA transfer are described in the second edition of this manual (126) and in *Handbook on Clostridia* (31).

17.5.2.1. Electroporation

Electroporation efficiencies are generally low in *Clostridium* spp. compared to many other organisms. In early studies, gene transfer by electroporation was highly strain dependent. For example, for *C. perfringens*, strain 13 has been used for genetic manipulation in preference to many other strains because it lacks certain restriction/modification systems that prevent the introduction of foreign DNA (176). Similar problems have been encountered in other clostridial species. However, methylation of plasmid DNA prior to electroporation enables plasmid transfer to many *Clostridium* spp. (31, 126). Systematic studies have not been published for increasing transfer efficiencies by electroporation or conjugation, but studies for optimization of DNA uptake may be useful to improve DNA transfer efficiency.

17.5.2.2. Conjugal Transfer between Clostridia

Conjugal transfer between the same and different species of *Clostridium* certainly occurs in the environment and in the gastrointestinal tracts of mammals, but it is not used for routine genetic manipulation. Conjugal plasmids have rarely been identified in clostridia, and so far have only been demonstrated in *C. perfringens* (176) and recently in *C. botulinum* (Johnson laboratory, unpublished data).

Intraspecies conjugal transfer frequencies are generally low, and transfer is strain specific. Therefore, host vector systems have been developed to facilitate gene transfer.

17.6. HOST VECTOR SYSTEMS

17.6.1. Host Strains

Due to a low efficiency of DNA transfer in clostridia, alternative hosts are used for clostridial gene manipulation. *E. coli* has mostly been utilized as a host for generation of gene constructs; thus, shuttle plasmids must contain both clostridial and *E. coli* replication sequences (126). *E. coli* strains are also used as donor strains for conjugative transfer of shuttle plasmids into clostridial strains. Shuttle plasmids designed for conjugal transfer carry the origin of transfer (*oriT*) from the IncP plasmid RK2 (237). Other conjugation functions are provided in *trans* from another IncP plasmid present in the donor strain (237) or from the chromosomal copy in the donor strain (111). In early studies *Bacillus subtilis* was also used as the host strain for plasmid transfer in *C. acetobutylicum* and *C. difficile* (132, 134).

17.6.2. Vector Systems

Most of the shuttle vectors described in the literature were originally developed for studies of *C. perfringens* and *C. acetobutylicum*. These vectors were later modified and adapted for use

in other clostridial species. However, systematic comparisons of various plasmid components have not been performed in different clostridial strains, and modifications of these vectors would require considerable cloning and gene manipulation. Construction of various vectors and detailed descriptions of vector components have been reviewed (31, 66, 110, 126, 133–135, 176, 177, 219, 237–239) and therefore will not be described here. In this chapter, we will only describe the replicons (Table 1), selective markers (Table 2), and reporter genes (Table 3) most frequently used for construction of clostridial shuttle vectors and then describe the latest developments in the field.

Recently the Minton laboratory designed and constructed a standardized modular system for generation of *Clostridium/E. coli* shuttle plasmids (66). This system enables construction of specific shuttle vectors suitable for a particular host and application by combining standardized plasmid components or modules; it is simple and rapid and the exchange of the modules does not require extensive cloning steps. A schematic presentation of this modular vector system appears in Fig. 2.

In this system, the necessary shuttle plasmid elements are organized into four different modules. The modules include (i) a gram-positive/*Clostridium* replicon, (ii) a selectable marker, (iii) a gram-negative replicon with or without a conjugal transfer function, and (iv) an application-specific module. Each module is flanked by two designated restriction sites of rare cutting type II restriction endonucleases: *AscI*, *FseI*, *PmeI*, and *SbfI*, which recognize 8-bp palindromes.

TABLE 1 Replicons used for construction of clostridial shuttle vectors

Plasmid	Organism	Comments	Reference(s)
Heterologous replicons			
pBC161	<i>Bacillus cereus</i>	Unstable in <i>C. acetobutylicum</i>	217
pPIM13	<i>B. subtilis</i>	ssDNA ^a replication	167

<i>tetC</i>	Tetracycline/pT127 <i>S. aureus</i>	217

These restriction sites are not present in any of the plasmid modules. In this system every shuttle vector contains one module of each of the four types, and the elements are always present in the same order. For certain applications a functional module can be replaced with a short spacer.

The elements for the modules have been selected from known plasmid components with a wide range of properties suitable for use in different clostridial hosts (Table 4). The first module contains four different gram-positive replicons flanked by *AscI* and *FseI* restriction sites. These include a novel replicon from indigenous plasmid pBP1 identified in *C. botulinum* strain NCTC 2916, from *B. subtilis* plasmid pIM13, from *C. butyricum* plasmid pCB102, and from *C. difficile* plasmid pCD6. The second module contains selectable marker genes flanked by *FseI* and *PmeI* restriction sites. Two of the most commonly used markers, *catP* and *ermB*, were selected along with the *tetA* gene from *C. perfringens* plasmid pCW3 and the *aad9* gene encoding resistance to spectinomycin from an *E. faecalis* plasmid. All four genes are also functional in *E. coli*. The third module contains gram-negative replicons and is flanked by *PmeI* and *SbfI* restriction sites. Two of the replicons selected are the high-copy-number ColE1 replicon, suitable for most applications, and p15a replicon

for low-copy-number plasmids for cloning and expression of potentially toxic products. The two replicons are also available in combination with a conjugal transfer function from RK2, which can be easily deleted by *Apal* digestion. Thus, four different elements are available for this module. The last module is designed for insertion of application-specific elements, such as a promoter or reporter gene. This module is flanked by *SbfI* and *AscI* restriction sites, and it contains a multiple cloning site (MCS) and two bidirectional transcription terminators on each side of the MCS (Fig. 2B). Three additional elements have been constructed for this module. Two of them contain the promoter and ribosome-binding site of the thiolase gene (*thl*) from *C. acetobutylicum* ATCC 824 (55) or the ferredoxin gene (*fdx*) from *Clostridium sporogenes* NCIMB 10696 (158). These are inserted between the *NotI* and *NdeI* sites, resulting in modules suitable for gene expression. In the third derivative, the entire *lacZ α* ORF is replaced by the *catP* ORF with an *NdeI* site overlapping the start codon, to serve as a reporter module. Each of the module elements is given a number, and therefore constructed vectors can be described by a standard nomenclature. The investigators have reserved plasmid designations pMTL80000 to pMTL89999, where the new shuttle plas-

mids are named by the combination of different elements in the determined order, as shown in Table 4.

It is possible to construct 400 different vectors by combining the 18 modules generated so far. The five vectors presented in Table 4 contain each of these 18 modules at least once, and therefore the system is very portable. New modules can be constructed using the same specifications described above. Construction of the modules, their properties, and testing of different module combinations in several clostridial species have been described in detail (66), and additional information is available at <http://clostron.com/>.

17.7. GENE MANIPULATION AND GENE INACTIVATION METHODOLOGIES

17.7.1. Classical Mutagenesis

One of the first demonstrations of deliberate isolation of mutants in clostridia was described by Sebald and Costilow

in 1975 (193). Nutritional auxotrophs were isolated using *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine and a chemically defined medium for selection. Strain development of *Clostridium thermocellum* for increased cellulase formation was also performed in the early 1980s using the chemical mutagen ethyl methanesulfonate (129). Chemical mutagenesis using *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine has also been applied to *C. butyricum*, *C. acetobutylicum*, and other clostridia for industrial process improvement (137). With the development of molecular and directed mutagenesis systems, chemical mutagenesis has largely been transcended in clostridial strain development, and especially in genetic analyses.

17.7.2. Transposon Mutagenesis

Transposons have played a crucial role in defining microbial gene functions. A revised nomenclature for transposable genetic elements has been described, and a registry for designation of Tn numbers is available (<http://www.ucl>).

ac.uk/eastman/tn/) (174). It is envisaged that the website will include sequence and ORF data and will be interfaced with ISfinder (174). In clostridia, generation of random mutants has been restricted to the use of the conjugative transposons Tn916 and Tn1545 (reviewed in reference 64). However, their utility has several significant limitations. These elements themselves are extremely large and may affect expression of genes near the integration site, and their transfer efficiencies are low. In some clostridial species Tn916 inserted randomly, while in others “hot spots” were identified. Moreover, a significant proportion of isolated transconjugants contained multiple copies of Tn916. In addition, Tn916 remains active after insertion, which can result in unstable mutants, and deletions of genome regions upon insertion of Tn916 have also been reported (7, 79, 104). Thus a smaller, nonconjugative element would provide much greater utility for generation of random mutants in clostridia. Until recently such elements had not been available for mutagenesis in clostridia.

Random mutagenesis methods based on transposition of a phage Mu and Tn5 have been recently reported for *C. perfringens* (98, 225). This approach appears to be more efficient and random than previously used conjugative transposons and, most importantly, generated mutants with only single-copy transposon insertions (98, 225).

The phage Mu and Tn5 transposon systems are based on the same principle and consist of similar components. The strategy involves an initial assembly of the transposition machinery in vitro, with subsequent introduction of these transposomes into the recipient cells by electroporation, resulting in genomic integration of the delivered transposon DNA within the recipient genome (57, 96). A transposition complex, or transposome, is formed between a transposase and the transposon by covalently linking the enzyme to the inverted repeat ends of the transposon. The transposome is catalytically inactive in the absence of divalent cations, but becomes activated for transposition chemistry in the presence of Mg²⁺ in the recipient cells (<http://www.epibio.com>).

Both Ez-Tn5- and bacteriophage Mu-based transposition systems are commercially available from Epicentre Biotechnologies and are described as simple, rapid, and straightforward methods for in vivo mutagenesis (<http://www.epibio.com>). This approach avoids the need to generate species-compatible transposase expression systems and specific suicide vectors, since transposition of the transposome does not require specific host factors. Therefore, this methodology is recommended for generation of mutant libraries in species that have poorly described genetic systems or lack adequate molecular tools but for which electroporation protocols have been established and reasonable electroporation efficiencies can be achieved. The higher the transformation efficiency of the target strain, the more

clones will be produced. Considering the low electroporation efficiencies reported for different clostridial species, it is not surprising that this mutagenesis strategy has been successful for generation of mutants in *C. perfringens* strain 13, where the highest electroporation efficiencies can be achieved. Interestingly, phage Mu-based mutants were generated not only in *C. perfringens* strain 13 and its derivative JIR25, but also in a field isolate after optimization of the electroporation protocol (98). In *C. perfringens* strain 13 derivative JIR25, 239 transformant colonies per 1 µg of Mu-transposome were obtained, as were 134 transformants in field isolate 56 (98), while ~50-fold more transformants (11,200) per 1 µg of EZ-Tn5 DNA were generated in *C. perfringens* strain 13 (225). Thus, a 2- to 3-log reduction in the number of transformants obtained in *C. perfringens* is observed compared to the number of transformants reported for *E. coli* target strains (<http://www.epibio.com>). Interestingly, 43% of the mutants obtained by the Mu system were inserted into rRNA genes (98), while in only 18% of the Tn5 mutants the element was inserted into the rRNA genes (225). However, for comparison of these two mutagenesis elements, more data are required, since 200 Mu clones and only 11 Tn5 clones were analyzed. Similar preferential insertion of the Mu-transposon into the rRNA cluster has also been described for *Saccharomyces cerevisiae* (151). It has been suggested that phage Mu insertions favor GC-rich sequences; this would explain insertion into rRNA genes. Detailed protocols have been described for construction of the EZ-Tn5 and Hyper-Mu transposons containing erythromycin resistance genes functional in clostridia for mutant selection, as well as for preparation of transposomes, electroporation into *C. perfringens* target strains, and clone analysis (98, 225). These studies are of considerable significance and should encourage research groups to adapt this mutagenesis technique to other clostridial species by optimizing and improving their electroporation efficiencies, as described by Lanckriet and coworkers (98).

17.7.3. Directed Gene Inactivation

17.7.3.1. Directed Gene Inactivation Using Host-Mediated Recombination

Generation of directed mutants using classical methods based on host-mediated recombination has been very inefficient in clostridia due to rare recombination events observed between the mutated and the wild-type gene, the lack of conditional shuttle vectors, and the relatively low efficiencies observed for DNA transfer by electroporation and conjugation. Over the past decades only a limited number of mutants have been isolated from a few *Clostridium* species, such as *C. perfringens*, *C. difficile*, *C. septicum*, *C. acetobutylicum*, *C. beijerinckii*, and *C. tyrobutyricum*

(reviewed in reference 64). Most of these mutants were derived by a single crossover integration of a replication-defective (suicide) plasmid by homologous recombination. Such integrants are segregationally unstable because the entire plasmid carrying the modified gene has integrated into the genome at the target site by a Campbell-like mechanism. Ideally, stable integrants resulting from allelic exchange are preferred; however, double-crossover mutants of several genes have been generated primarily in *C. perfringens*, mostly in strain 13, where the highest transformation frequencies have been observed (64), and for a single gene in *C. septicum* (91). In general, these experiments are tedious and require substantial time, effort, and a fortuitous outcome. In a recent review, different approaches used and problems encountered during generation of these single- and double-crossover mutants in clostridia are discussed (64).

17.7.3.2. Directed Gene Inactivation Using a Retargeted Group II Intron

An alternative approach to achieve gene inactivation in clostridia is to use DNA integration mechanisms that are independent of host recombination factors. One such system is based on mobile bacterial group II introns (88), which are found in bacteria and eukaryotic organelles, where they function as catalytic RNAs and retrotransposable elements (97). The mobilization mechanisms and target specificities of the group II intron from the *ltrB* gene of *Lactococcus lactis* have been described (reviewed in reference 97). The L1.LtrB is a site-specific retroelement that uses a mobility mechanism termed "retrohoming," by which the excised intron lariat RNA inserts directly into a DNA target site and is then reverse transcribed by the associated intron-encoded enzyme protein (IEP) (97). The insertion target site is recognized primarily by base pairing between the excised intron lariat RNA and the target-site DNA. Therefore, modification of the intron sequence at a small number of positions recognized by the protein can lead to altered target specificity (140). Based on these observations, Lambowitz and colleagues developed group II introns into a new class of gene-targeting vectors ("targetrons"), which can be reprogrammed to insert into desired DNA targets simply by modifying the intron RNA. Detailed analysis of the nucleotide frequencies at different active target sites resulted in generation of an algorithm that predicts optimal L1.LtrB intron-insertion sites and designs primers for modifying the intron to target any gene of interest (161). The IEP gene in the targetron is removed from the intron and placed downstream from the intron on the same plasmid. Such arrangement of the intron components (as a minitransposon) does not affect the intron mobility but results in stable mutants. By removal of the IEP-encoding plasmid after insertion of the element in the desired position, the intron is not able to splice out. Furthermore, to facilitate positive selection of inactivated genes, an antibiotic resistance marker designated retrotransposition-activated marker (RAM) was engineered into the group II intron (241). RAM is an antibiotic resistance gene interrupted by another intron, a self-splicing group I intron. The group II intron and RAM are positioned and oriented in such a way that only after insertion of the group II intron into the target site in the genome can the group I intron be removed by self-splicing, thus restoring the integrity of the antibiotic resistance gene and allowing positive selection for integration events. The L1.LtrB mobile group II intron has been commercially developed as a genetic tool (TargeTron) for

insertional inactivation of genes. Several vectors for targeting both gram-positive and gram-negative bacterial genes with or without positive selection (containing RAM) are available from Sigma-Aldrich (St. Louis, MO; <http://www.sigmaaldrich.com/life-science/functional-genomics-and-mai/targetron.html>).

The targetron technology has been adapted and successfully used for gene inactivation in clostridia by several research laboratories (23–25, 66). Construction of specific vectors and further improvements of this technology for inactivation of genes in different clostridial species have been recently reviewed (64).

The first report of inactivation of the *plc* gene in *C. perfringens* strain 13 using the group II intron technology was described by Chen and coworkers (24). Researchers used the basic TargeTron vector pACD3 (Sigma-Aldrich) and made modifications by including a clostridial replicon in the vector and replacing a gram-negative antibiotic resistance marker with a functional marker in *C. perfringens*. Additionally, the T7 promoter for transcription of the group II intron was replaced with a promoter region from the *C. perfringens* gene *cpb2*, generating the vector pJIR750ai. This vector was further modified for targeting the *plc* gene of *C. perfringens*. The targeting vector was transferred by electroporation into *C. perfringens* strain 13, and *plc* knockout clones were selected using a simple phenotypic screen followed by clone analysis with PCR and sequencing.

Plasmid pJIR750ai has also been used to construct a vector, pSY6, that was used for targeting two genes in *C. acetobutylicum*: *buk* (encoding the butyrate kinase) and *solR* (a putative repressor of solvent formation genes) (197). The targetron vector was constructed by inserting the group II intron from pJIR750ai into the *E. coli*-*C. acetobutylicum* shuttle vector pIMP1 (131), which is under control of the *C. acetobutylicum* phosphotransbutyrylase gene (*ptb*) promoter. The vector contains *B. subtilis* replication sequences. Transformants were screened by PCR in order to isolate *buk* and *solR* gene knockout clones.

Significant improvements of the group II intron technology for use in clostridia have been developed by the Minton laboratory (64, 65). Their system, designated ClosTron, is designed for generation of mutants in different clostridial species, and it enables positive selection of the mutants (64, 65). Positive selection was not used for mutant screening in the experiments described above for isolation of the *plc* mutant in *C. perfringens* and *buk* and *solR* mutants in *C. acetobutylicum*. The two RAM elements available for use with the L1.LtrB group II introns are based on kanamycin or trimethoprim selection (241); however, these cannot be used in clostridial species. Therefore, a new RAM gene was constructed based on the *ermB* gene from *E. faecalis* plasmid pAM β 1, which has been widely used for construction of *E. coli*-*Clostridium* shuttle vectors (126). The self-splicing group I intron from the *td* gene of phage T4 was inserted between the *ermB* ORF and its promoter region, and the new RAM was placed under control of a stronger promoter derived from the *C. acetobutylicum* thiolase gene (*thlA*) to ensure that expression of *ermB* from a single-copy gene on the chromosome was sufficient to provide erythromycin resistance in the host cells (65). The group II intron was transcribed from an isopropyl- β -D-thiogalactopyranoside-inducible clostridial *fac* promoter in pMTL007, and under constitutive *fdx* promoter in the second-generation ClosTron vector pMTL007C-E2 (64). The ClosTron vectors contain the *catP* gene, and these constructs are maintained in *E. coli* in the presence of chloramphenicol and in clostridia

in the presence of thiamphenicol. To ensure the loss of the vector upon intron insertion, ClosTron vectors contain a pCB102 replicon from *C. butyricum* that functions with various degrees of efficiency in different clostridial species. Therefore, the plasmid can be removed from the mutant strains by streaking out the integrant clones on media without thiamphenicol.

The ClosTron vectors can be transferred to clostridial strains by conjugation from a suitable *E. coli* donor strain (such as CA434) since the vectors carry the *oriT* region and *traJ* gene, as well as by electroporation. A new methylation plasmid, pAN2, compatible with pMTL007, also has been constructed. This plasmid is used to methylate ClosTron vectors prior to electroporation into clostridial strains to circumvent their type II restriction/modification systems. Lastly, to eliminate possible polar effects due to the presence of a powerful *thlA* promoter inside the intron, which can lead to increased expression of downstream and upstream genes, the *ermB* gene in the second-generation vector pMTL007C-E2 is flanked by FLP recombination target sites. This modification permits excision of the *ermB* gene in the presence of the FLP recombinase, which can be expressed from a segregationally unstable plasmid introduced into the mutant strains. Removal of the *thlA-ermB* gene from the mutants would significantly reduce potential polar effects and facilitate generation of multiple mutations by employing the ClosTron vectors with the same positive selection of mutants using erythromycin resistance. Detailed protocols for construction of retargeting intron plasmids for gene inactivation and other useful tools and information can be found at the TargeTron website (<http://www.sigmaaldrich.com/life-science/functional-genomics-and-rnai/targetron.html>) and at the ClosTron website (<http://clostron.com/>).

The group II intron mutagenesis system can be used not only for gene inactivation (knock-out) but also for gene transfer (knock-in). Such experiments have been successfully performed in clostridia. For example, Chen and coworkers (23) used the TargeTron vector pJIR750ai for insertion of the simian immunodeficiency virus (SIV) p27 gene into the theta-toxin gene (*pfoA*) on the *C. perfringens* chromosome, which simultaneously inactivated the theta-toxin gene and introduced the SIV p27 gene onto the bacterial chromosome. The mutant strain produced a large amount of SIV p27 protein and did not produce theta-toxin. This reengineered *C. perfringens* strain could provide a safe and efficient oral vehicle for delivery of antigens or therapeutic compounds to the gastrointestinal tract. The *virR* gene and its mutated form, *virRD57N*, were introduced into a unique MluI site in the TargeTron vector pJIR750ai (designed to target the *C. perfringens plc* gene) in such a way that the genes were transcribed in the same direction as the intron (25). The targeting plasmids pJIR3326 (*virR*) and pJIR3243 (*virRD57N*) were introduced into *C. perfringens* VirR mutant strain TS133 and single-copy integrants (in the *plc* gene) were isolated for both *virR* and mutant *virRD57N* genes. The mutant strains were used to further study the VirSR two-component signal transduction system and to elucidate the role of the phosphorylation of the VirR response regulator.

The ability to create desired mutations in genes using the group II intron mutagenesis system opens new horizons for functional genomic studies in clostridia. Considering that it takes as little as 10 to 14 days to generate mutants (64) and that the method is highly efficient and reproducible, new and interesting studies can be expected in the near future.

17.8. MODULATION OF GENE EXPRESSION WITH ANTISENSE RNA TECHNOLOGY

Antisense RNA (asRNA) technology offers an attractive alternative to gene knockout as a means of evaluation of gene functions as well as for modulation of gene expression. Most natural regulatory asRNAs are small molecules that bind to the complementary 5' untranslated regions of the target RNA, including the translation initiation site and/or coding regions, thus preventing RNA translation and facilitating its degradation (226). Generation of mutants using asRNA has several advantages over gene inactivation. First, asRNA technology is faster than isolation of gene insertion mutants, and the gene inactivation is not absolute. This is especially important for studies of genes with essential cellular functions, as their disruption would result in a lethal phenotype. Also, asRNA is invaluable for studies of genes organized in polycistronic transcription units, because complete inactivation of some genes in these units may prevent synthesis of the gene products located downstream from the mutated gene. Construction of an artificial asRNA is usually performed by insertion of the asRNA gene containing the ribosome binding site and a portion of the coding region of the target gene between a strong promoter and a transcription terminator in a high-copy-number vector (reviewed in reference 220). It has been shown that by including the ribosome binding region and 33 to 100% of the target gene's coding region for construction of asRNA, over 80% downregulation of the target gene can be achieved (220). Detailed experiments for designing efficient asRNA molecules have been performed in *C. acetobutylicum* in E. T. Papoutsakis' laboratory (34, 218, 220, 221). Initially, investigators used a software program, Gene Construction Kit (Textco, Inc., West Lebanon, NH), to generate the asRNA constructs, and then an analysis was performed of the secondary structure of these constructs using MFold (<http://mfold.bioinfo.rpi.edu/>). Only the asRNA constructs with the most energetically favorable structure as predicted by MFold were used for experiments. Use of this strategy enabled these investigators to generate significantly more efficient asRNA constructs compared to their previous constructs made without MFold analysis. The asRNA technology was used in combination with overexpression of certain genes for detailed studies of butanol, acetone, and ethanol production in *C. acetobutylicum* (reviewed in reference 216). Furthermore, these technologies have been employed for metabolic engineering of *C. acetobutylicum* to create strains of industrial importance for increased production of these organic solvents (34, 152, 201, 202, 216). The asRNA technology has also been used for metabolic engineering of other clostridial species, such as *C. beijerinckii* (107) and *C. saccharoperbutylacetonicum* (144).

asRNA technology has been useful for studies of functional genomics in clostridia. The enzymatic composition of cellulosomes produced by *Clostridium cellulolyticum* was modified by inhibiting synthesis of the major enzymatic protein Cel48F (159). The asRNA technology has also been used to decrease synthesis in *C. perfringens* of small acid-soluble spore proteins, enabling an analysis of resistance to moist heat and UV radiation (170). In toxigenic clostridia, asRNA was employed to demonstrate the role of BotR in the regulation of the expression of botulinum neurotoxin and its nontoxigenic components (124).

Further improvements of asRNA technology have been suggested by the Papoutsakis laboratory, including development of efficient computational methods for designing efficient asRNA constructs, generation of constructs that permit modulation of multiple target genes, and the use of different promoters to control efficient transcription of these

asRNAs (220). These researchers have proposed construction of efficient asRNAs for each of the ORFs, thus generating a library of strains that can be used to downregulate individual genes or gene operons in any clostridial strain for which the genomic sequence has been determined. Such libraries would facilitate molecular analysis to elucidate complex regulatory networks in these study organisms.

17.9. GENOME SEQUENCING AND ANALYSIS

Currently GenBank lists 91 genome sequencing projects of strains from 40 different *Clostridium* spp. (Table 5). Of these genome projects, 25 are completed genome sequences, 46 are draft sequences, and the sequencing of an additional 20 clostridial genomes is in progress. The complete sequences of 28 clostridial plasmids ranging in size from 2.4 kb to 270 kb have been determined and are also included in the table. Several strains have been identified that contain more than one plasmid. The most completed genomes are for *C. botulinum* (10); five genomes are at the draft stage, and the sequencing of two additional genomes is in progress. In *C. perfringens*, three genomes are complete and six draft genomes are available, while for *C. difficile* only one genome is completed, nine are in draft, and an additional five are being sequenced. While most of these sequences have been deposited in GenBank, only a few of the genomes have been analyzed in detail and published. These include *C. acetobutylicum* strain ATCC 824 (147); *C. botulinum* strain ATCC 3502 (190); *C. difficile* strain 630 (191); *C. kluyveri* strain DSM 555 (194); *C. novyi* strain NT (11); *C. perfringens* strains 13 (200) and SM101 and ATCC 13124 (143); *C. tetani* strain E88 (18); and *Mooerella thermoacetica* (formerly *C. thermoaceticum*) (165).

Based on completed genome sequences, DNA microarrays have been designed using several different platforms and used for the comparison of strains within the same species or related clostridia (see, for example, references 22, 74, 105, 172, and 207) as well as for characterization of transcriptomes (46, 199, 220, 242). The most comprehensive and detailed transcriptional analysis including the life cycle of *C. acetobutylicum* has been performed in the Papoutsakis laboratory (85, 152). This study described major cellular regulatory systems; sigma and sporulation factors, including activity assays for major sporulation factors of the canonical sets of genes from their regulons; assessment of expression intensities; and identification of putative histidine kinases that may phosphorylate Spo0A (85).

Microarrays have also been developed for detection of food-borne bacteria based on their 23S rRNA variable region (68), based on their virulence genes (195), or for biological warfare agent detection (60, 195, 205). Specialized arrays have been designed for genotyping *C. perfringens* toxins (5), as well as for screening of gram-positive bacteria for 90 antibiotic resistance genes (160). Availability of a large number of completed genome sequences from clostridia, including multiple genomes from the same species, will enable detailed studies of the evolution of the genus *Clostridium* and will facilitate functional studies of genes at the genome level.

17.10. HOMOLOGOUS AND HETEROLOGOUS EXPRESSION OF CLOSTRIDIAL PROTEINS

While not as well developed as expression systems in other gram-positive bacteria such as *Bacillus*, *Staphylococcus*, *Streptococcus*, and *Lactococcus*, homologous and hetero-

logous expression systems are available and are being improved in *Clostridium*. The clostridia produce more extracellular protein antigens than any other bacterial genus (223), and several species are prolific producers of toxins, enzymes, and other proteins (42). *Clostridium* has certain advantages for production of proteins, including efficient secretion systems and lack of endotoxins. However, compared to other systems such as *B. subtilis* (187), many species are pathogenic, and clostridia have not been granted "Generally Regarded As Safe" status by the U.S. Food and Drug Administration. Certain clostridia also have high A+T coding bias, which can create considerable difficulties in expression, and relatively little information is known regarding transcription and translation mechanisms.

The high A+T codon content exhibits strongly selected codon usage bias (198), and the disparity in codon usage causes inefficient translation by heterologous hosts; furthermore, expression of clostridial proteins is difficult in such hosts as *E. coli* and *B. subtilis*. This is particularly apparent for proteins of relatively high mass, i.e., <50 kDa. The secretion systems in other gram-positive organisms, including the Sec system, the Tat pathway, and signal recognition particle systems, have not been established in *Clostridium*. While *B. subtilis* can obtain very high cell densities and accumulate recombinant proteins to up to 10 to 30% of total cellular protein, the fermentative metabolism of clostridia limits the energy capacity for protein accumulation. The codon bias can be partially alleviated by supplementation with rare tRNAs or by use of synthetic genes for optimized *Clostridium* codon usage (117, 198, 234).

Attempted production of clostridial enzymes and toxins in heterologous hosts has often resulted in very low yields, insolubility, or truncated or full-length inactive proteins (see, e.g., reference 56). However, hyperexpression of glucanase B from *C. thermocellum* was obtained using an amplification unit, pE194 (162). Expression of beta-toxoid of *C. perfringens* at 200 mg per liter was achieved, but the beta-toxoid was poorly secreted (146). Eukaryotic hosts including baculovirus and *Pichia pastoris* have also been used to achieve high-level expression of clostridial proteins (8).

17.11. TARGETED EXPRESSION OF CLOSTRIDIUM PRODUCTS FOR HUMAN DISEASE

Clostridium toxins and spores have been used experimentally for the study of eukaryotic physiology using an intriguing targeting expression approach (reviewed in reference 130). It has been known for more than 60 years that *Clostridium* endospores, when administered systemically to humans, locate and germinate within the anaerobic environment of solid tumors (118, 155). Targeted vector expression systems have been developed that express antitumor factors from *Clostridium* spores (229). In one exemplary case, intravenously injected *C. novyi* spores germinated within the avascular regions of tumors in mice and destroyed surrounding viable tumor cells (30). When *C. novyi* spores were administered together with conventional chemotherapeutic drugs, hemorrhagic necrosis of tumors was observed within 24 h. Spores are nonimmunogenic and can be administered for long periods. In a species comparison, *C. novyi* and *Clostridium sordellii* had the most antitumor activity, probably due to their high mobility within the tumors giving maximum spread. A *C. novyi* strain made nontoxicogenic by genetic modification is in clinical trials for tumor ablation.

TABLE 5 Clostridial genome sequences^a

Species and strain	Chromosome and/or plasmid	Length (nt)	ORFs	rRNAs	GC content (%)	Accession no.	Status	Reference

^bSequencing performed at DOE Joint Genome Institute.

^cSequencing performed at Mississippi State University.

Clostridium spp. have shown enhanced oncolytic activity compared to other targeted organisms such as *Salmonella* and *Bifidobacterium*. The further development of genetic systems for *Clostridium* spp. will enhance their efficacy as oncolytic treatments for human diseases (214).

17.12. MOLECULAR TYPING AND GENETICS OF *CLOSTRIDIUM* POPULATIONS

The identification of *Clostridium* spp. has classically been performed on the basis of source of isolation, morphology, physiological and metabolic characteristics, pathogenicity and disease association, staining reactions, and serologic properties (63, 67, 142). Sequencing of 16S rRNA genes has become a powerful tool to identify and determine the species of the clostridia (26, 63, 81). However, 16S rRNA gene sequencing alone has certain limitations, including the inability to resolve recent speciations, and therefore it is recommended to combine ribosomal sequencing with determination of physiological properties and other typing methods such as multilocus sequence typing (see, e.g., references 72, 92, 103, 116, 145, and 183). Although many typing methods have been investigated, they vary in efficacy depending on their intended use, e.g., strain differentiation or understanding population structure.

Only recently, the population genetics and interactions in the environment of *Clostridium* spp. have begun to be investigated. The availability of genomic sequences (see section 17.9) provides insights into population genetics and evolution of *Clostridium* (see, e.g., reference 22). It is anticipated that considerable knowledge of the evolution of clostridia and novel methods for improvement of industrial processes will be gained in the near future.

17.13. CONCLUSIONS AND PERSPECTIVES

Considerable progress has been achieved in the analysis and genetic manipulation of *Clostridium* since the publication of the second edition of this manual in 1999. In particular, the availability of numerous clostridial genome sequences has initiated studies for evaluation of functional genomics at the genome level. There is an opportunity and a need for in-depth bioinformatic analyses of clostridial genomes to improve understanding of pathogenesis, metabolism, and evolution. A second major breakthrough has been the development of gene disruption systems. There is a need for further improvement of the knockout systems to achieve multiple gene deletions to facilitate studies of gene functions. Ideally, the development of further genetic tools will foster fruitful collaborations within the clostridial community to understand this complex and difficult organism.

Research in our laboratory has been supported by industry, the University of Wisconsin, and grants from the National Institutes of Health. We are grateful to our collaborators in this field.

Genetic Manipulation of Myxobacteria

WESLEY P. BLACK, BRYAN JULIEN, EDUARDO RODRIGUEZ,
AND ZHAOMIN YANG

18

18.1. INTRODUCTION

Myxobacteria, a coherent group of the *Deltaproteobacteria*, are recognized as important producers of secondary metabolites of industrial and medical importance. These gram-negative bacteria have fascinated scientists for over half a century because of their surface-gliding motility and their starvation-induced multicellular development (40, 84, 95). In more recent years, they have emerged as prominent producers of secondary metabolites, as discussed in several recent reviews (5, 6, 22, 23, 69). Myxobacteria as a group produce more bioactive compounds than any other gram-negative phylum and rank third after actinomycetes and bacilli (69, 70). Currently there are over 100 different known natural products from myxobacteria with about 500 structural variants (5, 6). *Sorangium cellulosum* accounts for nearly 50% of these and *Myxococcus* and *Stigmatella* account for about 25% (22, 23). Importantly, the bioactive compounds from myxobacteria tend to be novel and distinct (5). For example, *S. cellulosum* produces epothilone (33), which is currently marketed as an anticancer drug (Ixempra® by Bristol-Myers Squibb [Princeton, NJ]). Although epothilones act as microtubule stabilizers like paclitaxel (8), they remain effective against paclitaxel-resistant cancer cells (46). Genome sequencing of a few myxobacteria has revealed genes for the biosynthesis of unidentified secondary metabolites (6, 24, 74). Considering the need for new drugs to treat a variety of diseases, further exploration of the myxobacteria is imperative.

Tools for genetic manipulation of myxobacteria are important for identifying and engineering strains to maximize production of secondary metabolites. Fortunately, a considerable number of such tools have been developed over the years, including methods for mutagenesis, transduction, conjugation, and transformation. Several developments have enabled heterologous gene expression in myxobacteria, including the construction and development of regulated promoters and the identification of strong constitutive promoters. Recently, the first autonomously replicating plasmid was identified. While most genetic tools were first developed for the model myxobacterium *Myxococcus xanthus*, many have been applied to *S. cellulosum*, *Stigmatella aurantiaca*, and the lesser-known myxobacteria *Chondromyces crocatus*, *Cystobacter fuscus*, *Angiococcus disciformis*, and *Coralloccoccus macrosporus*. We describe these tools in this chapter and hope to facilitate the increased use of myxobacteria for applications in biotechnology and drug discovery.

18.2. TRANSFER OF DNA INTO MYXOBACTERIA

18.2.1. Transduction of Myxobacteria

18.2.1.1. Transduction of DNA from *Escherichia coli* to *M. xanthus*

The first reported transfer of DNA from *E. coli* to *M. xanthus* was associated with the coliphage P1 (41). P1 harboring a chloramphenicol resistance gene was shown to inject its DNA into *M. xanthus*, producing unstable drug-resistant transformants. Because P1 is unable to replicate in or lysogenize *M. xanthus*, it became the earliest suicide vector for delivery of Tn5 for transposon mutagenesis (48). Because P1 is a generalized transducing phage for *E. coli*, it has the ability to randomly package DNA. This was exploited to package plasmid DNA for transfer to *M. xanthus*. Because of the large size requirement, approximately 100 kb, to produce stable infecting P1 phage particles, the transfer of larger plasmids is more efficient than smaller ones (62). Using P1 for plasmid DNA delivery before the discovery of electroporation allowed for mutant complementation and strain construction. Two other *E. coli* phages, P2 and P4, bind to the same cell surface receptor as P1. P4 has been shown to inject DNA into *M. xanthus* using a P4::miniTn5Kan^r derivative. Like P1, P4 is unable to replicate or lysogenize in *M. xanthus* (B. Julien, unpublished results). Although P4 does not package DNA randomly, it can package plasmid DNA that contains the 125-bp recognition sequence for DNA packaging (94). With the development of electroporation protocols (see below), P1 is used less frequently to introduce plasmid DNA into *M. xanthus*. However, with the construction of bacterial artificial chromosome libraries harboring large polyketide synthase biosynthetic gene clusters, such as the ~70-kb amburicin gene cluster, the ability to move them into *M. xanthus* with P1 may prove useful since electroporation is not efficient with such large DNA (Julien, unpublished). For methods using P1 to transfer DNA from *E. coli* to *M. xanthus*, refer to O'Connor and Zusman (62).

18.2.1.2. Transducing Phages of *M. xanthus*

Currently, only four phages have been identified that infect myxobacteria, all of which were isolated using *M. xanthus* as a host. The first myxophage isolated was Mx1 (12, 13). It is a lytic phage and does not transduce chromosomal DNA.

The other three myxophages, Mx4, Mx8, and Mx9 (14, 21, 55), are temperate phages. Mx4 and Mx8 have been shown to transfer genetic markers between different strains of *M. xanthus*. They have been developed as generalized transducing phages for mapping mutations and strain constructions. Mutants of both have been isolated that carry out general transduction with improved efficiency (14, 21, 55). For those requiring transduction using Mx4 or Mx8, please refer to Campos et al. (14) or Martin et al. (55), respectively, for more details.

18.2.2. Transformation of Myxobacteria by Electroporation

Electroporation has become the most common technique to introduce DNA into myxobacteria, including the species *M. xanthus*, *S. aurantiaca*, *C. fuscus*, *A. disciformis*, and *C. macrosporus* (43, 63, 68, 72, 77). In addition to plasmids, it can be used with genomic DNA fragments, which is useful as a substitute for transduction to transfer mutations between *M. xanthus* strains (82). More recently, genomic DNA electroporation has been used to establish genetic linkages in *M. xanthus*. In our experience, markers that are about 10 kb apart can be cotransformed easily using genomic DNA transformation. Although electroporation of DNA into *S. cellululosum* has been reported (45), it has not been duplicated due to lack of details provided in the original publication.

Protocol 1. Electroporation Protocol for *M. xanthus*

This protocol is based on Kashefi and Hartzell (43), with all steps performed at room temperature unless otherwise noted.

1. Grow an overnight culture at 32°C in Casitone-Yeast Extract (CYE) to an optical density at 600 nm (OD₆₀₀) of ~0.5 to 1.0.
2. For each electroporation, pellet 1.5 ml of culture at 15,000 × g in a microcentrifuge for 4 min. Aspirate off medium.
3. Wash cells by resuspending in 1 ml of sterile distilled deionized water (ddH₂O).
4. Pellet cells as in step 2. Aspirate ddH₂O (pellet may become loose).
5. Repeat washing with sterile ddH₂O two or three times.
6. Resuspend cells in 40 μl of sterile ddH₂O.
7. Add 1 to 5 μl of salt-free DNA to the cell suspension and mix by vortexing. The amount of DNA to use for each electroporation is as follows.
 - a. 100 to 300 ng of replicative plasmid or plasmid with phage attachment site
 - b. 0.5 to 1.5 μg of plasmid for integration by homologous recombination
 - c. 3 to 5 μg of genomic DNA
8. Transfer cells and DNA to an electroporation cuvette with a 1-mm gap and perform electroporation with the following settings.
 - a. Resistance at 400 Ω
 - b. Voltage at 0.65 kV
 - c. Capacitance at 25 μF
 - d. Optimal time constant usually between 8 and 9.5
9. Quickly remove the cells from the cuvette with 1 ml of CYE and transfer to a tube with an additional 1.5 ml of CYE.
10. Incubate at 32°C for 4 to 5 h with shaking at 300 rpm for recovery. A 2- to 3-h incubation may suffice for phage attachment plasmids or replicative plasmids, but for homologous recombination with sequences less than 500 bp an overnight recovery may be necessary.

11. Plate cells on selective medium as follows.
 - a. For attachment or replicative plasmids, plate 100 μl directly and 100 μl of a 1/10 dilution.
 - b. For homologous recombination and genomic DNA transformations, plate 100 to 150 μl directly. Concentrate the rest and plate on two plates.
12. Incubate plates at 32°C for 5 to 6 days to obtain single colonies.

18.2.3. Conjugation of Myxobacteria

Conjugation is the most frequently used technique to introduce DNA into *S. cellululosum*, and several different protocols have been described (35, 44, 66, 75). Strain-specific modifications appear necessary to achieve maximal efficiency (44). Protocol 2 is a general conjugation procedure for *S. cellululosum*. This protocol is applicable to *M. xanthus* except that the cells do not need to be heat shocked and the medium used for growth of *M. xanthus* is CYE. Conjugation has also been used to create knockout mutations in *C. crocatus* (67). For *M. xanthus* and *S. aurantiaca*, electroporation is highly favored over conjugation for small plasmids. However, for large plasmids, ~100 kb, it is necessary to perform conjugation with *M. xanthus* (Julien, unpublished). For conjugation protocols using *M. xanthus* or *S. aurantiaca*, please refer to Breton et al. (11), Glomp et al. (23a), and Jaoua et al. (34) for more details.

