GENETIC ENGINEERING OF SECONDARY METABOLITE SYNTHESIS

IV

“Secondary metabolism” is the term used to describe the biosynthesis of compounds that are not essential to the growth or maintenance of the host organism. Secondary metabolites include thousands of compounds from plants, fungi, and bacteria, including large, complex molecules that have applications in the pharmaceutical, agricultural, chemical, and fuel industries. Examples include phenolics (antiaging agents), terpenoids (antimalarial agents), polyketides (antibiotics, antifungals, anthelmintics, hypercholesteroleemics), glycosides (antibiotics), and nonribosomal peptides (antibiotics and anticancer agents). Over the past 2 decades, the importance of secondary metabolites has driven significant efforts in the understanding of the genetics of their biosynthesis. Such efforts have produced the concomitant effects of the development of methodology for the genetic manipulation of many of the heretofore genetically intractable microorganisms, as well as the ability to place the genes responsible for the metabolic pathways into familiar organisms. These developments have enabled two important applications: novel, directed approaches to titer improvements, and the generation of novel derivatives of some of these secondary metabolites through manipulation of the corresponding genes. Both are represented in this section.

In chapter 24, “Glycosylation of Secondary Metabolites To Produce Novel Compounds,” Andreas Bechtold and Katharina Probst describe the biosynthesis of various glycosides of aromatic polyketides in various *Streptomyces* hosts, and how the understanding of the genetic bases of biosynthesis has enabled the production of novel, hybrid molecules. Methods to manipulate the described organisms are included in the chapter. In chapter 25, “Metabolic Engineering of *Escherichia coli* for the Production of a Precursor to Artemisinin, an Antimalarial Drug,” Christopher J. Petzold and Jay D. Keasling describe the assembly of genes in *E. coli* from bacteria and yeast to produce artemisinic acid, the sesquiterpene precursor to artemisinin. The chapter outlines how an “omics” (proteomics/transcriptomics/metabolo-mics) approach is being used to overcome bottlenecks in the biosynthesis of the product. In chapter 26, “Heterologous Production of Polyketides in *Streptomyces coelicolor* and *Escherichia coli*,” James T. Kealey describes the steps taken to move the genes that determine the polyketide synthase that catalyzes the production of the backbone of erythromycin from the producing organism, *Saccharopolyspora erythraea*, to the genetically tractable hosts *Streptomyces coelicolor* and *E. coli*, and the concomitant strategies undertaken to enable the latter to produce the required precursor, methylmalonyl-CoA.

Richard H. Baltz, Kien T. Nguyen, and Dylan C. Alexander, in their chapter 27, “Genetic Engineering of Acidic Lipopeptide Antibiotics,” describe the genetic basis for the production of the lipopeptide daptomycin,

a recently marketed antibiotic effective against methicillin-resistant *Staphylococcus aureus* infections, and the methodology developed to enable manipulation of the corresponding peptide synthetase to result in the production of novel derivatives in the producing host, *Streptomyces roseosporus*. The chapter includes descriptions of the biosynthesis of other lipopeptides in *Streptomyces* hosts. In "Genetic Engineering To Regulate Production of Secondary Metabolites in *Streptomyces clavuligerus*," chapter 28, Susan E. Jensen describes methodology developed to genetically manipulate *Streptomyces clavuligerus*, which enabled the determination of how the biochemical pathway for the production of cephamycin C, the chemical backbone of numerous marketed cephamycins, is regulated. In addition, the methodologies developed allowed the understanding of the biochemical pathway for this production, as well as the

genes for regulation, in the same host, of clavulanic acid, the natural product used as a codrug to inhibit β -lactamases found in various gram-positive bacteria that cause respiratory infections.

Finally, in chapter 29, "Genetic Engineering of Myxobacterial Natural Product Biosynthetic Genes," Bryan Julien and Eduardo Rodriguez describe the methods developed to manipulate the genomes of the myxobacterium *Sorangium cellulosum* and the various derivatives of the anticancer polyketide epothilone that were produced. This chapter, together with chapter 18, "Genetic Manipulation of Myxobacteria" (Black et al.) in Section III, presents a comprehensive set of methods and examples for the manipulation of these soil and marine microorganisms, which are rapidly becoming a new and important source of novel secondary metabolites.

Glycosylation of Secondary Metabolites To Produce Novel Compounds

ANDREAS BECHTHOLD AND KATHARINA PROBST

24

24.1. INTRODUCTION

Carbohydrates form the most abundant group of natural products. The central role of sugars and deoxysugars as energy and biosynthetic resources (for glycolysis, the pentose phosphate cycle, and the shikimate pathway), as energy storage devices (for photosynthesis), and as key structural elements in the formation of biological backbones (2-deoxyribose for DNA and *N*-acetylglucosamine for murein) has been well known for decades (74). But only recently it was recognized that carbohydrates also have crucial functions for signaling and information transfer in biological systems (59). In addition, carbohydrates are important and essential moieties of many pharmaceutical agents (92).

Although sugars and saccharides are involved in many processes within cells, the details of how saccharide structures influence biological functions remain one of the least explored avenues of chemical biology. This lack of knowledge compared to that of proteins and nucleic acids is due to the inaccessibility of numerous saccharide and oligosaccharide structures. Sugars can be connected by a wide range of regio- and stereochemically different linkages. This variability in structure makes classical synthetic chemistry difficult because multiple protection and deprotection steps are required (12). A highly attractive alternative is the use of biological systems or enzymatic tools. In this review, we summarize our own work on cloning and characterizing genes involved in sugar biosynthesis and attachment. We will give an overview of the methods which are available to create novel glycosylated compounds.

24.2. STRUCTURES AND MODES OF ACTION OF SELECTED NATURAL PRODUCTS

24.2.1. Avilamycin A

Avilamycin A (Fig. 1) and avilamycin C are produced by *Streptomyces viridochromogenes* Tü57. Along with curamycins, evernimicins (Fig. 1), and flambamycins, they belong to the orthosomycin class of antibiotics (96). Structural features of the avilamycins are a terminal dichloroisoverninic acid moiety and a heptasaccharide side chain consisting of *D*-olivose, 2-deoxy-*D*-evalose, 4-*O*-methyl-*D*-fucose, 2,6-di-*O*-methyl-*D*-mannose, *L*-

lyxose, and eurekanate. Avilamycin A shows excellent activity against a broad range of gram-positive pathogenic bacteria, including glycopeptide-resistant enterococci, methicillin-resistant staphylococci, and penicillin-resistant streptococci, and is therefore an interesting candidate for the generation of new antibiotics (26, 41, 67). In 2003 Treede et al. reported that the methylation of G2535 and U2479 in domain V of the 23S rRNA confers resistance to avilamycin by preventing the antibiotic from binding to the ribosome (Fig. 2) (84). Both rRNA methyltransferases responsible for methylation were crystallized, and their structures were resolved (65, 66). The investigation of the crystal structure of the 50S ribosomal subunit of *Deinococcus radiodurans* in a complex with gavibamycin L1, a desmethyl derivative of avilamycin A, revealed the unique inhibitory mechanism of orthosomycins. The binding sites of gavibamycin L1 are C2480 and C2537 of the 23S rRNA, located in helices 89 and 91, respectively. The binding of gavibamycin L1 probably prevents the binding of aminoacyl-tRNA, initiation factor 2, and the ribosome recycling factor RRF (38). Interestingly, gavibamycin L1 binds to the ribosome in a U form (10). Both ends of the molecule, the methyleurekanate and the orsellinic acid moiety, are involved in the interaction with the rRNA. Although not yet confirmed by X-ray crystallography, it appears that evernimicin interacts with the ribosome in a very similar way. Unfortunately, evernimicin was dropped from clinical trials some years ago due to toxicity problems. Nevertheless, as the binding site of the orthosomycins is distinct from those of other ribosome-targeting antibiotics, it may be a target for new antibiotics.

24.2.2. Saccharomicin A

The heptadecaglycoside antibiotics saccharomicins A and B (Fig. 3) are produced by the rare actinomycete *Saccharothrix espanaensis* and represent an interesting class of antibiotics (45, 82). Both compounds show potent antibacterial activity in vitro and in vivo against multiple-drug-resistant strains of *Staphylococcus aureus* and vancomycin-resistant enterococci. The saccharomicins consist of an oligosaccharide portion and the intriguing aglycone *N*-(*m,p*-dihydroxycinnamoyl) taurine, in which caffeic acid is linked to the amino sulfonic acid taurine via an amide bond. All 17 monosaccharide residues of the saccharide chain are 6-deoxyhexoses: 5 are

avilamycin A

evernimicin

saccharomicin A

FIGURE 3 Structure of saccharomicin A.

fucoses, 4 are saccharosamines, 4 are 4-*epi*-vancosamines, and 4 are a combination of rhamnose(s) and digitoxoses. The exact mode of action of saccharomicin A is not known. It has been shown that the *in vitro* activities of the saccharomicins against gram-positive bacteria are unaffected by the presence of Ca^{2+} or Mg^{2+} . In contrast, the activities against gram-negative bacteria are substantially reduced by these divalent cations. Like other antibiotics, saccharomicins self-promote their uptake into bacterial cells by interacting with the binding sites of the divalent cations on the lipopolysaccharide. Thus, the primary cellular target appears to be the lipopolysaccharides of the bacterial membrane.

24.2.3. Landomycins, Urdamycin A, Saquayamycin Z, and Simocyclinone

Landomycins (produced by *Streptomyces cyanogenus* S136 and *Streptomyces globisporus*) (31), urdamycins (produced by *Streptomyces fradiae* Tü2717) (17), saquayamycins (produced by *Micromonospora* sp. strain 6368) (83), and simocyclinones (produced by *Streptomyces antibioticus* Tü6040) (80) are angucycline-type anticancer agents (Fig. 4). All compounds contain an angucyclic polyketide core and one or more sugar side chains consisting of D-olivose and/or L-rhodinose moieties. Saquayamycin Z contains additional 2-deoxy-L-fucose and L-aculose moieties, and simocyclinone D8 contains a tetraene side chain and a halogenated aminocoumarin. The angucyclic polyketides differ in functional groups, oxidation state, and sugars/sugar chains, which are either O-glycosidically or C-glycosidically linked to the polyketide core. Landomycin A and saquayamycin Z in particular show powerful anticancer activities, especially against prostate cancer cell lines (3, 14). Like urdamycins and other members of the angucyclines, both compounds also show cytotoxic activity. In contrast to the other angucyclines, simocyclinone D8 is a potent inhibitor of gyrase supercoiling, having a 50% inhibitory concentration lower than that of novobiocin (23, 69). However, it exhibits no competitive inhibition of the DNA-independent ATPase reaction of GyrB, which is characteristic of other aminocoumarins.

Simocyclinone D8 also inhibits DNA relaxation by gyrase. It does not stimulate cleavage complex formation, as do the quinolones, the other major class of gyrase inhibitors. Instead, it prevents Ca^{2+} - and quinolone-induced cleavage complex formation. Results from binding studies suggest that simocyclinone D8 interacts with the N-terminal domain of GyrA, which is a novel mechanism for a gyrase inhibitor.

24.2.4. Aranciamycin and Polyketomycin

Aranciamycins (Fig. 5), which belong to the anthracycline group of natural products, have been isolated from *Streptomyces echinatus*. Aranciamycin A, the main compound, shows weak antitumor activity and appears to be a specific inhibitor of *Clostridium histolyticum* collagenase (11). Aranciamycin consists of the aglycone aranciamycinone and the sugar 2-O-methyl-L-rhamnose. It differs from the very well-known anthracyclines (e.g., daunomycin, adriamycin, and carminomycin) with respect to the substitution of ring A and the sugar moiety, which does not contain an amino group. The tetracyclic quinone glycoside polyketomycin (Fig. 5) was isolated from *Streptomyces diastatochromogenes* Tü6028 (71). It inhibits the growth of gram-positive bacteria and shows activity against several tumor cell lines. Polyketomycin consists of two polyketide residues, the decaketide polyketomycinone and the tetraketide 3,6-dimethylsalicylic acid. A sugar chain consisting of β -D-amictose and α -L-axenose connects both moieties. Structurally related to polyketomycin are the antitumor agents dutomycin from *Streptomyces* sp. strain 1725, the DNA methyltransferase inhibitor DMI-2 (a tautomer of dutomycin) produced by *Streptomyces* sp. strain 560, and the cervimycins isolated from *Streptomyces tendae* HKI-179. They share a *p*-quinone in ring D (15).

24.2.5. Lipomycin

α -Lipomycin (Fig. 6) is an acyclic polyene antibiotic isolated from *Streptomyces aureofaciens* Tü117 (47) and was named from the finding that antibiotic activity is antagonized by several lipids, including lecithin and some sterols. Its structure consists of a carbonyl group linking

FIGURE 4 Structure of selected angucyclines and functions of GTs involved in their biosynthesis.

a pentaene chain with a derivative of *N*-methyltetramic acid composing the aglycone. An *L*-digitoxose molecule is attached to the polyketide part of the aglycone. α -Lipomycin is active against gram-positive bacteria but has no effect upon the growth of fungi, yeast, and gram-negative bacteria. The tetramic acid (2,4-pyrrolidinedione) ring system has been known since the early 20th century, when the first simple derivatives were prepared. Natural products containing the tetramic acid moiety continue to arouse interest due to the range of biological activities they display, including antibiotic and antiviral activities, mycotoxicity, cytotoxicity, and phospholipase A2 inhibition. Other members of this class are responsible for the pigmentation of certain molds and sponges. Examples of natural compounds containing a tetramic

acid moiety are aurantioside B, militarinone B, erythroskyrin, fulgurubin, and olefinin (78).

24.2.6. Phenalinolactone

Phenalinolactone A and its derivatives B through D are terpene glycosides produced by *Streptomyces* sp. strain Tü6071 (Fig. 7). Phenalinolactones are active against some gram-positive bacteria. The tricyclic terpenoid backbone of phenalinolactone is connected to a γ -butyrolactone moiety, an O-glycosidically bound *L*-amicetose, and a pyrrole-2-carboxylic ester moiety. Additionally, the oxygen function at C-3 contains an acetyl group (19). The structure of the phenalinolactones resembles those of other terpenoids and especially that of brasillicardin from *Nocardia terpenica* (16).

polyketetomycin**aranciamycin**

FIGURE 5 Structures of aranciamycin and polyketetomycin.

24.3. CLONING OF BIOSYNTHETIC GENE CLUSTERS OF COMPOUNDS CONTAINING DEOXY SugARS**24.3.1. Generation and Screening of Cosmid Libraries**

One of the most frequently used bifunctional cosmid vectors in *Streptomyces* genetics is pOJ436 (6). This cosmid can replicate in *Escherichia coli* and *Streptomyces* and is therefore very useful for the preparation and screening of cosmid libraries and for heterologous expression. A reliable procedure is described below, although it may require some specific optimization for certain strains.

1. For the preparation of DNA from actinomycetes, the mycelia must be embedded in agarose.
2. After cell disruption, the genomic DNA is partially digested with *Sau3AI* and ligated into cosmid vector pOJ436, which has been digested with *HpaI* and *BamHI*. The DNA is then in vitro packaged with the Gigapack III Gold packaging extract kit according to the instructions of the manufacturer (Stratagene, San Diego, CA).
3. Robotically produced high-density colony arrays (Hybond N+; Amersham Pharmacia, Freiburg, Germany) can be utilized for the screening procedures. In each case, ca. 2,000 cosmid clones should be used.

 α -lipomycin

FIGURE 6 Structure of α -lipomycin and organization of the α -lipomycin biosynthetic gene cluster. The GT gene is shown in white, polyketide genes are shown in light gray, sugar biosynthetic genes are shown in dark gray, and all other genes are shown in black. Nrps, nonribosomal peptide synthase gene.

FIGURE 7 Structure of phenalinolactone and organization of the phenalinolactone biosynthetic gene cluster. The GT gene is shown in white, sugar biosynthetic genes are shown in gray, and all other genes are shown in black.

24.3.2. Gene Probes To Screen Cosmid Libraries

The best DNA probes are PCR fragments amplified from each individual strain. The PCR fragments can be obtained with primers directed toward conserved gene sequences for acyltransferase domains of polyketide synthase I (PKSI), polyketide synthase II gene (KS_{α}), nucleoside diphosphate (NDP)-glucose-4,6-dehydratase genes, and NDP-glucose-2,3-dehydratase genes.

The following primers may be used (abbreviations are according to standard International Union of Pure and Applied Chemistry nomenclature for degenerate nucleotides).

For cloning cosmids containing PKSI genes (e.g., the α -lipomycin gene cluster [7]):

5'-CTSGGSGACCCSATCGAG-3'

5'-CTSGGSGACCCSATCGAG-3'

For cloning cosmids containing PKSII genes (e.g., the polyketomycin cluster [15]):

5'-TSGCSTGCTTCGAYGCSATC-3'

5'-TGGAANCCGCCGAABCCGCT-3'

For cloning cosmids containing NDP-glucose-4,6-dehydratase genes (e.g., the phenalinolactone gene cluster [19]):

5'-CSGGSGSSGCSGGSTTCATSGG-3'

5'-GGGWRCTGGYRSGGSCCGTAGTTG-3'

For cloning cosmids containing 2,3-dehydratase genes (e.g., the saccharomicin gene cluster [4]):

5'-GAGGCSACSWSSAACTACAC-3'

5'-SWRGAASCGSCCSCCCTCCTC-3'

The following PCR protocol may be used to prepare the desired gene probe (PCR mixture components and concentrations: chromosomal DNA, 0.2 μ g/100 μ l; primers, 1 μ g/100 μ l; deoxynucleoside triphosphates, 200 μ M [each]; buffer, 25 mM Tris-acetate [pH 7.7], 100 mM potassium acetate, 1mM dithiothreitol; polymerase, 10 U; and dimethyl sulfoxide [DMSO], 1%).

1. Denaturation of DNA at 94°C for 3 min
2. Addition of reaction components and annealing at 60 to 72°C for 1 min
3. Elongation at 72°C for 2 min
4. Thirty cycles of denaturation (94°C for 45 s), annealing (60 to 72°C for 1 min), and elongation (72°C for 2 min)
5. Terminal elongation at 72°C for 7 min

Labeling of DNA probes and colony hybridization are performed by following standard procedures.

24.3.3. Cloning of GT Genes from Actinomycetes

For the cloning of unidentified glycosyltransferase (GT) genes, a specific PCR-based cloning strategy has been developed by Luzhetskyy et al. (53). Hybrid primers (P1 [5'-AGGTCTGCGGCCSCNCAYGCNMG-3''] and P2 [5'-GGTGGCGGCCNCCRTGRTG-3'']) for the amplification of GT genes involved in natural-product biosynthesis were designed by using sequences of genes (*desVII*, *eryBV*, *eryCIII*, *megDI*, *megCIII*, and *megBV*) encoding GTs catalyzing the deoxysugar attachment to a polyketide moiety. Preselected cosmid DNA hybridizing to one of the probes listed above may be used as a template in the PCR mixture (components and concentrations: chromosomal DNA, 0.5 μ g/100 μ l; primers, 1 μ g/100 μ l; deoxynucleoside triphosphates, 200 μ M [each]; buffer and polymerase; and DMSO, 1%).

1. Denaturation of DNA at 94°C for 5 min
2. Addition of reaction components and annealing at 45°C for 45 s
3. Elongation at 72°C for 1 min
4. Thirty-five cycles of denaturation (94°C for 1 min), annealing (45°C for 45 s), and elongation (72°C for 1 min)
5. Terminal elongation at 72°C for 5 min

Usually, a 900-bp fragment corresponding to an internal segment of a GT gene is amplified by PCR. The cloning of PCR fragments is performed by following standard procedures. Full-length sequences of the GT genes may be obtained using cosmids as a template.

24.4. GENE CLUSTERS ENCODING NATURAL PRODUCTS CONTAINING DEOXSUGARS

Most sugar components of natural products from actinomycetes are deoxygenated sugars. These deoxysugars usually derive from glucose 1-phosphate, which is converted by an NDP-D-glucose synthase to NDP-D-glucose. Dehydratases,

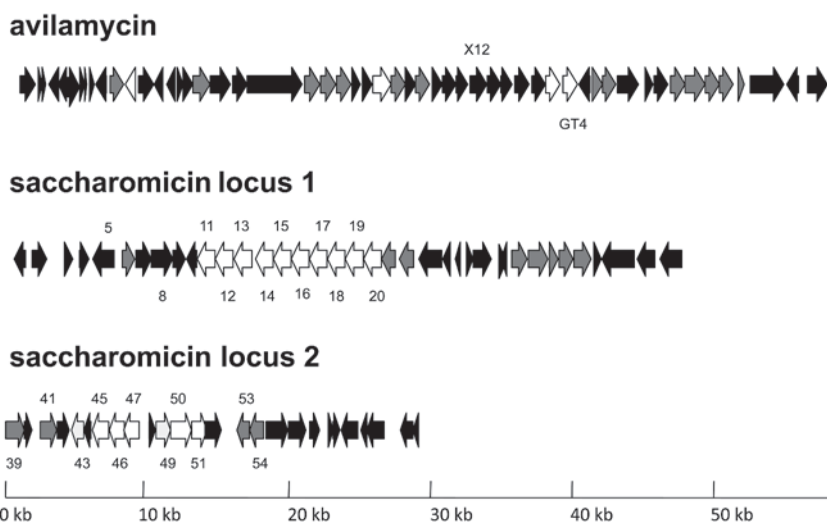

FIGURE 8 Organization of the avilamycin A and saccharomicin gene clusters. Two loci which may be involved in saccharomicin biosynthesis have been identified. GT genes are shown in white, sugar biosynthetic genes are shown in gray, and all other genes are shown in black. The locations of genes for AviX12 (X12) and AviGT4 (GT4), as well as some saccharomicin genes, are shown.

ketoreductases, epimerases, methyltransferases, and other enzymes are used to produce the nucleotide-activated sugar structures that are the substrates for GTs. In many cases, genes encoding these enzymes are located in the biosynthetic gene clusters, but they are usually not clustered into one transcription unit, nor are they necessarily present in an uninterrupted linear array. Here, we give an overview of the gene clusters cloned in our lab and discuss the functions of recently discovered genes and enzymes involved in sugar biosynthesis or attachment.

24.4.1. The Avilamycin Biosynthetic Gene Cluster

The avilamycin biosynthetic gene cluster was cloned in 2001 by using the 4,6-dehydratase gene as a probe (89).

The cluster is located within a 60-kb DNA segment of the chromosome. About 50 genes are involved in the biosynthesis of avilamycin A and its regulation (Fig. 8). The functions of several genes were elucidated by gene inactivation experiments (37, 85, 90) (Fig. 9). By deleting methyltransferase genes, novel desmethylated compounds that showed increased hydrophilicity could be generated (37). Biosynthetic enzymes involved in sugar biosynthesis or modification that have recently been investigated are AviGT4, a GT, and AviX12, a very unusual epimerase. AviGT4 catalyzes the attachment of a thus far undefined precursor of the eurekaate moiety to the L-lyxose moiety as part of a saccharide chain (37). The crystal structure of AviGT4 has recently been resolved (58). It contains two

FIGURE 9 Function of genes/enzymes involved in avilamycin A biosynthesis.

“Rossmann-like” (beta/alpha/beta) domains characteristic of the GT-B fold, one of the two folds found in GTs. It was suggested that AviGT4 is an ancestral enzyme, from which inverting and retaining GTs have evolved.

Inactivation of *aviX12* led to the formation of a novel avilamycin derivative named gavibamycin N1, which harbors glucose as a component of the heptasaccharide chain in place of a mannose moiety in avilamycin A. Antibacterial activity tests with a spectrum of gram-positive organisms showed that the new derivative possesses decreased biological activity compared to avilamycin A. Thus, *AviX12* seems to be involved in converting avilamycin to its bioactive conformation by catalyzing an unusual epimerization reaction. Sequence comparisons classified *AviX12* into the radical *S*-adenosyl-*L*-methionine protein family. It is the first member of this family known to catalyze an epimerization step (10).

24.4.2. The Saccharomicin Biosynthetic Gene Cluster

In order to clone the saccharomicin biosynthetic genes, the 2,3-dehydratase gene probe and the 4,6-dehydratase gene probe were used. Some cosmids hybridized to the 2,3-dehydratase gene probe (cosmid group 1) and some to the 4,6-dehydratase gene probe (cosmid group 2). No cosmid hybridizing to both probes was detected. Cosmids from both groups were sequenced. Analyses of the final contiguous DNA sequences revealed the presence of 38 open reading frames (ORFs) located on cosmids of group 1 and 26 ORFs located on cosmids of group 2 (Fig. 8). Cosmids of group 1 span a 48.7-kbp genome region; cosmids of group 2 comprise another 33.7 kbp. Twelve potential genes encoding the biosynthesis of the five *D*-glucose 1-phosphate-derived deoxyhexose moieties were found. Four of these genes (*sam39*, *sam41*, *sam53*, and *sam54*) were found in cosmids of group 2. Downstream of *sam10* (in the group 1 DNA region) are 10 ORFs named *sam11* to *sam20*, all transcribed in the same direction, which encode proteins similar to GTs that are involved

in secondary metabolism in three different actinomycete strains. Cosmids of group 2 carry another seven putative GT genes (*sam43*, *sam45*, *sam46*, *sam47*, *sam49*, *sam50*, and *sam51*). Additional genes in the cluster are regulatory genes, genes with unknown functions, and *sam5* and *sam8*. *Sam8* is a tyrosine ammonia-lyase, and *Sam5* is a 4-coumarate 3-hydroxylase, as revealed by expression experiments. Both are responsible for the formation of the caffeic acid moiety as part of *N*-(*m,p*-dihydroxycinnamoyl)taurine (4, 5).

24.4.3. The Landomycin A, Landomycin E, Urdamycin A, Saquayamycin Z, and Simocyclinone Biosynthetic Gene Clusters

The gene clusters of all five angucyclines have been cloned and sequenced (gene clusters of landomycin A, landomycin E, urdamycin A, and saquayamycin Z are shown in Fig. 10) (21, 22, 27, 86, 91). The amino acid sequences deduced from the PKSII gene sequences in all five biosynthetic gene clusters are similar to one another, with proportions of identical amino acids between 70 and 90%. Furthermore, most of the deduced amino acid sequences corresponding to cyclase genes, oxygenase genes, ketoreductase genes, GT genes, and sugar biosynthetic genes found in the clusters are very similar. Additional genes responsible for the formation and attachment of a PKSII unit and the halogenated coumarin are located in the simocyclinone gene cluster. During the last 10 years, our research has focused on the functions of GTs (Fig. 4). Genes for C-GTs (UrdGT2, SaqGT5, and SimB7) have been detected in the gene clusters for urdamycin A, saquayamycin Z, and simocyclinone (86). These enzymes share a high number of identical amino acids with the O-glycosyltransferases LanGT2 and LndGT2. The first characterized C-GT was UrdGT2. This enzyme is remarkably flexible. It tolerates *D*- and *L*-rhodnose and *D*-mycarose as donor substrates (35) and is also able to catalyze the O

FIGURE 10 Organization of the landomycin A, landomycin E, urdamycin A, and saquayamycin Z biosynthetic gene clusters. GT genes are shown in white, sugar biosynthetic genes are shown in gray, and all other genes are shown in black.

glycosylation of 1,2-dihydroxyanthraquinone (18). The crystal structure of UrdGT2 was resolved. Like almost all other GTs involved in natural-product biosynthesis, it belongs to the GT-B superfamily of GTs (64). Interestingly, the expression of *urdGT2* in the *saqGT5* mutant restored wild-type production of saquayamycin Z and galtamycin B. The expression of *simB7* led only to the production of monoglycosylated galtamycinone but did not restore wild-type production. The results of this experiment may indicate that SimB7 is not used to work in an enzyme complex and that therefore the biosynthesis is blocked (21). Further aspects of our angucycline GT work are outlined below. The biosynthesis processes for the sugar components, mostly D-olivose and L-rhodinose, are nearly identical in all pathways. NDP-4-keto-2,6-dideoxy-D-glucose is a key intermediate. After 4-ketoreduction, NDP-D-olivose is produced, and after dehydration, 5-epimerization, and 4-ketoreduction, NDP-L-rhodinose is produced. It has been shown that the NDP-sugar concentration and the enzyme expression level influence the substrate specificities of the GTs. When the pathway to D-olivose was blocked by deleting the 4-ketoreductase gene in the urdamycin producer, a novel urdamycin derivative carrying either a C-glycosidically attached D-rhodinose or L-rhodinose instead of a D-olivose was produced (32) (see above).

24.4.4. The Polyketomycin and Aranciamycin Biosynthetic Gene Clusters

The aranciamycin and polyketomycin biosynthetic gene clusters were isolated due to the capacity to hybridize to the PKSII gene probe and to the NDP-glucose-4,6-dehydratase gene probe, respectively. The polyketomycin cluster consists of 41 ORFs, located on 52 kbp of continuous DNA. The aranciamycin cluster is located on one cosmid and contains 24 ORFs in a 35.9-kb region. The arrangement of the minimal PKSII genes of the polyketomycin and aranciamycin gene clusters resembles that of other PKSII-type gene clusters (e.g., actinorhodin and granaticin gene clusters) (15, 54). Only AraGT, the GT involved in aranciamycin biosynthesis, has been investigated in detail. The expression of the aranciamycin gene cluster in a different actinomycete strain resulted in novel aranciamycin derivatives (Fig. 11). Due to the low sugar substrate specificity of AraGT, different sugars were attached to the aranciamycin aglycone (54, 55). Interestingly, the sugar biosynthetic genes are not clustered with the genes responsible for aglycone production.