Protocol 2. General Conjugation Protocol for *S. cellululosum*

1. Grow the myxobacterial strain in 50 ml of 307 medium to an OD₆₀₀ of no more than 1.0 (~1 × 10⁸ cells/ml) but aiming for an OD₆₀₀ of ~0.5.
2. The night before the myxobacterial strain is ready, grow the *E. coli* donor strain in 20 ml of LB containing 0.5% NaCl in a 125-ml flask at 37°C overnight without shaking.
3. The next day, heat shock 1 × 10⁹ *S. cellululosum* cells at 50°C for 10 min and then pellet cells. When performing conjugation to deliver the *mariner* transposon, this heat shock step is not necessary. Pellet 0.1 to 10 ml of donor *E. coli*. Decant supernatants, leaving about 400 μl of 307 medium for myxobacteria, and remove all LB from *E. coli*. Resuspend *S. cellululosum* in the remaining medium, add to the *E. coli* pellet, and resuspend those cells too.
4. Pipette the combined cells onto the center of an S42 plate. Use a dry plate to ensure that the liquid will be absorbed. Incubate at 30°C for 24 h.
5. Scrape off the cells, suspend in 1 ml of 307 medium, and plate various dilutions onto S42 plates containing kanamycin (Kan) at 50 μg/ml (to inhibit *E. coli*) and the appropriate antibiotic for selection in *S. cellululosum*. For integration of plasmid DNA by homologous recombination, plate 10 to 100 μl/plate from the 1-ml suspension. If conjugating the *mariner* transposon, suspend cells in 10 ml of 307 medium and plate 5 to 25 μl/plate.

18.2.4. Selectable Markers in Myxobacteria

A variety of antibiotic selection markers are used in myxobacteria. The most commonly used marker is *nptII* from Tn5 (2), which confers kanamycin resistance (Kan^r) and has been used with *M. xanthus*, *S. aurantiaca*, *C. fuscus*, *C. macrosporus*, and *A. disciformis* (48, 63, 67, 68, 72, 77). Kanamycin is typically used at 50 to 100 μg/ml. For *S. cellululosum* strains, which are naturally resistant to kanamycin, the best alternatives are hygromycin (Hyg) using the *hyg* resistance gene or phleomycin (Phleo) and its analogue bleomycin (Bleo) using the *bleo* resistance gene from Tn5. Hygromycin

is used at 60 $\mu\text{g/ml}$ (66) and phleomycin at 20 to 40 $\mu\text{g/ml}$ (37, 38). The *bleo* resistance gene also works well in *M. xanthus* using phleomycin concentrations of 20 to 50 $\mu\text{g/ml}$ (Julien, unpublished). When the *hyg* resistance gene is used with *C. crocatus*, selection requires 100 $\mu\text{g/ml}$ hygromycin (67). Tetracycline resistance (Tet^r), which is conferred by *tetA* from pSC101 or pBR322 (7, 18), has been used for selection in *M. xanthus* and *S. aurantiaca* (1). Due to the long incubations typical for myxobacteria, the more stable tetracycline derivative oxytetracycline is generally used at 15 $\mu\text{g/ml}$. Another good marker for *M. xanthus* is resistance to apramycin (Apra) conferred by the *aacC4* gene driven by the promoter from the Kan resistance gene *nptII* (4). Apramycin is typically used at 60 $\mu\text{g/ml}$ (Julien, unpublished). Although rarely used, trimethoprim (Tp) (250 $\mu\text{g/ml}$) can be used for selection in *M. xanthus* (19, 90).

18.3. MUTAGENESIS OF MYXOBACTERIA

Mutagenesis is fundamental to any genetic manipulation. Classical techniques utilizing UV irradiation and chemical mutagens have been used to introduce random point mutations in *M. xanthus*, especially in the early days of basic research (14, 30, 31, 58). Although it is laborious to identify a point mutation in myxobacteria, UV or chemical mutagenesis may prove valuable for the improvement of industrial strains. Interested readers are directed to Hodgkin and Kaiser (31) and Morrison and Zusman (58) for related protocols of chemical and UV mutagenesis. Here we will focus on mutagenesis procedures based on transposition and homologous recombination.

18.3.1. Transposon Mutagenesis of Myxobacteria

Transposon mutagenesis is critical for myxobacterial genetics due to the ease of mutation identification. As mentioned earlier, Tn5 was the first transposon utilized in myxobacteria (48). It proved powerful not only for mutagenesis, but also for mapping point mutations from previous studies. Several derivatives of Tn5 have been useful. Tn5-132 and Tn-Tp allowed in situ replacement of Kan^r with either Tet^r or trimethoprim resistance, respectively (1). It also made it possible to combine multiple Tn5 insertions in the same strain. Tn5*lac*, which contains a promoterless *lacZ*, has been useful in dissecting the temporal regulation of gene expression during *M. xanthus* development (47). Another useful derivative is Tn*phoA* (54), which creates translational fusions to the extracellular phosphatase, PhoA. Since PhoA is only active when exported to the periplasm, Tn*phoA* has proved useful in the identification of secreted proteins from *M. xanthus* (10, 42). A serious drawback of Tn5 is its lack of true randomness in transposition. It was determined that it transposes near sequences matching or resembling the consensus A-GNTYWRANC-T (25). As such, insertions in certain genes may never occur even when insertions in other genes are saturated or overrepresented.

A welcome development was the demonstration that *mariner*-based transposons are functional in *M. xanthus*. Transposons of the *mariner* family, which require only a TA dinucleotide for insertion, are nearly random in transposition (71). Several *mariner* derivatives have been used in myxobacteria. *magellan4*, which was initially constructed for mutagenesis in mycobacteria (71), was first used in *M. xanthus* by Youderian et al. (92) to identify genes required for motility. Another is *miniHimar1-Tet*, which was constructed by replacing the Kan^r from *magellan4* with Tet^r (H. Kaplan, unpublished data). This enables transposon mutagenesis in a strain that is already Kan^r . Julien and Fehd (38) developed

another *mariner* derivative for mutagenesis of *S. cellulosum*. This transposon, which can be conjugated into *S. cellulosum*, contains both kanamycin and bleomycin resistance for selection. The conjugative delivery plasmid also encodes a mutated transposase that increases the frequency of transposition. Another *mariner*-based transposon that can be conjugated into *S. cellulosum* (44) is similar to *magellan4* except that Kan^r was replaced with the hygromycin resistance marker.

Identification of the insertion site of *magellan4* and its derivatives is relatively easy due to the inclusion of the R6K γ replication origin in these transposons. Genomic DNA of a transposon insertion mutant is isolated and digested with a restriction enzyme that does not cut within the transposon. The DNA is self-ligated and transformed into a λ pir *E. coli* strain. Plasmids isolated from these transformants can be sequenced using primers complementary to the left and right insertion elements.

Protocol 3. Genomic DNA Preparation

This small-scale genomic DNA prep (65) is sufficient for genomic DNA transformations of *M. xanthus* and for the isolation of *mariner* insertions (see next section).

1. Pellet 3 to 4 ml of an overnight culture at an OD_{600} of ~ 1 .
2. Resuspend pellet in 500 μl of STE buffer (20 mM Tris-HCl [pH 7.5], 75 mM NaCl, 25 mM EDTA [pH 8.0]).
3. Add lysozyme to a final concentration of ~ 1 mg/ml (10 μl of a 50-mg/ml stock), mix by inversion, and incubate at 37°C for 30 min.
4. Add 50 μl of 10% sodium dodecyl sulfate (about 0.1 volume) and mix by inversion.
5. Add 15 μl of a 20-mg/ml stock of proteinase K, mix by inversion, and incubate at 55°C for 30 to 60 min.
6. Add 1/3 volume of 5 M NaCl (~ 190 μl) and mix by inversion.
7. Add 1 volume of chloroform (~ 760 μl) and mix by inversion until milky. Allow layers to separate for 2 to 3 min and mix once more.
8. Centrifuge for 5 to 10 min at $5,000 \times g$ in a microcentrifuge.
9. Carefully transfer the upper aqueous layer (~ 700 μl) to a new tube (avoid cell debris at the interface). Add an equal volume of isopropanol (~ 700 μl) and mix by inversion until DNA precipitates.
10. Centrifuge for 1 min at $15,000 \times g$ in a microcentrifuge and keep the white DNA pellet.
11. Wash DNA pellet with 750 μl of 70% ethanol and repeat step 10.
12. Air-dry the pellet on the bench or at 37°C for ~ 5 to 15 min.
13. Gently resuspend DNA pellet in ~ 100 μl of sterile ddH_2O or other suitable buffer (Tris-EDTA or 10 mM Tris-HCl [pH 8.0]). Typical yield should be ~ 1 to 2 $\mu\text{g}/\mu\text{l}$.

Protocol 4. Isolation and Identification of *mariner* Insertions

This procedure is based on that reported by Youderian et al. (92).

1. Isolate genomic DNA according to protocol 3.
2. Digest 1 μg of genomic DNA in 20 μl using 10 to 20 units of an appropriate restriction enzyme. (Generally SacII or BssHII is chosen because they do not cleave within *magellan4* and cleave the high-GC myxobacterial DNA more frequently.)

3. Heat-inactivate enzyme following instructions from supplier.
4. Use 10 μ l of the digestion to set up a 25- μ l ligation reaction. Incubate at 15°C for 4 h to overnight.
5. Use 4 to 5 μ l of the ligation mixture to transform λ pir *E. coli* such as DH5 α λ pir (71). Use electrocompetent cells or cells of high competence if prepared chemically.
6. Plate cells on LB plates with appropriate antibiotic.
7. Prepare plasmid DNA from the transformants.
8. Identify disrupted gene by sequencing using primers complementary to the left and right arms of *mariner*:
 - a. Mar1 (left): 5' CGCCATCTATGTGTCAGACCGGGG
 - b. Mar2 (right): 5' TGTGTTTTTCTTTGTTAGACCG

18.3.2. Random Mutagenesis through Homologous Recombination

A method based on homologous recombination provides an alternative to transposons for generating random insertions in myxobacteria (17). Cho and Zusman developed this method to identify genes important for development, and it has been used successfully to identify other genes (16, 17, 53). A plasmid library is constructed by cloning random genomic DNA fragments (~500 bp) into the *E. coli* plasmid pZerO-2 (Table 1), which is unable to replicate in *M. xanthus*. The library is electroporated into *M. xanthus* to create insertion mutations through homologous recombination. The mutations are identified by cloning the plasmid with flanking DNA in a similar fashion to that described for *mariner* insertions (see protocol 4).

TABLE 1 Selected plasmids for myxobacteria

Plasmid	Relevant characteristics	Reference
For integration by homologous recombination		
pZerO-2	Cloning vector, Kan ^r	33a
pBGS18	Cloning vector, Kan ^r	76
pBR322	Cloning vector, Tet ^r	7
Phage attachment for <i>M. xanthus</i>		
pWB200	<i>intP/attP</i> (Mx8), Kan ^r	91
pSWU19	<i>intP/attP</i> (Mx8), Kan ^r	87
pSWU30	<i>intP/attP</i> (Mx8), Tet ^r	9
pYC274	<i>intP/attP</i> (Mx8), Kan ^r	29
pKOS249-31	<i>intP/attP</i> (Mx9), Bleo ^r	37
Allelic exchange		
pBJ113	Kan ^r - <i>galK</i> cassette	39
pSWU35	Kan ^r - <i>sacB</i> cassette	88
Replicative		
pZJY41	<i>M. xanthus</i> replicative, Kan ^r	93
pZJY156	<i>M. xanthus</i> replicative, Kan ^r	93
pRP-GFP	<i>S. cellulosum</i> replicative, Tet ^r , P _{epoA} -GFP	80
Expression for <i>M. xanthus</i>		
pDAH217	Light-inducible: P _{canQRS} - <i>lacZ</i> , Kan ^r	50
pLOJ4	IPTG-inducible: P _{pilA} - <i>lacO</i> , Kan ^r (requires pLOJ28)	36
pLOJ28	P _{pilA} - <i>lacI</i> , <i>intP/attP</i> (Mx8), Tet ^r	36
pCT2	Tet-inducible: P _{tetA} , <i>galK</i> , Kan ^r	57

18.3.3. Targeted Insertion Mutagenesis through Homologous Recombination

Homologous recombination can also be used to inactivate a specific gene by insertion. A short internal fragment of a gene is cloned into an *E. coli* plasmid, and chromosomal integration of the plasmid into myxobacteria by homologous recombination leaves two copies of the target gene truncated at the 3' and the 5' ends, respectively (Fig. 1). In practice, PCR is often used to amplify the internal fragment, which is then cloned into a plasmid with Kan^r such as pZerO-2 (Table 1). Essentially any *E. coli* plasmid with a selectable marker for myxobacteria will serve this purpose, since none can replicate in myxobacteria. Insertional mutant alleles can be verified by Southern blot or PCR. One limitation of this method is the difficulty of disrupting small genes due to the length requirement for homologous recombination in myxobacteria. Fragments larger than 500 bp are generally not a problem, but fragments less than 500 bp can be very troublesome, with success requiring greater amounts of DNA for electroporation and longer recovery periods after transformation (60). There have been no reports of success with fragments smaller than 250 bp. One should also be mindful of the polar effects of an insertional mutation on downstream genes when they are in an operon.

18.3.4. Allelic Exchange through Homologous Recombination

An alternative to insertion is to construct an in-frame deletion through allelic exchange, which avoids the drawbacks of polar effects of an insertion. In principle, an in-frame deletion of a gene is first constructed on a plasmid with a cassette that enables both a positive and negative selection in myxobacteria. The first such positive-negative cassette developed for *M. xanthus* is based on Kan^r and the *E. coli galK* gene (39, 81). Initial plasmid integration is selected by Kan^r (Fig. 2). The replacement of the wild-type allele with the in-frame deletion is achieved by a second homologous recombination event that leads to the loss of the plasmid DNA from the chromosome. The second event is selected for with medium containing galactose, because galactose is toxic

FIGURE 1 Schematic for insertional inactivation. An internal fragment of the gene to be disrupted is cloned into a nonreplicative plasmid for integration by homologous recombination (Table 1). Single homologous crossover between the fragment and the chromosome results in plasmid integration and a partial merodiploid with a 3' and a 5' truncation of the gene.

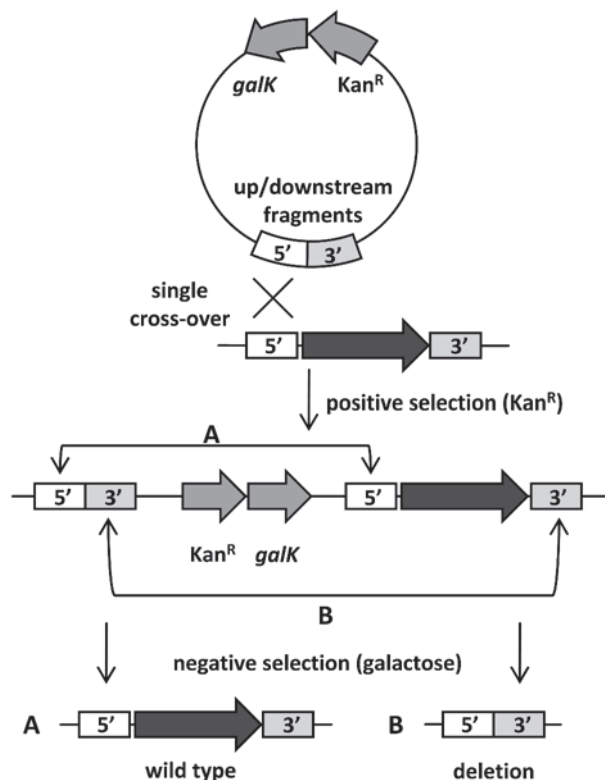

FIGURE 2 Diagram of allelic exchange to construct a deletion. A fragment containing the upstream and the downstream DNA of a gene (see text for details) is cloned into an allelic exchange plasmid (Table 1). The first round of homologous recombination, selectable by Kan^r, results in integration of the plasmid onto the chromosome. This may happen through the 5' or the 3' fragment. For simplicity, only integration through the 5' end is shown here. Kan^r transformants are plated for the selection of galactose resistance (negative selection) and the loss of the plasmid by a second round of recombination. Kanamycin-sensitive and galactose-resistant colonies may contain either the wild-type allele (A) or the deletion allele (B), depending on whether the second recombination occurred through the 5' or the 3' end, respectively.

to myxobacterial cells containing the *galK* product (galactokinase). Two outcomes are possible after plasmid loop-out (Fig. 2): restoration of the wild-type allele or its replacement by the deletion allele. PCR or Southern analysis can be used to identify which one occurred. In addition to *galK*, *sacB* from *Bacillus subtilis* has been used for negative selection (88), with sucrose used in place of galactose. The *sacB* system has been used in both *M. xanthus* and *S. aurantiaca*, while the *galK* system has only been used in *M. xanthus* (39, 83, 88). Both systems are likely applicable to *S. cellulosum* except that the Kan^r gene should be replaced with another marker suitable for *S. cellulosum*. Protocol 5 is a detailed protocol for making in-frame deletions in *M. xanthus*. A cautionary note here is that problems have been experienced by the authors and others with both the *galK*- and the *sacB*-based systems (88). The major issue is the emergence of galactose or sucrose resistance, apparently due to spontaneous mutations in the *galK/sacB* genes. It is therefore critical to test sensitivity to kanamycin before proceeding to mutant allele identification.

In-frame deletion alleles of a gene may be constructed in different ways. If a fragment with the full-length gene is

available, an internal fragment may be removed by restriction digestion and religation. A second method is to PCR amplify the upstream and the downstream regions of a gene, excluding the sequence to be deleted. For this method, the same restriction enzyme site is engineered into both the 3' end of the upstream fragment and the 5' end of the downstream fragment. These two can be digested with the same restriction enzyme, ligated, and cloned into a vector with the appropriate positive-negative selection cassette (Table 1). A third method that we use almost exclusively is to join the upstream and the downstream fragments by overlap PCR, as illustrated in Fig. 3 (61). The two fragments are PCR amplified first. Instead of a restriction site, the PCR primers are designed such that the 3' primer (R1) for the upstream fragment and the 5' primer (F2) for the downstream fragment are complementary for about 20 bp in sequence. The two PCR products are joined by a second-round PCR, which gives rise to the final PCR product with the designed deletion. The in-frame deletion alleles constructed by these methods are cloned into either the *galK*- or *sacB*-based selection plasmid (Table 1). It is desirable to ensure that the upstream and downstream fragments are of similar lengths. Otherwise, recombination will preferentially occur at the longer homologous sequence and result in a high percentage of wild-type alleles after the negative selection.

These positive-negative selection systems can also be used for the construction of point mutations through allelic exchange. This is similar to the construction of in-frame deletions described above. That is, the mutation is first constructed on a plasmid with the positive-negative selection cassette. The mutant allele is then used to replace the wild-type allele through two rounds of recombination. For the construction of the point mutation, an upstream and a downstream fragment with the desired point mutation are PCR amplified using complementary primers containing the desired mutation (R1 and F2 in Fig. 4). A second round of PCR is used to join the fragments, and the final PCR product containing the desired mutation is cloned into either the *galK*- or *sacB*-based selection plasmid (Table 1). It is always helpful to engineer a restriction site along with the point mutation to facilitate mutant identification in subsequent steps. When changing codons in myxobacteria, it is desirable to maintain a high-GC codon bias to ensure proper expression. Protocol 5 is a general protocol for performing allelic exchange in *M. xanthus* and should be applicable to other myxobacteria.

Protocol 5. Protocol for Allelic Exchange in *M. xanthus*

1. Transform ~0.5 to 1.5 μg of the plasmid with the mutant allele by electroporation as described in protocol 1. Allow recovery and plate on CYE with kanamycin. Incubate at 32°C for 5 to 7 days for colony formation.
2. Patch 5 to 10 colonies to a fresh CYE plate with kanamycin, and incubate for 1 to 3 days.
3. Transfer cells from the patches into 5 ml of CYE without kanamycin and thoroughly disperse cells. Cells may be incubated at 32°C with shaking at 300 rpm for several hours for better dispersion.
4. Plate cells using a series of 10-fold dilutions (i.e., undiluted to 10⁻⁵) onto CYE agar with 1% galactose (assuming a *galK*-based plasmid), and incubate at 32°C.
5. Allow 7 to 10 days for the appearance of galactose-resistant colonies.
6. Patch 20 to 30 galactose-resistant colonies onto CYE plates with galactose and patch these same colonies onto CYE plates with kanamycin.

FIGURE 3 PCR-based method for creating a deletion fragment. In the first-round PCR, primer pairs F1-R1 and F2-R2 are used to amplify the upstream and the downstream fragments individually. The 20 bases at the 5' end of primer F2 are complementary to primer R1. The fragments are gel purified, mixed, and subjected to the second round of PCR using only F1 and R2 to produce the deletion allele. For convenience, restriction sites may be engineered into primers F1 and R2 to facilitate cloning.

FIGURE 4 PCR-based method for introducing point mutations. In the first-round PCR, primer pairs F1-R1 and F2-R2 are used to amplify the upstream and the downstream fragments individually. Primers R1 and F2 contain the desired point mutation at the center and are fully complementary. It is desirable to engineer a restriction site within R1 and F2 for screening purposes in later steps. The fragments are gel purified, mixed, and subjected to the second round of PCR using only F1 and R2. For convenience, restriction sites may be engineered into primers F1 and R2 to facilitate cloning.

7. Analyze the galactose-resistant and kanamycin-sensitive isolates by PCR or Southern blot to identify mutants.

Note: If the mutant allele is constructed with a *sacB*-based plasmid, use 5% sucrose starting at step 4 instead of 1% galactose.

18.4. GENETIC MAPPING AND LINKAGE ANALYSIS IN MYXOBACTERIA

Genetic mapping and linkage analysis may be performed using generalized transduction or genomic DNA transformation by electroporation in *M. xanthus*. This is especially critical for the identification of point mutations from chemical or UV mutagenesis. Kuner and Kaiser used Mx4-mediated generalized transduction to link point mutations to Tn5 insertions (48). In principle, Tn5 or a *mariner*-based transposon is randomly inserted onto the chromosome. If an insertion occurs near the mutation of interest, the mutation will cotransduce with the insertion at a detectable frequency. The frequency of cotransduction is proportional to the distance between the mutation and the transposon insertion. That is, the shorter the distance between two markers, the more likely they will be cotransduced. Given that Mx4 and Mx8 package about 40 kb of DNA, the distance between two markers can be calculated from their cotransduction efficiency using the following Wu equation (89):

$$\begin{aligned} \text{frequency of cotransduction} \\ = [1 - (\text{distance between markers}/40 \text{ kb})]^3 \end{aligned}$$

As mentioned in section 18.2.2, transformation by electroporation using genomic DNA may be a viable alternative to transduction for linkage analysis (82). However, in this case, the integrity of the genomic DNA or lack thereof will influence the cotransformation frequency. It is not yet possible to calculate the distance between two markers from genomic DNA transformations, due to the lack of systematic studies.

18.5. HETEROLOGOUS GENE EXPRESSION IN MYXOBACTERIA

There are two areas of development that have made it possible to express desired genes in myxobacteria. The first is the ability to stably maintain exogenous DNA. The second is the availability of regulated promoters. The following section will focus on these two aspects, with an emphasis on heterologous gene expression.

18.5.1. Integrative Plasmids

Integration onto the chromosome is an effective way to maintain heterologous genes in myxobacteria. This can be achieved in two ways. The first is integration via phage attachment sites. The second is by homologous recombination.

The first phage attachment site used for the construction of integrative plasmids for *M. xanthus* was from the temperate phage Mx8 (51, 55). It was determined that the Mx8 *intP* gene itself contains all the necessary components required for integration, including the *attP* attachment site and the integrase gene (79). One problem with Mx8 is that integration of genes at the Mx8 *attB* site results in reduced gene expression (51, 85). More recently, an integrative plasmid containing the Mx9 phage integrase and attachment site was constructed (37). Mx9, a relative of Mx8, also contains all the necessary components for integration within the *intP* gene. Unlike Mx8, integration of genes at either of the two Mx9 *attB* sites does not result in an obvious

reduction in gene expression (37). Integration of Mx8 *attP* plasmids in *S. aurantiaca* has been reported, although it appears to result in developmental defects (59). See Table 1 for a list of plasmids with Mx8 and Mx9 attachment sites.

In addition to using native phage attachment sites, the ϕ C31 and ϕ BT1 attachment sites from *Streptomyces* phages (3, 26, 52) have been successfully utilized for integration of plasmids into the chromosome of *M. xanthus* (Julien, unpublished). Because integration of these phages requires only the *Int* protein, *attP* and *attB*, and no host factors, they have been developed as integration systems for a variety of *Streptomyces* (3) and other organisms, including eukaryotes (27, 28, 78). Insertion of the ϕ C31 and ϕ BT1 *attB* site into the chromosome of *M. xanthus* results in highly efficient integration of vectors harboring the corresponding *attP* sites and *int* genes. For ϕ C31, integration can occur at a low frequency in the *M. xanthus* chromosome without *attB*. This nonnative integration occurs at pseudosites, four of which have been identified in *M. xanthus* (Julien, unpublished). These sites can be engineered into any myxobacteria to provide a highly efficient means of integrating DNA into the chromosome for stable maintenance.

In some cases, it may be advantageous to integrate genes of interest at a site other than *attB*. This can be accomplished through homologous recombination by providing myxobacterial sequences on a plasmid. Strategies for both single crossover and allelic exchange have been devised for this purpose. Section 18.5.3 provides some examples.

18.5.2. Replicative Plasmids for Use in Myxobacteria

Self-replicating plasmids are now available for *M. xanthus*. Zhao et al. recently isolated a cryptic plasmid from *Myxococcus fulvus* (93). An ~2-kb fragment from this plasmid was found to contain the minimal region with an origin of replication. This fragment was used to successfully construct a couple of *E. coli*-*M. xanthus* shuttle vectors (Table 1). Although the initial constructs appeared somewhat unstable in *M. xanthus*, stable derivatives were isolated after passages through *M. xanthus*. These plasmids, which are maintained at approximately 10 copies per cell, provide promising leads for the development of heterologous expression systems in myxobacteria.

In addition, a broad-host-range plasmid (Table 1) that allegedly replicates autonomously in *S. cellululosum* strain So ce90 has been reported (80). This plasmid was able to express green fluorescent protein (GFP) in *S. cellululosum* and, as such, could be useful as a heterologous gene expression plasmid. However, this plasmid belongs to the IncP (RK4 derivative) incompatibility group with no additional origin of replication. Other IncP group (RP4 derivatives) plasmids were previously used as suicide vectors in both *M. xanthus* and *S. cellululosum* (11, 34, 35, 73). Since the 900-bp promoter driving GFP expression in the RK4 derivative (80) is from *S. cellululosum*, this plasmid has the potential to integrate by homologous recombination. This claim of autonomous replication may need further verification.

18.5.3. Regulated Gene Expression Systems for Use in Myxobacteria

Several systems have been used for regulated gene expression in *M. xanthus* (Table 1). The light-inducible *carQSR* promoter (P_{carQRS}) was the first described (32, 50, 56). P_{carQRS} , native to *M. xanthus*, was discovered through studies of carotenoid biogenesis in this bacterium. This promoter has relatively low basal activity and can be induced approximately 50- to

100-fold by light (32, 50). For maximal induction, genes to be expressed should be cloned downstream of P_{carQRS} and integrated at the $carQRS$ locus, not at the Mx8 $attB$ site (85). The major limitation of this system is the difficulty of exposing fermentation-scale cultures to light for the induction. The regulation of P_{carQRS} requires at least two proteins, CarQ (sigma factor) and CarR (anti-sigma factor), which may limit its use in species other than *M. xanthus*.

Another inducible promoter for *M. xanthus* was constructed using the *lac* regulatory element from *E. coli* (36). In this system, a *lac* operator was placed downstream of the strong and constitutive *pilA* promoter to make it LacI responsive. *lacI* is expressed from an additional *pilA* promoter integrated at the Mx8 $attB$ site using pLOJ28 (Table 1) (36). For heterologous expression, a gene can be cloned downstream of the engineered *pilA* promoter in pLOJ4 (Table 1) (36). The construct with the foreign gene can be integrated at the *pil* locus through homologous recombination. This system allowed very high levels of induction, although the basal level of expression is relatively high. In addition, this dual plasmid design requires integrations at both the Mx8 $attB$ site and the *M. xanthus pil* locus, which may limit its use to *M. xanthus*.

The *tetR-tetA* regulatory system from *E. coli* (86) was used recently to engineer another regulated promoter in *M. xanthus*. Mignot et al. (57) constructed pCT2 (Table 1), an integrative plasmid carrying a fragment with the *tetR* repressor and the *tetA* promoter (P_{tetA}) followed by a multiple cloning site. This fragment is flanked on both sides by sequences from the *car* locus to allow integration by homologous recombination at the *M. xanthus car* locus. The basal level of expression appears low, and expression can be induced by anhydrotetracycline at nanomolar concentrations without any toxic effects on the cells (57). Two nice features of this system are particularly noteworthy. The first is that correct integration at the *car* locus can be easily identified because the disruption of *car* genes leads to colony color changes on plates. Second, pCT2 carries *galK* for negative selection for the removal of the plasmid backbone along with Kan^r from the chromosome by selection on galactose. This eliminates the Kan^r marker and leaves behind the expression system intact at the *car* locus. On the other hand, the requirement for integration at the *car* locus may limit its use to *M. xanthus*. However, the *E. coli tetR* repressor and P_{tetA} are functional in *M. xanthus* with minimum modification. Since both elements are carried on the same DNA fragment, it is probably relatively easy to adapt this TetR- P_{tetA} system for use in other myxobacteria.

An additional inducible system utilizes the strong T7A1 promoter from the *E. coli* phage T7. This promoter utilizes the host RNA polymerase and not the T7 RNA polymerase. To regulate the T7A1 promoter, a version was engineered to contain two LacI binding sites to allow regulation by isopropyl- β -D-thiogalactopyranoside (IPTG) in *E. coli* (20, 49). To use this promoter in myxobacteria, a plasmid has been constructed with this modified T7A1 promoter along with the *lacI* gene under the control of the strong constitutive promoter from the epothilone biosynthetic gene cluster (P_{epo}). Fusion of this inducible promoter to *lacZ* reveals very little expression of β -galactosidase in the absence of induction in *M. xanthus*, while in the presence of IPTG, very high levels of expression are achieved (Julien, unpublished). This plasmid has been used to regulate the expression of *epoK* in both *M. xanthus* and *S. cellulosum* that produce epothilone D. In the presence of IPTG, the induced EpoK protein can effectively convert epothilone D to epothilone B (Julien, unpublished).

APPENDIX: STANDARD GROWTH MEDIA FOR SELECTED MYXOBACTERIA

M. xanthus

CYE medium (15) (per liter)	
Casitone	10 g
Yeast extract.....	5 g
MgSO ₄ ·7H ₂ O.....	1 g
MOPS (morpholinepropanesulfonic acid).....	10 mM

A MOPS stock at 1 M can be prepared and adjusted to pH 7.6 with KOH. Standard CYE plates contain 1.5% agar.

S. aurantiaca

Tryptone medium (64) (per liter)	
Tryptone.....	10 g
MgSO ₄ ·7H ₂ O.....	1 g

Adjust pH to 7.2. Standard tryptone media plates contain 1.5% agar.

S. cellulosum

307 medium (per liter)	
Casitone	9 g
Fructose.....	3 g
MgSO ₄ ·7H ₂ O.....	0.5 g
CaCl ₂ ·2H ₂ O.....	0.5 g
HEPES	12 g

Adjust pH to 7.6.

S42 plates (per liter)	
Tryptone.....	0.5 g
MgSO ₄ ·7H ₂ O.....	1.5 g
CaCl ₂ ·2H ₂ O.....	1 g
HEPES	12 g
K ₂ HPO ₄	0.06 g
Fe-EDTA.....	0.008 g
Glucose.....	3.5 g
(NH ₄) ₂ SO ₄	0.5 g
3.5% spent liquid medium	
Sodium hydrosulfite.....	0.1 g
Agar	15 g

Adjust pH to 7.4.

Strain Improvement of *Escherichia coli* To Enhance Recombinant Protein Production

MICHAEL E. PYNE, KARAN S. SUKHIJA, AND C. PERRY CHOU

19

Among many host systems developed for recombinant protein production, the gram-negative bacterium *Escherichia coli* still retains high popularity due to several technical advantages. First, its fast growth rate and superior environmental adaptability allow *E. coli* to be cultured easily, inexpensively, and if necessary, to a high cell density. Second, its genome-encoded proteins and metabolic pathways are well characterized. Third, numerous technologies and protocols for engineering *E. coli* strains are well developed. Fourth, heterologous proteins of interest can be expressed to high levels (up to 50% of total cellular protein). However, *E. coli* also has technical limitations in recombinant protein production. For example, many human therapeutic proteins require specific glycosylation for full bioactivity. These proteins cannot be produced in *E. coli*, which does not perform such glycosylation, although in some cases it has been possible to engineer a glycosylation pathway in *E. coli* (28). Also, many eukaryotic proteins have multiple domains or disulfide bonds and cannot be functionally expressed in *E. coli* primarily because the organelles and mechanisms in eukaryotic cells for assembling such highly complex protein structures are missing in *E. coli*.

The wild-type *E. coli* cell is not optimally designed for industrial applications. Hence, developing a bioprocess often starts with the construction of the host/vector system so that the *E. coli* strain can be genetically transformed and phenotypically suitable for biomanufacturing. Since the gene of interest is heterologously expressed along with cell growth during the cultivation stage for recombinant protein production, high-level gene expression and high-cell-density cultivation have to be performed simultaneously in order to optimize the culture performance. After cultivation for recombinant protein purification, either the cell pellet (for recombinant proteins retained intracellularly) or the extracellular medium (for recombinant proteins released extracellularly) is harvested and a series of downstream bioprocessing steps are carried out. Experience over the past few decades has shown that most biomanufacturing issues arising at various bioprocessing stages can be addressed through genetic manipulation of the host/vector system. It is the most effective and economic approach to enhance recombinant protein production in terms of mediating functional expression, increasing protein yield, and facilitating downstream purification. However, factors associated with the genetic mechanisms (i.e., replication

and gene expression steps) and bioprocessing conditions are often tangled in an unpredictable manner, resulting in complications in strategy development.

Various technical issues that potentially limit recombinant protein production in *E. coli* and the corresponding strategies to address them are summarized in Table 1. Many of these strategies involve alleviating (or even eliminating) the obstacle or limitation associated with a particular bioprocessing stage (i.e., gene expression, cell cultivation, or downstream processing) or with the recombinant protein itself. Typically, the biotechnological basis for strain improvement to enhance recombinant protein production relies on the permanent implementation of desirable traits into the production strain to stimulate both cell growth and functional expression of the target gene during the cultivation (Fig. 1). This is done by genetic restructuring of the production strain, involving both expression vector construction and genetic modifications to the host genome using either recombinant DNA technology, classical mutagenesis and screening technology, or both. Since genetic manipulation of *E. coli* host/vector systems is extensively described in the literature, this chapter reviews the major technical issues associated with *E. coli* strain engineering to enhance recombinant protein production and directs the reader to protocols appropriate for specific applications.

19.1. CONSTRUCTION OF EXPRESSION VECTORS

19.1.1. Genetic Elements of Expression Vectors

Heterologous gene expression in *E. coli* typically involves two major intracellular molecular mechanisms, namely, (i) replication of the expression vector and (ii) expression of the target gene, which includes transcription, translation, and posttranslational processing steps (Fig. 2). To improve a strain for recombinant protein production, effective replication should be ensured such that a high dosage of the target gene is maintained in all the cells of the population. Various genetic elements found in a typical expression vector used for recombinant protein production in *E. coli* are shown schematically in Fig. 3. The functions of each element and a list of common features are summarized in Table 2. Basically, these genetic elements are in place to increase the gene dosage and the efficiency of transcription, translation,

TABLE 1 Factors limiting recombinant protein production in *E. coli* and corresponding strategies for overcoming these limitations

Stage	Limiting events	Strategies for strain improvement	Reference(s)
Gene expression			
Replication	Plasmid instability	Genetically stabilize the plasmid, apply proper culture conditions	7, 39
	Gene dosage	Use a high-copy-number plasmid	35, 99
Transcription	Transcriptional efficiency	Use a strong inducible promoter	11, 95
	Promoter leakage	Use a tightly regulated promoter or other genetic configurations	37, 91
Posttranscriptional stage	mRNA secondary structure near the 5' terminus	Optimize gene sequence	53, 108
Translation	mRNA stability	Use an RNase-deficient mutant	48, 64
	Translational efficiency	Optimize the Shine-Dalgarno sequence for optimal binding of ribosome, optimize coding sequence	26, 53, 108
Posttranslational stage	Ribosome availability	Enhance the production of functional ribosome	104, 109
	tRNA availability (codon bias)	Coexpress the rare tRNA gene, optimize the codon	53, 108
	Protein translocation	Use a proper signal peptide	18
	Protein folding	Coexpress chaperones, use a low culture temperature, use protein fusion technology, secrete the protein into the extracellular medium	43, 51, 56, 82
	Protein disulfide bond formation	Secrete the protein into the periplasm or extracellular medium, coexpress factors involved in disulfide bond formation, use a mutant that can form disulfide bonds in the cytoplasm	24, 51
	Proteolysis	Use a protease-deficient mutant, use protein fusion technology, perform extracellular protein secretion	4, 32, 97
	Glycosylation	Use a genetically engineered strain	57, 84
Cultivation			
Cultivation	Physiological deterioration	Eliminate various deterioration factors	8, 30
	Heat shock responses	Manipulate heat shock responses	15, 110
	Nutrient uptake	Avoid nutrient overfeeding	61
	Toxic metabolite accumulation	Reduce the accumulation	17, 23
	Growth inhibition	Eliminate inhibitory factors	54, 76
	Downstream processing	Extracellular protein secretion	Use a proper secretion strategy
Protein recovery		Use protein fusion technology	97
Protein solubility		Use protein fusion technology, modify the protein sequence	66, 97
Protein feature			
Protein feature	Toxicity	Use a tightly regulated promoter to prevent expression leakage	37, 91
	High complexity and difficult expression	Use a special strain for functional expression	71, 105
	Proteolysis	Modify protein sequence	75

and posttranslational processing so that the target gene can be functionally expressed at a high rate. The copy number of the expression vector is intrinsically determined by the replication origin. A strong inducible promoter is required to increase the transcriptional efficiency and boost the mRNA level. Because of the coupling of transcription and translation, recombinant protein production is often improved simply by using a strong promoter. It may be necessary that the promoter be tightly regulated to avoid leaky expression

under noninduced conditions, which is particularly important for proteins with a high toxicity. The molecular details of the transcriptional regulation mechanism and whether it involves an activator or repressor can be very important for achieving maximum production. The terminator used is also important to ensure proper termination of transcription of the target gene, since transcription running past the target gene can interfere with other functions of the expression vector. The ribosome binding site and sequences near

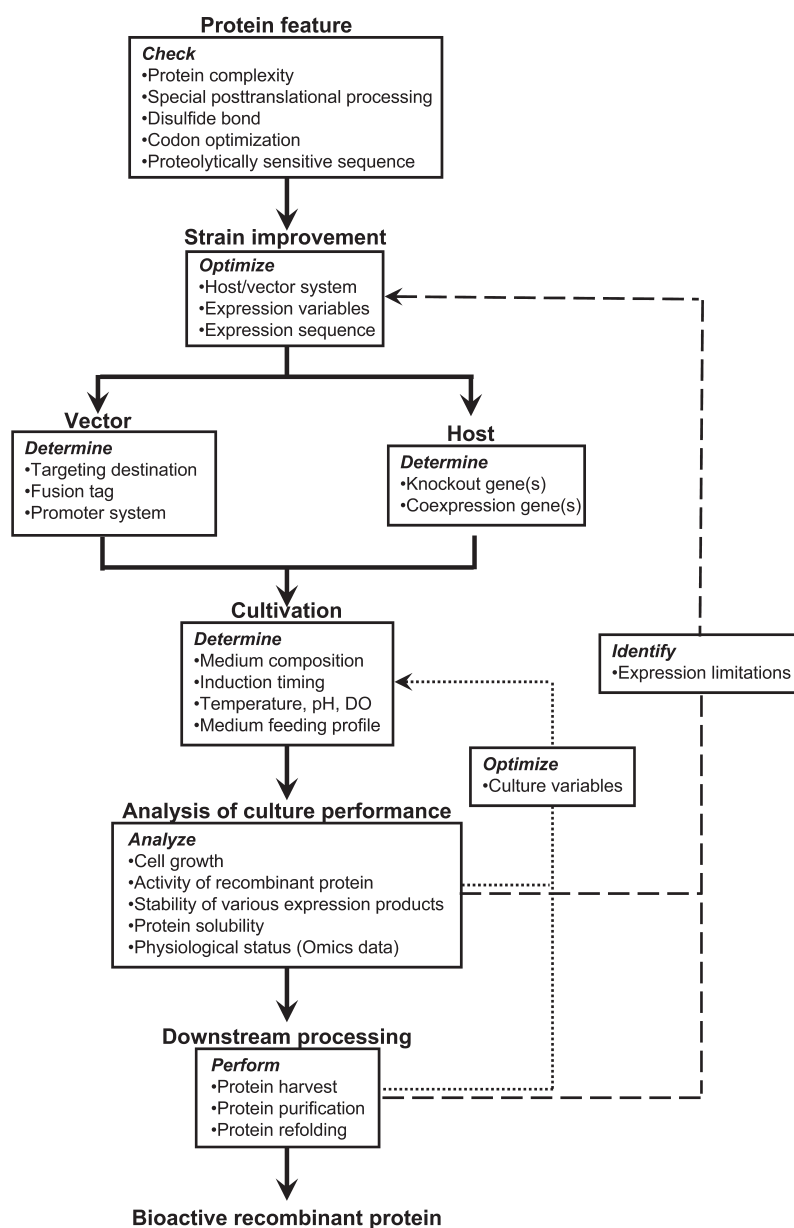

FIGURE 1 Flowchart for *E. coli* strain improvement to enhance recombinant protein production. The strategies depend on identification of the specific factors limiting the overall recombinant protein yield and include optimization of the host/vector system, expression variables, and expression sequence. Refer to Table 1 for a list of technical limitations and how to deal with them. DO, dissolved oxygen.

the start codon affect the efficiency of ribosome binding to the target mRNA and the rate of translation initiation. The antibiotic resistance marker enables selection for cells harboring the expression vector. The fusion tag, situated either at the 5' or 3' end of the target gene (so that the expressed tag is fused with the N or C terminus of the target protein), offers several expression advantages, particularly for soluble expression and protein purification. Most expression vectors have multiple cloning sites to enable flexible cloning of various target genes with transcriptional or translational fusions for different expression scenarios (Fig. 3). Many expression vectors with a selection of these genetic elements are commercially available and significantly facilitate the

construction work. While the construction of the expression vector is considered a key step for recombinant protein production, developing an effective bioprocess also relies on a proper design of the expression host, cultivation, and downstream processing that are compatible with the expression vector.