24.4.5. The Lipomycin Biosynthetic Gene Cluster

The entire lipomycin biosynthetic gene cluster (Fig. 6) was cloned using the PKS1 and deoxysugar 1 gene probes. Twenty-two genes are involved in lipomycin biosynthesis. In the center of this cluster is a polyketide synthase locus (*lipPks1* to *lipPks4*) that encodes an eight-module system comprising four multifunctional proteins. In addition, one ORF (*lipNtps*) encodes a product showing homology to non-ribosomal peptide synthetases, indicating that α -lipomycin belongs to hybrid peptide-polyketide natural products. Furthermore, the lipomycin cluster includes genes responsible for the formation and attachment of D-digitoxose (*lipDig1* to *lipDig5* and *lipGt*), as well as ORFs that resemble genes for putative regulatory and export functions. The function of LipGtf as a GT was proven by gene deletion experiments. It is one of the rare GTs glycosylating a linear polyketide moiety (7).

24.4.6. The Phenalinolactone Biosynthetic Gene Cluster

The phenalinolactone cluster (Fig. 7) was isolated using an NDP-glucose-4,6-dehydratase gene. It is located in a 42-kb region consisting of 35 ORFs and, thus far, is the largest identified cluster responsible for the biosynthesis of isoprenoids. The cluster contains a geranylgeranyl diphosphate synthase gene (*plaT4*) responsible for the generation of the polyprenyl chain, a terpene cyclase gene (*plaT2*), and a prenyltransferase gene (*plaT3*). A gene (*plaT1*) encoding an enzyme that is similar to a eukaryotic squalene epoxidase is also located in the cluster. In contrast to many other terpene cyclization processes in bacteria, the phenalinolactone cyclization process is putatively initiated by an epoxidation reaction of the linear terpene chain, as has been described for myxobacterial steroid formation. Five oxygenase genes (*plaO1* to *plaO5*) were also identified in the cluster. One (*plaO1*) codes for an α -ketoglutarate-dependent dioxygenase catalyzing the formation of the γ -butyrolactone moiety. The phenalinolactone gene cluster represents the complete natural pathway for the rare deoxyhexose amicitose. Eight genes can reliably be predicted to encode the biosynthesis and transfer of this sugar moiety. The multistep conversion of glucose 1-phosphate to NDP-L-amicitose includes NDP-D-glucose synthesis (PlaA4), 4,6-dehydration (PlaA3), 2,3-dehydration (PlaA2), 3-ketoreduction (PlaA5), and 3-deoxygenation (PlaA1) to obtain NDP-D-cinerulose. The final steps are 5-epimerization (PlaA8) and stereospecific 4-ketoreduction (PlaA7) toward NDP-L-amicitose. Finally, the attachment of NDP-L-amicitose to O-21 is probably catalyzed by PlaA6, which resembles many natural-product GTs. The enzyme for the further modification of the sugar ligand through 4-O-methylation is PlaM1 (19).

24.5. GENERATION OF NOVEL GLYCOSYLATED NATURAL PRODUCTS

The growing importance of natural-product sugar moieties has motivated scientists to develop methods for natural-product glycosylation. These methods range from whole-cell feeding experiments to enzymatic approaches, each having its advantages and disadvantages. Here, the different approaches are introduced with a focus on practicability and limitations.

24.5.1. Generation of Novel Compounds Using Living Cells (Biotransformation)

Biotransformation is the process whereby a substance is changed (transformed) from one chemical to another by a chemical reaction performed by a microorganism, plant, or animal. Several examples in which a variety of mostly aromatic compounds were glycosylated have been described in the literature (Table 1). In most cases, one organism was able to provide one sugar as a donor substrate and accepted several aglycones as acceptor substrates.

The biotransformation procedure can be performed as follows.

1. Use a seed culture to inoculate 100 ml of medium (preculture) (28°C).
2. After 3 to 4 days, use 5 ml of the preculture to inoculate 100 ml of medium (main culture).
3. After 3 days, add 5 mg of the desired aglycone (dissolved in 0.2 ml of DMSO) to the main culture.

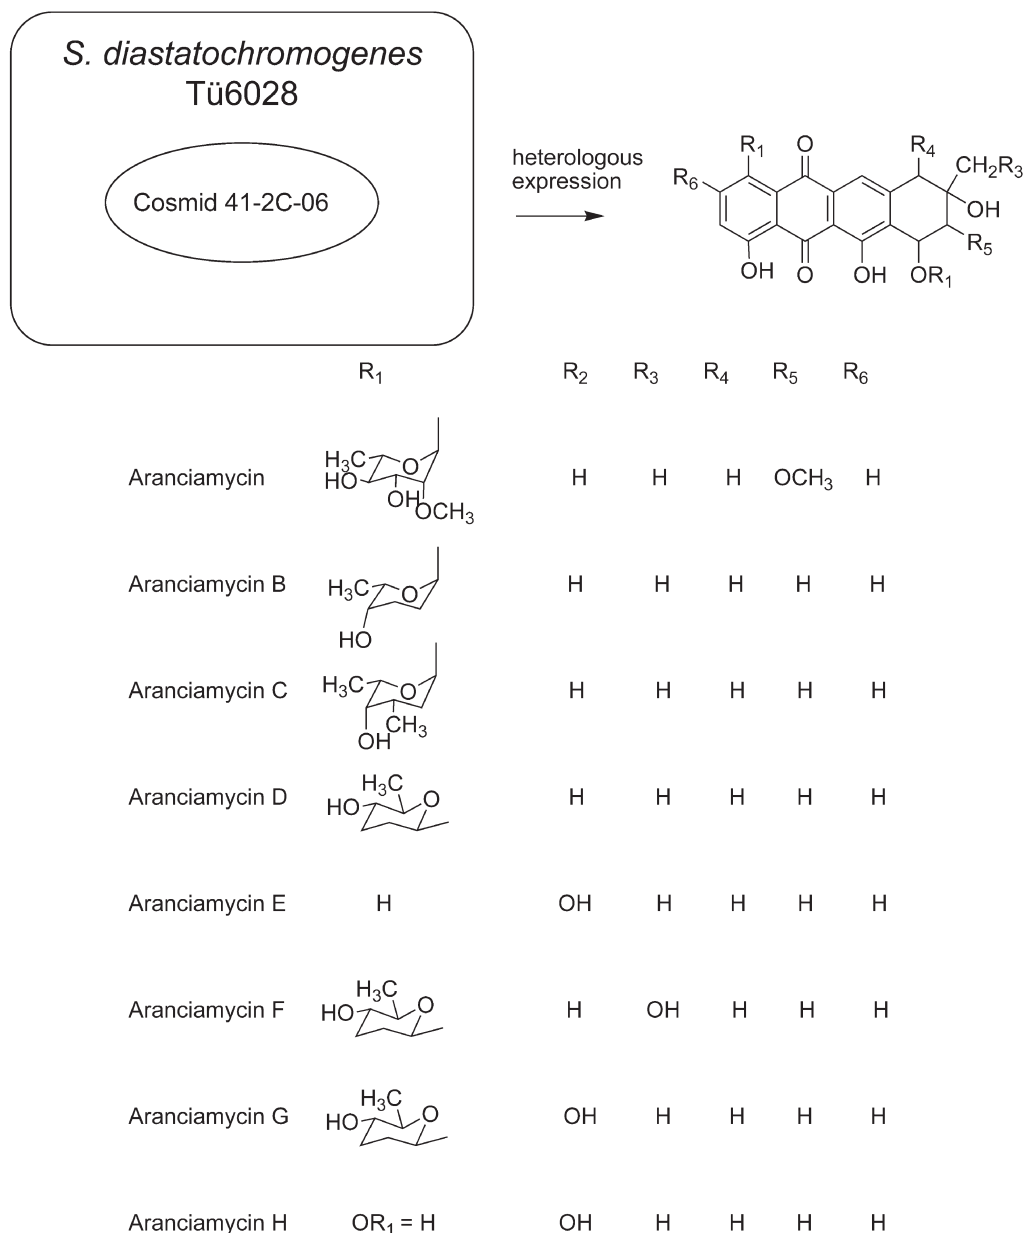

FIGURE 11 Heterologous expression of the aranciamycin gene cluster resulted in novel aranciamycin derivatives.

4. After 7 days, perform ethyl acetate extraction and high-pressure liquid chromatography analysis.

[Control experiments are performed (i) without the strain and (ii) without the aglycone.]

Advantages of this approach are that the yield of glycosylated compounds is often high and biotransformation is easy and quick to perform.

Disadvantages of this approach are that the aglycone substrate flexibility of the GTs seems to be restricted especially to aromatic compounds, and donor substrate variability is restricted to one sugar in most cases.

24.5.2. Generation of Novel Compounds Using GTs and Nucleotide-Activated Sugars (Glycorandomization)

The in vitro approach of glycorandomization is based on two steps. In the first step, natural or chemically derived

sugars are converted by an engineered galactose kinase and a nucleotidyltransferase into nucleotide-activated sugars (NDP-sugars). Then these NDP-sugars are used as substrates by GTs to glycosylate the aglycone. This approach has been used to produce libraries of various natural-product scaffolds, including glycopeptide antibiotics (Table 2) (9, 25).

The glycorandomization procedure can be performed as follows.

1. Provide sugar 1-phosphate “libraries” using chemically synthesized sugars and a genetically modified kinase (e.g., a Y371H GalK mutant).
2. Generate NDP-sugars using sugar 1-phosphates, dTTP, and the α -D-glycopyranosyl phosphate thymidyltransferase from *Salmonella enterica* LT2.
3. Generate glycosylated compounds using a GT, an acceptor molecule, and the dTDP-sugars.

TABLE 1 Glycosylation of compounds by biotransformation

Organism	GT(s)	Attached sugar(s)	Glycosylated compound(s)	Reference(s)
Bacteria				
<i>Bacillus cereus</i>		β -D-Glucose	Flavonoids	43, 76
<i>Streptomyces</i> sp. strain GöM1		6-Desoxy- α -L-talose	Benzoic acid derivates	8
<i>Streptomyces</i> sp. strain LS136		α -L-Rhamnose	Lignane	20
<i>Streptomyces</i> sp. strain Q53834		β -D-Glucose	Brefeldin A	81
<i>Streptomyces aureofaciens</i> B96		β -D-Glucose	Diverse anthraquinones and anthracycline, tetracycline	39, 40, 60
<i>Streptomyces griseoviridis</i> Tü3634		α -L-Rhamnose	Aromatic carbonic acids, emodin	28, 29
Fungi				
<i>Absidia coerulea</i>		β -D-Glucose	Anthraquinones	102
<i>Beauveria bassiana</i> ATCC 7159		β -D-Methylglucose	Anthraquinones, flavonoids	97
<i>Coriolus versicolor</i>		β -D-Xylose, β -D-glucose	Lignin	44
<i>Cunninghamella elegans</i> var. <i>elegans</i>		β -D-Glucose	Xanthohumol	42
Plant				
<i>Arabidopsis thaliana</i>	Various GTs	β -D-Glucose	Benzoic acid, caffeic acid, flavonoids, coumarin	49
	UGT78D1	α -L-Rhamnose	Quercetin	50

An advantage of this approach is that it allows for the preparation of a variety of glycosylated compounds.

Disadvantages of this approach are that the yield of glycosylated compounds is low and scale-up experiments are difficult to perform.

24.5.3. Generation of Novel Compounds Using Two GTs and a Nucleotide Diphosphate (Aglycone Exchange)

One of the newest approaches is the use of glycosylated natural products as the source of activated sugars. A GT

TABLE 2 Glycosylation of compounds

Glycosylation method	Lead compound(s)	Reference(s)
Glycorandomization	Novobiocin	2, 95
	Vancomycin	24
	Cardiac glycosides	48
	Colchicine	1
	Oleandomycin	93
	Flavonoids	93
	Coumarins	93
Aglycone exchange method	Amphotericin B	101
	Avermectin	99
	Calicheamicin	98
	Vancomycin	98
	Vicenistatin	63
	Erythromycin	100
Expression of deoxy-sugar gene cassettes	Tetraenomycin	51, 72, 73, 77
	Staurosporins and rebeccamycins	79

catalyzes the NDP-dependent deglycosylation and coupled formation of an NDP-sugar. The NDP-sugar is then used as a donor substrate by a second GT to glycosylate an aglycone. In 2005, Minami and coworkers reported that VinC, a GT that attaches NDP-vicenisamine to vicenilactam, is also able to catalyze the dTDP-dependent deglycosylation of vicenistatin to yield dTDP-vicenisamine (63). Subsequently, Zhang and coworkers expanded this approach by including a second GT, which is able to use the generated NDP-sugar (98) (Table 2).

The aglycone exchange procedure can be performed as follows.

Perform incubations with a glycosylated natural product, the corresponding GT, dTDP, a nonglycosylated natural product, and a second GT.

Advantages of this approach are that there is no need for the preparation of NDP-sugars and that once GTs are available the experiment is easy to perform; a disadvantage of this approach is that scale-up experiments are difficult to perform.

24.5.4. Generation of Novel Compounds by Genetic Engineering of Producer Strains (Pathway Engineering)

Pathway engineering in vivo is a fourth approach to generate novel glycosylated compounds. As the transfer of sugars is often a late biosynthetic step during the biosynthesis of natural products, genetic engineering of producer strains has become a powerful tool. Different strategies have been employed to create compound libraries with nonnatural glycosylation patterns.

24.5.4.1. Modification of the Aglycone Structure

Novel compounds have been generated by the deletion of genes of the aglycone structure and/or the expression of genes involved in modifying the aglycone structure. Many examples of this approach, especially processes resulting in novel macrolides and anthracyclines, can be found in the

literature (61). This approach proceeds in two steps. First, the genes involved in the biosynthesis of the aglycone are deleted from a strain. Thereafter, either the expression of other gene clusters (54, 55) or the feeding of other aglycones (mutasynthesis) (30, 88) in this strain finally results in novel glycosylated compounds. When a cosmid containing the aranciamycin biosynthetic gene cluster was expressed in *S. fradiae* A0, a novel product named aranciamycin B was generated. This compound contains an L-rhodinose moiety at the C-7-OH position of aranciamycinone instead of the original L-rhamnose (54, 55). Examples in which mutasynthesis resulted in novel glycosylated compounds were reported by Heide et al. (30) and Weist et al. (88).

24.5.4.2. Manipulation of Deoxysugar Biosynthetic Pathways

By either deletion or expression of sugar biosynthetic genes, a strain's capability to synthesize sugars can be altered, which may also lead to novel derivatives. When a gene encoding an NDP-4-keto-2,6-dideoxyglucose-ketoreductase in *S. fradiae* Tü2717 was deleted, the strain produced NDP-rhodinose in both D- and L-forms. Due to the flexibility of the GT UrdGT2, responsible for attaching D-olivose at C-9 of the aglycone in the wild-type strain, the mutant accumulated two novel urdamycin derivatives with either D-rhodinose or L-rhodinose at position C-9 (35) (Fig. 12). Novel tylosin derivatives were produced by expressing genes of the narbomycin pathway in the tylosin producer. Expression resulted in the additional formation of NDP-D-desosamine, which was used as a substrate instead of NDP-D-mycaminose (13). By combining the deletion of a gene (*dnmV*, encoding a ketoreductase) and the expression of a gene (*eryBIV*, encoding a ketoreductase with different stereospecificity from that of *DnmV*), Madduri and coworkers generated a strain producing epirubicin instead of doxorubicin. The two compounds differ in the configuration at C-4 of the sugar moiety (57).

The introduction of whole deoxysugar biosynthetic pathways into one strain, followed by the generation of novel compounds, has been very successfully performed by Méndez et al. (62). By this approach, novel tetracenomyacin and indolocarbazole compounds have been generated (Table 2).

24.5.4.3. Use of GT Genes as Tools

The most important tools for drug design in glycol biosynthesis are GTs. By deleting GT genes, nonglycosylated compounds or compounds with reduced numbers of sugars can be produced (56). The successful expression of a GT gene in a wild-type host has been described a few times. One example describes the expression of *lanGT4* in *S. fradiae* Tü2717, which resulted in the conversion of the trisaccharide side chain of urdamycin A into a tetrasaccharide chain (36). Due to the competition between the wild-type GT (*LanGT2*) and the heterologously expressed GT (*UrdGT2*), *S. cyanogenus* S136 harboring *urdGT2* did not produce novel derivatives or produced them in very small amounts. When *S. cyanogenus* S136 Δ *lanGT2* was used as the host, novel C-glycosylated tetrangulols were produced (Fig. 12) (52). Coexpression of two GT genes (*urdGT2* and *lanGT1*) from two different *Streptomyces* species (*S. fradiae* and *S. cyanogenus*) in a mutant of *Streptomyces argillaceus* in which either one or all GT genes were inactivated resulted in the production of 9-C-olivosylpremithramycinone, 9-C-mycarosylpremithramycinone, and their respective 4-O-demethyl analogues (87) (Fig. 12).

24.5.4.4. GT Engineering

Although the examples described above show that some GTs are sufficiently promiscuous for use in "combinatorial biosyntheses," the strict substrate specificities of others remain a limiting factor. Altering the substrate specificities of GTs and the generation of artificial nonspecific GTs are two important tasks (94). Successful examples have been described previously, but further work needs to be done in this important research field. The first successful results in the engineering of natural-product GTs were obtained with UrdGT1b and UrdGT1c, both involved in urdamycin biosynthesis. The enzymes share 91% identical amino acids, as the corresponding genes most probably derived from gene duplication. Surprisingly, the enzymes show different specificities for both nucleotide sugar donor and acceptor substrates. UrdGT1c accepts strictly dNDP-L-rhodinose and transfers it via an $\alpha(1-3)$ -glycosidic bond to the C-3 hydroxyl of D-olivose, while UrdGT1b transfers D-olivose to the C-4 hydroxyl group of L-rhodinose, forming a $\beta(1-4)$ -glycosidic bond. A region of 31 amino acids within UrdGT1b and UrdGT1c was identified to control the substrate specificities of both enzymes. By mutating this region, the selectivity for the donor and the acceptor substrates was changed (33, 34). The group of G. J. Williams worked with the macrolide GT OleD, a GT involved in oleandomycin biosynthesis. Sequence variants of OleD showed improved efficiency and accepted additional nucleotide sugar donors compared to OleD (93).

Both the UrdGT1 and OleD studies revealed N-terminal domain residues that control sugar binding. This finding was not expected, as in GTs of the GT-B family, almost all sugar binding residues are in the C-terminal domain (68, 75).

Recently, the swapping of the N- and C-terminal domains of GTs was described. Park et al. fused the N-terminal domain of KanF, involved in kanamycin biosynthesis, and the C-terminal domain of GtfE, involved in vancomycin biosynthesis, producing novel kanamycin derivatives (70).

Another aspect of GT flexibility was recently addressed. Oligosaccharide antibiotics like landomycin A, saquayamycin Z, and saccharomicin are made of disaccharide or trisaccharide units which can be found twice in one molecule. As the numbers of GT genes detected in the biosynthetic gene clusters for these compounds are lower than the numbers of sugar moieties, some GTs are acting iteratively during the biosynthesis of the side chains. This has been shown for LanGT1 (attaching the second and fifth sugars) and LanGT4 (attaching the third and sixth sugars), involved in landomycin A biosynthesis. While landomycin A is produced by *S. cyanogenus* S136, landomycin E is produced by *S. globisporus*. In *S. globisporus*, LndGT1 catalyzes the attachment of the second sugar during landomycin E biosynthesis. This enzyme does not work iteratively; thus, it was not able to attach a fifth sugar when expressed in a *lanGT1* mutant of *S. cyanogenus* S136. By generating several hybrids from LanGT1 and LndGT1 and by introducing mutations into both enzymes, amino acids that specifically contribute to iterative action were identified. All mutations have been made in the N-terminal domain (46).

An advantage of this approach is that once a genetic system for a strain is established, production of a desired product is simple. Disadvantages are that the genetic engineering of strains still requires much time, and the productivity of genetically engineered strains is usually lower than the productivity of the corresponding wild type.

FIGURE 12 Generation of natural products: (1) by UrdGT2 in the wild-type strain; (2 and 3) by combinatorial biosynthesis (*urdGT2* was expressed in *S. cyanogenus* S136 Δ *lanGT2*, a mutant lacking the GT *LanGT2* [2], and in *S. argillaceus* Δ *mtmGIV*, a mutant lacking the GT *MtmGIV* [3]); (4) by mutasynthesis (1,2-dihydroxyanthraquinone was fed to *S. fradiae* XKS containing a deletion in the polyketide synthase genes); and (5 and 6) by manipulating the deoxysugar biosynthetic pathway (compounds were produced by *S. fradiae* Δ *urdR*, a mutant lacking the dTDP-4-keto-2,6-dideoxy-D-glucose 4-ketoreductase UrdR).

24.6. CONCLUSION

In the light of applied pharmaceutical sciences, whole-pathway engineering and single-enzyme engineering have supported the development of novel glycosylated natural products. Different technologies are available for glycosylation. Improving these technologies toward higher product yields will be the most important issue for scientists in the next decade.

Metabolic Engineering of *Escherichia coli* for the Production of a Precursor to Artemisinin, an Antimalarial Drug

CHRISTOPHER J. PETZOLD AND JAY D. KEASLING

25

25.1. INTRODUCTION

25.1.1. Need

Malaria is a severe human disease caused by protozoan parasites of the genus *Plasmodium* that claims over two million lives annually and threatens hundreds of millions more. Recently, economical malarial treatments currently in use, such as quinine and chloroquine, have become less effective as multidrug-resistant malarial strains have begun to spread. This trend poses little risk to residents of more prosperous nations, who can afford the top-of-the-line therapies, yet the spread of multidrug-resistant malarial strains significantly increases mortality among malarial patients living in developing countries (64). To combat resistance, more advanced drug combination regimens, such as artemisinin-based combination therapies (ACTs), have been developed. ACTs are highly effective, yet the demand for over 100 million ACT drug courses per year (32) greatly exceeds the supply (26). The major component in ACTs is artemisinin, a terpenoid produced naturally by *Artemisia annua*, a plant that has been used in Chinese medicine for over 2,000 years to treat many illnesses, including malaria (7). The main active ingredient in *A. annua*, artemisinin, was not identified until 1971 (45). Since then, the utility of artemisinin to combat many diseases has sparked interest in identifying its chemical structure (34) and determining the biological reactivities of artemisinin and its derivatives (45, 46). Efforts in the 1980s to develop a more stable source resulted in several reports describing the total synthesis of artemisinin (78, 91). Unfortunately, chemical synthesis of artemisinin is complex and inefficient due to side product formation and multiple purification steps. Furthermore, expensive reactants and catalysts are needed in large quantities and are not environmentally friendly. Despite the high demand for artemisinin, total global production is low and highly variable, as demonstrated in 2004, when a seed shortage caused severe artemisinin shortfalls across the world (58). Overall, these issues contribute to the high costs of ACTs, which limit their utility to residents of developing countries. For the people most in need of the drugs, those living in developing countries in temperate areas of the world, ACTs remain prohibitively costly, prompting a need for the application of modern industrial biotechnology methods to reduce costs and stabilize supplies.

25.1.2. Biosynthetic Production of a Precursor to Artemisinin

Biotechnology offers multiple means for improving artemisinin production. Engineering of the native host to overproduce precursors to artemisinin is promising, but genetic tools for *A. annua* manipulation are not well developed, and currently the results have been limited (1, 18, 54, 87, 95). Synthetic biology and metabolic engineering of microbes offer an attractive alternative to natural sources as a means for inexpensive pharmaceutical production. A metabolically engineered microbe is an inherently scalable and robust platform for production that is advantageous compared to natural product extraction and chemical synthesis (41). For example, unlike extraction from plants, production by metabolically engineered microbes is not dependent on weather conditions or the political climate, thus providing a stable supply. Biosynthetic artemisinin can be produced without competing synthesis pathways, or pathways for other isoprenoids common to plants, reducing recovery expenses. Metabolic engineering approaches often utilize native enzymatic biosynthesis pathways to produce the target molecule, offering selectivity for the required stereochemistry and efficient conversion of intermediates to the final product (48). The isoprenoid precursors used in artemisinin biosynthesis are common to both prokaryotes and eukaryotes; consequently, model microbes, such as *Escherichia coli* and *Saccharomyces cerevisiae*, can be used to convert simple, cheap sugar to artemisinin precursors. The challenge associated with this process lies in engineering high carbon flux from sugar to the artemisinin precursors to reduce production costs. Using *E. coli* for artemisinin production is particularly advantageous due to the bacterium's limited isoprenoid metabolism, which minimizes losses to native processes and the production of structurally similar products. However, identification of the enzymes dedicated to artemisinin production and incorporation into and optimization in *E. coli* are necessary.

In the engineering of microbes to produce secondary metabolites, very different challenges from those associated with high-level production of pharmaceutical proteins arise. To optimize system characteristics for metabolite production, the expression of biosynthetic enzymes must be balanced with sufficient metabolite flux and microbial growth (39). Overexpression of biosynthetic enzymes reduces the

available carbon for metabolite conversion, whereas too little expression of biosynthetic enzymes reduces the rate of production and final titers. Beyond the need to balance enzyme expression, artemisinin production in *E. coli* is complicated by uncertainty in the native biosynthesis pathway. Indeed, the final steps in artemisinin biosynthesis may be nonenzymatic (18). Given that the conversion of artemisinic acid to artemisinin and its derivatives has been established (32, 74), metabolic engineering of *E. coli* focuses on two fronts, increasing the titer of the isoprenoid precursors via the incorporation of the mevalonate pathway into *E. coli*, and the subsequent conversion of mevalonate to artemisinic acid, a precursor of artemisinin.

25.2. INCORPORATION OF AMORPHA-4,11-DIENE BIOSYNTHETIC PATHWAY INTO *E. COLI*

One universal microbe is not likely to be appropriate for all metabolic engineering projects. Consequently, careful selection of the host is necessary. Well-characterized hosts such as *E. coli* and *S. cerevisiae* are often the first choices due to their amenable culturing conditions and high growth rates, the wide variety of genetic tools available for these organisms, and their significant history as biosynthetic platforms.

25.2.1. Isoprenoid Biosynthesis in *E. coli*

Prenyl pyrophosphate biosynthesis of isopentenyl diphosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP) occurs by two known pathways (Fig. 1), the mevalonate pathway in eukaryotes and the deoxyxylulose-5-phosphate (DXP) pathway typically found in prokaryotes (25, 35), although exceptions exist in both cases. There are a variety of detailed reviews of isoprenoid biosynthesis focusing on the mevalonate and DXP pathways (2, 20, 43, 47, 51, 89). In *E. coli*, the native DXP pathway produces isoprenoids for prenylation of tRNAs (17) and conversion into polyisoprenoids such as ubiquinones and menaquinones. However, the flux to these metabolites is significantly lower than what is needed to make biosynthetic artemisinin cost-effective; consequently, modification and improvement of the IPP/DMAPP biosynthesis pathway is necessary. One way increased flux can be achieved is by overexpression of the rate-limiting enzymes in the native (DXP) pathway. An advantage to this method is that utilization of native *E. coli* proteins alleviates the complications of expressing heterologous genes. Indeed, increased isoprenoid production was achieved by overproducing DXP (1-deoxy-D-xylulose-5-phosphate) synthase (encoded by the gene *dxs*) and the DXP reductoisomerase (encoded by the gene *ispC* [*dxr*]) in the DXP pathway and other native proteins (31, 39, 40, 42, 92). Similarly, β -carotene production in *E. coli* was enhanced by integration of additional copies of *dxs*, *ispC* (*dxr*), *idi*, and *ispA* into the chromosome (94). Efforts to optimize the DXP pathway by systematic and combinatorial gene knockouts (4) and promoter engineering (3) also yielded higher isoprenoid titers. Despite significant improvement in flux through the DXP pathway, the highest levels achieved were not feasible for inexpensive artemisinin production.

25.2.2. Addition of an Exogenous Mevalonate Pathway

The limitations associated with the DXP pathway led to the work of Martin et al. (56), whereby the incorporation of the eukaryotic mevalonate pathway into *E. coli* was used to divert more carbon to isoprenoid production. This strategy

has a couple of notable advantages. First, since the mevalonate pathway is exogenous in *E. coli*, regulation machinery that can limit production is absent. Furthermore, the intermediates in the exogenous pathway are less likely to be diverted to other cellular functions, enabling a net higher flux to be directed to artemisinin precursors. Incorporation of an exogenous pathway into *E. coli* has its challenges as well. Diversion of carbon from native processes can have wide-ranging effects on *E. coli* metabolism. Proper expression and folding of nonnative proteins are not certain because the metabolic burden of producing inactive proteins precludes optimal metabolite flux. Thus, careful monitoring of the production levels and enzymatic activity is required. Buildup of toxic intermediates is often immediately obvious, resulting in growth inhibition; however, more subtle impacts on native metabolism may occur as well.