19.1.2. Limiting Steps in Gene Expression

Recombinant protein production involves a series of molecular mechanisms that must be optimized, regulated, and coordinated. A malfunction at any of the steps (replication, transcription, translation, posttranslational processing, etc.) or the presence of various undesired events (such

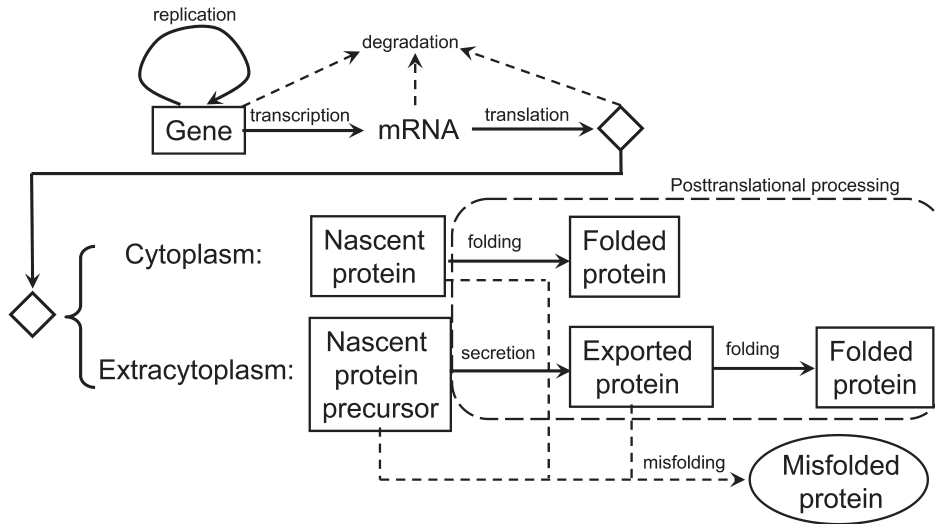

FIGURE 2 Molecular events associated with recombinant protein production in *E. coli*. Recombinant protein production involves a series of complex molecular mechanisms, such as replication of the expression vector, transcription and translation of the gene of interest, and various post-translational processing steps (including protein secretion, folding, and disulfide bond formation). Production can be limited by low efficiency at any one of these steps or by an abnormal event that diverts protein synthesis into a nonproductive pathway (e.g., protein misfolding or degradation of DNA, mRNA, or protein).

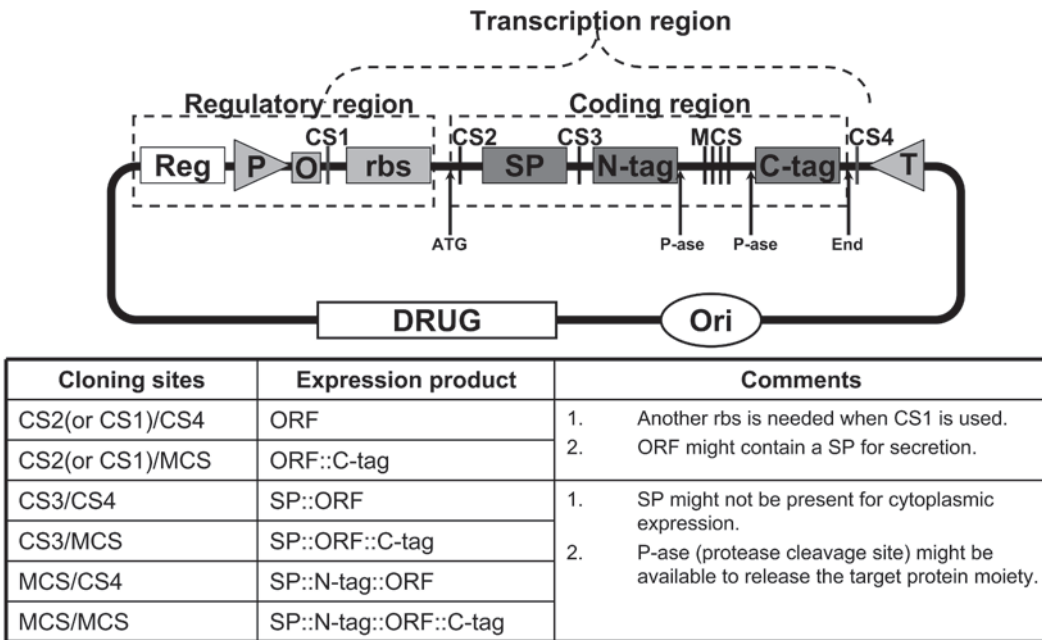

FIGURE 3 A typical *E. coli* expression vector (i.e., plasmid) for recombinant protein production. Several expression and cloning features are shown, including Reg (gene encoding the regulator, either transcriptional activator or repressor), P (promoter), O (operator), rbs (ribosome binding site), SP (signal peptide), N-tag (N-terminal fusion tag), C-tag (C-terminal fusion tag), T (terminator), CS (cloning site), MCS (multiple cloning sites), Ori (replication origin), DRUG (drug resistance gene), ATG (initiation codon encoding methionine), P-ase (protease cleavage site), and End (stop codon). Note that, depending on the cloning site(s) for insertion of a target gene (i.e., open reading frame [ORF]), a transcriptional or translational fusion vector can be constructed to express a gene product (either ORF or ORF-fusion) containing various feature domains and targeting in the cytoplasm or extracytoplasmic compartment.

TABLE 2 Genetic elements found in a typical expression vector used for recombinant protein production

Element	Common features	Function(s)
Origin	pUC, pMB1, ColE1, p15A, pSC101	Regulate gene dosage
Promoter	T7, <i>araB</i> , <i>lacUV5</i> , <i>tac</i> , <i>trc</i> , <i>tetA</i> , λ_L , λ_R	Enhance transcriptional efficiency
Terminator	<i>rmB</i> T1, T2	Ensure transcriptional termination
Regulator	Transcriptional activators or repressors	Regulate transcriptional efficiency
Ribosome binding site	Shine-Dalgarno sequence, translational enhancer	Improve translational initiation
Drug marker	Ampicillin, chloramphenicol, tetracycline, kanamycin	Select the transformed cell
Signal sequence	Tat, TorA, OmpA, PhoA, PelB, SpA	Translocate the protein precursor across the cytoplasmic membrane
Tag	Streptavidin-binding peptide (Strep), poly-histidine, FLAG peptide, DsbA, DsbC, thioredoxin (TRX), glutathione S-transferase (GST), maltose-binding protein (MBP), N-utilization substance protein A (NusA), calmodulin binding peptide (CBP), small ubiquitin-like modifier (SUMO)	Facilitate protein purification, improve protein solubility

as degradation or misfolding of the target protein) can jeopardize the production process (Fig. 2). A high yield of bioactive protein implies not only a high rate for all the expression steps (i.e., fluxes), but also coordination of various intracellular events to balance these expression fluxes. Typically, for a particular host/vector system under a specific growth condition, overall performance can be limited by a single expression step, which can result in the accumulation of an inactive intermediate prior to the limiting step or a reduced level of the intermediate after that step. Theoretically, strategies based on enhancing the limiting step can lead to an overall improvement in recombinant protein production. For example, transcription is recognized as a common step limiting the abundance of mRNA for subsequent translation. A stronger promoter can boost the mRNA level through increased transcriptional efficiency, and the recombinant protein yield is often increased as a result. In addition to the high expression rate, all the expression intermediates (i.e., mRNA and protein precursors) and the final gene product should remain stable in order to achieve a high protein yield during the production. There are cases where one or more of these intermediates are subject to intracellular degradation and recombinant protein production is reduced as a result. Strategies to stabilize these labile biomolecules can be developed for strain improvement.

While the limiting step is determined by the intracellular genetic makeup of the host/vector system, it is prone to change depending on the transient physiological state. This implies that the strategies for genetic construction of the production strain and for its biological cultivation should be simultaneously configured to optimize the culture performance for recombinant protein production. Technically, it is important that the limiting step be properly identified since improving the efficiency of that step should enhance the overall expression performance. However, improving a single expression step can simply shift the limitation to a different step, giving little to no improvement in the overall recombinant protein yield. For example, though the transcriptional efficiency can be enhanced by using a strong inducible promoter, the boosted mRNA level does not necessarily lead to the increased production of the target protein due to the limitation from another expression step, such as translation or protein folding. Even more troublesome,

the genetic strategy used to resolve one limiting step might actually cause the development of another limitation. For example, the presence of high-copy-number plasmids to increase the gene dosage or the induction of strong promoters to enhance the transcriptional efficiency could negatively affect the physiological condition of the producing cells, resulting in growth inhibition and a reduced recombinant protein yield. Such complications often limit the applicability of these genetic strategies.

19.1.3. Localization of Recombinant Protein

Another key issue for recombinant protein production in *E. coli* is the location to which the final protein product should be targeted, including the cytoplasm, periplasm, cell surface, or extracellular medium. This is determined by various factors associated with the recombinant protein, such as its susceptibility to intracellular proteolysis, its tendency to misfold, the requirement for disulfide bond formation, and the process used for downstream protein purification. While the cytoplasm is the intracellular compartment where all the nascent proteins are first synthesized and where most of them reside, it might not be a suitable destination for a recombinant protein. Therefore, the target gene product might require the secretion to either the periplasm or extracellular medium for functional expression (18, 32). The periplasm provides an oxidative environment that allows disulfide bond formation, as well as a separate compartment from the cytoplasm for facilitating protein purification. The expression of a recombinant protein on the *E. coli* cell surface is performed only for special applications other than mass production (62). Secretion to the extracellular medium is an alternative strategy for functional expression of recombinant proteins that are otherwise difficult to express intracellularly due to technical limitations such as protein misfolding or disulfide bond formation. With the host/vector system acting as a whole-cell biocatalyst, extracellular secretion enables the continuous production of recombinant protein and facilitates downstream purification. However, recombinant protein yields are often low when secretion is involved.

There are two major structural barriers to protein secretion, the cytoplasmic membrane and the outer membrane. Protein translocation across the cytoplasmic membrane is usually driven by the Sec-dependent type II secretion

pathway under the direction of a cleavable signal peptide at the N terminus of the secreted polypeptide. Technically, a DNA sequence encoding a signal peptide can be attached at the 5' end of the open reading frame encoding the target protein to form a translational fusion. The expressed polypeptide precursor is expected to be translocated across the cytoplasmic membrane under the direction of the signal peptide. Several signal peptides (see Table 2) have been adopted successfully for exporting recombinant proteins into the periplasm or onto the outer membrane of *E. coli*. Very few *E. coli* proteins pass the outer membrane and are secreted extracellularly. Two other secretion pathways (i.e., type I and type III) are known to be responsible for the extracellular secretion of certain *E. coli* proteins without involving a periplasmic intermediate (10, 98). Although biochemical and genetic strategies (36, 90, 102, 106) based on permeabilizing the outer membrane have been developed for the extracellular release of periplasmic proteins (which are typically exported from the cytoplasm via the type II secretion system), they often impair cell physiology and reduce productivity. The type I and type III secretion systems have been successfully used to secrete target proteins extracellularly, though the host/vector system often requires a specific design (9, 22, 29, 101).

19.1.4. Protein Fusion Technology

Protein fusion technology serves as a powerful tool with multiple applications for recombinant protein production (97). Basically, the target gene product is expressed as a fusion protein, where the fusion tag does not affect the bioactivity of the target protein. The typical fusion tag is one that can be captured by affinity chromatography, greatly facilitating downstream purification. In addition, a specific cleavage site can be engineered at the junction between the two fusion partners so that the target protein can be released as the native protein. While such tags theoretically can be fused with the target protein at either the N or C terminus, the N terminus is more often used because many N-terminal tags contain local DNA sequences optimized for translational initiation. With an appropriate design, the production of fusion protein can be enhanced. Furthermore, several fusion tags have been demonstrated to promote protein folding because they can rapidly attain their native conformation. As a result, the solubility and stability of a fusion protein are often superior to the heterologous protein alone (107). In some cases, particularly with a small tag, the target protein retains its bioactivity and can be used without removing the tag.

19.1.5. Protein Misfolding

Another common technical issue for recombinant protein production in *E. coli* is protein misfolding, which results in loss of bioactivity. The problem can be viewed as the expression flux imbalance between polypeptide formation and polypeptide processing at any posttranslational stage (including folding). Such imbalance diverts protein synthesis into a nonproductive pathway and results in the accumulation of misfolded protein species, which typically aggregate into insoluble inclusion bodies that are inactive. Inclusion bodies can be formed in either the cytoplasm or periplasm. Factors that can cause this expression flux imbalance and protein misfolding include heat shock, high protein concentration, certain amino acid sequences within the expressed protein, and physiological stress on the cells. Some of the strategies that can be used to alleviate this problem include lowering the cultivation temperature or

coexpressing particular chaperones. However, in some expression scenarios, the formation of inclusion bodies is considered advantageous, particularly for toxic proteins, since inclusion bodies are often easy to harvest and are less toxic to the production cell. The use of inclusion bodies as an expression strategy hinges primarily on the ease of recovering bioactivity through *in vitro* protein refolding.

19.2. DEVELOPMENT OF THE EXPRESSION HOST

19.2.1. Genetic Modification

Enhancing recombinant protein production relies on the construction of a compatible host/vector system for effective expression of the target gene. Wild-type *E. coli* cells have several mechanisms to protect them from environmental stress, and these can be activated during high-level recombinant protein production. These natural safeguards can potentially limit performance in industrial applications. For example, several nucleases and proteases can be induced to digest foreign DNA and protein, respectively, in response to the physiological stress caused by recombinant protein production. Hence, the host strain requires genetic modification to improve its suitability for biomanufacturing through the implementation of desirable traits on either the host chromosome or expression vector. Thus, obstacles to recombinant protein production due to the natural safeguard mechanisms mentioned above can be eliminated or at least mitigated through appropriate genetic engineering.

19.2.2. Identifying the Targets that Require Genetic Modification

Essentially, genetic modifications involve changing the expression level of certain key genes. At one extreme native *E. coli* genes can be knocked out, and at the other extreme heterologous genes encoding a useful activity can be expressed. Expression vectors provide a flexible way to coexpress multiple genes and can be used for such genetic modification (100). If necessary, the expression level can be fine-tuned with tunable promoters (25) or gene-silencing mechanisms (48, 49). Identifying the key genes that can directly or indirectly affect recombinant protein production is one of the most critical and difficult aspects in developing the genetic engineering strategy. While individual genes of potential value are constantly being identified in many research programs and large-scale random overexpression projects (65), recent progress in transcriptomic and proteomic analyses offers a systematic approach for rapid identification of hundreds of such candidates (1, 31, 38, 83, 111). However, proper selection of the key genes among the candidates that might facilitate optimal engineering of the production strain remains challenging.

General methods for engineering microbial strains to derive desired phenotypes have been extensively reviewed (78, 88). Whole-organism mutagenesis followed by phenotypic screening and selection has been the classical strategy for obtaining desirable traits for biomanufacturing, such as increased product titer (yield or productivity) and greater physiological robustness under the overproduction conditions. Random mutations can be introduced by exposing the production strain to UV light or a chemical mutagen such as *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, or by random genome-wide transposon insertions (2). Multiple rounds of mutagenesis and screening are often required to optimize the strain. This approach can potentially identify

multiple mutation targets leading to the desired phenotype, and the targets can be related to the production pathway in obscure ways. Given the increasing accessibility of genomic sequencing services, such mutations can be identified and novel mechanisms relevant to recombinant protein production can be discovered. A major drawback with multiple rounds of mutagenesis and screening is that the process can be time-consuming and resource intensive. Furthermore, the result of identifying the manipulation targets might not be reproducible. While mutagenesis is easy to perform, establishing an effective screening protocol can be challenging. Recent development in high-throughput screening technologies with advanced analytical tools such as flow cytometry, chromatography, and mass spectrometry significantly improves the screening efficiency, particularly in the area of metabolic engineering applications. However, these approaches are often product specific.

19.2.3. Physiological Improvement

The metabolic burden arising from recombinant protein production can induce physiological stress and in turn reduce recombinant protein yield. One strategy to alleviate the impact of this burden is to mimic or boost the natural stress response, thus maintaining healthy cell physiology during recombinant protein overproduction (20). Several types of genes can be useful for this strategy, one example being those encoding chaperones, which are often induced during the heat shock response and assist with folding of damaged or misfolded proteins in the cytoplasm (5) or periplasm (72). These chaperones can enhance the solubility, structural stability, translocation/secretion efficacy, or even disulfide bond formation of the expressed gene products (41, 55, 87). Various proteases (cytoplasmic, periplasmic, or membrane-bound) are also induced during stress responses that degrade damaged or abnormal proteins. Such proteases can also degrade the desired recombinant protein (42) and therefore represent major targets for gene knockout. While there are reports of using protease-deficient mutants to improve recombinant protein production (69), knocking out a large number of protease genes for this purpose will result in a sick strain because *E. coli* requires these proteases for regulated protein turnover and physiological adaptation. Some have reported improvement in both cell physiology and recombinant protein yield via protease coexpression, which is presumably mediated by selective proteolysis of misfolded proteins that may be toxic (47, 77). Various stress-sensing pathways have been identified (27, 45, 63), and genes involved in this process can be logical targets for genetic modification. Stationary-phase genes encode proteins that may lead to a reduction in cellular and metabolic activity, which can negatively affect recombinant protein production, and as such, these genes are targets for strain improvement (19, 46). Other metabolic engineering strategies that have been used to improve a strain's adaptation to harsh production conditions include reducing the secretion of toxic metabolites (34, 103), boosting the nutrient assimilation rate (67), or increasing the supply of limiting cofactors (86).

19.2.4. Genotypes Suitable for Recombinant Protein Production

E. coli strains engineered for the application of recombinant DNA technology have been derived from both K-12 and B strains. The K-12-derived strains (e.g., DH5 α and JM109) often carry several endogenous mutations (e.g., *endA*, *recA*, and *lacZ*) specifically designed for molecular cloning pur-

poses, though they can also be used as a host for recombinant protein production. On the other hand, *E. coli* B strains, e.g., BL21 F⁻ *ompT dcm lon gal hsdS_B(r_B⁻, m_B⁻)* (95) and its derivatives, are probably the most common production strains primarily owing to the two mutations in protease genes, i.e., *lon*, encoding intracellular ATP-dependent protease, and *ompT*, encoding outer membrane protease, which can potentially alleviate the degradation of heterologous protein products. In addition, BL21 is less sensitive to glucose than K-12 strains (80) and can tolerate higher levels of metabolic stress associated with recombinant protein production (44), making it suitable for high-cell-density cultivation. These technical advantages may be related to its more integrated outer membrane structure, since it is observed that BL21 cannot be used as a suitable expression host for cell-surface display or extracellular secretion of recombinant protein (N. Narayanan and C. P. Chou, unpublished data).

Several genetic traits have been introduced into BL21 to improve its utility as a protein overproducer. The most popular is the genomic integration of a DE3 lysogen that contains the T7 RNA polymerase gene, expression of which is regulated by the *lacUV5* promoter. The resulting strain, BL21(DE3), can be used with expression vectors containing the T7 promoter system for overexpression of recombinant protein (96). Other genetic features have also been included in BL21 to enhance its tolerance against physiological impacts associated with recombinant protein production (particularly for toxic proteins). For example, the basal level arising from leaky expression during noninducing conditions is minimized by replacing the isopropyl- β -D-thiogalactopyranoside (IPTG)-inducible *lacUV5* promoter in DE3 with the *araB* promoter for tighter transcriptional regulation (14) (e.g., BL21-A1TM, available from Invitrogen [Carlsbad, CA]). Alternatively, a plasmid (pLysS or pLysE with a p15A replication origin) or a mini-F plasmid containing the gene encoding T7 lysozyme, which is a natural inhibitor of T7 RNA polymerase (94), can be included to minimize leaky expression [e.g., BL21(DE3) (pLysS) and BL21(DE3) (pLysE) from Novagen (Madison, WI) or NEB Express and T7 Express from NEB (Ipswich, MA)].

Another interesting approach is to challenge the expression host with a plasmid that overexpresses a toxic protein and then screen for mutants that gain the ability to produce the protein. C41(DE3) and C43(DE3) (available from Lucigen Corp. [Middleton, WI]) contain mutations that facilitate overexpression of certain membrane proteins and were derived from BL21(DE3) by this strategy (71). The mutations resulting in the improved expression performance of these strains were recently identified to be located in the *lacUV5* promoter, and the discovery led to the construction of a BL21(DE3) derivative, i.e., Lemo21(DE3), with a precise T7 RNA polymerase activity for tunable protein expression (105). Precise control of expression has also been achieved with a *lacY* mutation (e.g., TunerTM and OrigamiTM B from Novagen). It appears that precise control of the expression level of the heterologous gene of interest is critical for achieving maximum protein production.

Since T7 RNA polymerase synthesizes mRNA rapidly, resulting in the uncoupling of transcription and translation, transcripts are subject to degradation by endogenous RNases. Mutation of the *rne* gene, encoding RNase E, the major enzyme for RNA degradation (64), stabilizes such highly expressed mRNA transcripts, and BL21 strains with this mutation are available (e.g., StarTM from Invitrogen).

The *endA* gene encodes a nonspecific endonuclease, endonuclease I, which can degrade plasmid DNA prepared by

the typical mini-prep protocols. In addition, *recA* encodes an ATPase involved in homologous DNA recombination *in vivo* (6). K-12 strains often carry mutations in these two genes to maintain the structural stability and product quality of plasmid DNA for molecular cloning. These two mutations have been introduced into BL21 strains for large-scale production of plasmid DNA (79). Though the functions associated with the *recA* and *endA* gene products might seem to be required for healthy cell physiology, protein overexpression using such double-mutant BL21 strains (e.g., Acella™ from EdgeBio [Gaithersburg, MD]) does not seem to encounter any problems associated with recombination or DNA degradation. Furthermore, such strains allow both protein expression and molecular cloning to be conducted in a single host.

Overexpression of heterologous proteins can potentially result in transient shortage of amino acids and the corresponding charged tRNAs for translation, which in turn can lead to the problems discussed above due to uncoupling of transcription and translation. This physiological regulation, known as the stringent response (12, 40), can be relaxed by the *relA* mutation such that RNA is still synthesized in the absence of protein synthesis. On the other hand, protein overexpression can be limited by depletion of certain rare tRNAs, particularly for expression of genes having a codon bias significantly different from that of *E. coli* (92). This limitation can be alleviated by coexpressing genes for those rare tRNAs, such as *argU*, *proL*, *ileY*, and *leuW*. Several BL21-CodonPlus® (Stratagene [La Jolla, CA]) and Rosetta™ (Novagen) strains expressing these tRNA genes are available, and their use for recombinant protein production appears to be justified (50). Alternatively, the heterologous gene can be modified or completely synthesized to have the optimal codon usage of *E. coli* (53, 74, 108).

For certain eukaryotic or therapeutic proteins, heterologous overexpression is limited by posttranslational processing, such as disulfide bond formation, which can be crucial for a protein's bioactivity. Though *E. coli* contains the oxidative milieu of the periplasm, where disulfide bonds can be formed *in vivo*, targeting of proteins to this compartment can be limited by the efficiency of translocation or periplasmic folding. Hence, there is a desire for strains that can produce proteins containing disulfide bonds in the cytoplasm. However, the *E. coli* cytoplasm contains two thioredoxins and three glutaredoxins, all of which are maintained in a reduced state by thioredoxin reductase (TrxB) and glutathione. Consequently, disulfide bond formation hardly occurs in this reduced compartment. Introducing mutations in the genes for both thioredoxin reductase (*trxB*) and glutathione reductase (*gor*) (or glutathione synthetase [*gshB*]) can transform the reduced cytoplasm into an oxidized one (93). This double mutation in the BL21 background is found in the Origami™ B strains (Novagen), which offer an alternative for the overexpression of proteins containing disulfide bonds in the oxidative cytoplasm. However, cell growth appears to be impaired by this double mutation.

Another host feature that can be useful for downstream processing is genomic inclusion of the λ R gene, encoding the λ lysozyme (i.e., endolysin). The resulting strain (X)Jb Autolysis™ from Zymo Research Corp. [Orange, CA]) is efficiently lysed by arabinose induction.

Note that most of the above mutations are implemented with an antibiotic resistance marker, which limits the choice of markers for the expression vector. In practice, it will be more convenient to construct mutants without drug markers using chromosomal engineering strategies developed recently (21).

19.2.5. Chromosomal Engineering of *E. coli*

Chromosomal engineering refers to the techniques for making site-specific insertions, replacements, or deletions in the chromosome. With an extensive ability to knock out an existing gene or express a foreign gene, the technique becomes a powerful tool for strain improvement. The most common one, known as recombineering, is based on homologous recombination (Fig. 4). In general, exogenous DNA containing an allele of interest is first delivered into the recipient cell directly or via a shuttle vector (either plasmid or virus based) or conjugation. Because *E. coli* is artificially transformable, conjugation is seldom used for delivering the exogenous DNA. The efficiency for homologous recombination *in vivo* can be enhanced (e.g., by expressing exonuclease and recombinase) so that the key allele in the delivered DNA can be site-specifically exchanged with the corresponding genomic allele or can be inserted into the chromosome. A cotransduced drug marker is often used for selection of the mutant derivative, whose genotype can be verified by colony PCR or genomic sequencing. Several methods based on transposon mutagenesis and homologous recombination (21, 33, 73, 112–114) have been developed for genomic modification to construct *E. coli* strains. Very large fragments carried on bacterial artificial chromosomes can be inserted into the *E. coli* genome (58, 85). This is particularly useful for metabolic engineering of *E. coli*, since novel strains can be constructed that express entire pathways for nonnative metabolites. A comprehensive *E. coli* mutant library was made using the chromosomal engineering protocol involving the λ Red-mediated recombination system (21). Each gene in the chromosome was replaced with a kanamycin resistance cassette flanked by homologous regions to the target allele. This library of single-gene knockout strains is called the Keio collection (3) (www.shigen.nig.ac.jp/ecoli/strain/top/top.jsp). Each mutant gene in the Keio collection can be transferred via P1-phage transduction (70) from its original BW25113 background to other genetic backgrounds using kanamycin for selection. Furthermore, the kanamycin resistance cassette between two flanking FLP recombination target (FRT) sites can be removed via FLP recombination using a helper plasmid (16). This will allow the construction of drug-resistance-free strains with multiple gene knockouts. The establishment of the Keio collection and its availability to researchers worldwide have marked an important biotechnological milestone by significantly facilitating *E. coli* mutant construction. The recently commercialized recombineering protocol from Gene Bridges (Heidelberg, Germany; www.genebridges.com), also based on λ Red-mediated recombination, allows versatile chromosomal engineering, including gene disruption, deletion, insertion, point mutation, modification, and even promoter fine-tuning, and can serve as a versatile manipulation tool for strain improvement and even optimization.

Protocol 1. Gene Knockouts in *E. coli* Using λ Red-Mediated Recombination

This protocol is based on Datsenko and Wanner (21) using the *E. coli* K-12 strain. There are other similar recombineering methods that use plasmids containing different promoters and markers, but these protocols are also based on the recombinases from either the λ prophage or bacteriophage λ or both (58). Genetic modification using recombineering is not limited to chromosomal genes, but can

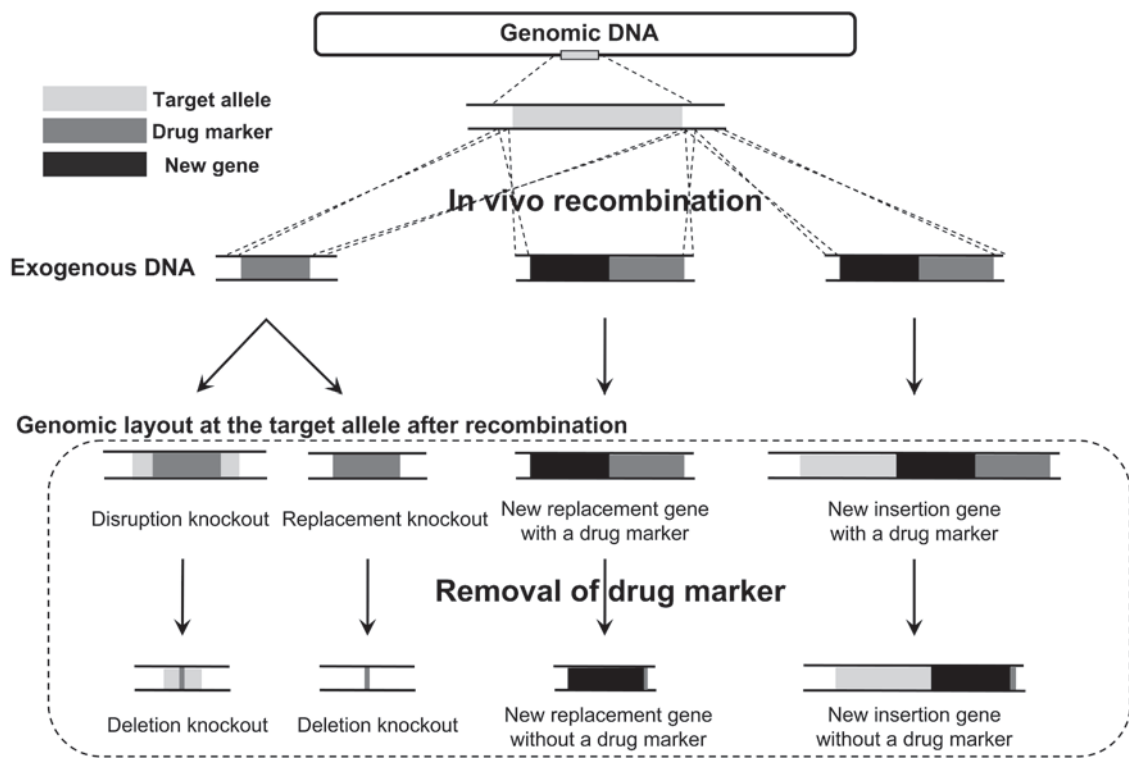

FIGURE 4 Chromosomal engineering of *E. coli* based on homologous recombination for either site-specific gene knockout or gene insertion. The target allele/site is first selected and the exogenous segment is prepared in vitro (e.g., by PCR). Because *E. coli* is artificially transformable, the exogenous DNA can be delivered into the recipient cell through electroporation. The efficiency of in vivo recombination can be enhanced by expressing key enzyme(s) associated with the recombination. A drug resistance marker is often introduced as the major replacing cassette or cotransduced with a new gene for selection of transformed cells, and can be subsequently deleted in vivo (e.g., by FLP recombination).

also be applied to extrachromosomal DNA molecules, such as plasmids and bacterial artificial chromosomes.

1. Obtain the set of recombinering vectors denoted pKD46, pKD3 (or pKD4), and pCP20.
2. Transform pKD46 into the *E. coli* strain containing the gene you wish to modify. The plasmid has a low copy number and a temperature-sensitive origin of replication, repA101. Thus, the cells should be incubated at 30°C during the transformation.
3. Design the primers for PCR amplification of the insertion cassette on a template plasmid (pKD3 or pKD4). The insertion cassette is flanked by approximately 35- to 50-bp homology extensions. These extensions are homologous to the sequences surrounding the chromosomal region to be replaced. The sense and antisense primers for the PCR should be designed such that the last 20 bp of each primer anneal to the insertion cassette to be amplified. The PCR product is gel purified, DpnI digested, and then repurified to ensure that all template plasmid is removed. The insertion cassette will contain the chloramphenicol resistance gene (for pKD3) or kanamycin resistance gene (for pKD4) between two FRT sites, which are used to remove the antibiotic resistance genes after recombination.
4. Make an electrocompetent cell suspension by growing a colony obtained from step 2 in LB medium containing 10% arabinose at 30°C to induce the expression of the three main λ Red genes on pKD46, *exo*, *bet*, and *gam*.
5. Electroporate approximately 0.5 to 1.0 μg of the insertion cassette prepared in step 3 into the electrocompetent cells by selection of the transformants on agar plates containing 34 $\mu\text{g}/\text{ml}$ chloramphenicol or 50 $\mu\text{g}/\text{ml}$ kanamycin at 37°C.
6. Verify the absence of pKD46 in the transformants by streaking and growing a few colonies on agar plates containing 100 $\mu\text{g}/\text{ml}$ ampicillin as well as agar plates containing 34 $\mu\text{g}/\text{ml}$ chloramphenicol (or 50 $\mu\text{g}/\text{ml}$ kanamycin). The cells that have lost pKD46 will only grow on the chloramphenicol (or kanamycin) plates, and not on the ampicillin plates. Insertion of the antibiotic resistance genes can be further verified using colony PCR.
7. Remove the antibiotic resistance gene via FLP-FRT recombination. Transform the recombinered cells with pCP20, which contains a temperature-sensitive origin of replication, repA101. Plate the cells on LB agar plates containing 100 $\mu\text{g}/\text{ml}$ ampicillin at 30°C.
8. Prepare overnight cultures of a few of the colonies obtained from step 7 in LB medium without antibiotic at 37°C to induce the expression of the flippase (*flp*) gene for excising the antibiotic resistance gene region between the FRT sites.
9. Verify the loss of all antibiotic resistance genes by streaking the overnight cultures on LB agar plates containing appropriate antibiotics and incubating overnight at 37°C. The loss of the antibiotic resistance genes can be further verified using colony PCR.

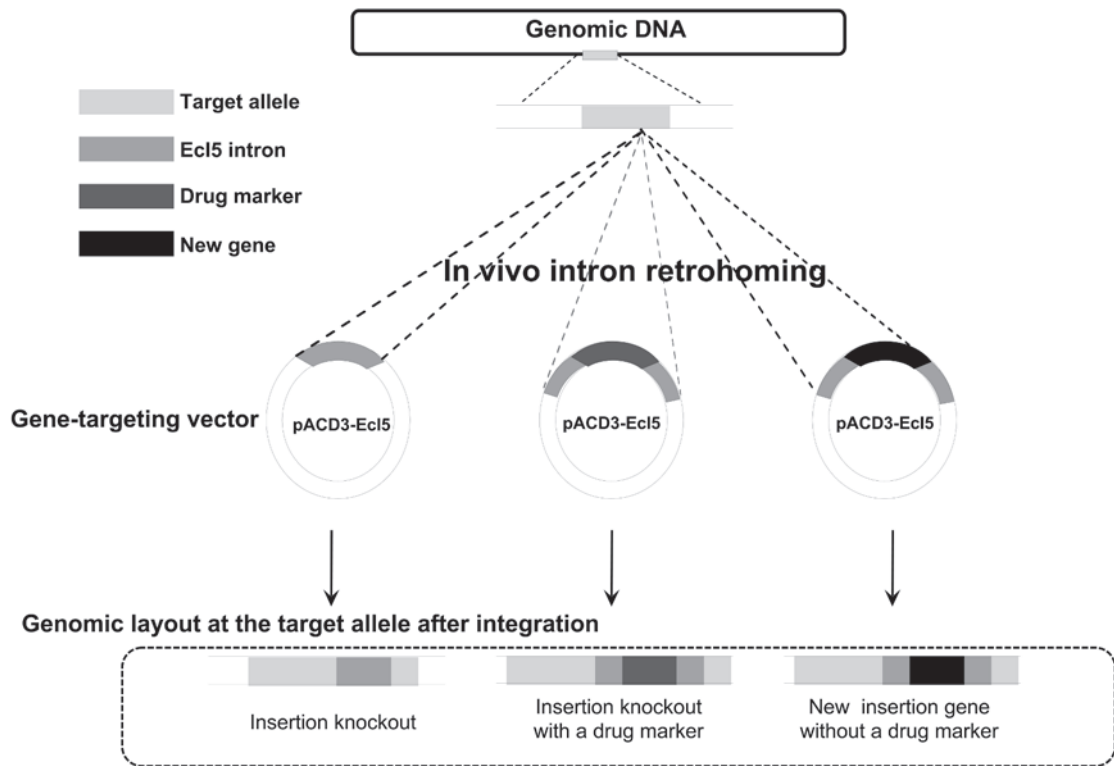

FIGURE 5 Chromosomal engineering of *E. coli* based on the intron gene-targeting system for either site-specific gene knockout or gene insertion. The target allele/site is first selected and the gene sequence is entered into the Ecl5 computer algorithm to obtain putative insertion sites and corresponding mutagenesis primers. The intron is then retargeted, ligated into a targetron vector, and expressed within the appropriate host strain. The pACD3-Ecl5 vectors contain a convenient MluI restriction site for inserting cargo genes such as a drug marker for knockout selection or a foreign gene for chromosomal expression in *E. coli*.

A chromosomal gene knockout strategy not involving homologous recombination is also available (Fig. 5). The technique utilizes a bacterial group II intron, such as L1.LtrB from *Lactococcus lactis*, and an intron-encoded protein (IEP), for site-specific integration via an in vivo retrohoming process (68). The mechanism begins with the IEP locating certain fixed nucleotide positions within the target DNA sequence, thereby facilitating specific base-pairing interactions between the intron RNA and target DNA. Due to both endonuclease and reverse transcriptase activity of the IEP, the intron RNA is able to hybridize with one strand of the target DNA and serve as a template for cDNA synthesis. Once the integration and reverse transcription events are complete, the nicked insertion site is sealed by host repair mechanisms to generate a stable and permanent 0.9-kb L1.LtrB intron insertion, which contains a stop codon in all six reading frames. Since specific base pairing between the intron RNA and target DNA occurs at only a few key regions (denoted IBS, EBS1d, and EBS2), it is possible to mutate and retarget the L1.LtrB intron for insertion into virtually any chromosomal site. Recently, a new bacterial group II intron isolated from *E. coli* O157:H7, called Ecl5, has been shown to possess higher site-specific integration frequencies than the L1.LtrB intron (115), eliminating the need for antibiotic selection markers.

Protocol 2. Gene Knockouts in *E. coli* Using the Ecl5 Intron

This protocol, based on the recent work by Zhuang et al. (115), describes gene knockout starting from Ecl5 intron

retargeting through induction of intron transcription and mutant screening.

1. Obtain the set of Ecl5 gene-targeting vectors denoted pACD3-Ecl5A, pACD3-Ecl5C, pACD3-Ecl5G, and pACD3-Ecl5T. The vectors differ in just one nucleotide position at the EBS3 site. The appropriate vector must be chosen such that the EBS3 nucleotide is complementary to the +1 position (IBS3) within the predicted Ecl5 intron insertion site.
2. Select a gene to be knocked out and input the coding sequence into the computer algorithm developed by Zhuang et al. (115). The algorithm ranks putative intron insertion sites and provides primer sequences corresponding to each insertion site.
3. Select at least two insertion sites and obtain the IBS1/IBS2, EBS1, and EBS2 primers for each site, in addition to the universal Ecl5 primer.
4. The Ecl5 intron is retargeted by a two-step PCR procedure in which the IBS1/IBS2 and EBS2 primers are used to generate a 336-bp PCR product, while the EBS1 and universal Ecl5 primer are used to generate a 230-bp PCR product. These small PCR products are then gel purified and used in a second PCR to generate the fully mutated and retargeted 546-bp product. The internal EBS2 and EBS1 primers contain 20 bp of overlap and are fused together in the second PCR using the flanking IBS1/IBS2 and universal primers. The final product is also gel purified.
5. The retargeted PCR product is flanked by XbaI and AvaII sites, which are present in the IBS1/IBS2 and

- universal EcI5 primers, respectively. The retargeted PCR product is swapped for the corresponding region in a previously targeted EcI5 targetron vector. Prepare restriction digests using *Ava*II and *Xba*I to digest both the intron PCR product and pACD3-EcI5A/G/C/T vector.
6. Gel purify the digested EcI5 targetron vector.
 7. Prepare a ligation reaction containing 15 to 30 ng digested PCR product and 50 ng digested and purified targetron vector. This corresponds to a molar insert-to-vector ratio of approximately 3:1 to 6:1.
 8. Inactivate the ligase using heat or phenol extraction.
 9. Transform 1 μ l of the ligation into an *E. coli* cloning strain using the heat shock or electroporation method. Plate the cells onto LB agar plates containing 25 μ g/ml chloramphenicol. All pACD3-EcI5 targetron vectors contain a chloramphenicol antibiotic marker for plasmid selection and propagation.
 10. Screen approximately five colonies by restriction analysis or colony PCR to verify the presence of the 546-bp insert.
 11. Prepare overnight cultures of two or three colonies containing the 546-bp insert at 37°C for approximately 16 h.
 12. Verify the IBS1, IBS2, EBS1, and EBS2 mutations by DNA sequencing using the universal T7 promoter sequencing primer.
 13. Transform the retargeted plasmid into the desired knockout strain using the appropriate strain-specific transformation protocol. Since the intron is expressed under the control of the T7 promoter system, the knockout strain should be a DE3 strain of *E. coli*. If the knockout is to be conducted in a non-DE3 strain, the cells must be supplied with a source of T7 RNA polymerase. Alternatively, gene knockouts can be conducted in DE3 strains and then transduced to non-DE3 strains using P1-phage transduction.
 14. Revive electroporated cells in 1 ml warm SOC medium (a nutrient-rich broth used to increase transformation efficiency) for 1 to 2 h at 37°C.
 15. Dilute the transformation reaction into 4 ml warm LB medium containing 25 μ g/ml chloramphenicol and grow for 16 h at 37°C.
 16. Inoculate 5 ml of fresh LB medium containing 25 μ g/ml chloramphenicol with 50 μ l of the overnight culture and grow to an optical density at 600 nm of 0.2 to 0.3.
 17. To induce intron transcription, inoculate 5 ml of fresh LB medium containing 100 μ M IPTG and grow for 3 h at 37°C.
 18. To remove excess IPTG, pellet the culture by centrifugation and resuspend in 1 ml fresh LB medium without antibiotic or IPTG.
 19. Dilute a portion of the culture 1,000-fold in LB medium and spread 50 to 100 μ l onto LB agar without antibiotic.
 20. Perform colony PCR on colonies using primers flanking the intron insertion site or one flanking primer and one intron-specific primer. The intron insertion is \sim 0.9 kb.