The mevalonate pathway (Fig. 2) was added to *E. coli* on two plasmids. The genes on the first plasmid, pMevT, include *atoB*, encoding an enzyme used to convert acetyl coenzyme A (acetyl-CoA) to mevalonate by means of the native acetyl-CoA thiolase, and two genes from *S. cerevisiae*, encoding 3-hydroxy-3-methylglutaryl (HMG)-CoA synthase (HMGS) and a truncated form of HMG-CoA reductase (HMGR). The second plasmid, pMBIS, consists of *S. cerevisiae* genes encoding enzymes that sequentially convert mevalonate to phosphomevalonate (mevalonate kinase [ERG12]), to diphosphomevalonate (phosphomevalonate kinase [ERG8]), and via decarboxylation, to IPP (mevalonate diphosphate decarboxylase [MVD1]). As will be described below, increasing the expression of two native *E. coli* genes, those for IPP isomerase (*idi*) and the farnesyl diphosphate (FPP) synthase (*ispA*), was also necessary to produce high levels of FPP. To establish that the exogenous mevalonate pathway was active, a strain in which the DXP pathway was inactivated was transformed with the pMBIS plasmid. Strain DYM1 (50) was selected because the gene encoding the second enzyme in the endogenous DXP pathway, *ispC* (*dxr*), was deleted, resulting in a growth defect without an alternate means of isoprenoid production. Because IPP and DMAPP are essential for growth, only a functioning mevalonate pathway in the DYM1 strain with exogenous mevalonate supplementation in the medium will result in active cultures. Both the DYM1 and DYM1 (pMBIS) strains grew on plates supplemented with 2-C-methyl-erythritol, the metabolic product of *ispC*; however, only the DYM1 (pMBIS) strain grew on plates supplemented with 1 mM mevalonate. For liquid-phase cultures, when supplemental mevalonate levels exceeded 10 mM, the growth defect returned (Fig. 3), indicating a toxic effect of the mevalonate or one of the downstream intermediates. This observation will be addressed in greater detail in section 25.3.2.

The addition of the entire mevalonate pathway (pMevT and pMBIS) directed a significant amount of metabolic flux to FPP. Because native *E. coli* metabolism utilizes FPP in the biosynthesis of ubiquinone and menaquinone, which are needed in small quantities only, it was necessary to convert the excess FPP to a metabolite that is not naturally consumed by the host. The first committed step toward artemisinin is the conversion of FPP to amorpha-4,11-diene via amorpha-4,11-diene synthase (13). Terpene synthases can be difficult to express in *E. coli* (55); consequently, the amorpha-4,11-diene synthase gene (*ADS*) (59) was codon optimized to aid expression and introduced into *E. coli* on a third plasmid (pADS). With all three plasmids (pMevT, pMBIS, and pADS) incorporated into *E. coli*, complete conversion of glucose to amorpha-4,11-diene was achieved.

FIGURE 2 Production of amorpha-4,11-diene via the DXP or mevalonate isoprenoid pathway and depiction of the synthetic operons used by Martin et al. (56). The amorpha-4,11-diene pathway was separated into three plasmids, with one plasmid carrying the steps from acetyl-CoA to mevalonate, the second plasmid expressing the steps from mevalonate to FPP, and the third plasmid encoding amorpha-4,11-diene synthase (ADS). Several intermediate plasmids converting mevalonate to mevalonate-5-diphosphate (pMKPMK), to IPP (pMevB), and to DMAPP (pMBI) were constructed for comparison to pMBS. *tHMGR*, truncated form of *HMGR* gene; A-CoA, acetyl-CoA; AA-CoA, acetoacetyl-CoA; MK, mevalonate kinase gene; PMK, phosphomevalonate kinase gene; MPD, mevalonate pyrophosphate decarboxylase gene; Mev-P, mevalonate phosphate; Mev-PP, mevalonate diphosphate; OPP, pyrophosphate; IPPHp, IPP, isopentenyl pyrophosphate; G3P, glyceraldehyde-3-phosphate; MEP, 2-C-methyl-D-erythritol 4-phosphate; CDP-ME, 4-diphosphocytidyl-2-C-methyl-D-erythritol; CDP-ME2P, 4-diphosphocytidyl-2-C-methyl-D-erythritol 2-phosphate; ME-2,4cPP, 2-C-methyl-D-erythritol 2,4-cyclodiphosphate; HMB4PP, 1-hydroxy-2-methyl-2-(*E*)-butenyl 4-diphosphate.

25.3. AMORPHA-4,11-DIENE PATHWAY OPTIMIZATION

25.3.1. Metabolite Analysis

Metabolic engineering for artemisinin precursor production required accurate, rapid, and sensitive metabolite analysis. Optimal metabolite analysis depends on the detection of all engineered pathway intermediates, the carbon source, and the common *E. coli* metabolites. However, not all intermediates are amenable to analysis, and highly abundant native metabolites preclude facile detection of low-concentration intermediates. To overcome these difficulties, a variety of extraction, separation, and detec-

tion techniques were used to identify and quantify native metabolites and pathway intermediates. Chromatography, both gas and liquid, and capillary electrophoresis were the main techniques used to separate the metabolites of interest from the rest of the metabolites present. In general, these methods were coupled to mass spectrometry (MS) for identification.

At the beginning of the work, the amount of mevalonate and/or amorpha-4,11-diene produced was used to measure progress toward the goal of economical artemisinin production. These two intermediates are easily extracted from the medium and analyzed via gas chromatography (GC)-MS. GC-MS analysis is a rapid and robust method

by which confident analyte identification is possible via comparison to the National Institute of Standards and Technology database. Additionally, the location of these intermediates in the biosynthesis pathway made monitoring of these molecules useful metrics; however, analytical measurements are only as good as the experimental technologies employed. Initial experiments (56) measuring pathway performance suggested that amorpho-4,11-diene was lost from the cultures due to its volatility, resulting in underestimation of production levels. To address this issue, a two-phase partitioning bioreactor was developed to trap the amorpho-4,11-diene produced (62). The organic partitioning layer effectively trapped amorpho-4,11-diene that had been lost to evaporation under normal conditions and also simplified extraction for GC-MS analysis. Additionally, any toxic effects associated with

amorpho-4,11-diene were minimized by sequestering it from the growing cells. Remarkably, cultures grown with a partitioning layer produced 0.4 g/liter, notably more amorpho-4,11-diene (8.5-fold) than the amount reported for the same culture grown without such a layer (62). Use of the two-phase partitioning bioreactor proved to be a robust method for characterizing amorpho-4,11-diene-producing strains.

25.3.2. Optimization of Metabolic Flux from Acetyl-CoA to Mevalonate

Improving carbon flux to amorpho-4,11-diene requires optimization of the pathway as a whole, but since the mevalonate pathway was separated into two plasmids (pMevT and pMBIS) (Table 1), optimization efforts were divided into mevalonate and amorpho-4,11-diene improvements. Though there were no bottlenecks at the mevalonate and amorpho-4,11-diene stages, the possibility that bottlenecks were present in association with other metabolites or enzymes could not be excluded. Detailed examination showed metabolite imbalances at both the top part of the pathway (acetyl-CoA to mevalonate) and the bottom part (mevalonate to FPP), resulting in significant growth defects (56, 69). Ultimately, optimal production of amorpho-4,11-diene requires careful control of metabolic flux upstream from the desired product. Because supplementation with exogenous mevalonate resulted in higher amorpho-4,11-diene titers than the utilization of the MevT plasmid (the upper mevalonate pathway) alone to produce mevalonate, efforts to improve carbon flux to mevalonate were initiated. The MevT enzymes were expressed from two separate plasmids (pBAD33MevT and pBAD24MevT) with the arabinose-inducible promoter (Table 1), which was stronger than the original *lac* promoter (69). However, as demonstrated in Fig. 4, a growth defect was noted for both strains. This toxicity may be due to increased protein production from the cells with pBAD-33MevT, pathway intermediate-induced stress, or a combination of both. Importantly, identification of the true nature of the toxicity required differentiation between the metabolic burden of protein production and the potential toxicity of intermediary metabolites. To this end, the HMGS was inactivated by mutation of the cysteine-159 residue to alanine (72). Induction of the inactive MevT pathway [carried on pMevT(C159A)] yielded a host that would experience the metabolic burden of protein expression without the related metabolic flux. Cells expressing the plasmid containing an inactivated HMGS gene grew only slightly slower than empty-plasmid controls, whereas cells expressing the active pathway showed severe growth inhibition. Thus, production of a potentially toxic metabolite appeared to be the cause of the stress. Individual expression of each protein from the MevT plasmid showed a growth defect for the HMGS-expressing strain. This result supported the hypothesis that HMG-CoA was the source of the growth defect since acetyl-CoA and acetoacetyl-CoA are native *E. coli* metabolites and high levels of mevalonate supplementation in the growth medium did not cause growth defects.

To verify this conclusion, high-performance liquid chromatography methods were developed to identify the intermediates produced by the MevT enzymes and several similar native metabolites. Direct analysis of acetyl-CoA, acetoacetyl-CoA, HMG-CoA, malonyl-CoA, and free CoA permitted direct determination of which intermediates were accumulating and whether levels of native metabolites

such as malonyl-CoA and free CoA were perturbed. To rapidly quench metabolism, the cells and growth medium were centrifuged through silicone oil into a trichloroacetic acid solution by the method described by Shimazu et al. (80). Analysis of the energy charge was used to verify that metabolism was quenched rapidly. These results showed that HMG-CoA accumulated in the strain harboring pBAD33MevT and in the strain expressing HMGS alone. Free-CoA levels were reduced when HMGS was expressed alone, while malonyl-CoA accumulated in both strains. Acyl-CoA analyses prompted efforts directed at achieving balanced enzymatic activity. Strains containing the pBAD-33MevT plasmid and an additional plasmid harboring an extra copy of either *atoB* or the HMGS or HMGR gene were cultured, and the changes in growth and acyl-CoA levels were monitored. The strain harboring pBAD33MevT and the plasmid with an additional copy of the HMGR gene showed restored growth and lower HMG-CoA levels. Characterization of the inhibitory effects of HMG-CoA will be discussed in section 25.4.1. Alternate methods for balancing the enzymatic activity, including varying plasmid

attributes, performing mutagenesis, and tuning intergenic regions to refine the conversion of acetyl-CoA to mevalonate, are discussed below.

25.3.3. Development of a Mevalonate Biosensor for High-Throughput Screening

Mutagenic and combinatorial methods are powerful tools for optimizing metabolically engineered systems. However, their utility is limited by the quality of screens available for the library of interest (49, 71, 86). Chromatographic methods for metabolite analysis, while sensitive and selective, are not readily compatible with high-throughput screening of thousands or tens of thousands of samples. To aid optimization of the top part of the mevalonate pathway (pMevT), an *E. coli* mevalonate auxotroph was engineered for use as a biosensor (67). The sensor reports the mevalonate concentration in the medium via a change in growth rate. The auxotroph was engineered to constitutively produce green fluorescent protein (from pKLN59) (Table 1) so that the change in growth rate could be conveniently monitored by fluorescence. The reporter strain was constructed by deletion of the native *E. coli* *ispC* (*dxr*)

FIGURE 4 Growth of *E. coli* with increasing expression of the MevT operon. *E. coli* DP10 cells harbored the following plasmids (in order of increasing expression of the MevT genes): pMevT (black circles), pBAD33MevT (gray squares), and pBAD24MevT (black triangles). Cells expressing pLac33 (open circles), pBAD33 (open squares), and pBAD24 (multiplication signs) were the respective empty-plasmid controls. Reprinted from *Metabolic Engineering* (69) with permission of the publisher.

gene, the second gene in the DXP isoprenoid biosynthesis pathway. Because both IPP and DMAPP are required for *E. coli* growth, isoprenoid biosynthesis was restored by insertion of the genes from the MBIS plasmid into the *E. coli* chromosome via the recombination method established by Martinez-Morales et al. (57) (yielding strain DP5) (Table 1). Following induction of MBIS with isopropyl- β -D-thiogalactopyranoside (IPTG), growth in the presence of mevalonate was restored. High-throughput screening of mevalonate production by mutant libraries in 96-well plates with the mevalonate auxotroph as a biosensor was implemented (Fig. 5).

This method was applied to measure mevalonate levels associated with a library of posttranscriptional control elements for the modulation of protein levels produced from MevT plasmids. Posttranscriptional engineering offers a second layer of control, beyond transcriptional control, to balance pathway flux (76). To this end, Pfleger et al. integrated a library of tunable intergenic regions between the coding regions of the MevT transcripts to modulate translation initiation, RNA stability, and translation termination (68). Then they used the mevalonate biosensor to screen a library of MevT plasmids containing over 600 tunable intergenic regions for production of increased mevalonate titers. The mevalonate producers were grown for 24 h at 37°C, at which point the cells were pelleted by centrifugation. Subsequently, the supernatant was added to a second 96-well plate containing new media and the mevalonate auxotroph. Following incubation, the wells containing the most mevalonate showed the strongest fluorescent signals.

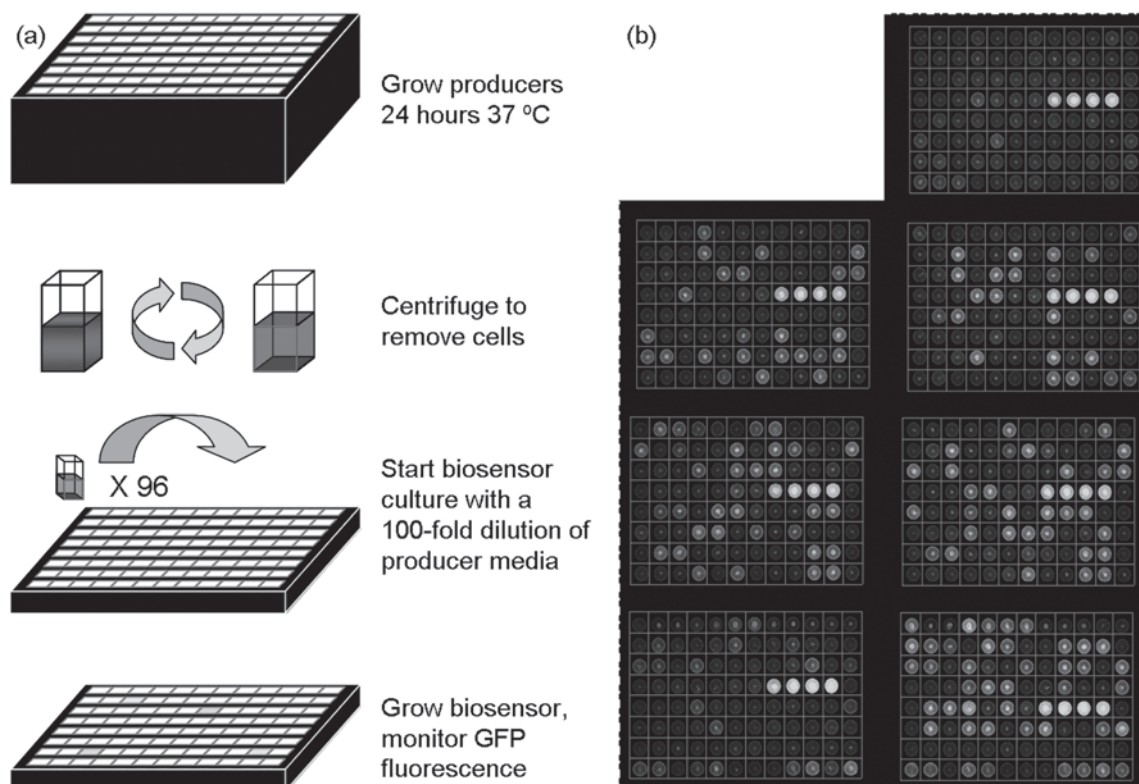

FIGURE 5 Mevalonate biosensor screening strategy. (a) Screening methodology. Mevalonate producers were grown in a 96-well format in C medium with inducers for 24 h. Producer cells were removed by centrifugation, and the spent medium was passed to new cultures inoculated with the biosensor. Wells containing the most mevalonate were the most fluorescent (they showed the greatest intensity of white on the plates). GFP, green fluorescent protein. (b) Mevalonate library. Seven 96-well plates are shown 15 h post-biosensor inoculation. The four white wells on each plate are mevalonate controls. Reprinted from *Metabolic Engineering* (67) with permission of the publisher.

By using this technique, Pflieger et al. isolated four strains that produce seven times more mevalonate than the strain containing the original *MevT* plasmid (68). The four isolated strains displayed improved growth (improved total production) and flux through the pathway (improved specific production). Notably, acyl-CoA analysis revealed increased acetyl-CoA levels relative to that from the original *MevT*-containing strain.

25.3.4. Optimization of Metabolic Flux from Mevalonate to Amorpha-4,11-Diene

Attempts to increase flux from mevalonate to FPP revealed growth inhibition when a plasmid (*pMevB*) containing only the first three genes (*ERG12*, *ERG8*, and *MVD1*) was expressed, as depicted in Fig. 3 (56). This inhibition increased with the concentration of exogenous mevalonate, indicating that the toxicity resulted from metabolite flux and not protein overproduction. Partial growth was restored when the IPP isomerase (*idi*) and FPP synthase (*ispA*) genes were coexpressed with the first three genes. These results suggest that IPP is a toxic intermediate; however, metabolite analysis using [³H]IPP and [³H]DMAPP indicated that FPP accumulation is also toxic. The growth defect persisted for a strain containing both the top (*pMevT*) and bottom (*pMBIS*) parts of the mevalonate pathway, confirming that the top part of the pathway produced over 5 mM mevalonate. Complete rescue from the growth defect occurred when the amorpha-4,11-diene synthase gene was expressed on a separate plasmid to consume FPP (Fig. 6). Both of these growth defects were observed as a result of native-metabolite imbalances. Hence, pulling on the pathway via the

amorpha-4,11-diene synthase is just as important as pushing flux through the pathway. Continuing work focuses on analyzing each intermediate in the lower part of the pathway.

25.3.5. Genetic Optimization of the Mevalonate Pathway from Acetyl-CoA to Amorpha-4,11-Diene

As shown by the metabolite analysis work described above, the amount of amorpha-4,11-diene produced by the original three-plasmid (*pMevT*-*pMBIS*-*pADS*) system, while significant, was not optimal. Steps to increase flux to amorpha-4,11-diene involved overexpression of pathway enzymes but did not address the metabolic burden of plasmid maintenance (27, 39), the maintenance of multiple antibiotic resistance genes, and total pathway protein overproduction. Tight control of enzyme concentration is especially important for efficient amorpha-4,11-diene production. Optimal pathway gene expression is dependent on a wide variety of factors (8, 37) including, but not limited to, gene product toxicity, solubility, codon usage, mRNA secondary structure (21, 22), mRNA stability, and translational efficiency. Additionally, plasmid-specific characteristics such as the type of origin of replication used, the ribosomal binding site strength (10), plasmid design, and promoter strength (3, 30, 38) generally can have a profound effect on the amount of protein produced in the cell at any given time.

Thus, in addition to the metabolite studies described above, effort was directed toward reducing the number of plasmids and balancing production of the pathway proteins from the new plasmids. The original plasmids were modified by the incorporation of all the genes required for the conversion of acetyl-CoA to amorpha-4,11-diene via the mevalonate pathway into one- and two-plasmid systems. To aid rapid development, the new plasmids were designed for facile substitution of promoters and operon constructs (5). The initial step in increasing amorpha-4,11-diene production was codon optimization of the *MevT* plasmid, followed by replacement of the wild-type *lac* promoter with the *lacUV5* promoter. The strain harboring the optimized *MevT* operon yielded 1.5 times more amorpha-4,11-diene than the original strain (5). This finding led Anthony et al. (5) to design a larger plasmid (*pAM45*) consisting of all the genes of the (codon-optimized) *pMevT* and *pMBIS* plasmids under the control of the stronger *lacUV5* promoter. The strain carrying *pAM45*, which harbored *pADS* (Table 1) as well, produced threefold more amorpha-4,11-diene than the original three-plasmid strain (5). Integration of *ADS* into the *pAM45* plasmid created *pAM92*. By using these variants, two limitations in the pathway were identified. Gene titration experiments involving the genes from the lower part of the pathway (the *pMBIS* genes) revealed that expressing additional copies of the mevalonate kinase gene improved amorpha-4,11-diene titers by 2.3-fold (5). None of the other genes significantly impacted the amorpha-4,11-diene titers when provided on another plasmid, indicating that they do not represent bottlenecks in the pathway. The second limitation was identified when *pAM92* was created. Although cells harboring *pAM92* produced more amorpha-4,11-diene than cells harboring the original three-plasmid system, they produced less than cells harboring both *pAM45* and *pADS* and exhibited decreased viability. When *ADS* was incorporated into *pAM45*, with the same promoter retained, the most likely cause of lower titers was the decrease in plasmid copy number (*pADS* was maintained at 20 to 30 copies/cell, while *pAM45* was present at 10 to 15 copies/cell). Amorpha-4,11-diene production was increased when the strain containing *pAM92* was transformed with the original *pADS* plasmid, confirming that the bottleneck occurred due to amorpha-4,11-diene synthase limitation. Ultimately, the highest amorpha-4,11-diene level (~0.3 g/liter/optical density unit at 600 nm in shake

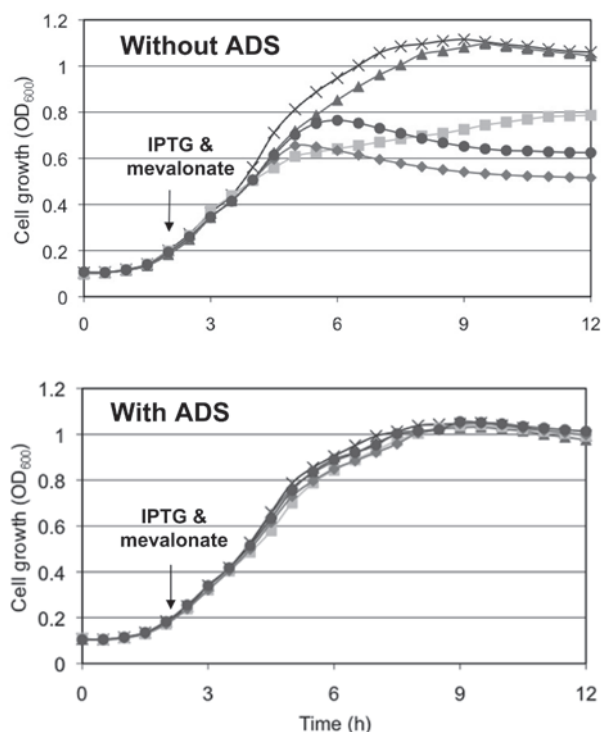

FIGURE 6 Effect of amorpha-4,11-diene synthase (*ADS*) expression on the growth of *E. coli* harboring *pMBIS*. Cells carried *pMBIS* and the empty expression vector *pTrc99A* (without the *ADS* gene) (top) or *pADS* expressing the amorpha-4,11-diene synthase (bottom). flask cultures) was produced by a strain containing pAM45 and pAM94, created via the incorporation of an additional copy of the mevalonate kinase gene into pADS.

25.4. "-OMICS" ANALYSES FOR INCREASED AMORPHA-4,11-DIENE PRODUCTION

The work described above focused on balancing amorpho-4,11-diene-producing pathways and optimizing their flux to meet stringent economic restrictions. As discussed above, biological factors such as gene selection, plasmid design, enzyme expression levels, and isoprenoid intermediate toxicity need to be considered when production of the highest titers of amorpho-4,11-diene and artemisinic acid is desired. Additionally, native host metabolism, especially for enzymes with a particular intermediate as a precursor metabolite, may have an impact on carbon flux through the engineered pathway (81, 83). However, effects that limit final production levels are not al-

ways obvious; perturbation of native regulation and disruption of complex interactions may manifest themselves in unique ways. Despite a vast amount of knowledge about *E. coli* metabolism, such interactions can be highly complex and difficult to elucidate via testable hypotheses. A complete systems-level understanding of the engineered host provides insight into the nonobvious perturbations to the system under amorpho-4,11-diene- and artemisinic acid-producing conditions.

Cell-wide studies of RNA (transcriptomics), proteins (proteomics), and metabolites (metabolomics) reveal the state of the cell under defined conditions, and comparison to the state of the cell under a second set of conditions points to subtle changes often overlooked by hypothesis-driven experiments. By combining the data from transcriptomics, proteomics, and metabolomics experiments, one can develop a greater understanding of the impact of metabolic engineering on the host metabolism and design ways to increase end product titers (Fig. 7). Ultimately, engineering

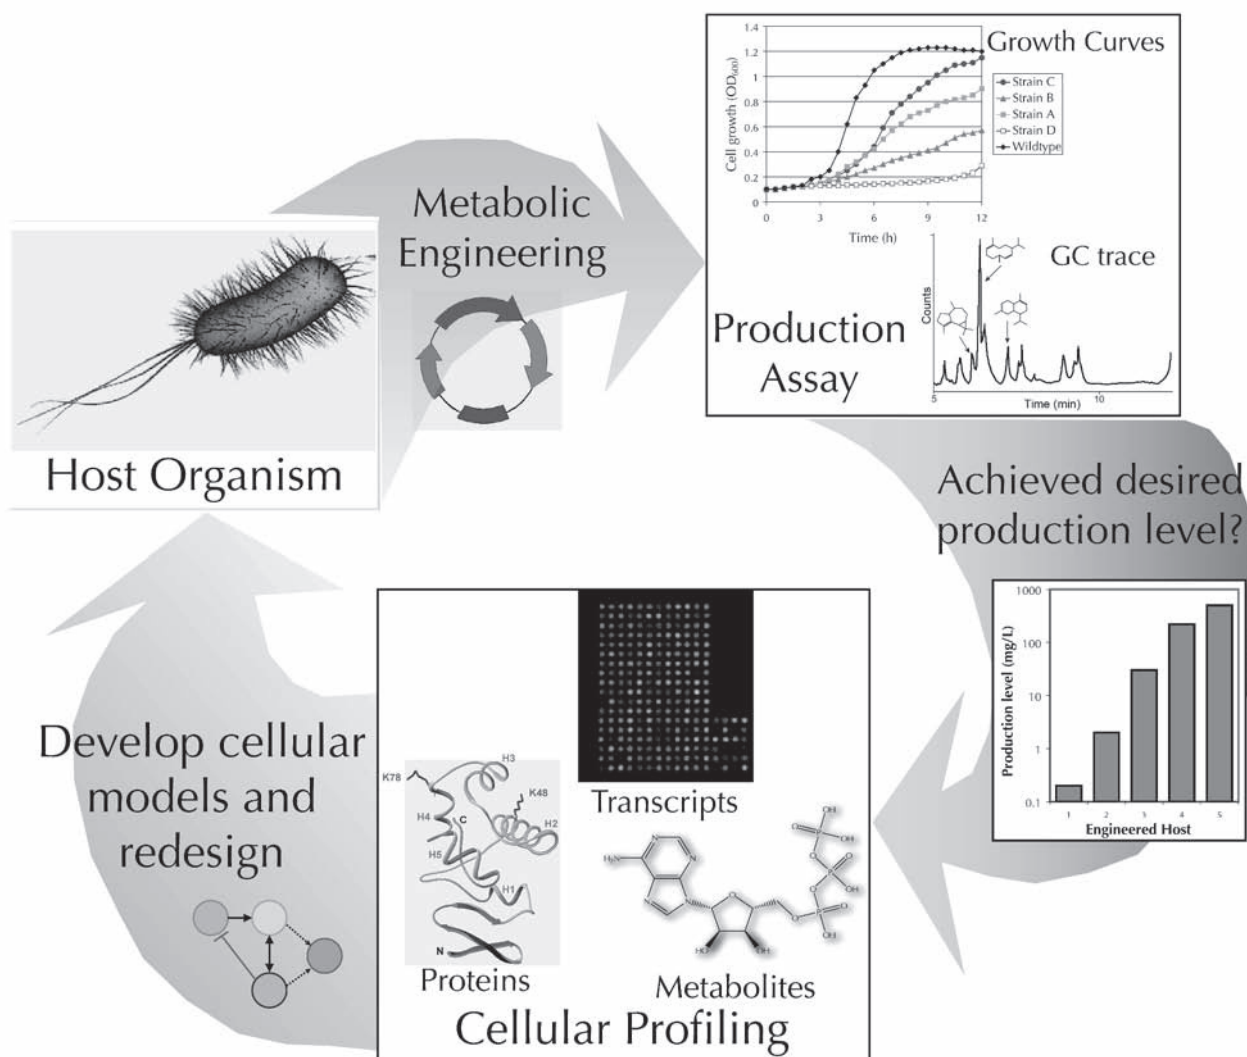

FIGURE 7 Flow chart of systems biology applied to achieving a production target. A host organism is selected and metabolically engineered to produce the molecule(s) of interest. The results of metabolic engineering are evaluated, for example, by monitoring phenotypes demonstrated by growth curves and product titers determined by GC. Cellular profiling is performed using measurements at all levels of the system, including mRNA, proteins, and metabolites, and flux analysis to identify bottlenecks in the pathway. Once bottlenecks are identified, another round of engineering is carried out to overcome the limitations. The cycle is completed once the desired production level has been achieved. OD₆₀₀, optical density at 600 nm. Reprinted from *Current Opinion in Biotechnology* (60) with permission of the publisher.

of microorganisms for efficient production of high levels of high-value compounds requires a comprehensive understanding of both the metabolite biosynthesis pathway and the native metabolism of the host. Combining targeted analyses with systems-level experiments offers the greatest chance to gain such an understanding. "Omics" analyses were used to examine the impacts of the increased metabolic burden of plasmid maintenance or protein expression, the accumulation of pathway intermediates, and the significant consumption of resources (e.g., carbon, ATP, and cofactors) during the production of amorpha-4,11-diene in an attempt to circumvent the corresponding constraints.