There are also efforts to reduce the *E. coli* genome, thereby removing nonessential regions without affecting the growth behavior (52, 81). With a cleaner and more efficient background, such reduced-genome *E. coli* strains (e.g., Clean Genome® *E. coli* from Scarab Genomics, LLC [Madison, WI; www.scarabgenomics.com]) have been demonstrated to be effective in the production of recombinant proteins, DNAs, and metabolites (13, 60, 89).

19.3. CHALLENGES FOR STRAIN IMPROVEMENT

Proteins having a complex structure or multiple domains or requiring complex folding, multiple disulfide bonds, or

other special posttranslational processing steps are difficult to express functionally in *E. coli*, and these technical difficulties still present a great challenge for strain improvement. Once the target protein is determined to be suitable for expression in *E. coli*, strain improvement is aimed at the host/vector system, target protein sequence, and various expression variables (Fig. 1). The general guidelines for strain improvement are (i) to ensure the genetic stability of the host/vector system, (ii) to maximize the synthesis fluxes for all the gene expression steps (i.e., transcription, translation, and posttranslational processing steps), (iii) to ensure the flux balance of these protein synthesis steps, (iv) to stabilize all the expression intermediates and final products, and (v) to minimize the physiological impact associated with high-level gene expression and high-cell-density cultivation. Successful strain improvement often relies on identification of the key steps limiting the overall culture performance. However, these limiting steps tend to be specific to the product of interest, difficult to identify, and subject to change. While certain types of limitations are now relatively easy to overcome, achieving a precise balance of the protein synthesis fluxes through optimization of the host/vector system remains challenging. In other words, we still do not have sufficient knowledge to undertake complete genome restructuring to achieve optimum strain performance in a given situation. Modern approaches based on systems biology and “-omics” studies continue to improve our knowledge, however. The genetic modifications currently adopted in most practical applications are primarily limited to gene knockouts and extrachromosomal overexpression, which cannot be fine-tuned. Modern chromosomal engineering techniques will potentially allow the inclusion of multiple exogenous genes as well as more precise regulation of the expression level of the modified genes in the chromosome. As a result, innovative strains can be more flexibly, effectively, and optimally tailored to enhance recombinant protein production. Despite the power of *E. coli* as an expression system, much work remains to be done to expand the types of protein products that can be functionally expressed and to improve its performance relative to the numerous alternative expression systems.

We greatly appreciate critical comments from George N. Bennett, Chris Reeves, and Richard Baltz.

Genetic Engineering Tools for *Saccharomyces cerevisiae*

VERENA SIEWERS, UFFE H. MORTENSEN, AND JENS NIELSEN

20

The yeast *Saccharomyces cerevisiae* is a widely used cell factory. Since ancient times it has been used for the production of bread, beer, and wine, and with the development of industrial processes for bioethanol production it has also become the cell factory of choice due to its high ethanol tolerance and high fermentative capacity. After the first demonstration of genetic engineering in *Escherichia coli*, techniques for genetic engineering of *S. cerevisiae* were rapidly developed, allowing its use for the production of biopharmaceuticals, e.g., human insulin. Since then many other pharmaceutical proteins have been produced using *S. cerevisiae*, including hepatitis virus and human papillomavirus vaccines. Furthermore, this yeast is currently being exploited as a production host for a number of fuels and chemicals, such as butanols, organic acids, novel antibiotics, and nutraceuticals such as resveratrol (89).

Among the advantages of using *S. cerevisiae* as a cell factory are: (i) it is the best-characterized eukaryotic microorganism in terms of genomics, biochemistry, cell biology, and physiology; (ii) it has a very efficient metabolism that can ensure very high glycolytic fluxes; (iii) many high-throughput experimental techniques were first developed for analysis of *S. cerevisiae*, and very large databases are available for this kind of data; (iv) detailed metabolic models have been developed for this organism; and (v) very efficient genetic engineering tools are available for this organism. This last is particularly important for metabolic engineering of *S. cerevisiae* (87, 95), as it is often necessary to evaluate many different strategies. An efficient metabolic engineering strategy may require many genetic modifications, such as gene deletion, promoter replacement, and/or heterologous gene expression. *S. cerevisiae* is probably matched only by *E. coli* in terms of the genetic engineering tools available.

20.1. YEAST TRANSFORMATION

Genetic engineering requires efficient transformation techniques, and many protocols for transformation of *S. cerevisiae* have been developed. These include methods involving spheroplast generation (48), electroporation (25), and biolistics with DNA-coated microprojectiles (6). The most widely applied method, however, is the lithium acetate/polyethylene glycol method first described by Ito et al. (1983) (50). This method has undergone many improvement steps over the years, one of them being the implementation of single-stranded DNA as carrier. It has also been

adapted to different needs (e.g., high-efficiency versus fast and easy protocol) (36, 37).

Fast and Easy Protocol

1. Scrape a 50- μ l volume of yeast from a fresh YPAD (1% [wt/vol] yeast extract, 2% [wt/vol] peptone, 2% [wt/vol] glucose, 80 mg/liter adenine hemisulfate, 18 g/liter agar) plate and suspend in 1 ml of sterile water.
2. Pellet cells in a microcentrifuge for 30 s and discard the supernatant.
3. Add 240 μ l of PEG 3350 (50% wt/vol), 36 μ l of lithium acetate (1 M), 50 μ l of single-stranded carrier DNA (2 mg/ml in 10 mM Tris-HCl, 1 mM disodium EDTA, pH 8; denatured by 5 min of boiling), and 34 μ l of sterile water containing any plasmid DNA (up to 1 μ g). Mix thoroughly (Vortex mixer).
4. Incubate at 42°C for 20 to 180 min (dependent on strain).
5. Pellet cells for 30 s and remove supernatant.
6. Resuspend pellet in 400 to 1,000 μ l of sterile water.
7. Spread 100 to 200 μ l on appropriate dropout selection plates and let the liquid be absorbed by the plates.
8. Incubate for 3 to 4 days at 30°C.

20.2. PLASMID VECTORS

For expression of heterologous genes or overexpression of homologous genes in *S. cerevisiae*, plasmid vectors are usually employed. Most are shuttle vectors that allow cloning and amplification in *E. coli*. Yeast plasmid vectors can be divided into different types. Yeast integrative plasmids (YIps) do not possess any yeast replication origin and can therefore only be maintained after chromosomal integration (see below). Yeast episomal plasmids (YEps) contain a replication origin derived from the endogenous yeast 2 μ m plasmid allowing autonomous replication. YEps usually exist at a level of 10 to 80 copies per cell. However, numbers vary between cells of the same population, and copy number as well as mitotic stability of the single plasmid may depend on the marker gene applied (116). Yeast replicating plasmids (YRps), which carry an autonomous replicating sequence instead of the 2 μ m origin, also provide a high copy number, but are less stable than YEps (128) and therefore not used very frequently. Insertion of centromere sequences into YRps led to the construction of yeast centromeric plasmids

(YCps). YCps have a higher mitotic stability than YRps and YEps, but exist usually only in one to two copies per cell. Additional cloning of telomere sequences into YCps allows the formation of yeast artificial chromosomes after linearization. Yeast artificial chromosomes are used for the construction of DNA libraries rather than for gene overexpression. They allow stable maintenance of inserts larger than 1 Mb, whereas the maximal insert capacity of plasmid vectors is around 20 kb.

20.2.1. Marker Genes

Selection of transformants and stable maintenance of plasmid-containing strains require the use of selectable marker genes. Table 1 lists a number of yeast selectable markers. However, many of them have only been used in a few studies and therefore may not be generally useful.

Probably the most widely used type of selectable markers are ones that confer prototrophy to auxotrophic strains containing mutations in amino acid and/or nucleotide biosynthetic pathways, e.g., *LEU2* and *URA3*. For plasmid maintenance, these systems are dependent on the use of chemically defined media, which are often not practical in industrial-scale fermentations and may lead to suboptimal growth and lower cell densities. Moreover, cross-feeding may result in mixed cultures, in which cells containing the marker gene secrete the required nutrient(s) or a pathway intermediate, thus allowing markerless cells to grow also (99).

An alternative is an autoselection system, where the marker gene is essential for cell viability independent of the medium composition. This allows the use of complex media for optimal growth conditions and avoids the possibility of cross-feeding. Examples are genes involved in cell division (e.g., *CDC4* or *CDC28*) or the glycolytic pathway (e.g., *PGK1*). Because such genes are essential, special procedures for establishing the desired strain are required. One method is plasmid shuffling, where the host strain contains a maintenance plasmid carrying a marker gene that can be counterselected after transformation with the expression vector (35).

Both prototrophic and autoselection markers imply the availability of strains that have the respective genes deleted. These are usually easy to obtain for haploid laboratory strains, but difficult to achieve for industrial strains, which are often diploid. Here, dominant resistance markers are required, which can be divided into three groups: (i) yeast wild-type genes that when overexpressed cause resistance to certain compounds, e.g., *ERG11* conferring resistance to azole antifungals (27); (ii) mutant alleles of yeast genes, such as *AUR1-C*, providing aureobasidin A resistance (47); and (iii) heterologous drug resistance genes, such as the widely used *kan* gene derived from *E. coli* (124). Drawbacks for some of these resistance markers are low transformation efficiency, the occurrence of background colonies, and spontaneous genomic mutant alleles (1). The high cost of some selective compounds limits their industrial applications, and the use of antibiotics is generally restricted for public health reasons, in particular for the production of feed, food, or pharmaceutical products.

Choice of the marker gene also may influence copy number and stability of the vector. For example, *URA3*-containing plasmids have a higher mitotic stability than plasmids carrying *LEU2* as a marker (92, 116). In order to achieve high copy numbers, a low expression level of the marker gene and/or a low activity of the resulting gene products may be advantageous. This may be obtained by using truncated promoters (29, 90) or heterologous promoters/genes (64, 123, 125).

The use of genes derived from other organisms has the additional advantage that they are not present in the *S. cerevisiae* genome, thus avoiding undesirable recombination events. Several heterologous and native marker genes are available as MX cassettes, in which gene expression is controlled by the *Ashbya gossypii* *TEF1* promoter and terminator (40, 41, 46, 51, 122–124).

20.2.2. Counterselection

The ability to select for the absence of a marker gene can be very useful, allowing an integrated marker to be removed for subsequent reuse (see below) or to eliminate the maintenance plasmid in an autoselection system. Several of the prototrophic markers offer this possibility, the most widely used being the *URA3* marker, which can be selected against using 5-fluoroorotic acid (5-FOA) (14). Further examples are the *LYS2(LYS5)/ α -amino adipate*, the *MET15*/methylmercury, the *TRP1/5*-fluoroanthranilic acid, the *GAP1/D*-histidine, and the *FYC1(FCA1)/5*-fluorocytosine systems (21, 24, 46, 51, 102, 115). Alternatively, an additional marker, which may itself not be selectable, can be employed. This could be a drug sensitivity marker such as *CAN1*, conferring canavanine sensitivity; *CYH2*, conferring cycloheximide sensitivity; or a marker gene that leads to growth inhibition when overexpressed under control of a strong conditional promoter, such as *GIN11* or *PKA3* (2, 93).

20.2.3. Promoters

Promoter choice and copy number are the most important factors for achieving the desired gene transcription levels. The choice of promoter can affect expression levels by up to 4 orders of magnitude. In general, one distinguishes constitutive and regulatable promoters. However, one should bear in mind that even promoters described as constitutive may have different expression levels depending on the environmental conditions, e.g., the applied carbon source. Furthermore, what are generally referred to as regulatable (inducible/repressible) promoters can be leaky; i.e., basal expression may be observed even under repressive conditions. Table 2 provides a list of *S. cerevisiae* promoters that have been used for heterologous gene expression.

Among strong constitutive promoters, the most commonly used for high-level gene expression are *P_{TEF1}*, *P_{ADH1}*, and promoters derived from glycolytic pathway genes. The best-studied regulatable promoters are the different *P_{GAL}* promoters, which are repressed by glucose and induced by galactose and reach high expression levels under induced conditions. Several approaches have been used to improve the *P_{GAL}* system, since galactose is a relatively expensive carbon source. *gall1 Δ* strains are not able to consume galactose and can be grown in media with both glucose for cell growth and galactose (which remains at a constant level) for gene induction (86). Additional deletion of *HXX2* relieves glucose repression of the *GAL* promoters, allowing gene expression even at high glucose consumption rates (68). However, deletion of *HXX2* attenuates the growth rate (and the glycolytic flux), and one may therefore alternatively delete the main transcriptional repressor of the *GAL* genes, Mig1p (56).

Promoters that are induced in late growth phase or stationary phase without requiring supply of an inducer can be useful for industrial fermentation applications. Examples are the glucose-repressed *P_{HXT7}* and *P_{ADH2}*, which become induced after glucose is depleted, or *P_{SP11}*, which is induced under different stress conditions including stationary phase.

TABLE 1 Marker genes

Marker gene	Gene product	Reference
Prototrophic markers		
<i>ADE2</i>	Phosphoribosylaminoimidazole carboxylase involved in purine biosynthesis	17
<i>ADE8</i>	Phosphoribosyl-glycinamide transformylase involved in purine biosynthesis	106
<i>ECM31</i>	Ketopantoate hydroxymethyltransferase involved in pantothenic acid biosynthesis	109
<i>HIS3</i>	Imidazoleglycerol-phosphate dehydratase involved in histidine biosynthesis	110
<i>LEU2</i>	β -Isopropylmalate dehydrogenase involved in leucine biosynthesis	110
<i>LEU2d</i>	<i>LEU2</i> with a partially defective promoter conferring a low expression level	29
<i>LYS2</i>	α -Amino adipate reductase involved in lysine biosynthesis	106
<i>LYS5</i>	Phosphopantetheinyl transferase involved in lysine biosynthesis	51
<i>MET2-CA</i>	L-Homoserine-O-acetyltransferase involved in methionine biosynthesis	93
<i>MET15</i>	O-Acetyl homoserine-O-acetyl serine sulfhydrylase involved in sulfur amino acid biosynthesis	24
<i>TRP1</i>	Phosphoribosylanthranilate isomerase involved in tryptophan biosynthesis	110
<i>TRP1d</i>	<i>TRP1</i> with a partially defective promoter conferring a low expression level	90
<i>URA3</i>	Orotidine-5'-phosphate decarboxylase involved in pyrimidine biosynthesis	110
<i>KIURA3</i>	<i>K. lactis</i> orotidine-5'-phosphate decarboxylase	64
<i>CaURA3</i>	<i>C. albicans</i> orotidine-5'-phosphate decarboxylase	41
Autoselection systems		
<i>CDC4</i>	F-box protein	55
<i>CDC9</i>	DNA ligase	117
<i>CDC28</i>	Catalytic subunit of the main cell cycle cyclin-dependent kinase	35
<i>FBA1</i>	Fructose-1,6-bisphosphate aldolase	23
<i>MOB1</i>	Component of the mitotic exit network	35
<i>PGI1</i>	Phosphoglucose isomerase	55
<i>PGK1</i>	3-Phosphoglycerate kinase	8
<i>POT</i>	<i>Schizosaccharomyces pombe</i> triose phosphate isomerase	114
<i>PSA1 (SRB1)</i>	GDP-mannose pyrophosphorylase	101
<i>TPI</i>	<i>Aspergillus nidulans</i> triose phosphate isomerase	55
<i>URA3 fur1</i>	Orotidine-5'-phosphate decarboxylase and uracil phosphoribosyltransferase	85
Dominant and semidominant resistance markers		
<i>CUP1</i>	Metallothionein conferring resistance to copper and cadmium	49
<i>ERG11</i>	Lanosterol 14 α -demethylase conferring resistance to azole antifungals	27
<i>GRE2</i>	Methylglyoxal reductase conferring resistance to methylglyoxal	82
<i>SSU1</i>	Plasma membrane sulfite pump conferring sulfite resistance	97
<i>SFA1</i>	Formaldehyde dehydrogenase conferring resistance to formaldehyde	119
<i>YAP1</i>	Transcription factor conferring resistance to cerulenin and cycloheximide	2
<i>ARO4-OPF</i>	Mutated DAHP synthase conferring resistance to fluorophenylalanine	32
<i>AUR1-C</i>	Mutated inositol-phosphoceramide synthase conferring resistance to aureobasidin A	47
<i>cyh2</i>	Mutated ribosomal protein conferring resistance to cycloheximide	26
<i>FZF1-4</i>	Mutated transcription factor conferring sulfite resistance	97
<i>LEU4-1</i>	Mutated α -isopropylmalate synthase conferring resistance to trifluoroleucine	13
<i>pdr3-9</i>	Mutated transcriptional activator conferring multidrug resistance	61
<i>SMR1B</i>	Mutated acetolactate synthase conferring resistance to sulfometuron methyl	126
<i>aroA</i>	5-Enolpyruvylshikimate-3-phosphate synthase conferring resistance to glyphosate	59
<i>ble</i>	Phleomycin binding protein conferring resistance to phleomycin	42
<i>bsd</i>	Blasticidin S deaminase conferring resistance to blasticidin S	33
<i>cat</i>	Acetyltransferase conferring resistance to chloramphenicol	44
<i>dehH1</i>	Fluoroacetate dehalogenase conferring resistance to fluoroacetate	119

(Continued on next page)

TABLE 1 (Continued)

Marker gene	Gene product	Reference
<i>dhfr</i>	Dihydrofolate reductase conferring resistance to methotrexate	78
<i>dsdA</i>	D-Serine deaminase conferring resistance to D-serine	122
<i>hph</i>	Phosphotransferase conferring resistance to hygromycin B	40
<i>kan</i>	Phosphotransferase conferring resistance to G418	124
<i>mdr3</i>	Phosphoglycoprotein conferring resistance to FK520	100
<i>nat1</i>	Acetyltransferase conferring resistance to nourseothricin	40
<i>pat</i>	Acetyltransferase conferring resistance to bialaphos	40
Other markers		
<i>GAP1</i>	General amino acid permease allowing growth on L-citrulline as sole nitrogen source	102
<i>FCY1</i>	Cytosine deaminase allowing growth on cytosine as sole nitrogen source	46
<i>FCA1</i>	<i>C. albicans</i> cytosine deaminase allowing growth on cytosine as sole nitrogen source	46

As mentioned before, it may be beneficial to minimize *S. cerevisiae*-derived sequences in an expression vector to avoid recombination. Apart from the *A. gossypii* *TEF1* promoter, which drives marker gene expression in the MX cassettes (see above), several other heterologous promoters, such as the constitutive GAP promoter from *Pichia pastoris* (121), the *TEF1* promoter from *Arxula adeninivorans* (15), and the regulatable *Candida tropicalis* ICL promoter (54), have successfully been applied in *S. cerevisiae*. The Tet system is widely used, and different versions of it allow either repression or induction of a *tet* promoter by doxycycline (12).

New promoter properties, e.g., altered regulation or enhanced expression, can be achieved by combining regulatory elements derived from different promoters. An example is the introduction of P_{GAL1} or P_{GAL10} upstream activation sequences into the *ENO2* promoter (118). Since highest gene expression levels may not always lead to highest protein production, promoter libraries can be used to fine-tune gene expression. These may be generated by error-prone PCR from existing yeast promoters (4) or by using primers that contain certain conserved regulatory elements, but are otherwise degenerate (53).

20.2.4. Terminators

Proper transcription termination is a requirement for mRNA stability and thus also for high expression levels. The origin of the termination signal is usually of less importance and even the presence of the native terminator, when expressing a heterologous gene, may be sufficient. However, an influence of the termination signal origin on protein expression levels has also been observed (69). The most common *S. cerevisiae* terminators used for heterologous gene expression are derived from the *PGK1*, *ADH1*, and *CYC1* genes.

20.2.5. Protein Secretion Signals

Even though the production of extracellular proteins using *S. cerevisiae* has some drawbacks (often lower efficiency than in other host systems, and problems with hyperglycosylation), it has found many industrial applications. Protein secretion requires the presence of an N-terminal signal sequence. If the protein is also secreted in its natural host, the genuine secretion signal may be sufficient for extracellular targeting in yeast. In case a yeast signal sequence is to be used, the leader of the mating pheromone α -factor (encoded by *MF α 1*) is usually chosen (18). It consists of a pre-peptide, a pro-peptide, and a Kex2p processing site. An alternative is the signal sequence of the *S. cerevisiae*

invertase *Suc2p* (91). Further secretion signals that can be applied are, for example, the leader of the *Kluyveromyces lactis* killer toxin (10) or the glucoamylase signal peptide of *Saccharomyces diastaticus* (65).

20.2.6. Available Expression Vectors

Table 3 lists several plasmid vectors used for gene expression in *S. cerevisiae* that are available from different suppliers and also specifies their main features.

20.3. CHROMOSOMAL INTEGRATION

Once the full genome sequence for *S. cerevisiae* was obtained (39), it became possible to introduce directed genetic changes by gene targeting (104). Using this technique, new strains can be tailor-made to produce new products and to display a preferred metabolic flux or growth pattern, ensuring maximum yield and desired product quality. Most commonly, this has been achieved by inserting new genes and/or by deleting or disrupting genes that influence a given process. However, gene targeting also allows metabolism to be engineered in more sophisticated ways. For example, it is possible to alter transcriptional activity of a selected gene by exchanging its native promoter for one with different strength or induction properties. Even point mutations can be introduced to change specific aspects of gene function. Hence, it is possible to alter the substrate specificity of a given protein or to specifically eliminate a single activity in a multifunctional protein. Furthermore, by using gene targeting, genes can be extended by sequences that encode new functions such as epitope tags, allowing for immunological detection of protein levels; visualization tags like green fluorescent protein (GFP) to address the localization of the protein in the cell; sequences to direct a protein to a specific compartment in the cell; and purification tags to facilitate protein isolation.

Gene targeting is particularly efficient in *S. cerevisiae* because DNA double-strand breaks are preferentially repaired by homologous recombination as opposed to non-homologous end joining (30). When a linear molecule of DNA is transformed into a yeast cell, the cell perceives the fragment as broken DNA that needs repair. If the fragment contains sequences that are identical to a target site in the genome, it will efficiently integrate at that target site via the homologous recombination repair process (94). Henceforth we refer to DNA fragments made for genomic integration at a specific locus as gene-targeting substrates because they represent substrates for DNA repair. The different types of

TABLE 2 Promoters for heterologous gene expression

Promoter	Gene product	Comment	Reference(s)
Constitutive promoters			
P _{ACT1}	Actin	Strong	79
P _{ADH1}	Alcohol dehydrogenase	Strong on glucose; long version is repressed by nonfermentable carbon sources	79, 81, 105
P _{ENO2}	Enolase II	Strong on glucose; expression level is carbon-source dependent	118
P _{KEX2}	Serine protease	Very weak	84
P _{PGK1}	3-Phosphoglycerate kinase	Strong on glucose; expression level is carbon-source dependent	79, 84, 120
P _{PPMA1}	Plasma membrane H ⁺ -ATPase	Upregulated on glucose	58, 108
P _{TDH3}	Glyceraldehyde-3-phosphate dehydrogenase (alias GPD)	Strong	9, 81
P _{TEF1}	Translational elongation factor EF-1 alpha	Strong	9, 81
P _{TP11}	Triose phosphate isomerase	Strong; expression level is carbon-source dependent	55, 98
Regulatable promoters			
P _{ADH2}	Alcohol dehydrogenase II	Repressed by glucose	66
P _{CUP1}	Metallothionein	Induced by copper(II) ions	60, 75
P _{CYC1}	Cytochrome c	Regulated by carbon source and oxygen availability	74, 81, 84
P _{DAN1}	Cell wall mannoprotein	Induced under anaerobic conditions	88
P _{FUS1}	Membrane protein	Pheromone-induced	31
P _{GAL1} /P _{GAL10}	Galactokinase/UDP-glucose-4-epimerase	Bidirectional promoter; induced by galactose, repressed by glucose	75, 80
P _{GAL7}	Galactose-1-phosphate uridyl transferase	Induced by galactose, repressed by glucose	75, 111
P _{HXT7}	High-affinity hexose transporter	Low expression at high glucose concentration, high expression at low glucose concentration	62
P _{MET3}	ATP sulfurylase	Repressed by methionine	7
P _{MET25} (P _{MET17})	O-Acetylhomoserine sulfhydrylase	Repressed by methionine	112
P _{PHO5}	Acid phosphatase	Induced at low phosphate concentration, repressed at high phosphate concentration	67
P _{SOR1}	Sorbitol dehydrogenase	Induced by sorbitol and xylose	76
P _{SPI1}	Glycosylphosphatidylinositol-anchored cell wall protein	Induced under stress and at stationary phase	19
P _{SUC2}	Invertase	Repressed at high glucose concentration	20

specific genetic manipulations listed above are obtained by varying the design of the gene-targeting substrate, as described in the following sections.

20.3.1. Integrative Plasmids

Integrative plasmids are most often used to insert a (novel) gene into the genome at a defined location. This is typically achieved by using *E. coli* vectors with an added yeast selectable marker gene (see above examples). The gene-targeting experiment is initiated by inserting Your Favorite Gene (YFG1) into such a vector using *E. coli*-based cloning. This vector is linearized by a restriction enzyme that cuts within the yeast marker gene. The resulting gene-targeting

substrate is transformed into yeast, where it integrates at the corresponding marker locus in the yeast genome by what is commonly referred to as an ends-in or loop-in recombination event (113) (Fig. 1). Notably, during integration the selectable marker is duplicated and will flank the inserted YFG1 as a direct repeat. If insertion of YFG1 significantly influences the fitness of the host strain, it is important to keep in mind that such insertions are inherently unstable, as direct repeat recombination (also known as pop-out or loop-out recombination) eliminates the inserted gene at a low rate (57) and the resulting recombinants may take over the population. To avoid this, genes can be inserted using gene-targeting substrates that integrate via separate

TABLE 3 Available plasmid expression vectors

Name	Description	Marker genes	Promoters	Reference(s)	Available from ^a
pRS series	Set of YCp, YIp, and YEp shuttle vectors containing different selectable markers	<i>HIS3, TRP1, LEU2, URA3</i>		22, 110	ATCC
p4XX(prom)	Set of YCp and YEp shuttle vectors based on the pRS series containing different promoters and the <i>CYC1</i> terminator	<i>HIS3, TRP1, LEU2, URA3</i>	P_{CYC1} , P_{TEF} (= P_{TEF1}), P_{ADH1} , P_{GPD} (= P_{TDH3}), P_{MET25} , P_{GAL1} , P_{GALL} , P_{GALS}	80, 81	ATCC
Y(C/E/I)plac series	Set of YCp, YIp, and YEp shuttle vectors based on pUC19 containing different selectable markers	<i>TRP1, LEU2, URA3</i>		38	ATCC
pFL series	Set of YCp, YIp, and YEp shuttle vectors based on pUC19 containing different selectable markers	<i>TRP1, LEU2, URA3</i>		16	ATCC
pIS series	Set of YIp shuttle vectors for single-copy chromosomal integration	<i>ade8, fcy1, his3, leu2, lys2, met15; URA3</i>		106	Euroscarf
pCM series	Set of YCp and YEp shuttle vectors containing tetracycline regulatable promoters	<i>TRP1, URA3</i>	<i>tetO</i>	34	ATCC, Euroscarf
pGREG series	Set of YCp shuttle vectors based on the pRS series; with and without tagging	<i>HIS3, TRP1, LEU2, URA3; kanMX</i>	P_{GAL1}	52	Euroscarf
pVV series	Set of YEp and YCp shuttle vectors for gateway cloning; with and without tagging	<i>TRP1, URA3</i>	<i>tetO</i> , P_{PGK1}	120	Euroscarf
pYES vectors	YEp vectors offering different tagging and cloning strategies	<i>URA3, TRP1</i>	P_{GAL1}		Invitrogen
pYC vectors	YCp vectors	<i>URA3, bsdR</i>	P_{GAL1}		Invitrogen
pESC vectors	YEp vectors for coexpression of two genes from one vector	<i>HIS3, TRP1, LEU2, URA3</i>	P_{GAL1}/P_{GAL10}		Stratagene
pKS vectors	YEp vectors with or without <i>SUC2</i> export signal	<i>kanMX</i>	P_{ADH2}		Dualsystems
p(prom)-MF	YEp vectors containing MF α leader sequence	<i>URA3</i>	P_{TEF1} , P_{GALL}		Dualsystems
p417-CYC, p427-TEF	YCp and YEp vector	<i>kanMX</i>	P_{CYC1} , P_{TEF1}		Dualsystems

FIGURE 1 Genomic integration using an integrative plasmid. *YFG1* and a selective marker, in this case *URA3*, are cloned into an *E. coli* plasmid. The plasmid is linearized at a site within *URA3* prior to transformation into a *ura3* strain. After integration, the *URA3* gene is duplicated, typically resulting in one functional and one nonfunctional copy. Chromosomal DNA is indicated by the presence of a gray oval representing the centromere.

recombination events at both ends, thus not generating repeats (see below).

Multicopy insertions of the same gene may be achieved if the gene-targeting substrate is designed to target repeated elements— δ -elements or ribosomal DNA (rDNA) repeats—in the genome. In this way, stable strains expressing 20 to 200 gene copies have been reported (71, 96). Selection for multicopy integrations can be performed by choosing a weakly expressed resistance marker such as *neo* (G418/kanamycin resistance). Addition of high concentrations of G418 selects for multiple integration events, as G418 resistance and *neo* copy number are roughly proportional (125).

20.3.2. Gene Disruption/Deletion

Elimination of gene functions is most commonly achieved by disrupting the *YFG1* open reading frame (ORF) or by deleting the entire (or part of) *YFG1* in a one-step recombination procedure. A typical gene-targeting substrate for ORF disruption is simply made by inserting a selectable marker into the *YFG1* ORF, generating a gene-targeting substrate with the selectable marker flanked by *YFG1* ORF up- and downstream sequences, respectively. For *YFG1* ORF deletion, a gene-targeting substrate composed of a sequence upstream of the *YFG1* ORF, a selectable marker, and a sequence downstream of the *YFG1* ORF is constructed. Such gene-targeting substrates integrate at endogenous *YFG1* by double homologous recombination to disrupt/delete *YFG1* in a process that does not generate repeats (Fig. 2).

The starting point for *YFG1* gene disruption is typically a plasmid containing *YFG1*. The gene-targeting substrate is then simply made by inserting a selectable marker into the *YFG1* ORF by conventional cloning. Finally, the gene-targeting substrate is liberated from the vector backbone by restriction enzymes to provide a linear gene-targeting substrate for transformation (Fig. 2A).

Gene-targeting substrates for gene deletion are composed of a selectable marker flanked by two sequences that are identical to sequences up- and downstream of the region to be deleted, respectively. Recombination between

such substrates and the genome results in integration of the marker and loss of the genomic sequence situated between the up- and downstream sequences (Fig. 2B). Deletion substrates can be constructed by conventional cloning or by PCR. However, since construction of gene-targeting substrates by PCR is generally more convenient, the following sections will focus only on procedures using PCR. In the simplest form, a gene-targeting substrate for gene deletion is generated by amplifying the selectable marker using PCR primers with extensions at their 5' ends homologous to the up- and downstream targeting sequences, respectively (11, 72). However, the efficiency of gene targeting dramatically decreases as the length of the homologous targeting sequences is shortened (73), and therefore it is advisable to use targeting sequences of at least 200 bp (maximum efficiency is achieved when the regions of homology are >500 bp). Since such long targeting sequences cannot be incorporated into a PCR primer, it is necessary to build the gene-targeting substrates in two steps. In a first round of PCR reactions, the two targeting fragments (up- and downstream of *YFG1*) and the marker fragment are amplified in separate PCR reactions. The gene-targeting substrate is completed in a second PCR reaction that fuses the targeting fragments to the ends of the fragment containing the selectable marker, as illustrated in Fig. 2C (5). Fusion of the primary PCR fragments is made possible by using primers in the first round with extensions at their 5' ends that overlap the pieces to which they are being fused. Alternatively, and using simpler PCR, the substrate can be made as a bipartite gene-targeting substrate (Fig. 2D) (28). In this case, one part of the substrate is made by fusing the upstream targeting sequence to a fragment containing the 2/3 upstream region of the selectable marker by PCR. The other part of the substrate is made by fusing the 2/3 downstream region of the selectable marker to the downstream targeting sequence. After transformation with the bipartite gene-targeting substrate, integration events can be selected because the selectable marker is reconstructed by homologous recombination (Fig. 3).

20.3.3. Iterative Gene Targeting

In many cases, a strain needs to be modified several times by successive gene-targeting steps before it obtains the desired genotype. With the gene-targeting principle described above, the selectable marker is stably integrated at the target site. Since in many strains the number of useful markers is limited, it is often necessary to recycle a favorable marker during a series of gene-targeting experiments. This requires that the selectable marker be eliminated from the targeted site between each round of gene targeting. Marker elimination can be achieved either by employing the Cre/Lox system (107), by spontaneous mutagenesis, or, if the selectable marker in the gene-targeting substrate is flanked by direct repeats, by recombination. In the Cre/Lox system, the selectable marker, typically *kanMX*, is flanked by the short (34-bp) *loxP* sequences (43). After gene targeting, the marker can be excised from the genome by expressing the Cre recombinase, e.g., from a plasmid. Recycling of a marker by spontaneous mutation or recombination requires that the selectable marker also can be counterselected. The most widely used marker for this purpose is *URA3*, but other markers can also be used (see above). In this case, it is useful to employ a functional marker from a related organism, e.g., *URA3* from *K. lactis*, to avoid recombination with the endogenous marker locus during transformation. Marker loss by mutation is rare. For *URA3* at its native location,

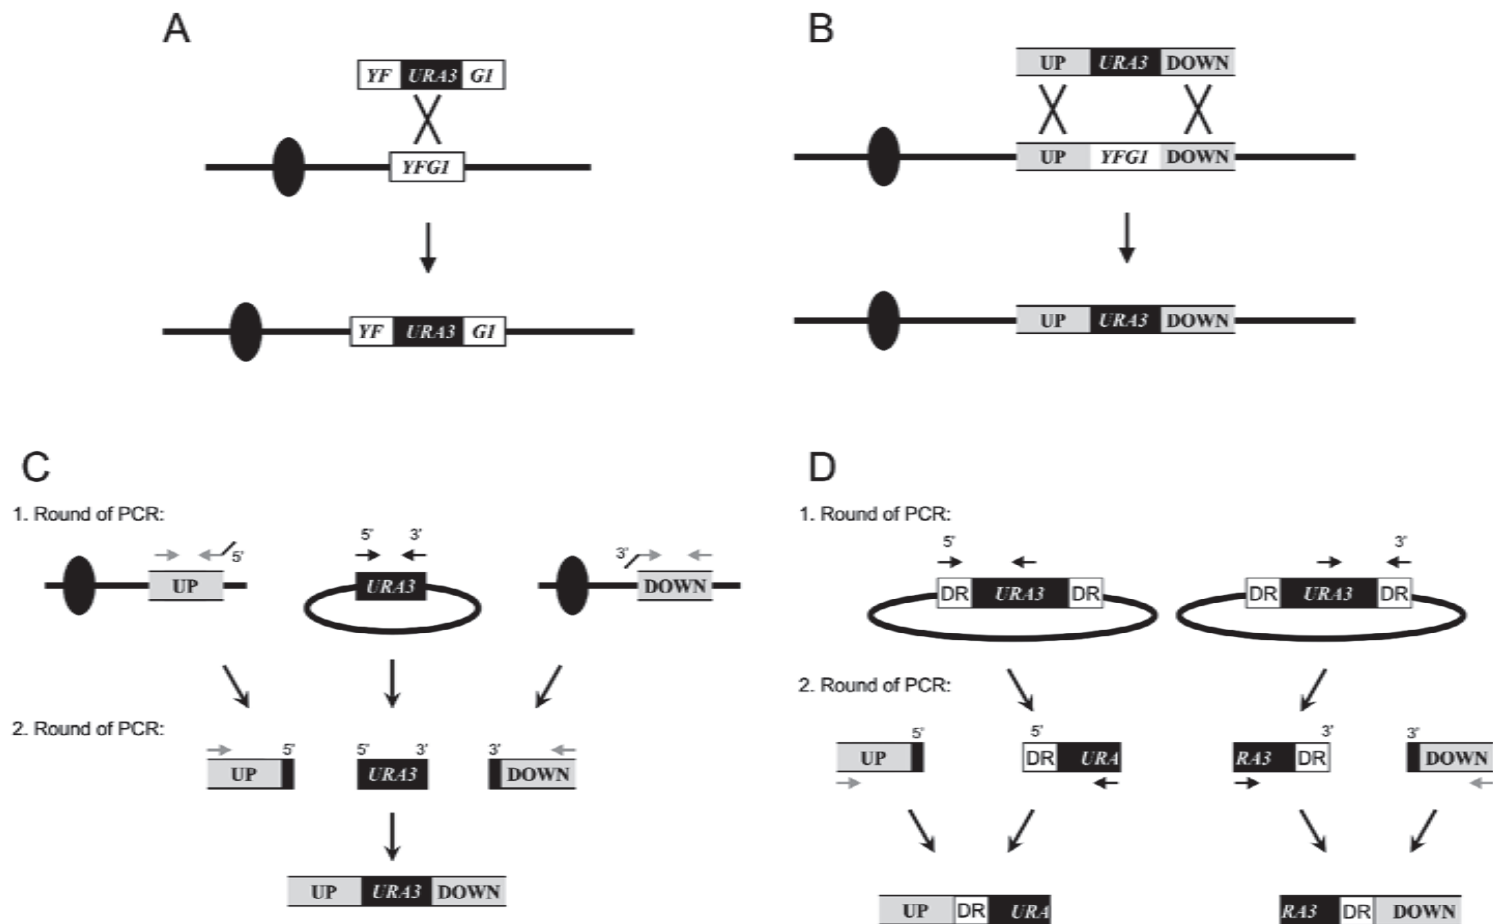

FIGURE 2 Substrates for disruption and deletion of *YFG1*. (A) Disruption of *YFG1* is achieved by using a linear substrate composed of a selectable marker (*URA3*) flanked by sequences up- and downstream of the integration site in *YFG1*. (B) Deletion of *YFG1* is achieved by using a linear substrate composed of a selectable marker (*URA3*) flanked by sequences up- and downstream of *YFG1*. Original sequences between the *YFG1* up- and downstream sequences will be deleted. (C) Construction of a gene deletion substrate by PCR. In a first round of PCR, fragments containing the up- and downstream sequences of *YFG1* and the marker gene (*URA3*) are generated in three independent PCR reactions. Note that one of the primers in the primer pair used to generate the upstream fragment is extended by a sequence identical to the extreme 5'-upstream section of *URA3* as indicated by a black line added to the gray primer. The sequence of the extension is complementary to the 5'-primer used to amplify *URA3*. Similarly, one of the primers used to amplify the downstream fragment is extended by a sequence that is complementary to the 3'-primer used to amplify *URA3*. The two primer extensions produce sequence overlaps that allow all three fragments to be fused and amplified in a second round of PCR. (D) Construction of a bipartite gene deletion substrate. The up- and downstream sections are generated in two individual PCR reactions. The primer extensions added to primers used to generate the up- and downstream sequences allow the up- and downstream fragments to be individually fused to the 5'-2/3 and 3'-2/3 *URA3* fragments in separate PCR reactions.