25.4.1. Transcriptomics Analysis of a Mevalonate-Producing Strain

Work by Pitera et al. (69), described in section 25.3.2, revealed that the accumulation of HMG-CoA is toxic to *E. coli* and that balancing the levels of HMGS and HMGR expression is necessary for robust growth and high mevalonate titers. Complementary to that work, transcriptomics analysis was used to elucidate which essential aspect of *E. coli* metabolism is impacted by HMG-CoA accumulation (44). To determine the stresses that come from flux through the pathway as opposed to the stress due to protein overproduction alone, the strain harboring a catalytically inactivated HMGS gene [on pMevT(C159A); discussed in section 25.3.2 above] was used as a control. The activated- and inactivated-pathway strains were analyzed separately over a time course and also subjected to cross comparison at the same time points (e.g., the activated-pathway strain versus the inactivated-pathway strain at time point 1). At time zero, just prior to induction, the transcriptomes for the active- and inactive-pathway strains were quite similar; however, several distinct differences were apparent postinduction. Several transcripts encoding fatty acid biosynthesis (FAB) proteins were upregulated over the time course (Fig. 8), as well as in the active-pathway strain compared to the inactive-pathway strain, in a pattern similar to that observed during FAB inhibition in *Mycobacterium tuberculosis* (12). Among the products of upregulated FAB genes (*fabB*, *fabD*, and *fabH*), only FabD interacts with malonyl-CoA, which accumulates along with HMG-CoA. The transcripts for biotin biosynthetic enzymes, which are associated with the initial steps of FAB, were also upregulated. Follow-up analysis of the impact of mevalonate production on FAB via fatty acid methyl ester analysis revealed a shift in fatty acid composition from saturated to unsaturated fatty acids in the active-pathway strain, consistent with observations of FAB inhibition and CoA depletion by Jackowski and Rock (36). Overall, the total amount of fatty acids as a percentage of dry cell weight decreased in the active-pathway strain. Medium supplementation with saturated fatty acids was capable of reversing the growth defect observed for the pMevT active-pathway strain.

25.4.2. Transcriptomics and Proteomics Analyses of an Amorpha-4,11-Diene-Producing Strain

Like genomics before it, proteomics began with relatively small sample sets and targeted analyses, yielding, as technology progressed, analyses of complex mixtures that represent the entire proteome for an organism, organelle, or other biological source (e.g., biofluid or tissue). Proteomics analysis represents the effort to establish the identities of all proteins present in an organism under experimental conditions. Significant strides toward complete proteome analysis have been made in the last 15 years. Liquid chromatography coupled to MS provides a highly sensitive analytical

method to analyze proteins from complex cell lysates. To enhance the ability to detect low-abundance proteins, such studies require extensive sample preparation, separation, and/or purification prior to mass spectrometric analysis. The strengths of MS, such as high-throughput capabilities, facile automation, and rapid protein identification, are well suited for the complex mixture analysis that large-scale proteomics requires. For metabolic engineering, quantitative proteomics is useful to compare the proteomes of several strains under a variety of conditions. Such comparisons produce insight into the bacterial responses to metabolite stresses or the expression of exogenous proteins, complementing transcriptomics and metabolite analyses. Transcriptomics analysis of the pMevT strain that experienced HMG-CoA toxicity (see above) revealed clearly different profiles from those of strains not showing toxicity. The differences manifested themselves most clearly via growth defects. A more subtle experiment was the comparison of an amorpha-diene-producing strain (harboring pMevT, pMBIS, and pADS) with its inactive analog, which consists of the same plasmids but with a point mutation (C159A) in the HMGS gene such that the gene is catalytically inactivated. Thus, following induction, protein is produced in the active and inactive strains; however, the inactive analog does not feel the stress of metabolic flux through the pathway. The three-plasmid-containing strain produces significant amounts of amorpha-4,11-diene without a growth defect. Yet results from gene titration experiments have shown that the system is not yet optimized. Consequently, cell-wide quantitative proteomics experiments were used to verify the observations. Liquid chromatography-tandem MS analysis of the three-plasmid system confirmed that the levels of production of HMGR and mevalonate kinase over a 24-h time course were significantly lower than those of the other pathway enzymes. By using transcriptomics and proteomics, several native *E. coli* processes (e.g., C1 biosynthesis and amino acid biosynthesis) were observed to change drastically in the active strain compared to those in the inactive strain. Follow-up experiments to characterize the effects of various medium supplements on mevalonate and amorpha-4,11-diene production are currently under way.

25.5. BIOSYNTHETIC OXIDATION OF AMORPHA-4,11-DIENE

25.5.1. Identification of the Native Amorpha-4,11-Diene Oxidase Gene

Production of high levels of amorpha-4,11-diene was an important step toward biosynthetically derived artemisinin. Yet three selective oxidation steps and one reduction step are required to convert amorpha-4,11-diene to dihydroartemisinic acid, the final enzymatic product prior to artemisinin. Chemical synthesis of artemisinin from amorpha-4,11-diene is feasible, yet chemical conversion of artemisinic acid can be achieved in only two steps with yields exceeding 30% (74). Consequently, oxidation of amorpha-4,11-diene to artemisinic acid via tailoring of enzymes is economically desirable. Ro et al. undertook an effort to identify the native enzyme or enzymes that convert amorpha-4,11-diene to artemisinic acid (70). In 2005, Berteau and coworkers (11) proposed that the enzymes responsible for the oxidation were cytochrome P450 monooxygenases. These enzymes catalyze a wide variety of reactions including hydroxylation, epoxidation, dehydrogenation, and other oxidations, yet such reactions are often highly specific for a particular substrate. The high degree of sequence variability found in P450 enzymes complicates

FIGURE 8 Transcript profiles of the initial steps of type II FAB in *E. coli*. Malonyl-CoA is synthesized from acetyl-CoA by the action of acetyl-CoA carboxylase, a heterotetramer composed of subunits encoded by *accABCD*. The malonate moiety is transferred from CoA to the acyl carrier protein (ACP) by the action of malonyl-CoA:ACP transacylase (FabD). Also shown (inset) are the expression values and *Z* scores (in parentheses) for FAB genes that exhibited biologically significant upregulation in the mevalonate-producing strain (*E. coli* DP10 containing pBAD33MevT and pBAD18) relative to the inactive-pathway control strain [*E. coli* DP10 containing pMevT(C159A) and pBAD18] in the microarray analysis. Values for the control strain were set at 1.0. Adapted from *Applied and Environmental Microbiology* (44).

the identification of specific P450 enzymes by homology. To narrow the search, Ro and coworkers undertook comparative genomic analyses of *A. annua*, chicory, lettuce, and sunflower, all members of the Asteraceae family, because they produce sesquiterpene lactones such as artemisinin. Ro et al. (70) obtained P450 expressed sequence tag libraries to target CYP71 and CYP82 P450 families in lettuce and sunflower. By using CYP-specific primers, several fragments were isolated from an *A. annua* trichome-enriched complementary DNA library. The product of the full-length open reading frame (CYP71AV1) from one of the fragments was found to oxidize amorpha-4,11-diene to artemisinic acid (up to 100 mg/liter) when expressed with its cytochrome P450 reductase (CPR) redox partner in *S. cerevisiae* (70). In vitro experiments showed that the isolated amorphadiene oxidase (CYP71AV1) catalyzed all three oxidations of amorpha-4,11-diene to artemisinic alcohol, artemisinic aldehyde, and artemisinic acid. Concurrently, Teoh et al. used expressed sequence tag libraries generated from *A. annua* trichomes to identify CYP71AV1 for amorpha-4,11-diene oxidation (84). Subsequent work by Zhang and coworkers (96) identified an artemisinic aldehyde Δ 11(13) reductase which catalyzes the reduction of artemisinic aldehyde to dihydroartemisinic aldehyde prior to the formation of dihydroartemisinic acid.

25.5.2. Expression of the Native Amorpha-4,11-Diene Oxidase Gene in *E. coli*

Despite successful production of artemisinic acid in *S. cerevisiae*, bio-oxidation of amorpha-4,11-diene in *E. coli* was desirable (16). Yet biotechnological use of plant P450s in bacteria has met with limited success and many difficulties. Functional expression of membrane-bound plant P450s in *E. coli* is hampered by problems associated with protein folding, membrane insertion, posttranslational modification, and cofactor utilization. Indeed, when native CYP71AV1-CPR was expressed in *E. coli*, no oxidation of amorpha-4,11-diene was detectable (15). Consequently, another plant cytochrome P450, 8-cadinene hydroxylase (CAH), was used to optimize functional expression in *E. coli* for application to amorphadiene oxidase. Initial production titers of 8-hydroxycadinene were low (0.4 mg/liter), but following addition of the lower mevalonate pathway and codon optimization for *E. coli*, production was increased to 25 mg/liter. Notably, when CAH was expressed with the CPR redox partner for the amorphadiene oxidase, production decreased 1.8-fold, indicating that interactions between the oxidase and reductase play a significant role in activity.

Increasing the solubility and stability of plant P450s in bacteria is a particular challenge. Previous studies have shown that modification of the membrane anchor can have a dramatic effect on enzymatic activity (9, 75, 77, 82). Consequently, several other anchors that had been previously characterized with respect to bacterial expression (9, 19, 73, 77, 79, 82) were used to replace the N-terminal portion of CAH. The production of 8-hydroxycadinene improved with all of the modifications, up to 105 ± 7 mg/liter with the anchor optimized for the expression of 17α -hydroxylase (9). Chang et al. applied the codon optimization and N-terminal transmembrane engineering methods to amorphadiene oxidase, yielding constructs capable of producing small amounts (5.6 mg/liter) of artemisinic alcohol (15). The oxidized amorpha-4,11-diene metabolite yield was further increased by switching from the pETDuet-1 vector to a P450-specific vector, pCWori (9). Changing to the pCWori vector also resulted in measurable amounts of artemisinic acid; however, artemisinic alcohol and aldehyde remained the

dominant products. By removing the dodecane layer, which sequestered the substrate and less-oxidized products, the artemisinic acid level was increased to 105 ± 10 mg/liter.

25.5.3. Engineering of *B. megaterium* P450 BM-3 To Oxidize Amorpha-4,11-Diene

Much of the effort associated with increasing amorphadiene oxidase activity in *E. coli* involved techniques to stabilize the native enzyme. An alternative method to achieving specific oxidation of amorpha-4,11-diene is engineering a bacterial P450 through mutagenesis to produce the desired product. Yoshikuni et al. recently mutagenized (+)- δ -cadinene synthase by using error-prone PCR and site-directed saturation mutagenesis to achieve higher specificity and activity (93). This method is attractive because the issues associated with expressing plant P450 enzymes can be avoided through judicious choice of the starting P450 enzyme. The bacterial P450 enzyme from *Bacillus megaterium*, P450 BM-3, is ideal because it benefits from good solubility and a high catalytic rate and is self-contained; thus, coexpression of a redox partner is not required (66). Additionally, the structure and activity of BM-3 have been extensively studied (33, 61, 65, 88), and the product specificity has been engineered previously for the oxidation of a wide variety of substrates (6, 14, 24, 28, 33, 52, 53). To increase the binding pocket for amorpha-4,11-diene, the wild-type BM-3 was mutated at residue Phe87 by Dietrich and coworkers (23). When the engineered BM-3 was incorporated into a strain that produced amorpha-4,11-diene, they observed a product with an electron impact mass spectrum and a retention time identical to those of an artemisinic-11S,12-epoxide (23). While the artemisinic epoxide is not an intermediate in the native artemisinin biosynthesis pathway, a high-yielding chemical synthetic route exists to convert the epoxide into dihydroartemisinic acid, the final enzymatic step prior to the formation of artemisinin (18, 84). Subsequent engineering of BM-3 production yielded more than 250 mg/liter artemisinic epoxide.

25.6. SUMMARY

The recent increase in multidrug-resistant strains of *Plasmodium falciparum* has pushed ACTs to the front of the worldwide fight against malaria. Development of artemisinin sources that are stable, sufficient to meet the growing need, and affordable represents the most significant challenge for combating malaria. Metabolic engineering of *E. coli* to meet these needs has progressed significantly in the last 8 years. The genes to convert acetyl-CoA to artemisinic acid have been cloned and expressed in *E. coli*. Ultimately, improvements in the titers of the end product (artemisinic acid) as well as the intermediates of the pathway have come from the manipulation of expression levels of the pathway genes or changes in copy numbers of the plasmids on which they are carried. Titers of amorpha-4,11-diene, the first committed step toward artemisinin, have been improved from levels in micrograms per liter in original strains to 0.3 g/liter in an optimized strain (5) and over 0.4 g/liter in cultures in a partitioning bioreactor (62). Furthering this work, Amyris Biotechnologies recently reported that they achieved commercially relevant titers of amorpha-4,11-diene (27.4 g/liter) in fed-batch fermentations (85). Careful selection of the promoter strength, plasmid, and gene copy number led to improved enzyme expression levels, reduced bottlenecks, balanced metabolite flux, and ultimately, increased titers of amorpha-4,11-diene. "Omics" analyses proved to be useful means for identifying bottlenecks in