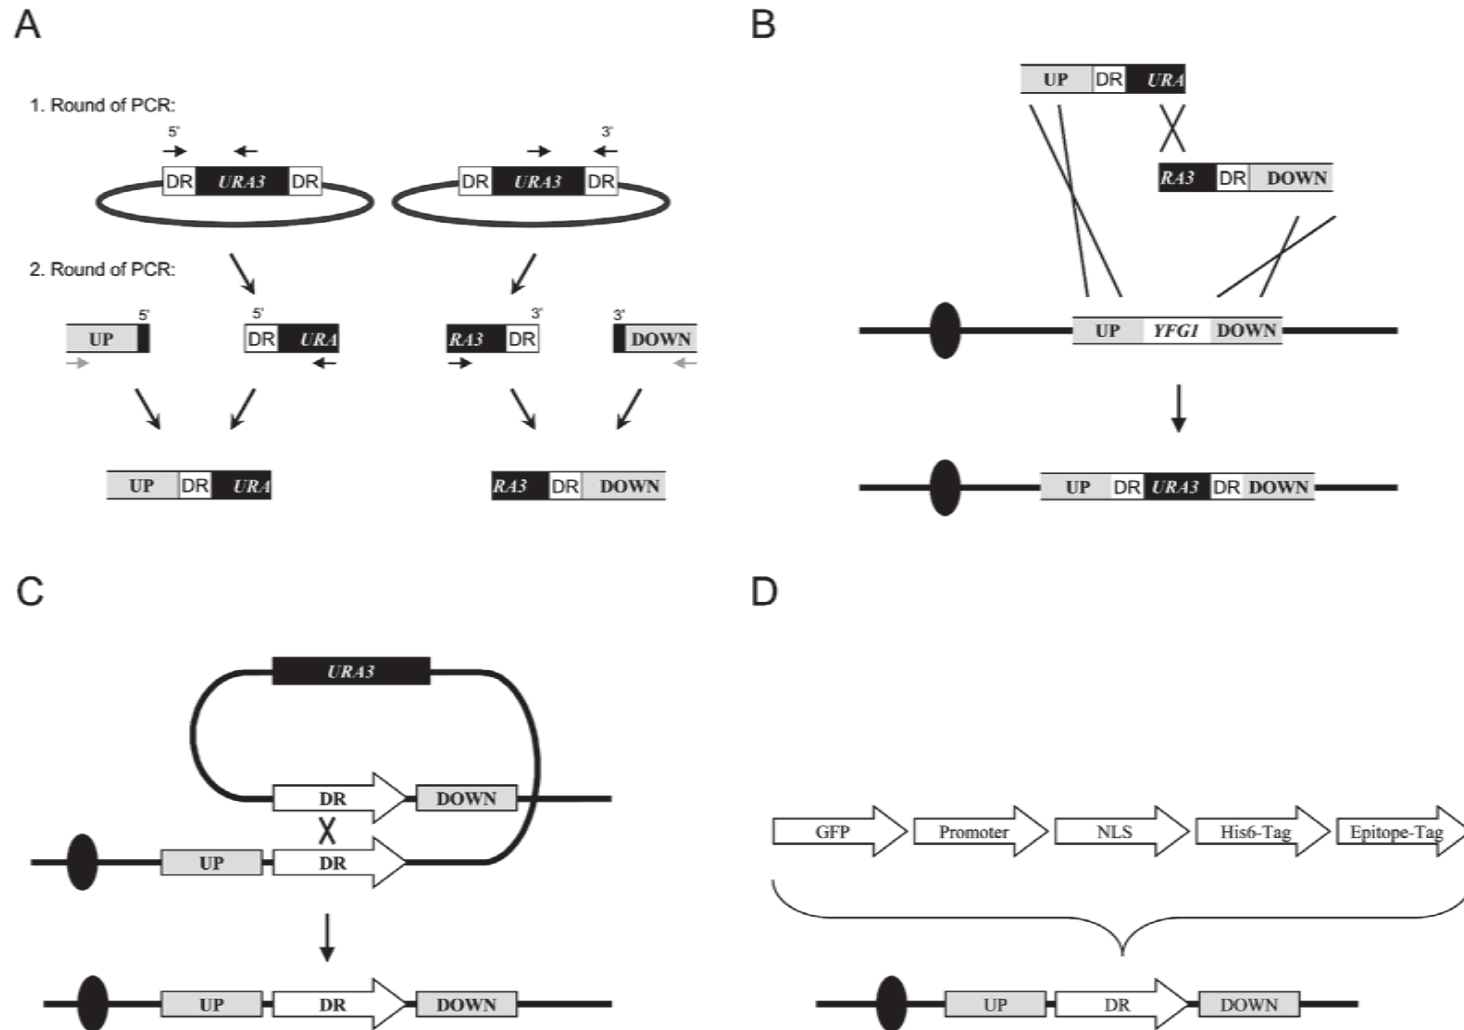

FIGURE 3 Substrates for iterative gene deletion. Direct repeats flanking the selectable marker allow the marker to be eliminated from the genome by recombination. If the selectable marker is *URA3*, recombinants can be selected using 5-FOA. (A) Construction of a bipartite gene deletion substrate with the marker flanked by a direct repeat (labeled DR). The template for the marker fragments is a plasmid that contains direct repeats flanking the marker. The remaining steps are similar to the legend for Fig. 2D. (B) Genomic integration of a bipartite gene-targeting substrate. Note that homologous recombination completes the selectable marker after cotransforming the two substrate fragments into the cell. (C) Direct repeat recombination eliminates the selectable marker from the genome. Note that one repeat remains in the genome. (D) By varying the sequence content of the DR repeats flanking the marker in the template plasmid, different useful sequences may be introduced between defined up and down sequences, as indicated; see text for details.

one 5-FOA-resistant mutant is generated per 5.4×10^8 cell divisions (63), and in some cases survivors may arise from mutations in another gene. For example, *ura5* mutants are also viable on 5-FOA medium (14). To eliminate the marker by recombination, it is necessary to build a gene-targeting substrate in which the selectable/counterselectable marker is flanked by direct repeats (3) (Fig. 3A, B, and C). Marker loss by direct repeat recombination is more frequent (one event per 10^4 to 10^5 cell divisions for repeats longer than 1 kb) (57) than by mutation. To reduce the size of the gene-targeting substrate, a repeat size of 143 bp is sufficient for efficient pop-out recombination (103). A continuous gene-targeting substrate based on a selectable marker flanked by a direct repeat is not easily assembled by PCR since PCR recombination between the repeats often eliminates the central part of the fragment (77). Accordingly, it is advisable to construct the substrate as a bipartite gene-targeting substrate, in which each repeat is contained within separate fragments (Fig. 3A). Selection is possible in such a bipartite gene-targeting substrate because the marker gene is reconstituted by homologous recombination after transformation. It is important to restreak the primary transformants on selective medium before counterselection, because the original transformation colony may contain untransformed cells that are kept alive by cross-feeding. These cells grow on counterselective medium and will provide undesired background.

20.3.4. Gene-Targeting Cassettes for Tagging Proteins

As described above, iterative gene targeting can be performed by flanking the selectable/counterselectable marker, e.g., *URA3*, in the gene-targeting substrate by direct repeats. After pop-out recombination, a single sequence unit of the repeat is left as a scar in the genome. This sequence scar can be highly useful as it allows a simple way to extend proteins with epitope, fluorescence, or purification tags etc. (Fig. 3D). For example, to extend a protein by GFP, the first step is to build two universal vectors that can be used for tagging proteins with GFP at any location in the sequence. In one vector, the DNA sequence encoding GFP is inserted upstream of *URA3*, and in the other, the GFP sequence is inserted downstream of *URA3* (70) (Fig. 4A). If the goal is to C-terminally tag a protein encoded by *YFG1*, a bipartite gene-targeting substrate for this purpose can easily be constructed. First, the two targeting sequences to direct the GFP sequence to the proper position are made by PCR using genomic DNA as template (Fig. 4B). The upstream targeting sequence is a fragment containing the sequence corresponding to the downstream end of *YFG1*, ending just before the stop codon. The downstream targeting sequence is a fragment that contains a stop codon followed by the 3' nontranslated region of *YFG1*. Both fragments are produced by primers containing extensions that allow them to be fused to the proper *GFP-URA3* fragments generated from the universal GFP-tagging vector set (see the legend to Fig. 4B). One part of the bipartite gene-targeting substrate is made by fusing the *YFG1* upstream targeting fragment to a PCR fragment containing the *GFP* sequence followed by the 2/3 upstream section of *URA3* (the latter fragment has been amplified from one member of the GFP-tagging vector set). The other part of the bipartite substrate is made by fusing a PCR fragment containing the 2/3 downstream section of *URA3* followed by the *GFP* sequence (amplified from the other member of the GFP-tagging vector set) to the *YFG1* downstream fragment.

FIGURE 4 Incorporation of GFP DNA sequence into the genome. (A) Universal vector set for incorporating the GFP DNA sequence at any location in the genome using a bipartite gene-targeting substrate. Positions of the primers are indicated. (B) Strategy to extend the protein encoded by *YFG1* C-terminally with GFP. The position of the primer pairs used to amplify the two targeting sequences is indicated. Each fragment will terminate with a sequence tag matching either the 5'- or the 3'-end of GFP as indicated. Note that a sequence complementary to a stop codon, shown as an open circle, must be incorporated in the forward primer used to amplify the downstream targeting fragment. This codon is positioned right after the GFP segment of this primer as indicated.

Hence, in this fragment the stop codon follows right after the GFP sequence. After transformation to integrate the construct, followed by pop-out recombination, the *GFP* sequence will be fused in frame to the *YFG1* sequence just after its last codon.

20.3.5. Genomic Site-Directed Mutagenesis

A simple variation of the gene-targeting methods described above allows the introduction of point mutations or similar small sequence modifications into the genome. The starting point is a sequence fragment that includes the mutation. In two separate PCR reactions, this mutant fragment is fused to both ends of the selectable marker (Fig. 5). These reactions are similar to what is shown in Fig. 2D, except that the up and down sequences in this case are the same mutant gene fragment. As a guideline, the mutant fragment should be around 500 bp or larger. Note that a nonlethal mutation can be introduced in an essential gene if the mutant fragment contains the entire ORF so that it is not disrupted as the result of the gene-targeting experiment (28). When the substrate integrates at the correct genomic locus, the mutation will be integrated as a direct repeat flanking *URA3*. Subsequent pop-out recombination leaves only the point mutation in the genome (Fig. 5). It is important to note that the substrate may occasionally integrate such that only one of the repeats contains the desired mutation (28). In this case, pop-out recombination yields both wild-type and mutant recombinants and a subsequent screen is necessary to identify the desired strain.

FIGURE 5 Substrates for introduction of point mutations. Identical direct repeats of *YFG1* sequences containing the relevant mutation flank a selectable marker (*URA3*). The substrate is shown as a bipartite gene-targeting substrate. Direct repeat recombination between mutant repeats leaves only the mutation in the genome.

To reduce the amount of screening, it is advisable to position the mutation in a central part of the targeting sequence, as it optimizes the chance of retaining the mutation in the genome.

20.4. FACTORS INFLUENCING TRANSLATION EFFICIENCY

The engineering tools discussed so far mainly aim at regulating gene expression levels through control of copy number and transcription. Although influencing translational processes is usually less often employed, there are important factors to consider.

Translation efficiency is to a certain extent influenced by the nucleotide sequence surrounding the AUG start codon. The consensus sequence for highly expressed yeast genes was determined as (A/U)A(A/C)A(A/C)AAUGUC(U/C) (45). An adenosine at position -3 relative to the AUG is especially important for high-level translation (127).

Another important factor can be the codon composition of the gene to be expressed. Often, heterologous genes—especially those that contain a high percentage of codons rarely used in yeast—are only poorly expressed in *S. cerevisiae*. Rarely used codons are reflected by a low abundance of the respective tRNA molecules. Therefore, overexpression of selected tRNA genes can improve the expression of difficult genes such as those with a high GC content (83). Generally, the use of codon-optimized synthetic genes is highly recommended. Since the codon composition at the gene's 5' end seems to be most important, it may be sufficient only to optimize the first 14 to 32 codons to achieve good expression (83). However, due to its ever-decreasing cost, the use of completely synthetic genes has become routine. Many companies offer the design and synthesis of genes based on a given protein sequence.

The algorithms developed for codon optimization follow two different strategies. In the first and most common strategy, the synthetic genes are optimized towards the most

frequently used codons, which will result in a high codon adaptation index. The second strategy optimizes towards the overall yeast codon usage. Usually, other factors are included in the optimization process as well, such as the GC content and avoidance of motifs leading to mRNA instability, premature translation termination, or RNA secondary structure. However, current knowledge about the relationship between the gene sequence and its expression level is still relatively limited, leaving room for improvement during the coming years.

Protein Expression in Nonconventional Yeasts

THOMAS W. JEFFRIES AND JAMES M. CREGG

21

21.1. INTRODUCTION

Heterologous expression of biopharmaceuticals and enzymes is common, but increasingly, metabolic engineering of biosynthetic or biodegradative pathways requires the balanced expression of multiple proteins under complex regulatory conditions. The transformation and manipulation of well-studied hosts such as *Escherichia coli* or *Saccharomyces cerevisiae* draw on many genetic tools and strains and a plethora of research into regulatory responses and protein functions. These data on familiar workhorses, while essential, represent only a small fraction of the biochemistry and physiology present in the microbial realm. Moreover, with the advent of whole-genome sequencing, it is becoming possible to obtain particular advantages by using different microbial systems for specialized applications.

21.1.1. Yeasts as Expression Hosts

As unicellular organisms, yeasts are relatively easy to isolate, scale up, and manipulate genetically. They can achieve high growth rates. Their thick cell walls make them more resistant to osmotic shock. Because they are larger than bacteria, they are easier to harvest by filtration or centrifugation. They will grow at an acidic pH, which discourages the growth of most contaminants. They are not susceptible to most viral infections, and they lack lipopolysaccharide endotoxins. They generally have minimal nutritional requirements and can be cultivated at very high cell density. Cell and protein yields are often high. Specifically with respect to heterologous proteins for therapeutic use, yeasts have an advantage over bacteria in their capacity to produce N-glycosylated proteins with disulfide linkages (42).

Some of the physiological features of yeasts cause difficulties. Their thick cell walls can make release of intracellular proteins more difficult, and their natural glycosylation systems differ from those of mammals. However, even these problems have been addressed with yeasts that secrete heterologous proteins and by the genetic development of strains having humanized glycosylation patterns.

Within the dikaryotic Ascomycetes to which the budding yeasts belong, at least 20 species of yeasts have been examined for their industrial properties. Several have been used for heterologous protein expression or metabolically engineered for novel properties. *S. cerevisiae* is the best studied of the ascomycetous budding yeasts. Genetically it is

the best understood eukaryote, which makes it very easy to manipulate. It is not as useful for heterologous protein production because it lacks respiration complex I and hence exhibits relatively low ATP and cell yields. It has relatively limited capacity to metabolize carbon sources other than glucose and sucrose. It tends to hyperglycosylate proteins, and it does not possess a strong secretion pathway, so proteins larger than about 30 kDa occur as intracellular or periplasmic products. Researchers and industrial processes have drawn on the features of nonconventional yeasts to overcome these problems.

21.1.2. Nonconventional Yeasts

Nonconventional yeasts can be roughly defined as any yeast other than *S. cerevisiae*. A number are used in industrial settings. If one says “yeast” without further clarification, *S. cerevisiae* is assumed. The realm of “yeasts,” however, is far more diverse. Closely related to *S. cerevisiae* are *Kluyveromyces marxianus* and *Kluyveromyces lactis*. Their expression vectors, selectable markers, and transformation systems are similar to those of *S. cerevisiae*. Nonconventional yeasts such as *Pichia pastoris*, *Hansenula polymorpha*, *Arxula adeninivorans*, and *Yarrowia lipolytica* cannot readily employ 2 μ m plasmid-based vectors and generally use selectable markers and autonomous replication sequences derived from autologous sources. These yeasts have found wide application in heterologous expression because they either produce very high levels of heterologous proteins, secrete proteins, or exhibit more versatile substrate utilization. The popularity of methylotrophic yeasts and particularly *P. pastoris* and *H. polymorpha* for heterologous protein production stems from the establishment of their Generally Recognized As Safe status, their capacity for cultivation at very high cell densities, and the existence of effective systems for transformation and expression.

Nonconventional yeasts are notable for their use of diverse carbon sources, physiological properties, and unusual biochemical pathways. Utilization of lactose and galactose is particularly important in the fermentation of whey (64), and xylose and cellobiose fermentations are important in the bioconversion of lignocellulosics (86, 141a). However, utilization of alkanes (117, 121) and particularly methanol (35) has proven significant because protein products can accumulate to high levels in these yeasts. Thermotolerance is also a valued trait that can suppress contamination

or increase growth rates. *A. adenivorans* will grow at temperatures up to 48°C (174), and *K. marxianus*, which will ferment cellobiose, will grow at temperatures up to 45°C, making it potentially useful for simultaneous saccharification and fermentation. *Debaryomyces hansenii* shows unusual osmotolerance (129). Production of extracellular enzymes such as lipase (14, 135, 153), amylase (23, 40, 100, 154), and endoglucanases (123, 124) is facilitated in yeasts with effective secretion systems. Finally, nonconventional yeasts are particularly useful in the production of glycerol (27), lactic acid (131), citric acid (73, 99), or carotenoids such as astaxanthin (111, 113, 164, 185). The capacities of nonconventional yeasts to produce useful products other than ethanol or to produce ethanol from substrates other than glucose, sucrose, and fructose have led to efforts that focus on their metabolic engineering for improved product formation.

Several researchers have previously reviewed the general transformation and expression techniques for non-*Saccharomyces* yeasts (15, 20, 37, 60, 61, 108, 127, 171), so our emphasis here will be on more generalized features of expression systems in nonconventional yeast systems.

21.2. ELEMENTS OF TRANSFORMATION VECTORS

All yeast transformation and expression systems require ways to introduce engineered DNA into a cell, enable it to survive, assist its propagation, and promote its transcription. The most essential requirements are a selectable marker and a functional promoter. With these two elements alone, it is possible to introduce modified genes and effect transformations of the DNA. The efficiencies of such simple systems, however, are very low. Linearized DNA is susceptible to degradation by endo- and exonucleases, and the DNA cannot be transcribed until it has become integrated into the genome, which can occur only after the DNA enters the nucleus. To increase the probability of survival, replication, and expression, autonomous replication sequences (ARSs) are often incorporated into the transformation vector. In the case of *S. cerevisiae* and related genera, these are derived from the origin of replication (Ori) sequences of native 2- μ m plasmids that are found in *Saccharomyces* and *Kluyveromyces* species. While the 2- μ m origin of replication will function in many yeasts, it is often inefficient or poorly stable in yeasts outside of the *Saccharomyces-Kluyveromyces* clade. Occasionally an ARS identified through functional studies in *S. cerevisiae* can be used in another yeast (137); however, the efficiency of transformation is generally low. It is often necessary to isolate an ARS from the species of interest.

21.3. SELECTABLE MARKERS

A selectable marker enables the isolation of cells that have taken up the exogenous DNA. They can be based on complementation of genetic lesions that create nutritional deficiencies (auxotrophies) or on genes that enable acquired resistance to otherwise toxic medium constituents. The latter are termed dominant selectable markers. These are preferred since they can be employed with commercial yeast strains that are diploid or lacking auxotrophic deficiencies. Drug resistance markers are often used, but they should not be left in the final construct for commercial strains. This is especially true of yeasts that are used in producing food-grade products.

21.3.1. Auxotrophic Markers

By far the most common auxotrophic selectable marker employed is *URA3* (13, 39, 52, 91, 120, 139, 184). Its popularity is attributable to the relative ease of obtaining *ura3* mutations by selection for resistance to the orotic acid homolog 5'-fluoroorotic acid (5'FOA). Also, if *URA3* carried on an episomal vector is used to complement a *ura3* mutation, it is very easy to cure the host by cultivation on medium containing 5'FOA (13). Cells with a complete pathway for uracil biosynthesis take up the 5'FOA antimetabolite and incorporate it into their RNA. The 5'-fluoro group causes mispairing, and cells prototrophic for uracil biosynthesis are killed. 5'FOA selection plates also contain uracil or uridine at a concentration of 50 to 100 μ g/ml. If a cell is deficient in either orotidine-5'-phosphate decarboxylase (*URA3*, *pyrG*) or orotate phosphoribosyltransferase (*URA5*) (39, 120), it will not take up the 5'FOA, and the mutant survives by using the uracil or uridine provided in the medium. The *ura3* mutant must be homozygotic for the trait in order to survive in the presence of 5'FOA, so it is sometimes necessary to sporulate the culture prior to selection. Also, residual orotidine-5'-phosphate decarboxylase in the cell cytoplasm can be sufficient to incorporate 5'FOA, so it is useful to cultivate sporulated or mutated cells on medium containing uracil for a few generations prior to selection on 5'FOA plates.

Other popular auxotrophic markers include the multifunctional *HIS4* gene (109, 119), the *LEU2* gene for 3-isopropylmalate dehydrogenase (16, 41, 71a, 112, 142, 175), the *TRP1* gene for phosphoribosylanthranilate isomerase (28, 154, 155), and the *ADE1* gene for *N*-succinyl-5-aminoimidazole-4-carboxamide ribotide (SAICAR) synthetase (24, 71a, 109). Recipient hosts can be obtained either through random mutagenesis and screening, which is not recommended for industrial strains since it can result in other unwanted changes, or by targeted deletion using transposable elements, *URA3*, or some other selectable marker. Auxotrophs in general and *Leu2* and *Ade1* auxotrophs in particular often grow poorly—even when their deficiencies are compensated with nutritional supplements—and are not highly suitable for industrial applications. Backcrossing the mutated cells against a parental strain and subsequent screening and selection for the desired auxotrophic marker are recommended.

21.3.2. Drug Resistance Markers

Drug resistance genes are widely used as dominant selectable markers to transform yeasts, other fungi, and bacteria. Their extreme utility means that this practice will continue, but possible proliferation of drug resistance into human, plant, and animal pathogens requires good practices in biosafety containment. Where possible—and certainly when modified organisms are to be released into nature—dominant resistance markers that do not use or that compromise clinically important drugs should be employed. Alternatively, once the genetic modification is completed, the marker should be excised (see below).

To be effective for transformation, the target yeast must be susceptible to the antibiotic, and the protein must confer resistance even when expressed at a low level. Both of these requirements can present problems when developing transformation systems with nonconventional yeasts. Non-*Saccharomyces* yeasts often exhibit high levels of drug resistance. This means that high concentrations need to be used in the selection plate in order to kill the cells, and the specialized antibiotics used for yeasts are often expensive.

Second, many of the drug resistance markers are derived from bacterial proteins, and expression of functional proteins occurs at only a low level in many yeasts. A significant fraction of yeasts belonging to the genus *Candida*, along with *Debaryomyces hansenii*, *Clavispora lusitanae*, *Lodderomyces elongisporis*, *Candida rugosa*, and others, use CUG (CTG in DNA) to code for serine rather than leucine (51, 158). While the CUG codon is infrequently used by these species, bacteria use it regularly. The substitution of serine for a leucine can disrupt protein structure, so the CUG yeasts do not express the bacterial drug resistance markers properly. To get around this problem, correct expression of bacterial drug resistance markers in CUG yeasts requires changing CUGs to some other codon for leucine (101, 102, 161) or synthesizing the gene with optimum codon usage (see below).

When employing a drug resistance marker for transformation, it is necessary to add a short recovery incubation period (ca. 4 h) in complete medium without the antibiotic to allow expression of the drug resistance protein before exposing the cells to the selective agent.

The two most widely used resistance markers are genes that code for aminoglycoside-3-phosphotransferase, which confers resistance to Geneticin (G418) or kanamycin. The *kan^r* marker is widely available (53, 67, 145, 171). To inhibit yeast growth, Geneticin is typically used at a concentration of about 50 µg/ml in the final medium. It is soluble in water at 50 mg/ml and stable at room temperature. A 1-mg/ml solution in 0.1 M potassium phosphate buffer (pH 8.0) should be sterilized by filtration, stored at 2 to 8°C, and used within 30 days. Kanamycin is likewise used at about 50 µg/ml. It is much less stable than Geneticin and even less stable than penicillin at 25 to 37°C (50).

The gene for hygromycin phosphotransferase, *hph* (66, 187), confers resistance to hygromycin B. It is widely used as a selectable marker for yeasts and filamentous fungi (3, 7, 21, 68, 137, 152, 165, 186). At a concentration of 0.38 mM, hygromycin completely halts growth of eukaryotic cells even in rich medium by blocking chain elongation in ribosomes (65). Typical concentrations used to inhibit yeasts and fungi are about 0.2 to 1.0 mg/ml. Hygromycin B is stable in solution for about 2 years at 4°C and about 1 month at 37°C (77).

Some yeasts and fungi are notably resistant to gentamicin and hygromycin, so other drugs must be used. In recent years, Zeocin has proven to be very useful as an inhibitory antibiotic for yeasts and other organisms (1, 4, 102). Zeocin effectively inhibits growth at a concentration of 25 to 100 µg/ml. It is stable in a dry powder form for up to a year at -20°C, but in solution, it is light sensitive. Plates containing Zeocin can be stored for several weeks at 4°C in the dark. The mechanism of action of Zeocin is not known, but it is structurally similar to bleomycin and phleomycin, which complex with Fe²⁺ to cleave DNA (18). The resistance factor *ble* codes for a protein that binds bleomycin, thereby eliminating its DNA cleavage activity (46). *ble* genes have been described from a number of bacterial sources (85). In addition, the bacterial gene for chloramphenicol acetyltransferase (*cat*) can impart resistance to phleomycin when it is expressed properly in yeasts (31). It also has been widely used to transform various yeasts (85).

The gene for nourseothricin acetyltransferase (*nat1*) from *Streptomyces noursei* confers resistance to the aminoglycoside antibiotic nourseothricin (63, 144, 167), which is effective at concentrations of 25 to 100 µg/ml and stable for up to 2 years at 20°C. In solution it shows some light sensitivity.

Most eukaryotic cells are sensitive to inhibition by the glutarimide antibiotic cycloheximide, but resistance to it is widespread among yeasts (156). Cycloheximide binds to the 80S ribosomal subunit, thereby inhibiting translation. The resistance mechanism is attributable to a specific amino acid difference in ribosomal protein L41. Yeasts that are susceptible to cycloheximide can be transformed with a mutated form of L41 to confer resistance (92).

21.3.3. Dominant Non-Drug Resistance Markers

With the spread of antibiotic resistance among clinical isolates, concern is rising over the use of drug resistance markers to transform medically important human, animal, or plant pathogens. One useful selectable marker that does not use drug resistance is the *IMH3* gene for inosine monophosphate (IMP) dehydrogenase, which confers resistance to mycophenolic acid (MPA). IMP dehydrogenase catalyzes an NAD-dependent rate-limiting step in the biosynthesis of guanine nucleotides. Growth of *Candida albicans* is inhibited by 1 µg/ml of MPA, which is a specific inhibitor of the *IMH1* form of IMP dehydrogenase. However, transformants overexpressing a different form of IMP dehydrogenase, the *C. albicans IMH3* gene, will resist up to 40 µg/ml of MPA (11, 88, 95). The bioavailable form of MPA, mycophenolate mofetil, has a number of clinical applications, mainly as an immune suppressant for transplantation, but it is not widely used as an antimicrobial. The *CaIMH3* gene has been used successfully as a dominant selectable marker in *Candida parapsilosis* and *C. albicans* (11, 44, 55).

Sulfite resistance has long been studied in yeasts since it is important in wine making. Two genes for sulfite resistance from *S. cerevisiae*, the transcription activator *FZF1-4* (*RSU1-4*) and to a lesser extent its regulated target, *SSU1*, have been used as dominant selectable markers in sulfite-susceptible strains (125). The latter is a plasma membrane sulfite pump, which enables cells to survive in the presence of sulfite.

21.4. EXCISION ELEMENTS

Most nonconventional yeasts have only a few selectable markers for genetic transformation. It is therefore very useful to be able to recover them for reuse. *URA3* is almost unique in exhibiting a bidirectional selection. It is possible to identify *URA3* transformants by selecting for growth on uracil⁻ (Ura⁻) medium, and it is possible to select for *URA3* by plating on 5'FOA. Normally the reverse selection is employed when the *URA3* gene is carried on an autonomous plasmid. However, it is also possible to design *URA3* and other selectable markers so that they will excise readily. Direct flanking repeat sequences on either side of the selectable marker will occasionally (ca. 10⁻⁵) recombine to excise the intervening sequence (169). For example, short (40-bp) flanking direct repeat sequences from λ phage promoted the spontaneous excision of *URA3* after it was used to disrupt *LEU2* (112). The excised *URA3* mutants were recovered on 5'FOA plates. In the case of selectable markers that do not have such sensitive means for identifying spontaneous excision reversions, two recombinase proteins can greatly enhance the frequency.

The Cre recombinase from bacteriophage P1 has been shown to excise intervening DNA that is flanked by direct repeats of its cognate *loxP* sequence. The efficiency of this excision approaches 70%, making identification of the resulting marker-deficient strains relatively easy (67). In a similar manner, the F1p recombinase, encoded by the 2µm

plasmid of *S. cerevisiae*, specifically recognizes 13-bp repeat elements found in the 2 μ m circle. When these are present as flanking direct repeats, the intervening sequence is excised (6). When these or the *loxP* sequences are in opposite orientations, the intervening sequence is inverted.

21.5. PROMOTERS

In the past, promoter selection for heterologous expression has been based on experience with a relatively limited set of genes. In recent years, however, as we have gained powerful tools for large-scale quantification of promoter expression profiles, selection has become tuned to specific applications. When faced with developing promoters for a new yeast system, little is likely to be known about promoter properties since the strength and expression profiles can vary widely from one organism to another. Genome-wide expression arrays provide the most comprehensive way to identify useful promoters. The induction patterns for *S. cerevisiae* genes can be obtained from the *Saccharomyces* genome database (<http://www.yeastgenome.org/>).

ADH1 has been employed for strong heterologous expression in *S. cerevisiae*, and the *ADH2* promoter has been used for glucose-repressible expression. However, few other yeasts exhibit such high levels of fermentation. The galactokinase (*GAL1*) or the bifunctional UDP-glucose-4-epimerase (Galactowaldenase), aldose-1-epimerase (Mutarotase) (*GAL10*) promoter can be used for regulated (glucose-repressed/galactose-induced) expression. Both of these are widely distributed among yeasts. The *TDH3* (*GAP*) promoter is often used for strong constitutive expression (25, 34, 71, 74, 81, 104, 146). Triose phosphate dehydrogenase has three isoforms in *S. cerevisiae* and between one and three isoforms in other yeasts. This is also true in *Pichia stipitis* (87). Alternatively, the translation elongation factor (*TEF1*) promoter (2, 15, 161) or the histone H4 (*AHSB4*) promoter has been used for strong constitutive expression (173).

In *P. pastoris* and *H. polymorpha*, promoters that are responsive to the presence of methanol are used. Even though these yeasts are frequently employed for heterologous protein production, only a limited set of promoters is in common use (146). The *AOX1* promoter for alcohol oxidase is most often employed. It is very strong, tightly controlled through glucose repression, and highly induced upon a shift to methanol as a carbon source (38). The promoter for formaldehyde dehydrogenase, *FLD1*, is sometimes used as an alternative to *AOX1* (147). Occasionally more precise expression levels are required for optimal protein production. For this purpose, a library of *P. pastoris* promoters has been characterized (69). The use of a constitutive promoter such as *PMA1* for plasma membrane H⁺-ATPase can avoid the fire hazard inherent in the use of methanol as a carbon source at large-scale use (35).

21.6. REPORTER GENES

Once a promoter is isolated, it is necessary to determine its relative strength. This is most conveniently done through the use of reporter genes. β -D-Galactosidase (*lacZ*) is commonly used due to the availability of a rapid screen (22, 136). Some yeasts, however, such as *P. stipitis*, *D. hansenii*, *Pichia guilliermondii*, *K. marxianus*, and *K. lactis* possess β -D-galactosidase that can interfere with heterologous expression assays. Also, CUG yeasts will not translate *lacZ* properly. For example, *E. coli lacZ* contains 54 CUG codons.

Even more popular than *lacZ* is green fluorescent protein (GFP). While the quantitative analysis of expression requires a measurement of fluorescence, this marker is particularly useful when expression occurs only in a fraction of the cell population, during a certain phase of the cell cycle, or in a region of the cell. The native GFP does not express well in yeast, and especially in CUG yeasts; however, a codon-optimized form of GFP, in which all of the CUGs have been replaced with TTT to specify leucine, expresses well in both *C. albicans* and *S. cerevisiae* (33).

21.7. INTEGRATED EXPRESSION

Integrated expression (expression of genes after integration into the chromosome) is critical for stable industrial production strains. Even with integrated expression, mutations that enable more rapid growth of the host to the detriment of product formation can proliferate. The use of episomal vectors can result in strain instability and inconsistencies from batch to batch (61).

Integration can be random or targeted to a particular site. Targeted integration is generally preferred since this yields better-defined transformants with potentially higher productivity. Regulatory certification is easier to obtain if the integration site is defined, and by knocking out genes that can form by-products, cell yields are increased.

Integration of exogenous DNA requires double-strand break (DSB) repair, which can occur either through homologous recombination (HR) or through nonhomologous end joining (NHEJ). The former is mediated by Rad52-related proteins (97) and the latter by Ku70/Ku80, Lig4, and a number of other gene products (5, 46, 143). HR requires relatively long regions of homology to repair a DSB, whereas NHEJ requires little or no homology to join two broken strands (Fig. 1).

HR predominates in *S. cerevisiae*, but in *P. stipitis*, *K. lactis* (97), fungi such as *Aspergillus* (160) and *Neurospora* (122) spp., and higher organisms (78), the frequency of NHEJ can be 1 to 4 orders of magnitude higher than targeted integration by HR. Mutating the *KU80* or *KU70* genes in *K. lactis* (97), *P. stipitis* (94, 114), and other fungi (122) greatly increases the proportion of targeted disruption by HR; however, the overall number of recovered transformants drops by more than an order of magnitude. Even though there are fewer total transformants, recovery of site-specific integrants is much easier because they represent 80 to 97% of the recovered mutants (Fig. 2A).

FIGURE 1 Homologous recombination and nonhomologous end-joining mechanisms for recombination.

A

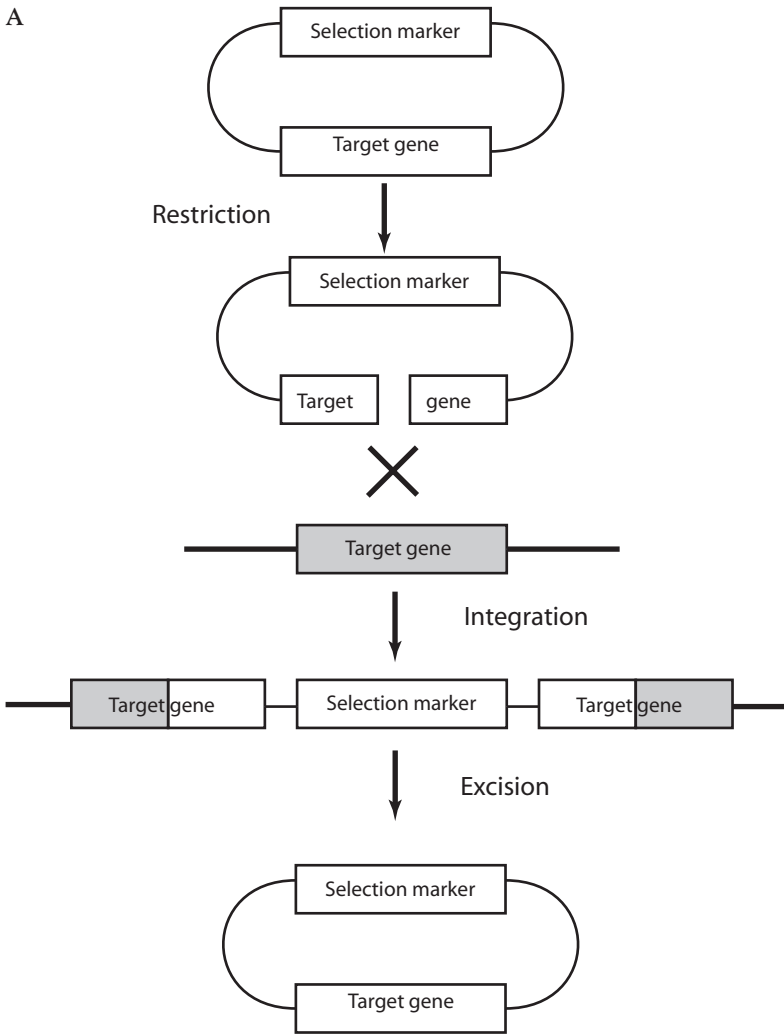

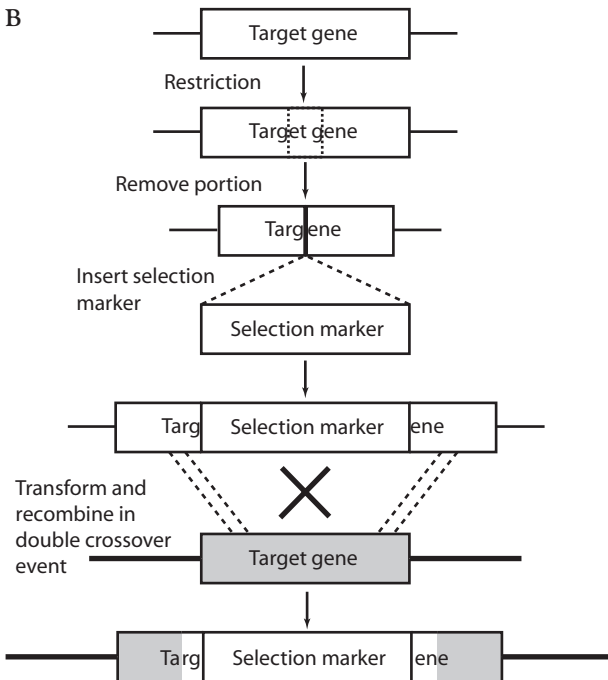

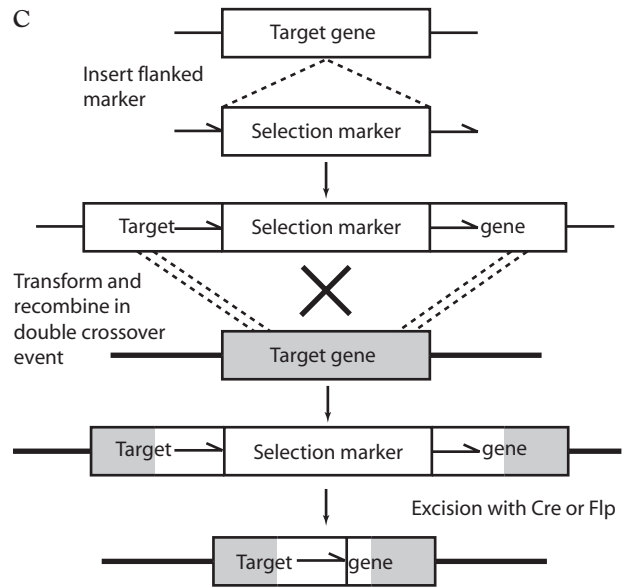

FIGURE 2 Targeted integration of plasmid. (A) The efficiency of integration for a selection marker is greatly increased by linearizing the vector within a sequence found in the target genome. Simple integration without deletion or modification of the cloned gene essentially doubles the gene copy. (B) By deleting a portion of the target gene before integrating the selectable marker, it is possible to disrupt the target. For this to be effective and to achieve high levels of transformation, it is necessary to excise the disruption cassette from the vector and transform with a fragment having sequences that overlap with the target gene. (C) It is possible to subsequently recover the selection marker by flanking it with direct repeats.

B

C

Aside from targeted integration, restricting the efficiency of the promoter of the selectable marker will also increase the recovery of transformants with multiple integration events. In *Arxula adenivorans*, it was possible to obtain transformants with multiple integrational events for amylase production by reducing the length of the *LEU2* promoter from its initial 565 bp to only 56 bp (154). Transformants recovered from the complete promoter contained only a single integration event, but transformants obtained with the abbreviated promoter contained up to eight integrated copies when both were targeted to the 25S RNA gene (Fig. 2B). Presumably, strains with more integrated copies are favored for growth because they achieve a functional level of *LEU2* expression. Madzak et al. have reported similar results with the use of a defective *URA3* marker (115).

Restriction endonuclease-mediated integration has been reported to increase the frequency of site-specific integration (43, 166). While it does improve the overall frequency of integration events, linearization alone is effective as well (Fig. 2C). In fact, Maassen et al. (114) have suggested that the increase in integration events that they observed when transforming *P. stipitis* with plasmids along with the restricting enzymes was attributable to the prevention of recircularization rather than to any specific effect on the target genomic DNA.

The frequency of integration events can also be increased by incubating the host cells with sublethal doses of bleomycin just prior to transformation with linearized DNA. Bleomycin introduces DSBs in DNA, so exposure to sublethal doses of this antibiotic increases opportunities for recombination.

21.7.1. Multicopy Integration

More than 400 copies of the long terminal repeat elements of Ty1 and Ty2 are found in the *S. cerevisiae* genome. These have been used as targets for multiple integration events in order to increase the stable transmission of heterologous genes (106). Transformation frequencies are higher and stabilities are greater when two flanking copies of the δ -region are used (105). This technique has been fairly widely used in *S. cerevisiae* (29, 47, 93, 106), and use of the same sequence has been attempted in *K. lactis* (172).

Ylt1 is a repetitive element that exists in about 35 copies with an additional 30 copies of long terminal repeat elements in the *Yarrowia lipolytica* genome. Relatively high-copy-number integration events could be obtained when a defective *URA3* allele was used as the selectable marker. Most of these were direct tandem integration events (90, 126).

The ribosomal DNA (rDNA) locus has been used as a site for multiple integration events in *Y. lipolytica*, *K. lactis*, *S. cerevisiae*, *Candida utilis*, *Schizosaccharomyces pombe*, and *Phaffia rhodozyma* (19, 21, 33, 37, 39, 44).

21.8. EXPRESSION FROM AUTONOMOUS PLASMIDS

An ARS can greatly increase the efficiency of transformation by enabling replication of plasmid DNA in its target host. An autologous ARS can be obtained from the prospective host by cloning a library of short restriction fragments from the host into a vector bearing a selectable marker. The library is then transformed into the target host. The transformed yeasts are pooled, and a plasmid preparation is made from the yeast cells. Any rescued plasmids are transformed back into *E. coli*,

and a number of clones are selected for characterization. After two or three cycles of transformation and rescue, it is possible to obtain an ARS that allows stable replication in both hosts (1, 17, 30, 96, 119, 157, 168, 184). Alternatively, it is possible to synthesize a library of random AT sequences and screen for ARS activities in the same manner (54). Centromeric sequences are needed for appropriate partitioning (168, 182, 183).

21.9. TRANSFORMATION OF *P. PASTORIS* AND *H. POLYMORPHA*

The logic for expression of recombinant genes in either *P. pastoris* or *H. polymorpha* is much the same. Both yeasts are strong methanol-inducible yeast species, and methanol-regulated promoters are most often utilized for expression. Thus, one clones the recombinant gene under control of a methanol-regulatable promoter such as that from the alcohol oxidase gene (known as the *AOX1* gene in *P. pastoris* and the *MOX* gene in *H. polymorpha*). Then one proceeds to culture the expression strains in glucose for growth and strain maintenance. Under these conditions, expression of the recombinant gene is "off," minimizing selection against a strain that produces large amounts of foreign protein when induced. When production of the recombinant protein is desired, one switches to a methanol medium. A difference between the yeasts is that the *P. pastoris* *AOX1* promoter is strictly dependent on methanol and requires the alcohol for full expression levels, whereas the *H. polymorpha* *MOX* promoter can be derepressed to full expression levels by feeding of glycerol as a carbon source or by feeding glucose at a carbon limited rate. If ethanol is a problem for production with *P. pastoris*, then a variety of other promoters are available for this yeast, such as the *GAP* promoter, which is constitutive, or the *ADH* promoter, which can be derepressed to a high level of expression in response to growth rate-limiting amounts of glucose. Another difference between these yeasts is growth temperature. *P. pastoris* does not grow well above 30°C, whereas *H. polymorpha*'s optimal growth temperature is about 37°C. As a result, *H. polymorpha* grows significantly faster than *P. pastoris* and most other yeasts, and processes for *H. polymorpha* take a significantly shorter time. An advantage of *P. pastoris* is that the strains and vectors needed for recombinant gene expression are commercially available through Invitrogen (Carlsbad, CA) and other sources, whereas the *H. polymorpha* system is not sold commercially and is more difficult to obtain. In addition, the *P. pastoris* system has been much more extensively utilized, and therefore there is much more published literature available on expression in this yeast.

Techniques for culturing *P. pastoris* or *H. polymorpha* at the bench level are very similar to those used for *S. cerevisiae*. The most common rich medium for cultivation of either yeast species is YPD (1% yeast extract, 2% peptone, 2% dextrose), and defined medium is YNB (0.67% yeast nitrogen base with ammonium sulfate and without amino acids, 2% dextrose plus any amino acids or nucleotides required for growth at ~50 μ g/ml each). Growth of *P. pastoris* or *H. polymorpha* on methanol requires that the dextrose be replaced with methanol to 0.5%. Incubations of *P. pastoris* are typically done at 30°C, whereas those for *H. polymorpha* are generally done at 37°C. In liquid YPD, *P. pastoris* has a generation time of ca. 90 min, and *H. polymorpha* at 37°C in the same medium has a generation time of approximately 1 h. With methanol as sole carbon source

and a defined culture medium, the generation time of *P. pastoris* is around 5 h and that for *H. polymorpha* is about 3 h per generation at 37°C.

The first consideration in the selection of a *P. pastoris* or *H. polymorpha* expression vector is whether you intend the yeast to secrete a protein product or produce it intracellularly. A general rule of thumb is to produce a recombinant protein in the same way that it is expressed in its native host: if a protein is produced intracellularly by its native host, one should also produce it intracellularly in the yeast host; if the protein is secreted from its native host, secrete it from the yeast system. Although there have been exceptions to this general rule, it is generally best to follow it since the intracellular and secretory environments are very different from each other and synthesis of a protein in the wrong compartment may result in improper folding or degradation. A number of vectors have been constructed for each yeast species; a list and detailed discussion of these vectors for *P. pastoris* can be found in Lin Cereghino et al. (109) and at www.Biogrammatomics.com, and *H. polymorpha* is discussed in reference 61.

These days, genes to be expressed are usually obtained by PCR amplification from genomic DNA or cDNA, or by gene synthesis; either method facilitates the incorporation of convenient restriction sites, signal sequences, purification tags, etc. When the goal is efficient secretion of the gene product, the cloning can be a little trickier. Use of the native secretion signal sequence associated with the heterologous gene is the most straightforward, but those signal sequences may not be efficiently used by the yeast host. Alternatively, a yeast signal sequence, such as that for the *S. cerevisiae* alpha mating factor (α MF), can replace the heterologous signal sequence in the expression vector. The α MF secretion signal is commonly used because it has been proven to give efficient secretion of many types of recombinant proteins. Although the recombinant protein may be successfully secreted using the α MF signal, proper N-terminal processing of the heterologous protein may not occur, and modifications of the α MF signal, or the use of an alternative secretion signal sequence, may ultimately be necessary to obtain a properly processed protein.

21.9.1. Transformation by Electroporation

For transformation of either *P. pastoris* or *H. polymorpha*, electroporation is the most commonly used procedure, and therefore a modified version of that described by Becker and Guarente (10) will be related here. For the other procedures, readers are referred to either of the volumes of *Methods in Molecular Biology: Pichia Protocols* (36, 72); for *H. polymorpha*, please refer to *Hansenula polymorpha: Biology and Applications* by G. Gellissen (59).

21.9.2. DNA Preparation

For all transformation methods, linearized plasmid DNA is most commonly transformed into either yeast for integration into the yeast genome. The DNA sequences at the ends of the linear plasmid DNA stimulate integration by a single crossover recombination event into the locus shared by vector and host genome. Therefore, linearization of an expression plasmid is performed within a yeast sequence such as the promoter sequence. The final vector, prepared in *E. coli*, is cut with a restriction enzyme that linearizes the vector, and then the DNA is purified and concentrated to approximately 100 ng/ μ l prior to transformation. At this point the vector is ready for transformation into yeast.

Preparation of Electrocompetent Cells for Transformation of *P. pastoris*

The procedure for growth and preparation of electrocompetent *P. pastoris* cells is taken from Lin-Cereghino et al. (110) and is described below. All solutions should be autoclaved except for the dithiothreitol (DTT) and HEPES solutions, which should be filter sterilized.

1. Electroporation instrument: BTX Electro Cell Manipulator 600 (BTX, San Diego, CA). Parameters for electroporation vary considerably depending on the apparatus used. Check the instructions provided by the manufacturer for specifics for each instrument.
2. Inoculate 10 ml of YPD medium with a single fresh *P. pastoris* colony of the strain to be transformed from an agar plate and grow overnight with shaking at 30°C.
3. Use the overnight culture to inoculate a 500-ml YPD culture in a 2.8-liter Fernbach culture flask to a starting optical density at 600 nm (OD_{600}) of 0.01 and grow to an OD_{600} of 1.0 (ca. 12 h).
4. Harvest the cells by centrifugation at $2,000 \times g$ at 4°C, discard the supernatant, and resuspend the cells in 100 ml of fresh YPD medium plus 1 M HEPES buffer (pH 8.0) in a sterile 250-ml centrifuge tube.
5. Add 2.5 ml of 1 M DTT and gently mix.
6. Incubate at 30°C for 15 min with slow rotating.
7. Add 150 ml of cold water to the culture and wash by centrifugation at 4°C with an additional 250 ml of cold water. At this stage and from here on, keep the cells ice cold and do not vortex the cells to resuspend them (slow pipetting is best).
8. Wash cells a final time in 20 ml of cold 1 M sorbitol, then resuspend in 0.5 ml of cold 1 M sorbitol (final volume including cells will be 1.0 to 1.5 ml).
9. Use these cells directly without freezing to achieve the most transformants.
10. To freeze competent cells, distribute in 40- μ l aliquots to sterile 1.5-ml minicentrifuge tubes, and place the tubes in a -70°C freezer.

Electroporation Procedure

1. Add up to 1 μ g of linearized plasmid DNA sample in no more than 5 μ l of water to a tube containing 40 μ l of frozen or fresh competent cells and then transfer the entire mixture to a 2-mm gap electroporation cuvette held on ice.
2. Pulse cells according to the parameters suggested for yeast by the manufacturer of the specific electroporation instrument.
3. Immediately add 0.5 ml of cold 1 M sorbitol and 0.5 ml of cold YPD, then transfer the entire cuvette contents to a sterile 1.5- to 2.0-ml minicentrifuge tube.
4. Incubate for 3.5 to 4 h at 30°C with slow shaking (100 rpm).
5. Spread aliquots onto selective agar plates and incubate for 2 to 4 days.
6. To avoid mixed colonies, pick and restreak transformants on selective medium at least once before proceeding with further analysis.

Preparation of Electrocompetent Cells and Electrotransformation of *H. polymorpha*

The procedure for growth and preparation of electrocompetent *H. polymorpha* cells is taken from Gellissen (59) and is

described below. All solutions should be autoclaved except for the DTT solution, which should be filter sterilized.

1. Inoculate 200 ml of YPD medium with an appropriate volume of fresh preculture and grow until the cells reach an OD_{600} of 0.8 to 1.2.
2. Harvest the cells by centrifugation and resuspend them in 0.2 volume of prewarmed (37°C) 50 mM potassium phosphate buffer (pH 7.5), then add DTT (1 M) to a final concentration of 25 mM.
3. Incubate the cells at 37°C in a water bath (without shaking) for 15 min.
4. Harvest the cells by centrifugation and wash twice: the first in 1 volume and the second in 0.5 volume of STM buffer (270 mM sucrose, 10 mM Tris-HCl, pH 7.5, 1 mM MgCl_2) while being kept at 0°C .
5. Resuspend the final cell pellet in 0.005 volume of STM buffer and dispense the cells in 60- μl aliquots. Freeze the aliquots at -70°C .
6. To transform, thaw aliquots of competent cells in ice, and add plasmid DNA (200 ng to 1 μg). Transfer the cells to a prechilled 2-mm cuvette.
7. After careful drying with a paper towel, place the cuvette in the electroporator and pulse (e.g., 2.0 kV, 25 μF , 200 ohm, for a Bio-Rad Gene Pulser II device). Note: Conditions for electroporation vary considerably depending on the instrument. Be sure to follow the instrument's instructions.
8. Immediately add 1 ml of YPD medium, transfer the cells to a microtube, and incubate at 37°C for 1 h of recovery.
9. Harvest cells by centrifugation, wash them once in 1 ml of selective medium, and suspend them for plating on selective plates. Incubate plates at 37°C for 2 to 3 days.

Protocol for Small-Scale Expression in *P. pastoris*

This protocol describes how to perform a shake flask study of two *P. pastoris* strains, one secreting a protein, human serum albumin (HSA), and a second expressing an intracellular enzyme, bacterial β -lactamase (β -lac) (see Fig. 3). The HSA gene is expressed from the methanol-inducible *AOX1* promoter, whereas the β -lac gene is expressed constitutively from the *GAP* promoter. (These strains can be obtained from the authors by contacting J.M.C.) For the strains

expressing HSA, samples of culture medium are collected and subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). For strains expressing β -lac, a simple qualitative enzyme assay is employed.

Secretion of HSA

1. Pick a colony of an HSA-secreting strain and inoculate into 50 ml of YPD medium in a sterile Erlenmeyer flask. Incubate with shaking overnight.
2. The next day, shift the cultures by centrifugation. To shift, determine the OD_{600} of each culture and centrifuge 200 OD_{600} units (OD_{600} unit = volume in milliliters \times OD_{600} reading) of each culture.
3. After centrifugation, decant the supernatant and suspend each cell pellet in 10 ml of BMMY medium (1% yeast extract, 2% peptone, 100 mM potassium phosphate [pH 6.0], 1.34% YNB with ammonium sulfate and without amino acids, 0.5% methanol). Transfer each culture to a small (50-ml) sterile shake flask and place in a 30°C incubator with vigorous shaking. Before starting the induction, harvest 0.5 ml of each culture for a $t = 0$ sample.
4. Centrifuge the $t = 0$ samples in a microcentrifuge for 5 min at maximum speed. Transfer the supernatants to a clean tube. Discard the cell pellets but save the supernatants by storing them frozen at -20°C .
5. Add methanol to each culture to a final concentration of 0.5%, every 12 h.
6. Take additional aliquots of HSA-secreting culture (or negative control) at 12, 24, 48, and 64 h and prepare them for storage at -20°C as described above.
7. Thaw and analyze proteins in each HSA sample by SDS-PAGE to evaluate HSA synthesis and secretion over time. For each sample, mix 25 μl of culture medium supernatant with 4 μl of the 6 \times SDS-PAGE loading. Load 25 to 30 μl on an SDS-polyacrylamide gel. Follow standard procedures for Coomassie staining of an SDS-polyacrylamide gel.

Expression of β -lac

1. Pick a colony of each of the two β -lac-producing *P. pastoris* strains and inoculate into 50 ml of YPD medium. In one strain, the gene for *bla* is fused to the inducible

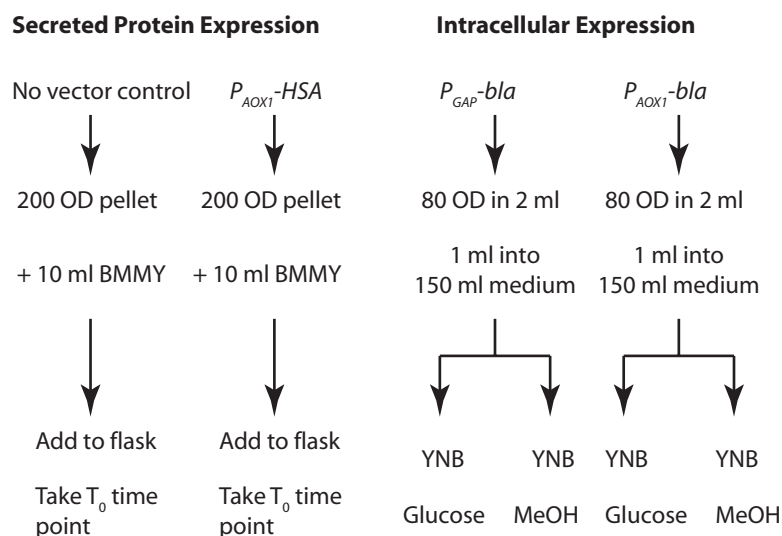

FIGURE 3 Protocol for assays of protein expression in *P. pastoris*.

- alcohol oxidase (*AOX1*) promoter. In the other, *bla* expression is regulated by the constitutive glyceraldehyde-3-phosphate dehydrogenase (*GAP*) promoter.
2. The next day, remove a 1-ml aliquot of each culture to a clean microcentrifuge tube. Determine the absorbance of each culture at OD₆₀₀ and centrifuge 80 OD₆₀₀ units of each. Then resuspend the 80 OD₆₀₀ units in 2 ml of sterile water.
 3. For each culture, add 1 ml of cells to each of two flasks containing 150 ml of medium, one with YNB glucose medium and one with YNB methanol medium.
 4. Determine the OD₆₀₀ of each culture and harvest 20 OD₆₀₀ units of each by centrifugation. Decant the supernatant medium and save the pellets at -20°C. These are *t* = 0 samples.
 5. Place the remainder of the two cultures at 30°C with shaking. Add additional methanol to each methanol medium culture (i.e., not the glucose medium cultures), to a final concentration of 0.5%, at 12 h.
 6. At 6, 12, and 24 h, determine the OD₆₀₀ of each culture and harvest 20 OD₆₀₀ units from each. Centrifuge each sample, decant the supernatants, and store cell pellets in labeled tubes at -20°C.
 7. Transfer all β-lac 20-OD₆₀₀ cell pellet samples from storage at -20°C (plus at least one nonexpressing negative control sample) to an ice bucket to thaw.
 8. Suspend cell pellets in 100 μl of ice-cold breaking buffer (25 mM Tris-HCl, pH 7.5). Add one scoop (~100 μl) of glass beads to each sample.
 9. Vortex as vigorously as possible. Multiple samples (up to 12) can be broken simultaneously using a multisample vortex head (Disruptor Genie, Scientific Industries, Inc.) in the cold box by vortexing constantly at 4°C for 10 min.
 10. Centrifuge samples for 10 min at full speed in a microcentrifuge at 4°C.
 11. Transfer each supernatant to a clean minicentrifuge tube. (Be careful to avoid transferring pellet and cell debris; i.e., transfer only clear cell extract.) Save supernatants (cell-free extracts) in labeled tubes specifying the strain and time point.
 12. Determine protein concentration in each sample using the Pierce assay or other method.
 13. Carry out assays for β-lac activity in extracts as follows. For each strain and time point, transfer 5 μg of protein to a microcentrifuge tube containing 198 μl of ice-cold breaking buffer. Include a negative control with breaking buffer substituted for extract. Start the assay by adding 2 μl of PADAC substrate solution. Mix and incubate at 30°C for 5 min. β-Lac activity is indicated by a change of color from purple to yellow.

21.10. SYNTHETIC DNA

As synthetic DNA continues to drop in price, it is now routinely used to speed up construction of expression cassettes for metabolic engineering. Gene synthesis is useful to eliminate unwanted restriction and alter specific regions of the protein. More importantly, through codon optimization, it can also increase translation rates. Codon optimization was based initially on the observation that organisms use a nonrandom subset of the 61 possible sense codons available in the genetic code. This can result in a bias in their codon usage. Codon usage varies from one species to another. It is consistent within the genes of any given genome, and the codon usage in open reading frames correlates with the

most abundant aminoacyl-tRNAs present in the cell (150). It is not clear, however, that altering codon usage alone will result in an optimal translation rate. In addition to codon preference based on tRNA usage, it is also necessary to take into account secondary structures and contextual optimization. For example, it is possible to increase protein synthesis by optimizing the initial codons in an open reading frame, thereby avoiding the formation of secondary structures which may interfere with the ribosomal complex (76, 80, 98). Codon optimization can adjust the overall G+C usage to something more appropriate for the producing organisms, and contextual codon optimization can avoid the sequential use of certain acyl-tRNAs that interfere with one another during translation (70). Optimization of codons based on frequency of acyl-tRNA usage alone does not give consistently better results, so care should be taken in considering the various factors in designing synthetic genes.

While limited sequence optimization—such as the elimination of restriction sites or specific codons—might be done manually, the optimization of open reading frames for various codon usage tables can be aided through the use of software (53) or online tools (180). Reducing ambiguity in the overlaps for optimized gene assembly requires elaborate algorithms and significant computational power (103).

Codon optimization can be highly effective in the expression of bacterial (19, 178) or human proteins in yeasts. It can eliminate cryptic polyadenylation signals in native mRNA, such as AT-rich stretches (76), thereby increasing the efficiency of protein synthesis (162). Codon optimization has been used to increase production of several proteins in *P. pastoris* (75, 76, 118, 170, 179).

Synthetic DNA can be used to increase expression of open reading frames, but it is somewhat more difficult to apply to the construction of eukaryotic promoters since these often have high AT content, along with inverted and direct repeats that can interfere with DNA synthesis. The cost of synthetic DNA is dropping rapidly, and genes up to 1,500 bp in length can be obtained from commercial operations with turnaround times of a few weeks or less.

21.11. ENHANCING OVEREXPRESSION OR SECRETION

Many factors besides transcript formation determine the efficiency of protein production. One of the most critical is oxygen supply. During heterologous protein production in large-scale bioreactors, regions of the reactor vessel are relatively poorly mixed. Moreover, even if the whole vessel is mixed, packets of fluid are rapidly depleted in oxygen, generating cycles of aeration and oxygen deprivation. This is particularly true in high-density fermentations for the production of enzymes or other heterologous proteins. The oscillation between aeration and oxygen limitation can disrupt cellular metabolism. One interesting approach to overcome this problem is the heterologous expression of a bacterial hemoglobin (Vhb) from the gram-positive bacterium *Vitreoscilla* (159). Trapping oxygen when cells are exposed to aerobic conditions and releasing it when under less aeration can mitigate the effect of poor mixing. Expression of Vhb increased recombinant β-galactosidase production in *P. pastoris* (181), improved cell growth and secretion of extracellular enzymes in *Y. lipolytica* (12), and enhanced ethanol production by *S. cerevisiae* (26), including the production of ethanol from xylose (141).

Excessive oxygen can be toxic to yeasts due to the production of reactive oxygen species such as superoxide

anions ($O_2^{\cdot-}$). Superoxide dismutase, which catalyzes the conversion of $O_2^{\cdot-}$ into oxygen and hydrogen peroxide, is the first line of defense (130). In *K. lactis*, overexpression of *KISOD1* effectively reduced oxygen stress during heterologous protein production.

21.12. CHAPERONE, FOLDASE, CELL WALL, AND ER FACTORS

Overexpression of heterologous proteins in a recombinant host can saturate or overload the endoplasmic reticulum (ER) secretory pathway, thereby resulting in misfolding (57, 148, 151). There are two basic modes of eukaryotic protein translocation. In cotranslational translocation, secretion occurs contemporaneously with peptide synthesis. The growing polypeptide chain moves from the ribosomal tunnel into a membrane channel formed by the Sec61 membrane complex, and the whole process is driven by GTP hydrolysis during translation. In posttranslational translocation, the Sec62 membrane complex forms a pore between the cytosol and the ER membrane. It binds the signal sequence of the preformed protein, which is then drawn through the membrane (132).

Kar2p (the yeast equivalent to the mammalian BiP) is a member of the Hsp70 family of heat shock proteins that serves as a ratchet to draw the preformed protein through the membrane in posttranslational secretion. Further processing such as folding, disulfide cross-linking, and glycosylation then occurs in the lumen of the ER (9, 32, 62).

Several proteins in the ER are involved in this process. Protein disulfide isomerase (PDI) appears to play a role in folding. Overexpression of proteins involved in the ER secretory pathway has been reported to improve secretion in *S. cerevisiae*. Overexpression of PDI in *K. lactis* strongly stimulated secretion of highly disulfide-bonded serum albumin (8) and human lysozyme (82). Likewise, overexpression of PDI in *P. pastoris* was able to increase secretion of a hookworm vaccine protein that contained 20 disulfide linkages (79). Overexpression of the chaperones Kar2, Ssa1, or PDI can improve protein secretion by two- to sevenfold in *P. pastoris* (188).

A systematic study of yeast genes to enhance protein secretion in *S. cerevisiae* showed the cell wall protein Ccw12 and the ER resident thiol oxidase, Ero1, as lending the most general enhancement (176). Gasser et al. (58) used a transcriptomics-based approach to examine a *P. pastoris* strain that would overexpress human trypsinogen, in comparison with one that would not. More than 500 genes were significantly upregulated in the secreting strain. Of these, 13 had potential function in secretion pathways. Based on previous studies of secretion enhancement in *S. cerevisiae*, these 13 genes, along with homologs to genes previously characterized as having roles in secretion, were cloned and overexpressed in *P. pastoris*. Ero1, Kar2, and Sso2 (involved in fusion of secretory vesicles at the plasma membrane), along with Bfr2 and Bmh2 (involved in protein transport), the chaperones Ssa4 and Sse1, the vacuolar ATPase subunit Cup5, and Kin2 (a protein kinase connected to exocytosis), all proved effective at increasing production of antibody fragments.

21.13. HUMANIZED YEAST EXPRESSION SYSTEMS

21.13.1. Market

Monoclonal antibodies (MAbs) represent the fastest growing sector of biotherapeutic proteins (107). The global

therapeutic MAb market grew to \$5.4 billion in 2002, with chimeric MAbs accounting for 43% of sales (133). From 2004 to 2008, growth actually exceeded expectations (128). The global sales of MAbs have been reported as \$33 billion in 2008 as compared to \$27 billion in 2007 (116). This explosive growth stems from the tremendous ability of MAbs to bind a plethora of antigens ranging from toxins, viruses, and bacteria to cancer cells. The main applications, however, lie in their potential to boost novel treatments of cancer and inflammatory and infectious diseases. In 2004, the global clinical antibody pipeline had 132 products in development (133). As of 2009, more than 500 antibody-based therapeutics were in development, with 200 more in clinical trials (84, 128, 134). These factors suggest that large-scale antibody production in yeasts and fungi might be a major emerging opportunity (see reference 56).

Clinically proven MAbs have been produced in tissue culture (49), mainly Chinese hamster ovary cells, with its incumbent costs (107). This technology results in MAbs similar but not identical to their native counterparts. Large-scale tissue culture (up to 200,000 liters) has an estimated productivity of only 1 to 2 mg liter⁻¹ h⁻¹, with an estimated annual productivity of 8 to 16 kg/year (177). In 2006, the estimated cost for producing a MAb by mammalian tissue culture was between \$300 and \$3,000 (US) per g, with the major cost centers coming from low titers and downstream purification (49). While such MAbs are valuable as biopharmaceuticals, the doses required are typically much larger than for other biologics (89), typically >100 mg, due to their low potency (84). As a result, MAbs are among the most expensive pharmaceuticals available, with annual costs for cancer therapies reaching up to \$35,000 US/year per patient (48). Clearly this is an area in need of improved production technology, especially in light of efforts to control medical costs while expanding coverage.

21.13.2. Yeast Production Systems

MAbs must be capable of two binding events if they are to be therapeutically effective. In the first event, the variable domain, which determines the antibody specificity, binds to a specific target protein on the cell surface. In the second event, the immune system's effector cells bind to constant region (Fc) of the antibody and destroy the cell to which the antibody is attached through a process known as antibody-dependent cell cytotoxicity. This cytotoxic process depends on a specific Fc Asn₂₉₇ N glycosylation and is affected by the glycan composition of the constant region (108, 140). Glycosylation patterns vary with different mammalian cell lines, and the pattern elucidating the most potent antibody-dependent cell cytotoxic response for a given cell type is complex, which leaves open the possibilities of further development and optimization.

MAbs are obtained by (i) immunizing mice with a specific antigen, (ii) harvesting the mouse spleen lymphocytes, (iii) hybridizing the lymphocytes with myeloma cells, (iv) screening the resulting hybridoma cells for antibodies to the desired antigen, and (v) carrying the selected potent clones into tissue culture. Antibody production then depends on the efficiency of the scale-up and downstream processing (84). To produce antibodies in yeast cells, it is further necessary to clone the specific variable sequence into a host for which the glycosylation machinery has been altered to match that of humans.

P. pastoris is preferred for the production of N-glycan-containing biopharmaceuticals since it exhibits a low frequency of serine O-mannosylation. Moreover, mannoglycosylation is much less extensive in *P. pastoris*,

and unlike *S. cerevisiae*, *P. pastoris* lacks the transferase necessary to create terminal α -1,3-linked mannosyl residues that can cause strong antigenic responses in humans (42). The glycosylation pathways for yeasts and mammalian systems have recently been reviewed in excellent detail and do not need to be repeated here (83, 138). In brief, deletion of *OCH1*, which codes for the mannosyltransferase of the *cis*-Golgi apparatus, eliminates the native hypermannosylation machinery. Combining the correct Golgi leader sequence from *P. pastoris* with the appropriate catalytic domains of human Golgi α -(1-2)-mannosidases IA, IB, and IC enabled construction of humanized complex-type N-glycans (GlcNAc2Man3GlcNAc2) (138). A complete protocol for production of complex N-glycosylated proteins in *P. pastoris* has recently been published (83).

Posttranslational modification such as N glycosylation is initiated in the ER lumen. Proteins are exported to the Golgi only if they have folded in the correct conformation (57). For heterologous expression, genes for MAb heavy- and light-chain domains are fused to a Kar2 signal peptide to ensure processing and secretion through the ER along with an appropriate promoter (107). When transformed into wild-type *P. pastoris* cells, the antibodies yield high-mannose-type proteins.

Genetics, Genetic Manipulation, and Approaches to Strain Improvement of Filamentous Fungi

VERA MEYER, ARTHUR F. J. RAM, AND PETER J. PUNT

22

22.1. INTRODUCTION

Only a limited number of filamentous fungi are used in industry for the production of enzymes or metabolites. They include *Aspergillus niger*, *Aspergillus oryzae*, *Trichoderma reesei*, and *Penicillium chrysogenum*. An industrial filamentous fungus must meet several demands such as strong and versatile metabolic capacities, good growth characteristics on low-cost substrates, and the ability to be cultivated in large-scale fermentors. In addition, the strain should not be pathogenic or produce any toxic by-products during the fermentation process. Finally, to allow further improvements and optimization of the production process, a successful industrial filamentous fungus should be amenable to genetic manipulation and genomic approaches. The filamentous fungi exploited these days as cell factories all meet these criteria (Table 1). Within the past few years, genome sequences of several industrial fungi have been published (34, 36, 47, 56), clearly documenting the genetic diversity remaining to be understood and exploited for the production of new proteins or metabolites. In addition to the genome sequence data, related “omics” approaches also have the potential to generate leads for further strain improvement by genetic engineering. With the recent breakthroughs in DNA and RNA sequencing methods, the number of fungal genome sequences continues to grow, as does the need for efficient fungal expression platforms to produce new and interesting compounds. In this review, we will focus on some recently developed genetic tools and strain improvement approaches for further optimizing protein production in filamentous fungi in the “omics” era. The technologies and approaches described are mainly focused on *A. niger*, but in principle could be applied to any of the other industrially relevant filamentous fungi.

22.2. GENETICS OF FUNGAL CELL FACTORIES IN THE “OMICS” ERA

Within the past 5 years, genome sequences for the most important industrial filamentous fungi have become available (Table 1), facilitating four main areas of current research: (i) genome mining and identification of new compounds and enzymes; (ii) in silico reconstitution of metabolic pathways; (iii) systems biology approaches to comprehensively understand the complex regulation of growth, physiology, and metabolism in fungi; and (iv) further development

of industrial strains as cell factories for the production of enzymes or compounds.

22.2.1. Genome Mining and Identifications of New Proteins and Metabolites

Without exception, the analysis of the genomes of industrial filamentous fungi has uncovered previously unknown enzymes, especially for carbohydrate metabolism (16, 34–36, 47). In order to predict the functions of these new enzymes, BLAST analyses and searches for carbohydrate-active domains in the CAZy database are combined with expression profiling of the respective genes. A great challenge is to determine substrate specificities and catalytic properties of these enzymes (7). Genome sequences have also revealed many new proteases and lipases, which are interesting candidate products for other industrial applications (27, 34, 47).

Filamentous fungi, including the industrial strains, are well known for their capacity to produce an astonishing wealth of secondary metabolites including both commercially exploited compounds and unwanted mycotoxins (1, 24, 26, 51). Compounds produced by industrial filamentous fungi include penicillin, by *P. chrysogenum*, and lovastatin by *Aspergillus terreus* (6, 56). The availability of genome sequence data and various genomics tools, including DNA microarrays, has allowed the comparison of low- and high-producing strains and identification of the factors involved in metabolite synthesis at the molecular level (6, 56).

The analysis of genomic data from *A. niger* and *A. oryzae* has revealed the presence of several secondary metabolite gene clusters. The numbers of polyketide synthase (PKS) (34), nonribosomal peptide synthase (NRPS) (17), and hybrid PKS-NRPS (7) genes in *A. niger* illustrate its potential for secondary metabolite production (47). Among these secondary metabolites, mycotoxins like fumonisins can potentially be produced (18). However, the structure of most fungal secondary metabolites has not been elucidated, and the growth conditions required for their synthesis are not known. Therefore, much current research is focused on identifying the products of these new secondary metabolite clusters. A straightforward approach to this end is (i) deletion of, e.g., a PKS-encoding gene, (ii) cultivation of the mutant strain and the respective wild-type strain under various growth conditions, and (iii) comparison of their metabolic profiles to identify missing or altered metabolite(s) in the mutant strain (13).

TABLE 1 Overview of selected industrial filamentous fungi, their products, and the current “omics” status (spring 2009)

Organism	Main products	Genomic sequence available (reference)	Transcriptomics platforms available	NHEJ-deficient strains available
<i>A. niger</i>	Citric acid Amylases Lipases Proteases Phytases Xylanases Lactoferrin Chymosin Glucose oxidase	Yes ^a (47; www.broad.mit.edu)	Yes (Affymetrix)	Yes (37)
<i>A. oryzae</i>	Kojic acid Amylases Glucose oxidase Phytases	Yes (34)	Yes (Affymetrix)	Yes (53)
<i>A. terreus</i>	Itaconic acid Lovastatin	Yes (www.broad.mit.edu)	Yes (cDNA arrays)	No
<i>C. lucknowense</i>	Hemicellulases	Yes (www.dyadic.com)	No	Yes (59)
<i>P. chrysogenum</i>	Penicillin	Yes (56)	Yes (Affymetrix)	Yes (52)
<i>T. reesei</i>	Cellulases Cellobiohydrolases Xylanases Hydrophobins	Yes (36)	Yes (cDNA arrays, TRAC ^b)	Yes (20)

^aThe genome sequences of two *A. niger* strains have been published, strain CBS 513.88 (47) and ATCC 1015 (www.broad.mit.edu).

^bTRAC, transcript analysis with aid of affinity capture.

22.2.2. Reconstitution of Metabolic Pathways and Systems Biology Approaches

Using the complete genome sequences of *A. niger* and *A. oryzae*, Nielsen and coworkers have reconstructed the metabolic networks of both organisms, leading to genome-scale metabolic models for both fungi (3, 47, 64). These metabolic networks, in combination with newly established tools for filamentous fungi such as transcriptomics, proteomics, and metabolomics (see reference 5 for details), will provide new leads for process development and strain improvements. In addition, in top-down systems biology approaches, large data sets from transcriptomic, proteomic, or metabolomic studies are used in an unbiased way to perform statistical data analysis (preferably multivariate data analysis) and to identify relevant genes, proteins, or metabolites. Two recent publications (10, 46) provide good examples of how the application of systems biology tools helps to understand biological processes in filamentous fungi and generates leads for process and strain improvement programs.

22.3. GENETIC MANIPULATION

One key step in the improvement of fungal production strains is their optimization at the molecular level. Two complementary approaches can be followed: nonrecombinant and recombinant methods. The power of nonrecombinant approaches to achieve genetic alterations, e.g., by mutagenesis or protoplast fusion, was reviewed in the last edition of this manual (62). During the past decade, however, considerable progress has been made in establishing very efficient recombinant methods to introduce and control gene expression in filamentous fungi. In this chapter, we focus on

the most recent key concepts and technologies for genetic engineering of filamentous fungi. To obtain deeper insights into the theoretical basis of these technologies, the reader is directed to a number of recent reviews (39, 40, 45, 50).

One of the first steps in a project aimed at efficient production in a fungal host is the choice of the host strain itself. The suitability of the specific host strain depends on the amenability of the strain for genetic transformation and the availability of large-scale fermentation processes. With respect to efficient production of specific proteins, important considerations include the availability of suitable expression cassettes, appropriate secretion signals, and protease-deficient strains (to ensure low proteolytic activity against the protein of interest). For most of the strains listed in Table 1, good transformation characteristics using a variety of selection markers have been published.

22.3.1. Selection Marker

For fungal transformation, various dominant and auxotrophic selection markers have been developed (Table 2). Very versatile dominant selection markers include hygromycin B and phleomycin resistance based on prokaryotic resistance genes (49). However, for use in industrial hosts, selection based on auxotrophic and nutritional markers is highly preferred, as these markers can also be used in so-called self-cloning approaches. In the European Union (EU), the definition of self-cloning is described in Directive 90/219/EEC: self-cloning is the reintroduction of DNA “into cells of the same species or into cells of phylogenetically closely related species which can exchange genetic material by natural physiological processes where the resulting micro-organism is unlikely to cause disease to humans, animals or plants”.

TABLE 2 Selection markers, respective vectors, and the impact of the selection strategy on integration events

Selection marker	Origin	Type	Multiplicity selection ^a	Locus-specific integration ^b	Available vector	Reference
Hygromycin B resistance	<i>Escherichia coli</i> (<i>hph</i>)	Dominant	+	–	pAN7-1	48
Phleomycin resistance	<i>Streptoalloteichus hindustanus</i> (<i>ble</i>)	Dominant	+	–	pAN8-1	49
Acetamidase	<i>Aspergillus nidulans</i> (<i>amdS</i>)	Dominant	++	–	p3SR2, pMTL-25synAmdS	15
Orotidine-5'-phosphate decarboxylase	<i>Aspergillus niger</i> / <i>oryzae</i> (<i>pyrG</i>)	Auxotrophic	–	+	pAB4-1, pAO4.1, pABpyrGNot	17, 58
Orotidine phosphoribosyl transferase	<i>A. niger</i> (<i>pyrE</i>)	Auxotrophic	–	+	pBluepyrE	61
Acetamidase/orotidine-5'-phosphate decarboxylase	<i>A. nidulans</i> (<i>amdS</i>) <i>A. niger</i> (<i>pyrG</i>)	Dominant and auxotrophic	++	+	pAMDSPYRG-M1	23
Hygromycin B resistance/ orotidine-5'-phosphate decarboxylase	<i>E. coli</i> (<i>hph</i>) <i>A. niger</i> (<i>pyrG</i>)	Dominant and auxotrophic	+	–	pAN7-1pyrG	Punt, unpublished

^aIn *A. niger*, the use of the selection marker results in medium (+; 1–10) or high (++; 10–200) copy numbers.

^bIn *A. niger*, the use of selection marker results in locus-specific integration (+) or heterologous integration (–).

Self-cloning may also “include the use of recombinant vectors with an extended history of safe use in the particular micro-organisms” (15a).

Along these lines, various vectors for a dominant nutritional marker, *amdS*, were developed (15) (Table 2). In relation to protein overproduction, the *amdS* marker in particular allows isolation of transformants carrying multiple vector copies (29). Other versatile auxotrophic selection markers that fulfill the EU requirement are based on complementation of *pyrG*[–] or *pyrE*[–] mutant strains (58). The availability of combined *pyrG/amdS* selection markers may be useful in cases where the use of the single dominant selection marker is limited by a high level of background growth and, consequently, low transformation frequencies (P. Punt, unpublished observations). In that case, the *pyrG* marker can be used for initial selection, while the presence of the *amdS* marker allows selection of those transformants carrying multiple vector copies. The advantage of a *pyrG* or *pyrE* complementation approach is that *pyrG*[–] or *pyrE*[–] strains can easily be obtained by direct selection on 5'-fluoroorotic acid (FOA) medium without any mutagenic treatment. Another advantage of *pyrG* and *pyrE* markers is that they can be used repeatedly (e.g., after integration of a *pyrG*[–] or *pyrE*[–]-containing plasmid into the genome, the transformants can be cured from *pyrG* or *pyrE* by cultivating them on FOA plates).

The procedure to obtain *pyrG*[–] or *pyrE*[–] strains is based on the observation that mutants resistant to the antimetabolite FOA lack one of the two enzymes required for the conversion of orotic acid into uridine 5'-phosphate. *pyrE* encodes an orotate phosphoribosyltransferase, required for the first step in this conversion (orotic acid into orotidine 5'-phosphate), and *pyrG* encodes an orotidine 5'-monophosphate decarboxylase, required for the conversion of orotidine 5'-phosphate into uridine 5'-phosphate. Mutations in *pyrE* or *pyrG* prevent the conversion of FOA into a toxic compound, making the strains auxotrophic for uridine or uracil, but resistant to

FOA (8). The following protocol for the generation of *pyrG*[–] and *pyrE*[–] mutant strains of *A. niger* can, in our experience, also be applied to other filamentous fungi.

Protocol for Generation of *pyrG*[–] or *pyrE*[–] Strains

1. Inoculate 2×10^5 to 2×10^7 cells or spores on an FOA plate containing minimal medium (MM) supplemented with 0.75 mg/ml FOA and 10 mM uridine. Proline at 10 mM is usually used as nitrogen source. Note: Do not autoclave FOA, uridine, or proline; use filter-sterilized solutions. MM contains 1% glucose, 2 mM MgSO₄, trace element solution (63), 7 mM KCl, 8 mM KH₂PO₄, and 70 mM NaNO₃ and has been adjusted to pH 5.5.
2. Incubate for 1 to 2 weeks at an appropriate cultivation temperature and transfer FOA-resistant mutants onto fresh FOA plates for purification.
3. Test for uridine/uracil auxotrophy. Mutants should not be able to grow on MM lacking uridine or uracil.
4. To discriminate between *pyrE* or *pyrG* auxotrophic mutants, transform the mutant strains with a *pyrG*[–]-containing plasmid (e.g., pAB4-1 [58]) and a *pyrE*[–]-containing plasmid, pBluepyrE (61).

The *amdS* gene is a popular and frequently used selectable marker for fungal transformations, because it is a dominant, nonantibiotic marker. Dominant selectable markers are preferable to auxotrophic markers because they can be used directly without the need to generate mutant strains. The *amdS* gene encodes an acetamidase, enabling the strains to grow on acetamide as the sole nitrogen source. Most interestingly, the *amdS* gene can even be used as a dominant marker in fungi that harbor an endogenous *amdS* gene (54). In these cases, any background growth can be suppressed by the addition of cesium chloride to the selection medium. In addition, multiplicity transformants can easily be screened using acrylamide instead of acetamide as nitrogen source. Finally, the *amdS* gene

can be used, much like *pyrG* and *pyrE*, as a bidirectional marker by counterselecting for the loss of *amdS* with media containing the antimetabolite fluoroacetamide (FAA). To further simplify cloning procedures using the *amdS* selection marker, we have also designed a synthetic *amdS* selection marker gene in which most of the 6-bp cutter restriction sites have been removed (pMTL25synAmdS; Punt, unpublished).

Protocol for *amdS* Selection Media

1. To select for *amdS* integration in an *amdS*⁻ recipient strain, supplement MM (without any N source) with 10 mM acetamide.
2. To select for *amdS* integration in a wild-type recipient strain, supplement MM with 15 mM cesium chloride and 10 mM acetamide.
3. To select for multicopy *amdS* integration, supplement MM with 15 mM cesium chloride and 10 mM acrylamide. Note: Do not autoclave acetamide, acrylamide, or cesium chloride; use filter-sterilized solutions.

Protocol for Curing of the *amdS* Selection Marker from *amdS*⁺ Strains

1. Inoculate 2×10^5 to 2×10^7 cells or spores on an FAA plate (MM supplemented with 0.2% FAA; 10 mM urea is usually added as additional nitrogen source). Note: Do not autoclave FAA or urea; use filter-sterilized solutions.
2. Incubate for 1 to 2 weeks at an appropriate cultivation temperature and transfer FAA-resistant mutants onto fresh FAA plates for purification.
3. Test for growth on acetamide medium. Mutants should not be able to grow on MM containing 10 mM acetamide as sole nitrogen source.

22.3.2. Transformation

The establishment of a suitable and effective transformation method for the fungus of interest is of crucial importance for any genetic engineering approach. As summarized elsewhere, four transformation methods have been shown to be valuable tools for filamentous fungi—protoplast-mediated transformation, *Agrobacterium*-mediated transformation, electroporation, and biolistic transformation—each technique having its own advantages and disadvantages (see reference 39 and references therein). Protoplast-mediated and *Agrobacterium*-mediated transformation, however, seem to be the most commonly used techniques for filamentous fungi. In our hands, both of these methods have been successful in transforming different (industrially used) filamentous fungi belonging to the Ascomycetes, Basidiomycetes, or Zygomycetes. As a detailed protocol for *Agrobacterium*-mediated transformation has recently been published (41), we here describe a protocol for the transformation of *A. niger* protoplasts which can be used for many other filamentous fungi. In general, the yield of protoplasts depends on both the quality and quantity of the lytic enzyme batch used and the age of the culture used as starting material.

Protocol for Protoplast-Mediated Transformation

1. Inoculate 2.5×10^8 spores in 250 ml of complete medium (CM) and incubate for 16 to 18 h at 30°C and 0 to 50 rpm (CM is MM supplemented with 0.1% Casamino Acids and 0.5% yeast extract).
2. Prepare protoplastation solution as follows: dissolve 400 mg of Lysing Enzymes (Sigma) or 400 mg of

Vinoflow FCE (Novozymes) in 10 ml of SMC (1.33 M sorbitol, 50 mM CaCl₂, 20 mM morpholineethanesulfonic acid [MES] buffer; pH 5.8). Set pH to 5.6 with 1 M NaOH. Filter-sterilize the solution and transfer it to a sterile 50-ml tube.

3. Harvest the mycelium by filtration through sterile Miracloth (CalBiochem) or a sterile coffee filter and wash 1 time with SMC. Add less than 0.5 to 1 g of mycelium (wet weight) to the protoplastation solution and incubate for 1.5 to 2.5 h at 37°C with gentle shaking at 60 to 75 rpm, adjusting the tube in a shaker horizontally. Check protoplast formation under the microscope after 1 h of incubation and then every 30 min.
4. Before harvesting protoplasts, add 10 ml of STC (1.33 M sorbitol, 50 mM CaCl₂, 10 mM Tris HCl; pH 7.5) to the protoplastation sample and mix carefully by repeatedly pipetting up and down (this additionally releases protoplasts from the mycelium).
5. Collect protoplasts through a sterile Miracloth filter (or silica wool). Mycelial debris is not able to pass through the Miracloth (or silica wool).
6. Centrifuge at $2,000 \times g$ for 10 min at 10°C and decant the supernatant.
7. Gently resuspend the pellet in 1 ml of STC and centrifuge for 5 min at $3,000 \times g$. Discard supernatant and repeat the STC wash step twice.
8. For each transformation sample, add to a sterile 50-ml tube and gently mix: 200 μ l of protoplasts (2×10^6 to 2×10^7), 20 μ l of DNA solution (8 to 10 μ g), and 50 μ l of freshly made PEG buffer (per 10 ml: 2.5 g of PEG-6000 in 50 mM CaCl₂, 10 mM Tris HCl; pH 7.5).
9. Add 1 ml of PEG buffer and mix gently. After exactly 5 min of incubation (do not extend this incubation period because PEG is toxic for protoplasts), add 2 ml of STC and mix gently by tipping.
10. Add top agar (0.95 M sucrose in MM, 0.6% Oxoid agar; 47 to 50°C) to a total volume of 30 ml and gently mix by inverting the tube several times. Pour 7 ml onto each of four selective transformation plates (0.95 M sucrose in MM, 1.2% Oxoid agar; use 15-cm petri dishes). An alternative method which does not make use of top agar is to directly plate the protoplasts onto transformation plates. In our experience, this procedure can even improve the transformation efficiency when selecting for *pyrG/pyrE* or *amdS*.
11. Incubate selective transformation plates at an appropriate temperature for 3 to 6 days until colonies become visible. Purify primary transformants at least twice by plating diluted spore suspensions on selective medium in order to get homokaryotic transformants.

22.3.3. High-Throughput Screening of Transformants

Two approaches can be used to analyze transformants at the gene level and to verify that the DNA has inserted correctly: diagnostic PCR and Southern analysis of genomic DNA. For both approaches, we have developed high-throughput, rapid, and small-scale methods to isolate genomic DNA from transformants (V. Meyer, unpublished). We routinely use both methods to isolate high-molecular-weight genomic DNA from different *Aspergillus* species or other filamentous fungi.

Protocol for Isolation of Genomic DNA for Diagnostic PCR

1. As starting material, either spores (simply taken off a colony with 5 μ l of 0.05% Triton X-100), substrate

mycelium (scraped from a colony with a sterile toothpick), or young mycelium (grown overnight in 2-ml Eppendorf tubes containing 700 μl of CM) can be used. If spores or substrate mycelium are used, transfer them into 2-ml Eppendorf tubes containing 600 μl of H_2O . If young mycelium is used, harvest the mycelium by centrifugation ($10,000 \times g$), wash it twice with 1 ml of H_2O , and resuspend it in 600 μl of H_2O .

2. Disrupt cells by repeated freezing in liquid nitrogen and thawing in a 75°C water bath (three times). It is not necessary to include in this step any DNA extraction buffer or to treat the samples with proteinases or RNases.
3. Extract the genomic DNA once with an equal volume of phenol and once with an equal volume of chloroform/isoamylalcohol (24:1).
4. Precipitate the DNA from the aqueous phase with 2 volumes of 96% ethanol and 1/25 volume of 3 M sodium acetate (pH 6). Incubate the mixture for 1 h at -80°C . (Note: This incubation is crucial for efficient precipitation.)
5. Centrifuge at $10,000 \times g$ for 15 min, discard the supernatant, and wash the DNA pellet with 100 μl of 70% ethanol. (Note: The DNA pellet is not easy to see.)
6. Resuspend the DNA in 20 μl of H_2O and incubate the solution at 65°C for 15 min in order to completely dissolve the DNA. One microliter of the DNA solution can directly be used in a PCR reaction.

Protocol for Isolation of Genomic DNA for Southern Analyses

1. Grow strains overnight in 20 ml of rich CM at 30 to 37°C .
2. Harvest mycelium by filtration through sterile Miracloth or a sterile coffee filter and transfer it without washing into a 2-ml Eppendorf tube (fill the tube up to the 0.5-ml line with mycelium).
3. Freeze samples at -80°C or in liquid nitrogen and dry the samples overnight in a freeze-dryer.
4. Grind the mycelium using small-scale pellet pestles (Fisher Scientific) for 10 to 20 s and resuspend the pulverized cells in 800 μl of extraction buffer (0.5% sodium dodecyl sulfate, 10 mM Tris HCl, 0.1 M EDTA; pH 8.0).
5. Add 1 μl of RNase (10 $\mu\text{g}/\mu\text{l}$) and incubate the suspension for 30 min at 37°C . Shake the mixture occasionally.
6. Extract the genomic DNA twice with an equal volume of phenol-chloroform-isoamylalcohol (25:24:1) and once with an equal volume of chloroform.
7. Precipitate the DNA from the aqueous phase with 1 volume of isopropanol and 1/10 volume of 3 M sodium acetate (pH 6).
8. Centrifuge at $10,000 \times g$ for 15 min, discard the supernatant, and wash the DNA pellet with 100 μl of 70% ethanol.
9. Resuspend the DNA in 30 to 50 μl of H_2O and incubate the solution at 65°C for 15 min to completely dissolve the DNA. About 2 to 10 μl of the DNA solution (about 5 μg) is usually used for Southern analyses.

To analyze transformants for production of specific proteins or metabolites, we have also developed various growth and detection assays that can be performed in a microtiter plate (MTP) format. The assay can be greatly affected by the cultivation conditions, which in turn depend on the growth characteristics of the specific host strain being studied. Recently, it was found that a newly developed fun-

gal production host, *Chryso sporium lucknowense* C1, can be cultivated in MTPs (61). Consequently, high-throughput screening can be used to analyze large collections of strains of this species in a short time frame (61). Many protocols have been published for MTP-based enzyme activity assays. In our research, we have in particular found the various hydrolase substrates sold by MEGAZYME very useful for development of MTP assays.

Protocol for MTP-Based Hydrolase Activity Assay

1. Use for cultivation Corning no. 3799 MTPs (or other round-bottom MTPs) and add 200 μl of the preferred growth and induction medium per well. Inoculate each well with spores or mycelial fragments using toothpick transfer.
2. Incubate the MTPs in an MTP shaking device until sufficient growth is obtained. In our experience, the Multitron equipment (INFORS) allows efficient submerged growth for filamentous fungi such as *Trichoderma* and *Chryso sporium*. However, for some other species such as *A. niger*, even incubation in the Multitron gyrotory MTP incubator (INFORS) results in an undesirable surface growth. (Note: If longer incubation times or higher growth temperatures are required, the outer wells of the culture plates should be filled with culture medium only, to limit evaporation of the center wells.)
3. After cultivation, centrifuge MTPs for 10 min at $3,500 \times g$. For surface-grown cultures, this step may not result in sufficient separation of mycelium and supernatant, thus requiring an additional transfer step to a second sample plate.
4. Perform the hydrolase activity assay as follows. Fill the assay-MTP (any MTP type) with 500 μl of 0.2% azo-dyed cross-linked (AZCL) substrate in any appropriate buffer. Using a multichannel pipette, add 10 μl of culture medium (or any other required dilution) to the substrate, followed by appropriate incubation. Depending on the hydrolase expression level, various incubation times and temperatures may be chosen.
5. After incubation, centrifuge the assay MTP for 10 min at $3,500 \times g$.
6. Transfer 100 μl of the supernatant to the measure-MTP (Corning no. 3596). Measure absorption at 590 nm using a microplate reader (Tecan Infinite 200 or a similar apparatus).

22.4. STRAIN IMPROVEMENT BY GENETIC ENGINEERING

Genetic engineering approaches can be used with both natural and recombinant production strains to increase production levels, to produce novel compounds, or to direct synthesis toward a desired metabolite. Some of the concepts and tools that have proven particularly powerful for optimizing industrial fungal strains will be discussed in the following sections.

22.4.1. Gene Overexpression and Protein Secretion

Different approaches are available for overexpression of a gene of interest. For example, targeted integration of a gene into a genomic locus known to be transcriptionally active is a strategy that provides good protein synthesis in a highly controlled fashion. An alternative method to maximize protein production is to integrate multiple copies of the

gene at multiple genomic sites. Here in particular, the use of the *amdS* gene as a selection marker is a favorable option. In general, efficient gene transcription, translation, and (preferably) secretion of the protein can be achieved by the use of appropriate expression cassettes. Several expression vectors have been used to successfully express proteins in different fungal host strains, as summarized in Table 3.

The basic expression vector (type I) consists of an efficient fungal promoter and a suitable fungal terminator sequence. In our research on *Aspergillus*, we have primarily used two promoters: P_{gpdA} (glyceraldehyde-3-phosphate dehydrogenase A promoter) and P_{glaA} (glucoamylase A promoter). In particular, the *gpdA* promoter has been shown to be very useful for a wide variety of fungal species, allowing constitutive expression of the gene of interest under various culture conditions. Type II expression vectors carry, in addition to the basic expression cassette, a sequence encoding a secretion signal from *A. niger*, e.g., from the *glaA* gene. Using this vector type, the gene of interest will be fused downstream of the *glaA* secretion signal sequence, resulting in an efficient secretion of the gene product. A third type of vector, also designed to lead to secretion of the gene product of interest, contains, besides the basic expression cassette and the *glaA* secretion signal sequence, a gene encoding an efficiently secreted *A. niger* protein (*glaA*). The design of this vector is based on results obtained with the so-called gene fusion approach (for a review of this approach, see reference 19).

Although filamentous fungi are very efficient cell factories for the expression of proteins of fungal and nonfungal origin, the expression and secretion levels of heterologous proteins are usually two to three orders of magnitude lower than homologous proteins. Besides aspects of protein secretion, another reason for this discrepancy could be that the heterologous gene uses codons that are rarely used by the fungal host strain. Furthermore, A-T-rich sequences within heterologous mRNA molecules might be recognized as cryptic polyadenylation signals (19). These signals probably cause premature polyadenylation of some heterologous transcripts and rapid degradation by the nonstop mRNA decay system (55). One strategy to overcome this is to synthesize the gene with the codon usage of the fungal host strain. Such "codon optimization" has been shown to improve heterologous gene expression considerably

in different industrial *Aspergillus* strains (12, 28, 55). Most recently, a method applying genetic algorithms to optimize both single codon fitness and codon pair fitness was published (50a), which clearly showed that increased protein expression levels can be achieved, e.g., in *A. niger* by optimized protein coding sequences. During recent years, chemical DNA synthesis has become relatively inexpensive and the length of DNA that can be synthesized has extended from <1 kb to >30 kb (67). Hence, codon optimization and other targeted gene modifications can nowadays easily be designed in silico and manufactured rapidly by use of synthetic DNA technology. Various commercial suppliers offer these services.

22.4.2. Gene Targeting

Whereas overexpression of genes as described in the section above has been successful in many industrial strain development programs, high-level production of a heterologous protein can be hampered by other issues, the most prominent being production of endogenous proteases by fungi. A conceptually straightforward approach to reduce protease production is the targeted deletion of relevant protease genes (9). However, gene targeting has historically been a difficult venture in filamentous fungi. Due to very low frequencies of homologous recombination, any DNA that is introduced predominantly integrates randomly in the genome as a result of a nonhomologous integration event. Therefore, it has not been trivial to modify or delete an endogenous gene, or to target a gene of interest to a particular genomic locus. Fortunately, this limitation has recently been overcome. In 2004, Ninomiya and colleagues reported that *Neurospora crassa* mutant strains, lacking components of the nonhomologous end joining (NHEJ) pathway, became extremely efficient recipient strains for gene targeting (44). Since this breakthrough, many other NHEJ mutant strains, such as Ku70, Ku80, and Lig4 mutants, were generated in other filamentous fungi, and it was demonstrated that they all gave rise to very high homologous recombination frequencies (reference 39 and references therein). For example, deletion of the Ku70 homologue in *A. niger* reached more than 80% homologous integration efficiency, compared to 7% in the wild-type background, when 500-bp homologous flanks were used (37). Thus, targeted genetic alterations are more straightforward and considerably less time-consuming in NHEJ-deficient

TABLE 3 Vectors for improved protein production and secretion

Vector	Promoter	Secretion sequence	Terminator	Cloning sites (5' → 3')	Accession no. or reference
Type I

^aaa, amino acids.

strains. One important observation, however, is that NHEJ mutant strains might also show some undesired phenotypes such as reduced fitness and diminished stress resistance (37, 43, 52). A very elegant solution to bypass this drawback has recently been reported for *A. nidulans* (43) and *Chrysosporium* (59). This rationale involves silencing the NHEJ machinery transiently, a concept that can easily be adapted to any other filamentous fungus. Basically, a gene encoding one component of the NHEJ machinery, e.g., *ku70*, is disrupted by inserting a counterselectable marker, e.g., *pyrG*. Most importantly, the *pyrG* marker is flanked on each side by a short *ku70* sequence, forming a direct repeat. After the desired genetic manipulation has been carried out, the *ku70* gene becomes restored by growing the strain on FOA medium, whereby recombination between the direct repeats causes excision of the *pyrG* marker and re-establishment of an intact *ku70* gene copy (43).

22.4.3. Gene Silencing

The knockout of genes encoding enzymes in pathways leading to side products can redirect the flux into the product-forming pathway. Such a gene knockout can be achieved by deleting or disrupting a gene of interest. However, to circumvent the need for gene targeting, RNA-based tools ("gene knockdown" tools) may be attractive alternatives. Several gene knockdown techniques, such as antisense

RNA, hammerhead ribozymes, and RNA interference, have been developed for filamentous fungi. Common to these methods is that they silence gene expression posttranscriptionally and, depending on how it is done, can silence gene expression partially to almost completely (references 2 and 39 and references therein). Basically, gene knockdown tools are superior to gene knockout approaches when (i) gene targeting approaches fail, (ii) multiple copies or close homologues of a gene of interest are present in the genome, (iii) isogenes might compensate for the knockout of the deleted gene, (iv) gene knockouts are lethal, and/or (v) partial reduction of gene expression is required to obtain the preferred phenotype. For more information on the principles of gene knockdown technologies and their applicability for filamentous fungi, we recommend recent reviews such as those in references 39 and 42. Most recently, the robustness and stability of the RNA interference silencing tool were demonstrated in *T. reesei* and *A. niger*, supporting the usefulness of gene silencing tools in industrial applications (11).

22.5. ALTERNATIVE STRAIN IMPROVEMENT APPROACHES

22.5.1. Screening for Protease-Deficient Strains

Besides the various genetic engineering approaches described above, classical strain improvement approaches

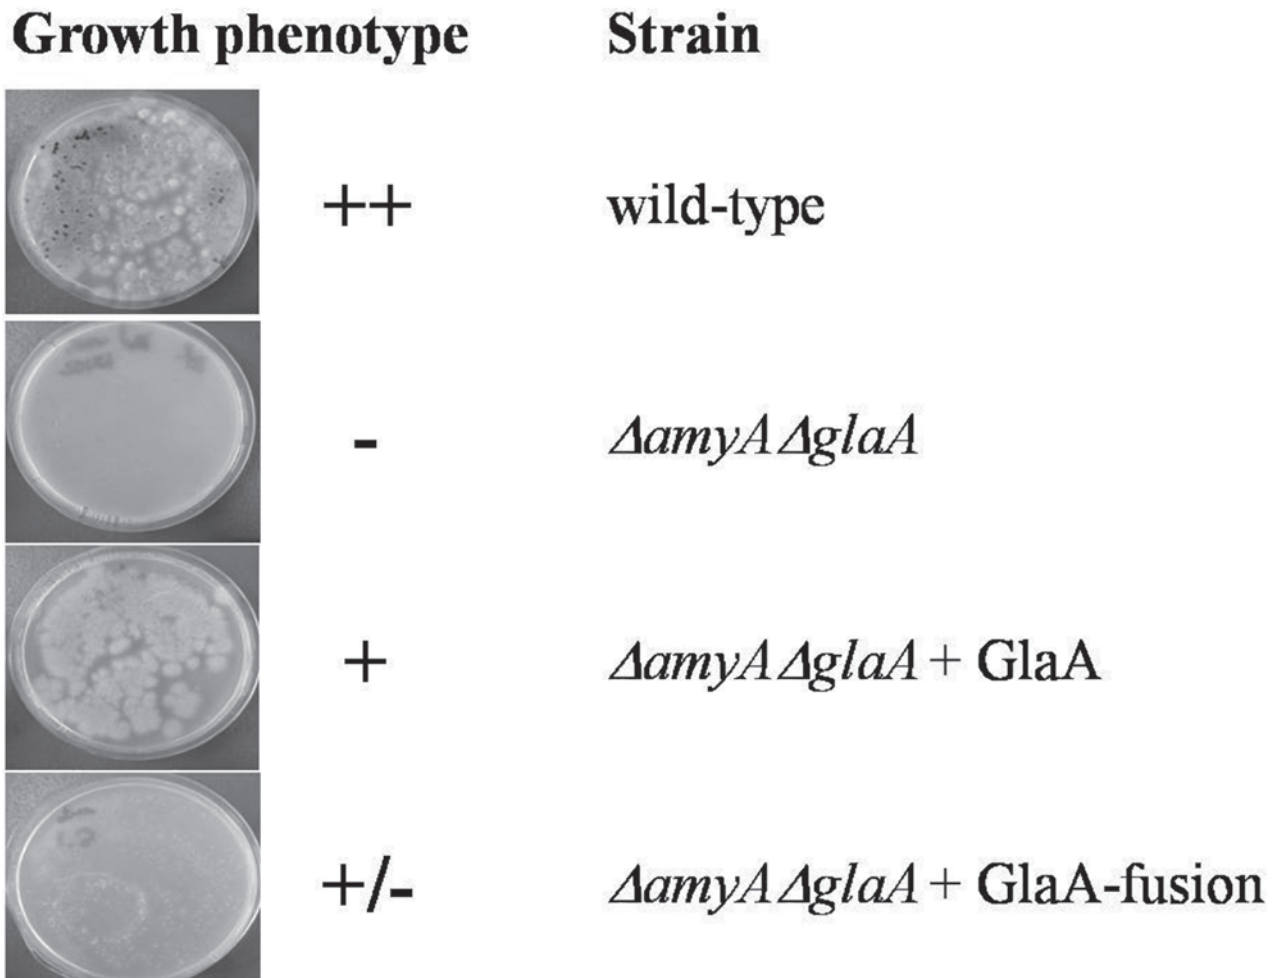

FIGURE 1 Growth phenotypes of different *A. niger* strains obtained on starch plates.

remain important for industrial strain development. Recently, we have developed a very successful selection approach using classical mutagenesis and screening, based on a so-called suicide substrate (9). In this approach, protease-deficient mutants can be selected efficiently from a background of wild-type host strains, resulting in identification of promising protease-deficient mutant strains at a 10,000-fold higher frequency compared to a typical screening approach.

22.5.2. Screening for Hypersecretion Strains

To improve laccase-producing *A. niger* strains, we have also developed a screening approach that combines classical mutagenesis and a glucoamylase-fusion approach (see section 22.4.1). The glucoamylase carrier approach was combined with the use of a specifically designed starch-nonutilizing host strain (65) generated by deleting the two genes encoding the major amylolytic proteins, i.e., acid amylase and glucoamylase (*aamA* and *glaA*, respectively). The resulting host strain ($\Delta aamA$, $\Delta glaA$) is practically unable to use starch as carbon source. Reintroduction of the native glucoamylase gene results in a strain that regains the ability to grow on starch, whereas introduction of a fusion gene encoding a poorly secreted glucoamylase-laccase (or any other fusion gene) into this strain results in transformants which grow only poorly on medium containing starch as sole carbon source (Fig. 1). One of these poorly growing glucoamylase-laccase transformants was mutagenized with UV light and mutants were selected for better growth on starch medium. This provided strains with increased laccase production levels (65).

22.6. DESIGNING A STRAIN IMPROVEMENT PROGRAM—AN EXAMPLE

One of our research interests is in the production of a separate starch-binding domain (SBD). SBDs are part of the group of carbohydrate-binding modules (CBMs) that are noncatalytic, polysaccharide-recognizing domains present in polysaccharide-degrading enzymes such as cellulases and chitinases. They bind to the insoluble polysaccharide and disrupt its structural organization. CBMs can be applied in various ways, e.g., to lower the tensile index of paper (32) or, if fused to another enzyme, to change the affinity and/or activity of the enzyme (31). In order to overproduce an SBD from the glucoamylase of *A. niger*, we have developed a screening approach to identify SBD-hyperproducing strains based on the starch-nonutilizing *A. niger* host strain described above. In this approach, we used a glucoamylase fusion to directly select for starch growth and thereby to identify the most productive transformants. In this case, no mutagenesis step was applied, and the best-performing transformants were selected directly. A related approach was recently also used for the identification of a novel GH13 amylase-like protein (57). In the following paragraphs, we detail the steps of our approach, providing a “how to” guide for strain improvement programs for filamentous fungi.

Based on publicly available sequence information, the DNA fragment encoding the *A. niger* glucoamylase SBD (CBM20 domain) was identified. The fragment encodes the C-terminally localized SBD preceded by a small threonine-rich linker region (108 amino acids encompassing C⁵⁰⁹TTPTA....VTDTWR⁶¹⁶; see also reference 30). The DNA-encoding SBD domain was amplified by PCR and subsequently cloned into the expression vector pAN56-1 (Table 3). The resulting vector carries the *gpdA* promoter, which drives expression of

the glucoamylase-SBD fusion product with the glucoamylase sequence separated from the SBD sequence by a dibasic endoprotease cleavage site (NVISKR). This site is recognized by a secretion pathway-specific intracellular protease of *A. niger*, resulting in the release of the SBD as soon as the mature glucoamylase-SBD fusion becomes exported from the cells. To explore the possibility of increasing the SBD yield and possibly adding new cross-linking functionalities, expression of a dimeric SBD module was investigated too. For this purpose, a DNA fragment encoding a dimeric SBD in the form of SBD₁-flex-SBD₂ was synthesized (“flex” represents the amino acid sequence GGGGSGGGGSGGGGS) and cloned into pAN56-1 (Table 3).

Both SBD expression vectors were introduced into a starch-nonutilizing, protease-deficient *A. niger* strain ($\Delta aamA$, $\Delta glaA$, *prtT13*) using cotransformation with the *amdS/pyrG* selection vector pAMDSPYRG-M1 (Table 2). For our specific purposes, this strain has an additional advantage over the ones already mentioned above, in that deletion of *glaA* and *aamA* also removed the only two genes encoding proteins with endogenous CBM20 domains. Primary *amdS*⁺ (co)transformants obtained were subjected to a round of selection by transferring them to starch plates as well as to acetamide-containing plates. (Increased) growth on the former designated the transformants as true cotransformants and allowed selection of the best-growing strains. Cultivation of selected transformants in shake flasks and analysis for the presence of glucoamylase and SBD in the culture supernatants (using relevant antisera) allowed selection of SBD-hyperproducing strains. Finally, cultivation of the best-performing strains in 5-liter bioreactors (applying a fed-batch cultivation protocol) resulted in the production of a few grams of free SBD (P. Punt, unpublished data; Fig. 2).

FIGURE 2 Production of SBD in *A. niger* during fed-batch cultivation. Depicted is a protein gel loaded with protein samples from culture supernatants obtained from different time points during cultivation. Indicated are the protein bands of the glucoamylase (GLA) and the starch-binding domain (SBD). B1–B2, medium samples from batch phase; F1–F5, medium samples from feed phase; U1, starch-unbound protein fraction; E1, starch-eluted protein fraction.

22.7. THE ULTIMATE TEST OF CANDIDATE STRAINS: CULTIVATIONS IN LAB-SCALE BIOREACTORS

Promising candidate strains—selected either from MTP-based screening approaches or from shake-flask cultivations—must ultimately perform under controlled cultivation conditions, in a bioreactor. As a standard reactor, we recommend the use of the BioFlo3000 fermentor (New Brunswick Scientific), which allows cultivation in a total working volume of 5 liters. Depending on the final product, batch, fed-batch, or chemostat cultivations should be performed. Depending on the strain (*A. niger*, *C. lucknowense*, *P. chrysogenum*, *T. reesei*, etc.) and expression cassette used, different conditions should be tested (medium composition, pH, temperature, inducing agents, etc.). It is thus impossible to give here a detailed protocol that would apply to any of the strains or products. However, we summarize in the following protocol some rules of thumb that we found critical for successful cultivation of filamentous fungi in a bioreactor. For more information, e.g., on the respective medium compositions, cultivation time, physiology, and achievable biomass and product yields, refer to references 4, 25, and 38.

Protocol: Guidelines for Bioreactor Cultivations

1. Equip the fermentor vessel with cooling tubing that surrounds the headspace of the vessel to limit wall growth in the headspace.
2. Use two Rushton impellers, one in the bottom of the vessel and one just below the level of the intended culture volume (5-liter maximum). In between these two impellers, it is possible to mount a marine downflow impeller.
3. Mount an air/O₂ sparger near the bottom of the vessel and equip off-gas outlets with a cooling device and overpressure valves.
4. If spores are used for inoculation, inoculate the medium with 10⁹ spores/liter. Use in the beginning a low initial agitation speed (such as 250 rpm) and headspace aeration in order to keep spores from being blown out from the medium. After spore germination has been completed, increase impeller speed up to 750 to 800 rpm and switch headspace aeration to sparger aeration.
5. If precultures are used for inoculation, make them by inoculating 100 ml of CM with, e.g., 1 × 10⁶ spores/ml. After 1 to 2 days of growth, use two flasks, each containing 100 ml of preculture, to inoculate the fermentor. Start directly with an impeller speed of 750 to 800 rpm and sparger aeration.
6. Always add antifoam to the medium (if spores are used for inoculation, add the antifoam after they have germinated). Use either 0.01% sterile polypropyleneglycol or 0.01% Struktol J673.
7. Maintain the dissolved oxygen at 20% by controlling the agitation speed. If dissolved oxygen drops below 20%, substitute air sparging for O₂ sparging. In general, the use of an airflow of 1 to 1.2 liters/min is sufficient.
8. Maintain the pH of the medium either by using 8 M KOH and 2 M H₃PO₄ or by using 1 M HCl and 2 M NaOH as titrants.

22.8. FINAL CONSIDERATIONS AND OUTLOOK

The high protein-producing capacity of filamentous fungi such as *A. niger*, *A. oryzae*, and *T. reesei* has prompted their development as cell factories for the production of heterologous proteins (33, 50). Multiple studies, however, have

shown that upon expression of these heterologous proteins, the unfolded protein response pathway becomes induced in filamentous fungi (see for example references 14, 66), suggesting that heterologous proteins become misfolded and subsequently degraded during their way through the secretory pathway. Genome-wide transcriptomic approaches have thus been used to identify genes that are induced or repressed during the expression of heterologous proteins and have provided target genes for genetic manipulation and strain improvement approaches (21). Jacobs et al. have taken it one step further by integrating transcriptomic and proteomic data sets for further strain improvement (22). Leads from such studies can rapidly be tested by the use of NHEJ-deficient recipient strains, which have been established for most of the industrial filamentous fungal strains.

Several reports have already emphasized the importance of highly controlled and reproducible growth conditions to perform reliable transcriptomic, proteomic, and metabolomic analyses (6, 9, 22, 25). Genome-wide studies should therefore be designed and performed under defined conditions which can only be ensured by cultivations in bioreactors. Here, medium composition, pH, temperature, and impeller speed can be controlled and physiological data can be obtained—e.g., from off-gas analyses and titrant addition—and product formation can be determined online as well.

Finally, continuing advances in high-throughput DNA sequencing (such as 454 Life Science pyrosequencing and Illumina sequencing technologies) are revolutionizing fungal biotechnology and leading to the identification of many more interesting enzymes (e.g., glycosyl hydrolases, proteases, lipases) and potentially interesting secondary metabolite gene clusters. The filamentous fungi listed in Table 1 will continue to be used as chassis for screening approaches as well as for the production of newly identified proteins. It is likely that industrial fungi with well-known and well-developed fermentation characteristics also will be used as production hosts for secondary metabolites discovered from fungi less suited to industrial exploitation.

Genetic Manipulation of Mammalian Cells for Protein Expression

ANNE KANTARDJIEFF, WEI-SHOU HU, GARGI SETH, AND R. SCOTT McIVOR

23

23.1. INTRODUCTION

Genetic manipulation of mammalian cells is used in a wide spectrum of applications. Foremost, genetically engineered mammalian cells are used in the production of a variety of therapeutic proteins such as factor VIII, protein C, and a number of antibodies. In laboratories, proteins which require extensive posttranslational modification and are difficult to produce in an active form in other systems are also expressed in genetically manipulated mammalian cells. While the majority of protein expression is for secreted proteins, a number of receptors and membrane proteins are also expressed in mammalian systems. In many applications, the genetic manipulation is intended to impart some desirable properties to the cell, rather than producing the protein *per se*. This is often referred to as cell engineering or metabolic engineering. These metabolically engineered cells are used for research purposes, for *in vitro* or *in vivo* studies, or in the bioprocess production of other proteins. For example, the overexpression of heat shock protein 70 (Hsp70) is often used in baby hamster kidney (BHK) cells to enhance the productivity of factor VIII (46). A variety of cells have also been engineered to overexpress antiapoptotic factor(s), thus delaying the onset of apoptotic cell death (4). Depending on the objective, genetic manipulation may also take a different path. For overproduction of a product protein, the protocol of genetic manipulation may include a gene amplification step to maximize cellular content of the product's transcript. In contrast, for cell engineering purposes, an appropriate expression level, which may not be very high, is necessary to confer the desired physiological effect.

For many applications, it is necessary to generate a permanent population of cells for production purposes or research use. In other cases, the genetic element introduced remains inside the cell for only a short duration, during which the protein produced is harvested for study or the cellular properties imparted are characterized. This process is referred to as transient expression. Both stable and transient expression are widely used in research and at the production scale. Transient expression is used in production scale of hundreds of liters or more, although the protein produced is mostly used for chemical and physical characterization or research use, rather than as therapeutic proteins. When stable expression is used, the transfected cells may be used as a population wherein each cell may have integrated the gene of interest in different locations of the genome. As a result,

not all cells in the population will have the same properties or productivity. For many applications, especially when generating a commercial protein product, clones originating from a single cell are isolated, characterized, and used in the production. In this chapter, all of the above-mentioned aspects of genetic manipulation will be discussed.

23.2. BASIC STEPS IN GENETIC MANIPULATIONS FOR HETEROLOGOUS PROTEIN PRODUCTION

Expressing genes in mammalian cells has become increasingly important to understand their functional significance. Heterologous expression in mammalian cells is also the primary method of production of proteins for therapeutic use. Only a few cell lines account for the majority of secreted proteins produced in mammalian cells, namely Chinese hamster ovary (CHO) cells, mouse myeloma cells (NS0, Sp2/0), and BHK cells. However, other mammalian expression systems are also available, including human embryonic kidney (HEK-293) cells, African green monkey CV1 kidney (COS) cells, and Madin-Darby canine kidney (MDCK) cells. In this section, the basic steps of genetic manipulation for heterologous protein production are outlined.

23.2.1. Vectors

For heterologous expression, the foreign gene is inserted into a plasmid that includes genetic elements that facilitate genetic manipulation, vector production, and expression in the host cell (Fig. 1). These elements include a bacterial origin of replication and a bacterial selectable marker. The vector introduced into the host cell will need to be translocated into the nucleus for transcription, and in the case of stable transfections, the inserted sequences will be integrated into the chromosome. Only a small fraction of foreign DNA entering the cell reaches the nucleus, whether in plasmid form or as virus genomes; an even smaller fraction is integrated into the chromosomes. In most transfection processes, a very large portion (typically 30 to 90%) of cells will not express the foreign gene, as judged by the expression of a reporter or selectable marker, either because those cells fail to take up the plasmid or because the plasmids taken up fail to reach the nucleus. In expressing a foreign protein, the selection and design of a vector will critically affect the outcome.

FIGURE 1 Typical vector for expression of antibody product in mammalian cells. This representative plasmid contains both the heavy-chain (VH, CH1, CH2, CH3) and light-chain (VL, CKappa) genes of the IgG gene. Each is driven by its own promoter (PCMV) and has a polyadenylation signal (PolyA) downstream. A leader sequence (L) which serves as a signal for secretion is present for each IgG gene. A mammalian selectable marker, *Neo* in this case, is included with its own promoter (PSV40) and polyadenylation signal (SV40 pA). Sequence elements for replication and selection in *E. coli* are also included, namely, an origin of replication (pUC ori) and selectable marker (*Amp*).

23.2.1.1. Basic Components

Genetic elements of interest (promoter, coding sequence, polyadenylation signal, selectable marker, or reporter gene) are collected and combined in the form of a plasmid, followed by insertion of the gene of interest. There are multiple criteria to consider when choosing a vector, including but not limited to maximum insert size required, commercial availability of expression systems, and availability of a suitable multiple cloning site for insertion of the gene of interest. Multiple genes can also be expressed from the same plasmid, provided that each gene has its own accessory sequences (i.e., promoter, etc.). One common example of such an approach is to include the coding sequences of both the heavy and light chains of the immunoglobulin G (IgG) gene on the same plasmid (Fig. 1). Selectable markers are discussed in section 23.2.3.1, while reporter genes are discussed in section 23.3.3.

Promoters regulate transcription of the gene of interest and any selectable markers, so the appropriate choice of promoters is critical. Promoters are short sequences, typically <1 kb, that bind to endogenous transcription factors. Some promoters are known to be active only in certain cell types, and this should be considered when selecting a promoter. Also, many promoters may function well in different species, yet their expression strength and response to regulatory elements may not be identical in cells of different species. Another consideration is the desired level of expression. Genetic manipulation for heterologous protein production often requires high-level expression, so for this purpose, strong constitutive promoters are typically used. Table 1 shows commonly used constitutive promoters.

The presence of a polyadenylation signal determines the 3' terminus of mRNA and directs the addition of a poly(A) tail to the nascent mRNA transcript, often enhancing transcript stability and increasing expression. A polyadenylation signal consists of a conserved sequence (AAUAA) 20 to 30 nucleotides upstream of the 3' end and a GU- or U-rich region downstream. While different sources of polyadenylation signals are used, the most common include those derived from bovine growth hormone, mouse β -globin, the simian virus 40 (SV40) early transcription unit, and the herpes simplex virus thymidine kinase genes (59).

23.2.1.2. Optional Components

In addition to the basic components described above, optional sequence elements can be incorporated into expression vectors with the aim of facilitating transcriptional activity of the foreign DNA inside the cell. These elements can help modulate the influence of neighboring elements at the site of transgene integration. They can also help prevent the decline of transgene expression with time, which could be occurring as a result of structural effects such as gene elimination or epigenetic silencing.

23.2.1.2.1. Enhancer Elements

Enhancer elements work in concert with promoters to recruit transcription factors and stabilize the transcription initiation complex. Many enhancers confer cell- and tissue-specific expression and have been used extensively to boost expression in the engineering of cultured cells for high-level recombinant protein expression. Several classes

hEF-1 α	Human translation elongation factor 1 α subunit gene
β -Actin.....	Chicken β -actin gene

of enhancer elements have been identified and applied in expression engineering. The first such class is STAR elements, or stabilizing and antirepressor elements. These elements were first identified based on their ability to block chromatin-associated repression (55). They are typically on the order of 500 to 2,000 bp and are thought to reduce the extent of histone deacetylation and the spread of methylation in the vicinity of the inserted transgene. Their utility has been demonstrated in CHO-K1 cells and a human osteosarcoma cell line (55).

The second class of elements is known as S/MAR elements (scaffold/matrix associated regions). It has been proposed that these AT-rich sequences serve as boundaries between active and inactive chromatin elements, interacting with the nuclear matrix. This interaction creates loops of coordinated gene expression, maintaining the DNA in a lightly wound conformation and insulating sequences from repression (33, 34). However, the exact molecular mechanisms involved are still under investigation. The chicken lysozyme MAR and human β -globin MAR have been applied to successfully increase transgene expression in CHO cells. Identified elements are ~3 kb in size and have been reported to be independent of the cell line or promoter used (53, 96).

A third class of elements was identified from housekeeping genes and is known as UCOE (ubiquitous chromatin opening elements). Housekeeping genes are highly transcriptionally active, with high histone acetylation, and elements within their promoter regions have been successfully used to increase expression in a number of cultured cell lines (3, 8, 91). While these are typically large elements (~16 kb), the use of shorter fragments (~2.5 kb) has been reported.

23.2.1.2.2. Introns

Studies have shown that inclusion of an intronic sequence, although not necessary for expression, can increase transgene expression by as much as 10- to 20-fold (16). This beneficial effect has been attributed to enhanced RNA polyadenylation and/or nuclear transport as a consequence of RNA splicing (45). Note that the intron must be flanked by appropriate 5' and 3' sequence signals to ensure effective splicing. However, caution should be exercised when including these elements, as their presence in the 3' end of transcripts has been reported to lead to aberrant splicing (44, 92). The inclusion of cytomegalovirus intron has been shown to

increase recombinant factor VIII expression in CHO cells (18) and COS cells (21).

23.2.2. Introduction of DNA

There are many different methods for the transfer of expression vectors into cells. The choice of method depends on the host cell to be used, the number of cells to be transfected, and the efficiency of transfection. The different transfer strategies include chemical (DNA-calcium phosphate coprecipitation, cationic polymers, liposomes, molecular conjugates), physical (electroporation, microinjection), and biological (viral vectors; see section 23.3.1). While maximizing transfection efficiency is an objective when introducing foreign DNA into the cell, this usually comes at the cost of increased toxicity. Consequently, a trade-off should be struck which maximizes transfection efficiency while minimizing toxicity. Typically, for the transfection of adherent cells, reagents containing calcium phosphate, cationic polymers, or liposomes are used. For the transfection of suspension cells, electroporation or liposome-mediated transfection are commonly used. For detailed protocols of the methods described below, the reader is referred to references 39, 42, 54, and 75.

In calcium phosphate transfection, a precipitate containing calcium phosphate and DNA is formed by diluting DNA in a solution buffered within a narrow pH range and containing a low concentration of phosphate ions. Calcium ions (as CaCl_2) are added and the DNA is coprecipitated with the inorganic salts. These precipitates are then added to the cells (69). Parameters that can be utilized to optimize this process include the amount of DNA in the precipitate, the period of time the precipitate is left on the cells, and the possible inclusion of glycerol or dimethyl sulfoxide treatment, which has been shown to increase transfection efficiency in some cases. One of the main advantages of this method is low cost. Disadvantages include the need to use large amounts of DNA for efficient precipitate formation, and the somewhat variable nature of the procedure. This method is used for both transient and stable transfections.

Polycation-mediated DNA uptake involves the formation of complexes between positively charged polymer and negatively charged DNA. DEAE-dextran is the most commonly used polymer, but protamine and polyethyleneimine are also employed. The mechanism by which cells take up DNA in this method involves interaction of the condensed DNA with the negatively charged cell surface, followed by

endocytosis (69). Parameters to optimize for this method include the number of cells transfected, the DNA concentration, and the DEAE-dextran concentration. The major advantages of this technique are its relative simplicity and speed and its limited expense. Disadvantages include cell growth inhibition. This method is most often used for transient transfections or transfections with episomal vectors.

Liposome-mediated transfection involves the formation of lipid-DNA complexes by using cationic lipids. The cationic lipids combine with the negatively charged DNA through electrostatic interactions. The condensed aggregates then interact with the negatively charged and hydrophobic plasma membrane and enter the cell (63). Parameters used to optimize this method include the DNA and lipid concentrations and the incubation time of these complexes with the cells. Advantages of this approach include high transfection efficiencies. Disadvantages include higher reagent costs, as compared to other transfection methods.

Electroporation is the most commonly used physical method of DNA delivery. This method uses a high-voltage electric pulse to introduce DNA into the cell. Cells are placed in an electroporation buffer and transferred to an electroporation cuvette, after which DNA is added. An electrical pulse of defined magnitude and length is applied, most often using a commercial device, and cells are subsequently transferred to normal growth medium (75). Parameters to optimize include the amplitude and length of the electrical pulse. This method is less affected by the amount of DNA used in the transfection. Advantages include high transfection efficiencies and the ability to deliver large DNA molecules, as well as its applicability for a broad range of cell types. Disadvantages include the need for specialized equipment, and difficulty in processing many samples, although industrial-scale continuous-flow electroporation is feasible. This method is used for both transient and stable

transfections and has been shown to be very efficient for suspension cells.

23.2.3. Isolation of Transfectants

After introduction of the vector, the resulting host cell population is invariably heterogeneous, including cells not expressing any transgene and others exhibiting a wide range of expression. Typically, selection pressure is applied to enrich for cells that express the selectable marker and thus carry the transfected vector. By cultivating the surviving cells in the presence of a selection agent for a sufficient period of time (usually 2 weeks), the surviving population will contain only cells in which the selectable marker gene has integrated into a chromosome (Fig. 2). Such a cell population remains heterogeneous. For applications in which the primary objective is to characterize the properties of cells expressing the target gene, or to produce proteins for research use, obtaining a heterogeneous population of cells is sufficient. To establish a reproducible process of protein production, it is critical to establish a steady supply of cells that originate from a single cell clone. In such clonal isolates, variability in productivity and even in some key characteristics of the protein product, such as glycosylation, is unavoidable. It is thus critical to isolate a reasonably large but manageable number of clones and to establish a method of screening these clones to identify those candidates with the best combination of important features for protein product expression. Several commonly used selection and screening methods are described below.

23.2.3.1. Selection Methods

Approximately 1 in 10^4 cells in a transfected population will stably integrate foreign DNA carried in plasmids, with varying efficiencies observed in different cell types. It is therefore necessary to include a selectable marker in order to select cells that have integrated the foreign DNA.

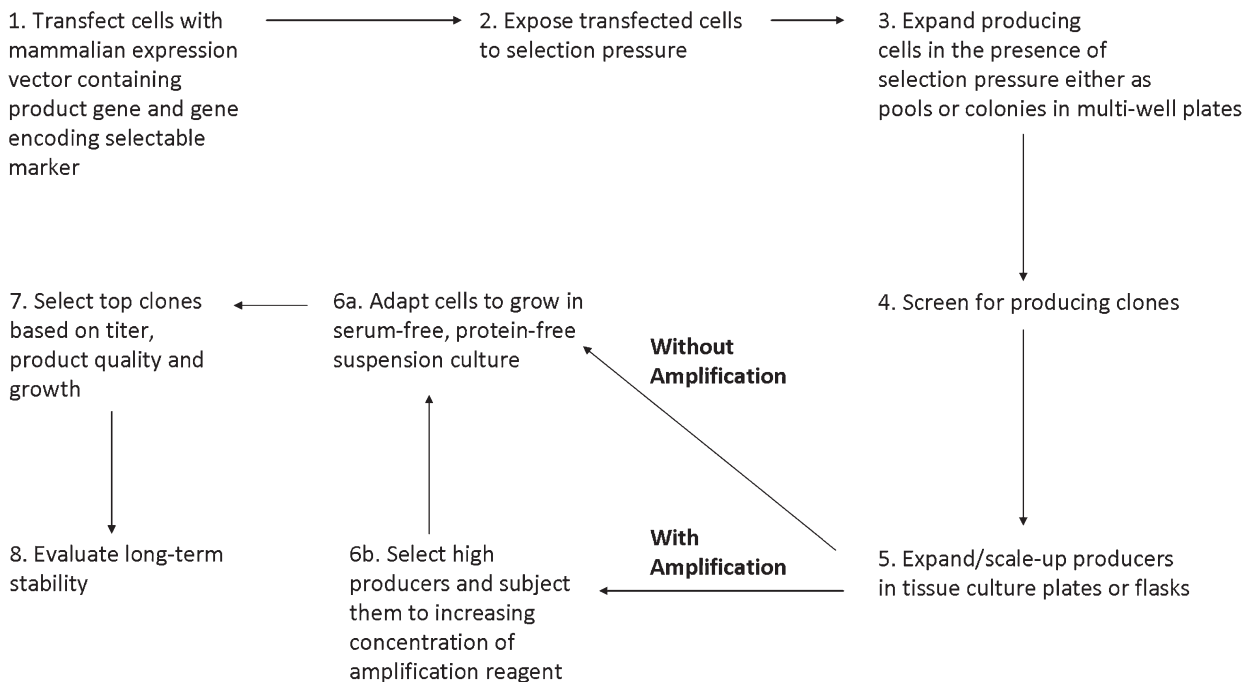

FIGURE 2 Overview of selection of stable and amplified clones.

Selectable markers include recessive markers, in which the recipient cells must have a special phenotype and introduction of the selectable marker provides a selection advantage over the host background, and dominant markers, in which no special phenotype is necessary in the recipient cell population. Commonly used recessive markers include wild-type dihydrofolate reductase (DHFR) (discussed in greater detail in section 23.2.4.1, where the recipient cells lack DHFR activity, and thymidine kinase, where the recipient cells lack thymidine kinase activity. In this latter system, the herpesvirus thymidine kinase gene is introduced into the cells, and positive transfectants are selected in HAT (hypoxanthine aminopterin thymidine) medium. Several dominant selectable markers are available for selection in mammalian cells, and some commonly used markers are shown in Table 2.

23.2.4. Amplification

Certain selectable markers can also be used for gene amplification by applying systematic increases in selective pressure. Gene amplification is commonly used to increase the number of copies of the transgene and its transcript levels, thus generating high levels of recombinant protein expression. In the presence of selective pressure, the selectable marker is coamplified alongside the product gene, and copy numbers between tens and several thousands have been reported (7, 14, 51).

23.2.4.1. DHFR System

One of the most commonly used gene amplification systems is based on the DHFR gene, whose chemical antagonist,

methotrexate, can be used for gene amplification. DHFR is an enzyme which catalyzes the conversion of folate to tetrahydrofolate, a compound required for the biosynthesis of glycine, thymidine monophosphate, and purine nucleotides. CHO cells deficient in DHFR were isolated after ethyl methanesulfonate- and UV irradiation-induced mutagenesis (86, 87). These DHFR-deficient cells require the addition of thymidine, glycine, and hypoxanthine to the medium. These cells do not grow in the absence of added nucleosides unless they acquire a functional DHFR gene.

The primary advantage of the DHFR selection system is the ability to select for cells which contain an amplified copy number of DHFR genes. Methotrexate, a folate analogue, binds and inhibits DHFR, thereby leading to cell death. When cells are selected for growth in methotrexate, the surviving population contains increased levels of DHFR, resulting from an amplification of the DHFR gene. This is also accompanied by amplification of 10 to 10,000 kb of DNA surrounding the site of integration (24, 83). Therefore, by introducing a gene of interest (e.g., protein product gene) alongside the DHFR gene, coamplification of the product gene can be achieved. Upon further increases in methotrexate concentration, cells with higher degrees of DHFR gene amplification are obtained. Highly methotrexate-resistant cells have been obtained that contain several thousand copies of the DHFR gene (93). Thus, DHFR-deficient CHO cells have proven a useful host for gene transfer experiments devoted towards high-level expression of heterologous genes, due to their ability to amplify

TABLE 2 Commonly used selectable markers

Selectable marker	Example of selection conditions	Mechanism of action	Comments	References
Neomycin phosphotransferase (neo, G418, APH)	100 to 800 $\mu\text{g/ml}$ G418	G418 inhibits protein synthesis by interfering with ribosomal functions. Gene expression detoxifies G418.	Resistant colonies usually take 1 to 2 weeks to emerge.	82
Hygromycin B phosphotransferase (HPH)	10 to 400 $\mu\text{g/ml}$ hygromycin B	Hygromycin inhibits protein synthesis via translocation disruption and promotion of mistranslation. Gene expression detoxifies hygromycin through phosphorylation.	Selection typically takes 10 days to 3 weeks.	38, 71
Puromycin <i>N</i> -acetyltransferase (PAC, puro)	0.5 to 10 $\mu\text{g/ml}$ puromycin	Puromycin inhibits protein synthesis. Gene expression detoxifies puromycin through acetylation.	Cell death occurs very rapidly and colonies can be obtained in as little as 7 days.	26
Bleomycin (phleo, bleo, zeocin)	0.1 to 50 $\mu\text{g/ml}$ phleomycin	The gene encodes a protein which stoichiometrically binds the drug and inactivates it.	Selection typically takes 10 days to 3 weeks.	67, 85
Blasticidin-S deaminase (bsr)	3 to 50 $\mu\text{g/ml}$ blasticidin	Blasticidin inhibits peptide bond formation by the ribosome, preventing protein synthesis.	Cell death occurs very rapidly and colonies can be obtained in as little as 7 days.	49

the gene copy number of DHFR. It should be noted that methotrexate resistance can also emerge from other cellular modifications, including altered methotrexate transport properties (79) or the development of a methotrexate-resistant DHFR enzyme (29, 64).

23.2.4.2. Glutamine Synthetase System

The glutamine synthetase selection system is based on the biosynthetic pathway of glutamine from the substrates glutamate and ammonia. Most mammalian cell lines require glutamine supplementation in their culture media to grow, and their endogenous glutamine synthetase activity is low. The glutamine synthetase expression vector contains a glutamine synthetase gene along with the gene of interest, allowing for selection by growth in glutamine-free cell culture medium. The glutamine synthetase gene is usually driven by a weaker promoter, typically the SV40 promoter (10). With a high concentration of the glutamine synthetase inhibitor methionine sulfoximine, it is possible to select for transfectants with gene amplification.

Several variations on the systems described above have been reported, aimed at increasing achievable expression levels. The use of DHFR in conjunction with an impaired neomycin resistance gene has been reported, resulting in the isolation of high-level-expressing clones with only a few integrated gene copies (6). In another application, expression of the protein product gene was coupled to that of the selectable marker using bicistronic expression vectors with an internal ribosomal entry site (IRES) (2, 9). It should be noted that in amplified systems, it is common to see a reduction in protein titers upon removal or reduction of the selective pressure.

23.2.4.3. Cell Clones versus Cell Pools

After transfection and selection, a mixture of transfected cells is present in the population. These cells are heterogeneous. Each originally transfected cell has a different chromosome integration site and copy number; each is also likely to exhibit different growth rates, kinetics, and productivity (78). A subpopulation which has a high productivity may be masked by others, thus giving an overall medium productivity level. Over time, one subpopulation may outgrow the others. This mixture of transfected cells is referred to as a cell pool. For the development of industrial recombinant protein-producing cell lines, it is required to isolate clonal lines to ensure a robust production process. However, such clonal lines are not always necessary for research applications or in cell engineering. Cell cloning is a long and tedious process, since each clone must start from a single cell. It takes more than 10 population doublings for a small colony to be visible to the naked eye. In certain applications, it may therefore be desirable to forgo the time-consuming step of generating clones and instead characterize the behavior of a pool of transfectants.

23.2.4.4. Cell Clone Screening

Screening is a crucial component in isolating the desired clones, but the process can be both time-consuming and labor-intensive. For industrial producers, typical protocols involve screening hundreds of clones. Consequently, instrumentation has been developed to facilitate high-throughput screening of cell clones. Below, we discuss some of the available cell line screening methods, a number of which are amenable to high-throughput screening. For a recent review on the subject, the reader is referred to reference 15.

23.2.4.4.1. Screening for Protein Expression Level or Productivity

It is a common practice to combine limiting-dilution cloning with productivity measurements, typically using enzyme-linked immunosorbent assay (ELISA), during cell screening. In this procedure, cells are diluted in microtiter plates to ensure that the probability of the presence of more than one growing cell per well is sufficiently low. Therefore, cells growing out in any well after a sufficient number of cell doublings can be considered to have originated from a single cell. Supernatants from positive wells can be assayed for product titer, usually using ELISA, and a number of producing clones, usually those with higher product concentrations, will be expanded for further characterization. There is a wide distribution in expression levels of the transgene among different clones. A wide range of possible causes may contribute to different productivity, such as the different sites of chromosomal integration of the transgene, and the difference in copy number of the transgene. This broad range of expression levels and productivities is the main driver for screening multiple clones.

In an effort to increase throughput, there has been a growing use of automation at various stages in the process, including the use of liquid handling systems for cell seeding and plating, and automating product quantification assays such as ELISA. One platform in particular has been developed with the aim of automating the entire cell line development platform: the Cello robotic system from the Automation Partnership (<http://www.automationpartnership.com>). This system incorporates clone screening, cell expansion, and product quantification. Contained within a laminar flow cabinet, it automates cell seeding following transfection, microscopic monitoring of microtiter plates, expansion of individual wells, and supernatant collection for product quantification. The system, though rather expensive, can currently process 600 to 800 plates.

23.2.4.4.2. Screening Based on Fluorescence

The occurrence of a high producer is a rare event in a heterogeneous population of producing cells. The use of flow cytometry can improve the odds of identifying these rare events, due to its ability to screen millions of cells, a scale that is far beyond the capability of the limited-dilution method. We describe here a number of methods that incorporate flow cytometry for sorting high-producing cells.

One approach to identify potential high producers has been to correlate productivity with the presence of product molecules on the cell surface. Upon labeling with fluorescent antibody, cells are sorted based on fluorescence intensity. Since the protein of interest is usually a secreted product, fluorescent staining of product molecules on the cell surface captures only those in secretory vesicles near the cell surface in the process of being excreted. A correlation between cell surface labeling and expression level has been reported in many cases, but does not always hold true (22, 62, 65, 77). Reporter proteins, such as green fluorescent protein (GFP), have been applied for screening potential high producers. In one approach, GFP was coexpressed with the product gene and cells were sorted based on fluorescence intensity (60, 66). The use of two fluorescent reporters for antibody production has also been reported, whereby the heavy-chain and light-chain constructs each express a different fluorescent reporter. Cell populations can then be selected for maximal double fluorescence (80). The use of fluorescent methotrexate has also been applied for cell screening. Cells are sorted based

on fluorescence intensity as a result of methotrexate bound to the DHFR enzyme (95).

23.2.4.4.3. Screening Based on Protein Secretion

Another type of screening method relies on confining the secreted product to the vicinity of the cell, thus allowing for detection and isolation of cells secreting a high level of the desired protein product. The final product concentration in a growing culture is the combined result of many factors, including cell growth rate, the ability to reach and sustain a high cell concentration, and the specific productivity of the product. These methods aim to capture cells with the highest final product level, as opposed to the methods described in the above section, which capture the ones possibly having a faster secretion rate or specific productivity, but not necessarily robust growth characteristics.

Gel microdrops have been used to encapsulate single cells in biotinylated agarose droplets, consequently capturing proteins secreted by the cell. To allow protein-specific capture, antibodies are bound to the biotin-derivatized gel matrix and captured protein is then quantified using a fluorescent detection antibody (89, 90). Due to their small size (20 to 50 μm in diameter), gel microdrops can be sorted using fluorescence-activated cell sorting. This technique has been used to select high-level producers in hybridoma cells (37) and CHO cells (41). In matrix-based secretion assays, a product-specific antibody is immobilized on the cell surface, allowing capture of the secreted protein. Quantification of the secreted protein can be accomplished through immunostaining with a detection antibody, which can also be used for cell sorting. In order to prevent the secreted product from binding to neighboring cells, cells are typically cultured in a high-viscosity medium, thereby minimizing diffusion of the secreted product. This approach was originally described in hybridomas and activated T lymphocytes (61), and has since been applied to CHO (11) and NS0 (43) cells. A number of automated systems have recently been developed that make use of these screening approaches to isolate high-level-producing clones. The first is LEAP (laser-enabled analysis and processing). This system combines the use of product capture and individual cell protein secretion measurement with laser-mediated cell removal. Briefly, secreted protein is captured *in situ* using a capture matrix, and product secretion from individual cells is determined using a fluorescent detection antibody. The system, which incorporates automated image analysis, then secreting identifies highly secreting cells. Nonsecreting or poorly secreting cells surrounding the desired colonies are killed using laser irradiation, allowing the remaining colonies to proliferate.

A number of automated colony pickers have been commercialized that allow for automatic selection of high-level-producing clones. In these systems, cells are immobilized in semisolid medium at sufficiently low densities to allow colony formation. The secreted proteins are retained in the vicinity of the cell and can be visualized using appropriate detection methods. When the method is applied to screen for antibody production using secondary antibodies, colonies with large "halos" of captured secreted antibody are excised and expanded. Commercialized systems include the ClonePix™ from Genetix (<http://www.genetix.com>) and the CellCelector™ from Aviso (<http://www.aviso-gmbh.de>).

The cold capture antibody secretion assay is another method which allows retention of the secreted product in the vicinity of the cell. In this method, producing cells are isolated and maintained at low temperature, which is thought to retard plasma membrane turnover and the

release of protein being secreted to the plasma membrane. Subsequently, staining with a fluorescent antibody allows cells to be sorted based on fluorescence intensity (13).

23.2.4.4.4. Screening Based on DNA or mRNA Levels

Attempts have been made to correlate productivity and titer with DNA and mRNA levels of product gene or selectable/amplifiable marker (e.g., DHFR). Good correlations have been observed between specific productivity and antibody product mRNA levels in CHO cells (56, 58) and hybridomas (28), with heavy-chain IgG being a better predictor of productivity than light chain. In one study of CHO cells, heavy-chain IgG mRNA levels were measured in a panel of clones both at the 96-well plate stage and further in the expansion process (58). While a good correlation was observed between mRNA levels and specific productivity in the expanded clones (cultured in 125-ml shake flasks or 50-ml tubes), mRNA levels at the 96-well plate stage could only be used for prediction of the top 25% producing clones upon expansion.

23.2.5. Characterization of Transfectants

From the screening and selection stage, a small number of clones are isolated for further study. Those clones can possibly exhibit a wide range of behavior even though they have all been screened for a common property, typically the productivity level. Some may exhibit diminished growth, or produce excess amounts of undesired metabolites, or secrete product molecules that have an altered glycoform. Thus, at the minimum, the expression of the transgene and growth kinetics of these clones should be characterized.

23.2.5.1. Expression Characterization

Following screening and selection of stable transfectants, several characterization steps may be included to verify integration and expression of the protein product. These include measuring mRNA levels of the expressed gene using quantitative real-time PCR, confirming presence of the target protein using Western blots, measuring protein levels using ELISA, and analyzing samples for product quality attributes.

23.2.5.2. Cell Characterization

The growth behavior of the isolated clones should be characterized. Different clones may even have different nutritional requirements in terms of their need for animal serum or special growth factors. Clones used for industrial production of recombinant protein need to be stable in terms of their growth, protein productivity, and quality over a time span that takes into account the duration of a manufacturing campaign, from a frozen vial to the manufacturing-scale bioreactor. The level of protein production can be measured using assays like ELISA and high-pressure liquid chromatography, and needs to be demonstrated to be stable. Even for research use, the stability of the transfectant should be examined for any cell age effects, although not necessarily over a duration as stringent as in industrial production.

23.2.6. Transient Expression

In transient expression, plasmids or virus vectors harboring the protein product gene are introduced into the cell and maintained and/or replicated as an extrachromosomal unit. Transfection efficiency, or the percentage of cells taking up and expressing the DNA of interest, is the most

important factor controlling the overall expression level. High transfection efficiencies ($\geq 70\%$) are desirable in order to attain a manageable protein concentration. The duration of protein production using transient expression systems is usually limited by loss of vector DNA from the cell population with time, and the toxic effect of high copy numbers of foreign DNA.

Protein concentrations attainable in transient systems range from ≥ 1 to 100 mg/liter (corresponding to specific productivities of approximately 0.1 to 1 pg/cell/day) in approximately 5 to 10 days (5). While not suitable for long-term production or commercial manufacturing, these systems are extremely useful for rapid production of research material in small quantities, for drug candidate identification, and for in vivo evaluation, assay development, structural studies, and toxicology studies. Large-scale transient transfection cultures up to 100 liters have been reported, with yields of 75 mg (32).

Both viral and nonviral expression vectors are used for transient expression. Episomal systems, which allow extrachromosomal replication of the expression vector in mammalian cells, are commonly employed. These include the Epstein-Barr virus and SV40, which require expression of the Epstein-Barr virus nuclear antigen 1 (EBNA1) and SV40 large-T antigen, respectively, for replication. Transient expression typically requires a large amount of plasmid DNA, on the order of 1 to 1.25 $\mu\text{g/ml}$ of culture (5). Large-scale production of plasmid DNA is therefore a significant contributor to the overall cost of transient transfection.

As reviewed in section 23.2.2, several methods are available for DNA delivery into the cell. One consideration when selecting a delivery method for transient transfection is cost, especially for large-scale transient transfections. While lipid-mediated transfection is very effective, it is not frequently used at large scales due to its comparatively higher cost. Polyethyleneimine-mediated transfection is more frequently employed at larger scales (5).

The host cells frequently used for transient expression include HEK-293, COS, and BHK cells (5). As CHO cells are a major workhorse for industrial protein production in mammalian cells, there have been developments in their use as a platform for transient expression. However, transient production in CHO cells has been reported to be comparatively lower than in HEK-293 cells (5).

23.3. GENETIC MANIPULATIONS FOR CELLULAR ENGINEERING APPLICATIONS

Within the context of cell engineering applications, genetic manipulations are employed to modify cellular functions. In such applications, the objective may not be to get maximal expression of the gene of interest, but rather to achieve the desired phenotype. Consequently, transfectants will be selected on the basis of their phenotype, rather than maximal recombinant protein production. The steps involved in genetic manipulations for cell engineering remain largely the same as described previously. However, additional options have now become available, including wider choices in vector expression platforms, promoters for transgene expression, and the possibility of using reporter constructs. These are discussed below.

23.3.1. Additional Vector Expression Systems

Plasmid DNA constructs, described in section 23.2.1, can be used as vehicles for gene delivery in cell engineering

applications. However, a number of other expression systems are also commonly employed in such applications. These include the use of transposon-mediated gene delivery, such as the Sleeping Beauty (47) and piggyBac (27) systems, reviewed in reference 48. The use of viral expression systems is also common in cell engineering applications and is described below.

While viral vectors are rarely used for stable production of recombinant proteins, they are commonly used in cell engineering and other research applications. A number of viral vectors are available for gene expression, and the choice of system depends mainly on infectivity of the host cells, whether host cells are resting or dividing, and whether stable integration of the gene of interest is desired. Table 3 summarizes some of the viral systems available for gene expression. Retroviral vectors represent one of the most commonly used viral expression platforms, with wide commercial availability. We will therefore focus the discussion solely on this system.

Retroviral vectors are based on the *Retroviridae*, enveloped RNA viruses that contain two identical molecules of linear, single-stranded RNA. These are packaged into virion particles, which consist of an inner core containing the viral genome, an outer shell formed by capsid proteins, and an envelope surrounding the entire particle. This envelope consists of a lipid bilayer and includes virus-specific glycoproteins that are responsible for entry of the virion particle into the host cell through interaction with cell surface receptors (72). While many retrovirus species have been used to generate expression vectors, the most commonly used vectors are based on Moloney murine leukemia virus, whose biology has been extensively studied.

The retroviral genome contains several characteristic genes, including *gag*, *pol*, and *env*. The *gag* gene encodes the Gag polypeptide, which is cleaved into several structural subunits essential for virion assembly (Fig. 3). The *pol* gene encodes the enzymes reverse transcriptase and integrase, responsible for converting the viral RNA genome to DNA and mediating the incorporation of the viral DNA into the host chromosome, respectively. Finally, the *env* gene encodes viral surface glycoprotein, which interacts with host cell surface receptors to mediate infection. The retroviral genome is flanked by sequences known as long terminal repeats (LTRs), which are replicated during reverse transcription of the RNA genome. Each LTR is further divided into three functionally distinct regions: U5 (unique 5'), R (repeat), and U3 (unique 3'). The U3 region contains the viral promoter, including a TATA box and other transcriptional regulatory elements (72).

The life cycle of a retrovirus begins with entry of the virion particles into the host cell, either through direct fusion or through endocytosis-mediated fusion. Both infection processes require the interaction of the viral surface glycoproteins with cell surface receptor proteins. Once inside the cell, the virion sheds its envelope and the viral RNA genome is reverse transcribed to DNA using reverse transcriptase contained within the viral particle. This DNA is then transported into the nucleus and integrated into the host chromosome. This is followed by transcription and translation of the viral genome and assembly of new virions, which bud from the cell surface (45). One virion produces one integrated copy of the viral genome. Retroviral vectors typically contain a modified retrovirus genome to make them replication defective. This is accomplished by removing the viral coding sequences from the vector, i.e., the *gag*, *pol*, and *env* genes. In order for the vector system

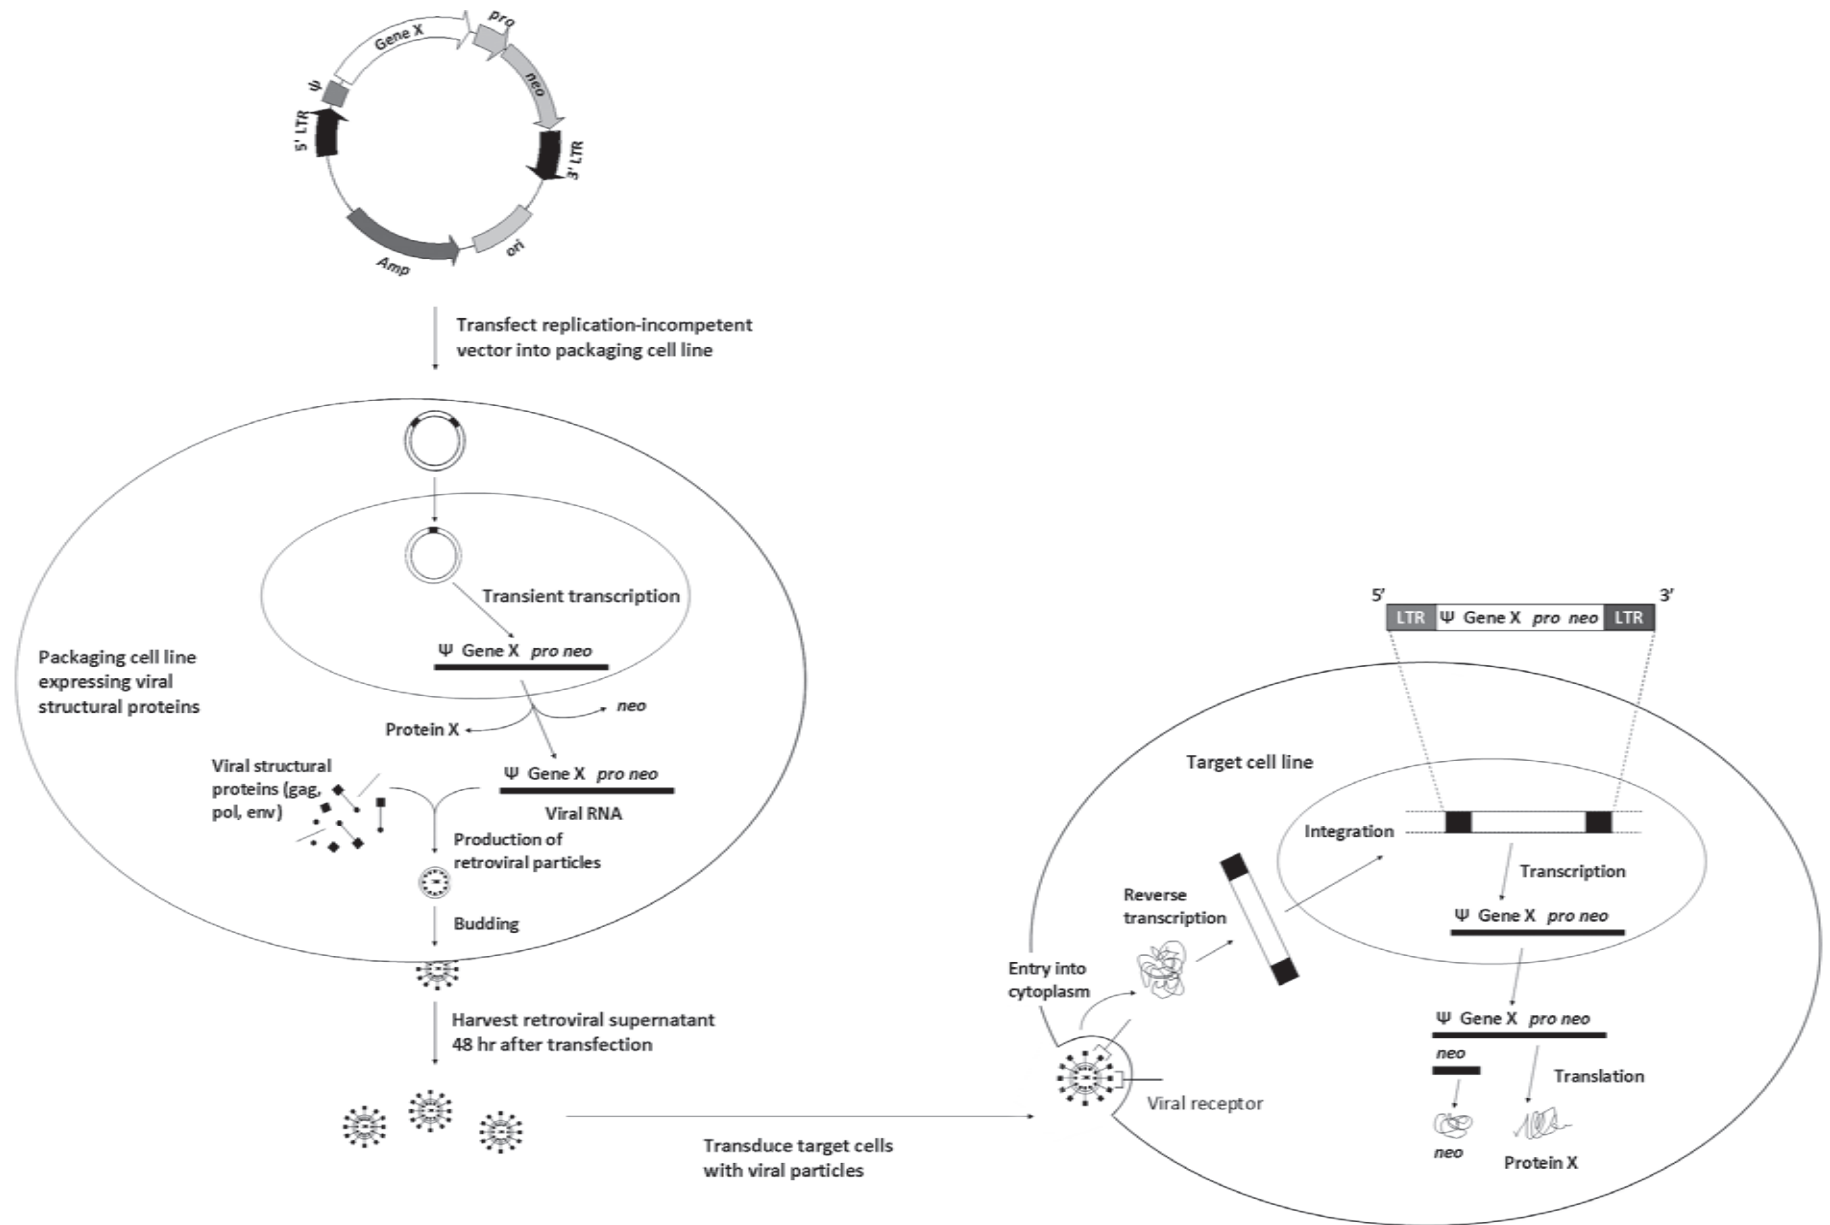

TABLE 3 Common viral expression systems

Virus	Genome ^a	Integration into host chromosome?	Insert size	Comments	Reference
Herpes simplex virus	Enveloped, dsDNA	No	≤30 kb	Broad mammalian host range	17
Epstein-Barr virus	Enveloped, dsDNA	No	~180 kb	This plasmid can be maintained episomally, given the viral origin of replication (<i>oriP</i>) and the viral gene encoding the <i>trans</i> -acting factor EBNA-1.	52
Simian virus 40 (SV40)	Nonenveloped, dsDNA	Yes	≤5 kb	Can integrate into the host genome and be maintained episomally in the presence of SV40 <i>ori</i> and large-T antigen	84
Adeno-associated virus	Nonenveloped, ssDNA	>90% episomal, <10% integrated	≤5 kb	Can integrate into the host genome and be maintained episomally	94
Adenovirus	Nonenveloped, dsDNA	No	~15 kb	Broad mammalian host range. This plasmid is maintained episomally.	12
Vaccinia virus	Enveloped, dsDNA	No	≤25 kb	Broad mammalian host range. Used for <i>trans</i> gene expression and vaccination.	19
Baculovirus	Enveloped, dsDNA	Yes	≤40 kb	Broad host range. Use of mammalian promoters allows <i>trans</i> gene expression in mammalian cells.	23
Retrovirus	Enveloped, ssRNA	Yes	≤9 kb	Host range: ecotropic virus replicates solely in cells derived from the host species, while amphotropic virus replicates in a wide range of mammalian cells.	72
Lentivirus	Enveloped, ssRNA	Yes	≤9 kb	Transduces both resting and dividing cells	31

^adsDNA, double-stranded DNA; ssDNA, single-stranded DNA; ssRNA, single-stranded RNA.

FIGURE 3 Overview of production of replication-defective retroviral particles using packaging cells and subsequent transduction of target cells. A replication-incompetent vector, which includes the 5' and 3' LTR regions, the packaging sequence (ψ), a gene of interest (Gene X), and a mammalian selectable marker (*neo*) with its own promoter (*pro*), is introduced into a packaging cell line which supplies the required viral accessory proteins, namely Gag, Pol, and Env. This bacterial plasmid also contains the required genetic elements for replication (*ori*) and selection (*Amp*) in *E. coli*. Upon entry into the packaging cell line (via any desired transfection methodology), the plasmid is transported into the nucleus, where it is transiently transcribed. The viral transcript initiates at the 5' LTR and terminates at the 3' LTR, generating a full-length viral transcript. It contains the packaging sequence (ψ), which allows packaging into viral particles. Fully assembled viral particles subsequently bud out of the packaging cell line. These viral particles are harvested from the supernatant 48 h after transfection. The virus-containing supernatant is subsequently incubated with the target cells, and entry of the viral particles occurs through interaction with host-cell receptors. Once the viral core is released into the cytoplasm, reverse transcription of the RNA viral genome begins using reverse transcriptase contained within the viral particle. The DNA copy of the viral genome then integrates into the host genome, and the gene of interest and selectable marker can be expressed. One infectious virion produces one integrated copy of the viral genome. Figure adapted from reference 20.

to be functional, these sequences must be supplied in *trans* (57). This is known as packaging and is typically carried out in 3T3 or HEK-293 cells. The necessary *trans*-retroviral elements are either constitutively expressed by the packaging cell line or cotransfected into the packaging cells with the retroviral vector. Along with the gene of interest and LTR sequences, the retroviral vector must also contain a packaging sequence (ψ) that is required for incorporation of the transcript into the viral particle. Active viral particles can then be produced in these cells and secreted into the growth medium, where they are harvested and used for subsequent transduction of a target cell line (81). These retroviral particles can infect the target cell and integrate the transgene into the host genome, yet are unable to replicate further and infect neighboring cells. The term “transduction” is typically used to refer to viral gene transfer using replication-defective particles, while “infection” refers to the use of replication-competent virus. The choice of viral receptor will determine which cell types the assembled viral particles can infect, and recombinant retroviral vectors can be pseudotyped using envelope proteins from different viruses. A commonly used envelope protein is vesicular stomatitis virus G protein (VSV-G), as it allows for efficient transduction in a broad range of species (72).

Transduction of target cells with retroviral particles is a relatively straightforward procedure. Typically, 12 to 18 h prior to transduction, cells are subcultured in fresh growth medium. For infection, the infectious retroviral particles are added along with a polycation, such as Polybrene, which promotes vector-cell interaction. After 4 to 24 h of incubation, the vector-containing medium is removed and replaced (or the cells are replated) with fresh growth medium. Integration and expression can be expected within 24 to 48 h and generally reach a plateau after 72 h (81). An additional factor to consider when attempting to maximize gene transfer efficiency is the multiplicity of infection (MOI). MOI represents the ratio of infectious particles to infection targets (i.e., cells). Optimal MOI values vary from cell to cell, although an MOI of 10 to 20 infectious vector particles per cell is common (25).

Retroviral vectors have several advantages, including their effectiveness with cell types which are difficult to transfect, as well as providing a single integrant for the gene of interest, a direct consequence of the mechanism of retroviral integration. Furthermore, it should be noted that the use of certain viral expression systems can require additional biosafety considerations, especially when pseudotyping viral particles for broad infectious potential (e.g., the use of VSV-G).

23.3.2. Constitutive and Inducible Promoters

Promoters can be broadly classified as constitutive or inducible. While inducible promoters are widely used for the production of heterologous proteins in bacteria, recombinant protein production in mammalian cells most often involves the use of a strong constitutive promoter, as discussed in section 23.2.1.1. However, cellular engineering applications can potentially benefit from the use of an inducible promoter system so that the desired cell phenotype is only expressed under induced conditions. For a thorough review of inducible expression systems, the reader is referred to reference 30.

Another class of promoters includes tissue-specific and developmental stage-specific promoters, whose expression is specific in some tissues or development stages. A large

number of genes exhibit a wide range of dynamics responsive to various events, such as growth rate, for which no single “inducer” has yet been identified. These promoters allow the expression of the transgene to be conditional upon the event or tissue location. For a list of known event-triggered promoters, the reader is referred to reference 68.

We present here a summary of commonly used small-molecule-inducible gene expression systems, of which many are commercially available. Inducible expression systems should ideally have the following features: minimal baseline expression of the transgene under noninduced conditions; adjustable expression of the transgene, subject to dose response of the inducer molecule; the ability to achieve high expression levels that rival those of commonly used constitutive promoters, under induced conditions; rapid transition from noninduced to induced state, and vice versa; and straightforward design and development of inducible cell lines.

The Tet-inducible systems, which are referred to as Tet-OFF (tTA) and Tet-ON (rtTA), are perhaps the most widely used inducible promoter systems and have been extensively studied (40). These systems were originally burdened by high basal expression “leakiness” as well as a low efficiency of regulation (1). However, second-generation systems which address these issues have now been commercialized by a number of vendors (73). In the Tet-OFF system, the *tetO* operator sequence linked to a minimal promoter is used to regulate transgene expression (35). In the absence of tetracycline, a fusion protein consisting of the tetracycline repressor (TetR) and the VP16 transactivation domain (TA) from herpes simplex virus is bound to the operator sequence, allowing expression of the gene of interest. Addition of tetracycline displaces the complex from the operator sequence, thus suppressing transgene expression. A tetracycline derivative, doxycycline, is also commonly used in place of tetracycline. In the Tet-ON system, the fusion protein is based on a reverse Tet repressor (rTetR). In the absence of doxycycline, the fusion protein cannot bind the operator sequence, thus preventing expression of the transgene. Upon addition of doxycycline, the fusion protein can now bind to the operator, thereby allowing expression of the gene of interest (36).

Another inducible system based on the addition of a chemical inducer molecule is the rapamycin-dependent gene expression system. This system relies on the expression of two critical transcription factor binding domains, and these separate polypeptides are cross-linked using a chemical dimerizing drug as an inducer for transcription. Rapamycin binds two peptides, FKBP12 (FK506 binding protein of 21 kDa) and FRAP (FKBP rapamycin-associated protein). These have been modified by fusing the FKBP12 domain to the ZFHD1 (zinc finger homeo domain) DNA binding domain and fusing the rapamycin-binding domain of FRAP to a transcriptional activation domain from the p65 subunit of NF- κ B (76). This system has been reported to provide tight expression control, with robust peak expression levels (74). This system is one of many dimerizer systems that are reviewed in reference 74.

A number of steroid receptor-derived inducible gene expression systems are also commonly used. One such class is based on insect steroid receptors. Ecdysteroid hormones, such as ecdysone, regulate a number of developmental processes in insects. Ecdysone binds and activates its receptor, EcR, leading to the formation of a heterodimer with the ultraspiracle protein (USP). This results in activation of gene expression. This system

has been adapted and commercialized under the name Rheoswitch® (New England Biolabs). In this system, the original DNA binding site of *Drosophila melanogaster* EcR was replaced with a GAL4 DNA binding domain, while the activation protein was replaced with human fusion protein. Furthermore, induction is now achieved through the addition of a nonsteroidal synthetic ligand (70). This system has been reported to have high sensitivity to ligand induction, low background activity, and high inducibility of target gene expression (88).

23.3.3. Reporter Genes

Reporter systems are frequently used to track the quantity, spatial localization, and dynamics of the promoter by which their expression is controlled. Their applications are thus many, such as quantifying the efficiency of transfection, visualizing the dynamics of a regulatory element, and sorting a subpopulation based on gene expression. A number of reporter genes of both prokaryotic and eukaryotic origin are available. Ideally, a reporter system should exhibit phenotypic characteristics that are absent in the experimental system and for which there is a sensitive detection method

with a broad linear dynamic range that is quantitative, reproducible, and cost-effective.

Depending on the application, different reporter constructs are required. When measuring transfection efficiency or sorting transfected cells, a reporter gene driven by a strong constitutive promoter is typically employed. When characterizing regulatory sequences, expression of the reporter gene is put under the control of the regulatory sequences under study. Finally, for the study of cellular trafficking, protein fusion constructs are used, where the reporter gene coding sequence is linked to the protein of interest, usually through the addition of a short linker sequence. Table 4 presents a summary of commonly used reporter genes along with their advantages and disadvantages. GFP and other fluorescent proteins are most commonly used to assess the frequency of gene transfer in transfected cell populations. Firefly luciferase and secreted alkaline phosphatase are more commonly used to assess overall gene expression. The advantage of secreted alkaline phosphatase is that it does not require cell lysis for sample preparation, while luciferase offers a remarkably broad range of quantification (as high as 10^5 -fold).

TABLE 4 Commonly used reporter genes (adapted from reference 50)

Reporter gene	Detection assay	Advantages	Disadvantages	Detection limit (no. of molecules)	Cost/assay (US\$)
Green fluorescent protein (GFP)	Fluorescence	Fluorescence is species independent; useful for high-throughput assays performed in 96-well plates	Signal intensity may be too weak for some applications (although can use brighter GFP, e.g., EGFP).	NA	No additional reagents required
Secreted alkaline phosphatase	Colorimetric, bioluminescence, or chemiluminescence	Nonisotopic; secreted reporter protein; various assay formats available; useful for high-throughput assays performed in 96-well plates	May not be suitable for cells expressing low levels of placental-type alkaline phosphatase; may not be suitable if experimental conditions are known to impact cellular secretion	10^4 – 10^5	0.01–0.04
Firefly luciferase	Bioluminescence	Nonisotopic; good sensitivity and broad linear range; minimal endogenous activity in mammalian cells	Short half-life of protein; conventional assay lacks reproducibility	1×10^5 – 2.5×10^5	0.10–0.25
Chloramphenicol acetyltransferase	Chromatography, differential extraction, fluorescence, or immunoassay	Minimal endogenous activity in mammalian cells; various assay formats available	Assays are time-consuming and laborious; most require expensive radioactive substrate; relatively low sensitivity and narrow linear range; short half-life of CAT mRNA	5×10^7 – 10×10^7	2.00–7.00
β -Galactosidase	Colorimetric, fluorescence, or chemiluminescence	Nonisotopic; various assay formats available	Many cell types have high endogenous β -galactosidase activity.	10^4 – 10^5	0.01–0.02

23.4. CONCLUDING REMARKS

This chapter describes basic methodology used in expressing heterologous proteins in mammalian cells and in engineering their characteristics. Although expression of proteins in mammalian cells is more technically involved than commonly used microbial systems, especially *E. coli*, the wide range of vectors and commercial kits that are readily available has made their genetic manipulation easily accessible to researchers in need of carrying out the task. The development of new technologies for genetic manipulation of mammalian cells and their screening will continue to drive discovery and improve robustness of our protein production processes.