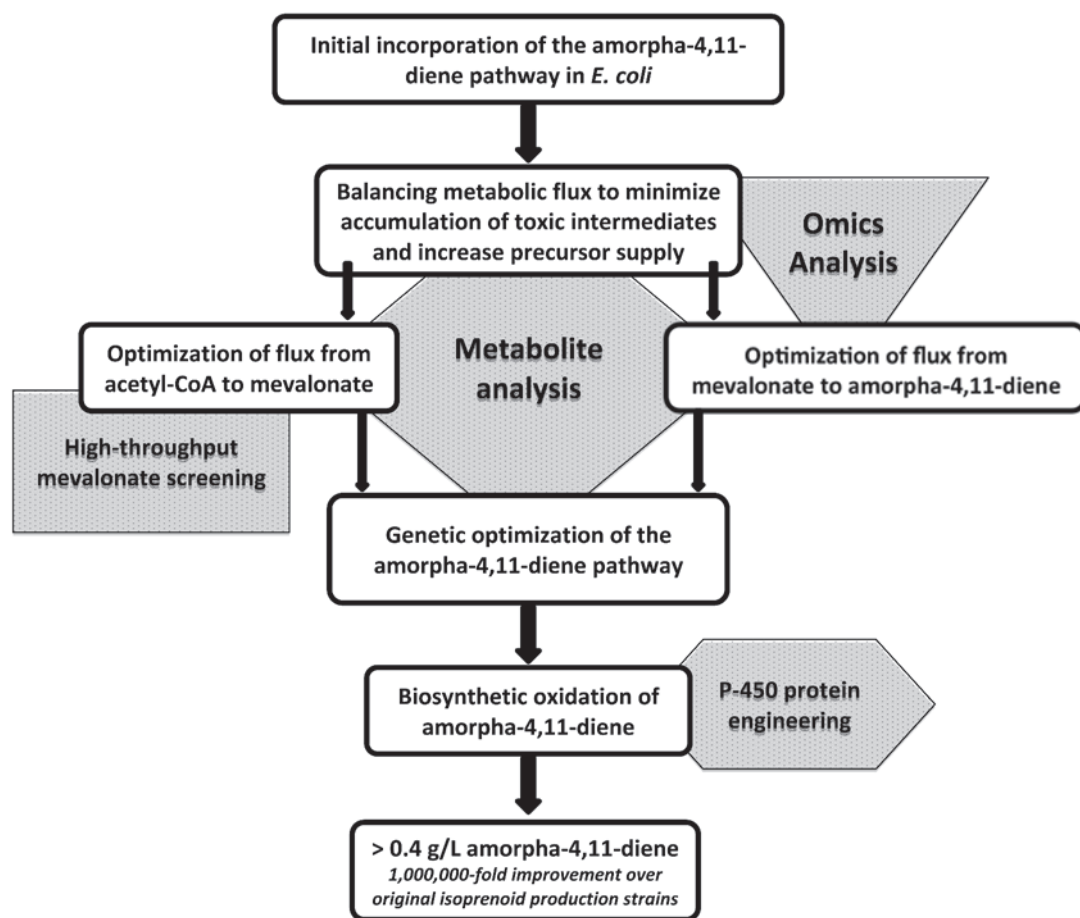

FIGURE 9 Flow chart of metabolic engineering efforts for the high-level production of precursors to artemisinin.

the flux of intermediates through the pathway, enabling a series of subsequent directed genetic manipulations that proved effective in improving the titers. This multifaceted approach is outlined in Fig. 9.

Identification of the native amorpha-4,11-diene oxidase revealed that amorpha-4,11-diene was oxidized in three steps to artemisinic acid. The gene for this P450 enzyme was successfully cloned into *S. cerevisiae*, but unfortunately, expression of amorphadiene oxidase in yeast was not predictive of success in *E. coli*. Improvements in the expression of plant P450 enzymes in *E. coli* were made through codon optimization and N-terminal anchor modification to ultimately produce over 0.1 g/liter of artemisinic acid (15). An alternate means of amorpha-4,11-diene oxidation by engineering a substrate-promiscuous P450 was developed to complement the native-enzyme efforts. Protein engineering of *B. megaterium* P450 BM-3 yielded selective oxidation of amorpha-4,11-diene at a high rate to produce artemisinic epoxide at titers of 250 mg/liter. Taken as a whole, past efforts have led to significant progress in engineering *E. coli* for the production of high levels of artemisinin precursors through a variety of traditional and modern methods.

Heterologous Production of Polyketides in *Streptomyces coelicolor* and *Escherichia coli*

JAMES T. KEALEY

26

Polyketides are structurally diverse secondary metabolites produced in bacteria, fungi, and plants. As a class of natural products, polyketides have contributed to a wealth of valuable pharmaceuticals, including antibiotics (e.g., erythromycin), cholesterol-lowering agents (e.g., lovastatin), immunosuppressants (e.g., rapamycin), and anticancer compounds (e.g., daunorubicin and epothilone). Because advanced genetic and fermentation systems are often not available for native polyketide producers, there has been interest in developing generic and genetically tractable host systems for therapeutically important polyketides.

This chapter will review the development of heterologous polyketide production systems in *Streptomyces coelicolor* and *Escherichia coli*, providing specific examples of polyketides produced in these hosts to illustrate the utility of the approach. The first section covers *S. coelicolor*, an actinomycete that produces a number of polyketides, most notably the blue pigment actinorhodin (3). Heterologous polyketide production in *S. coelicolor* demonstrated the feasibility of the approach, albeit in a host that naturally produces polyketides. The success with *S. coelicolor* provided motivation to develop heterologous production systems in *E. coli* and *Saccharomyces cerevisiae*, user-friendly organisms for which advanced molecular biology tools and fermentation systems are available. In the second section, the development of an *E. coli* production system is described. Demonstration of polyketide production in *E. coli* showed that all activities necessary for polyketide production can be recapitulated in a host that does not naturally make polyketides. The availability of *E. coli* as a heterologous host has accelerated the discovery of new polyketide analogs, as well as facilitated studies of polyketide synthase (PKS) enzymology.

26.1. PRODUCTION OF POLYKETIDES IN *S. COELICOLOR*

26.1.1. Strains, Vectors, and General Methods

Except where noted, the PKS-related genetic engineering described in this chapter generally involves standard molecular biology techniques (50). Intermediate cloning steps are performed with *E. coli* (e.g., XL1-Blue or DH5 α), and target DNA fragments are transferred into *Streptomyces/E. coli* shuttle vectors (see Table 1) by standard ligation-based methods. Efficient cloning is facilitated by engineering unique and strategic restriction sites into cloning vectors

and target DNA fragments. Large DNA fragments (≥ 10 bp) can be separated on low-percentage, low-melting-point agarose gels with subsequent manipulations performed “in gel” as outlined in protocol 1.

PKS genes are expressed from the *S. coelicolor actI* promoter, which is activated by *actII*-open reading frame 4 (ORF4), the actinorhodin (*act*) pathway-specific activator gene and positive regulator of transcription. The *actI* promoter-*actII*-ORF4 expression system is upregulated in stationary phase of mycelial growth and therefore couples heterologous expression to the onset of secondary metabolite production in *S. coelicolor*.

Standard *Streptomyces* transformation methods (27) are employed to introduce expression plasmids into *S. coelicolor* CH999, a strain that contains a chromosomal deletion of the actinorhodin gene cluster encoding the activities required for the synthesis of the aromatic polyketide actinorhodin (35). CH999 was constructed by integration via homologous recombination of the *ermE* gene fragment (conferring lincomycin resistance) into the *act* locus. Because *S. coelicolor* has a methyl-specific restriction system, plasmids must first be passed through a methylation-deficient *E. coli* host, such as ET12567. Alternatively, plasmids can be expressed in *Streptomyces lividans* K4-114, a strain with an inactive *act* gene cluster that can be transformed with methylated DNA at high levels of efficiency (63). CH999 and K4-114 are considered “clean hosts” because they contain the necessary ancillary pathways for polyketide production but do not naturally produce the targeted polyketide whose biosynthesis genes are introduced into these hosts.

Protocol 1. In-Gel Ligation of Large DNA Fragments

1. Prepare low-melting-point agarose gel (0.8 to 1%) in TAE buffer (40 mM Tris, 20 mM acetic acid, 1 mM EDTA, pH 8). To minimize breakage upon handling, place the gel into the refrigerator/cold room and chill for at least 30 min before use. Following electrophoresis, stain the gel with ethidium bromide and visualize *briefly* under long-wavelength UV light to enable the excision of relevant DNA bands. Care should be taken to excise the region of the band where DNA is most concentrated, thereby avoiding excessive dilution of the DNA.
2. Melt agar gel pieces containing target DNA at 65°C and add directly to ligation mixtures. Ligation reaction mixtures (40 μ l) contain 15 μ l water, 4 μ l of 10 \times T4 DNA

ligase buffer, molten gel fragments containing insert and vector DNA (20 μ l total combined volume), and 1 μ l T4 DNA ligase. In practice, a series of ligation reactions are set up to evaluate a range of insert-to-vector ratios (0.5 to 5).

- After incubating the ligation reaction mixtures for 1 h to overnight at room temperature ($\sim 25^\circ\text{C}$), stop the reactions (and melt the agar) by heating the mixtures at 65°C for 5 min and add 40 μ l of TCM buffer (10 mM Tris, pH 7.5, 10 mM calcium chloride, 10 mM magnesium chloride). Use an aliquot (10 to 25 μ l) of the resulting mixture to transform 100 μ l of chemically competent *E. coli* cells (e.g., XL1-Blue or DH5 α). Typically, the entire transformation mixture is plated onto Luria-Bertani (LB) agar plates containing appropriate antibiotics.

26.1.2. 6-MSA

6-Methylsalicylic acid synthase (6-MSAS) from the fungus *Penicillium patulum* catalyzes the synthesis of a simple fungal

polyketide, 6-methylsalicylic acid (6-MSA; compound 1) (Fig. 1 and 2), from the acyl coenzyme A (acyl-CoA) precursors acetyl-CoA and malonyl-CoA. The biosynthesis of 6-MSA has been studied extensively and proceeds via three iterative condensation reactions and NADPH-dependent ketoreduction. The single β -ketoacyl acyl carrier protein (ACP) synthase active site of the 6-MSAS monomer is used three times during the synthesis of one molecule of 6-MSA.

The 6-MSAS gene from *P. patulum* has been cloned and sequenced (1). For heterologous expression in *S. coelicolor*, the 6-MSAS ORF was reconstructed from a 7-kb *P. patulum* genomic DNA fragment (2). Exon 2 (5,235 bp) was joined to a synthetic version of exon 1 (87 bp), thereby removing the single 69-bp intron. To facilitate heterologous expression, the synthetic fragment contained a ribosome binding site complementary to the 3' region of *S. coelicolor* 16S rRNA and four of the first seven codons were changed to synonymous codons that better matched codon bias in *S. coelicolor*. Unique PacI and NdeI restriction sites (the lat-

ter including the ATG start codon) were introduced at the 5' end of the gene, and a unique XbaI site was introduced at the 3' end. The PacI-XbaI cassette containing the 6-MSAS ORF and the *S. coelicolor* ribosome binding site was introduced into PacI- and XbaI-restricted pKOA18', a modified version of pRM5 (35) (Table 1), placing the 6-MSAS gene under the control of the *actI* promoter and *actII*-ORF4 transcriptional activator, resulting in plasmid pDB106.

The 6-MSAS expression plasmid pDB106 was introduced into protoplasts of *S. coelicolor* CH999, transformants were grown on R5 agar medium (27) for 6 days, and the agar and mycelia were extracted with ethyl acetate–1% acetic acid. Analysis of extracts by thin-layer chromatography revealed the presence of a UV-active product from the CH999(pDB106) fermentation that was not present in CH999 harboring a vector plasmid lacking the 6-MSAS gene. Further characterization by nuclear magnetic resonance confirmed that the UV-active compound was 6-MSA, which was produced at 60 mg/liter, a titer 10-fold lower than that produced by the native host, *P. patulum* (52). Production of 6-MSA in *S. coelicolor* demonstrated that all of the requirements for successful heterologous production of a fungal polyketide were present or facilitated in the bacterial heterologous host, including adequate precursor supply, proper monomer folding and tetramer assembly, and successful posttranslational modification of the ACP domain of the PKS with the 4'-phosphopantetheine moiety.

26.1.3. 6dEB

6-Deoxyerythronolide B synthase (DEBS) from *Saccharopolyspora erythraea* catalyzes the synthesis of the erythromycin precursor polyketide 6-deoxyerythronolide B (6dEB; compound 2) (Fig. 1B and 2). The three DEBS proteins (DEBS1, DEBS2, and DEBS3) are encoded by three large genes, *eryAI*, *eryAII*, and *eryAIII*. The catalytic sites of the DEBS megasynthase are organized into six modules, each

of which catalyzes a two-carbon condensation reaction and subsequent β -carbonyl processing. As the prototypical example of a modular PKS, DEBS has been extensively studied (for reviews, see references 21, 24, 25, 48, and 53). The *ery* genes from *S. erythraea* span 32 kb of contiguous DNA sequence, which posed a formidable challenge for cloning and introduction into *S. coelicolor*. Kao and colleagues used a strategy of recombinational cloning into *E. coli* to assemble the *ery* genes and place them under the control of the *S. coelicolor actI* promoter (20). A donor plasmid contained a temperature-sensitive replicon and carried the 3' end of *eryAI* and intact *eryAII*–*eryAIII* genes. The recipient plasmid, a derivative of pRM5 (35), contained the *S. coelicolor actII*-ORF4 transcriptional regulator, the *actI* promoter upstream of the 5' end of *eryAI*, a tetracycline resistance marker, and the 3' end of *eryAIII*. Enrichment and isolation of the recombinant plasmid arising from double crossover was accomplished by plating *E. coli* transformants onto agar medium with appropriate antibiotic supplementation at the restrictive temperature. The final plasmid, pCK7, was recovered from *E. coli* and introduced into *S. coelicolor* CH999 by a standard protoplast transformation procedure (27).

CH999(pCK7) transformants were grown on R2YE medium (27), and two macrolides were isolated from the strain. As confirmed by nuclear magnetic resonance spectroscopy, the most abundant macrolide was 6dEB (compound 2; 40 mg/liter) (Fig. 1B and 2), which is the aglycone product of the DEBS PKS primed with a propionate starter unit. The aglycone arising from the incorporation of an acetate starter unit, 8,8a-deoxyerythronolide (compound 3) (Fig. 1B and 2), was also observed as a minor product (at 10 mg/liter). The latter fact demonstrates that the DEBS loading module displays relaxed specificity for the starter unit (see also section 26.2.4), as has been demonstrated *in vitro* (33, 45, 46). The final ratio of aglycone products (compound 2 to compound 3) produced in the heterologous host is expected to reflect both the intracellular

concentrations of propionyl-CoA and acetyl-CoA and the relative specificity of the DEBS loading domain for the corresponding acyl-CoA. Accordingly, the ratio may be changed by providing additional propionate in the growth medium. In the native erythromycin producer, *S. erythraea*, the ratio of propionate-derived erythromycin to acetate-derived erythromycin (15-norerythromycin) is extremely high (26), indicating that host-dependent factors can influence product profiles. For example, Hu et al. found that an editing type II thioesterase from *S. erythraea* functions to remove misprimed acetate units from the DEBS PKS, thereby accounting for the high compound 2/compound 3 ratio observed in the native host (18). Kim et al. have also identified a type II esterase associated with the pikromycin PKS in *Streptomyces venezuelae* (28).

The pioneering work of Khosla and colleagues demonstrated functional expression of a large modular PKS in an actinomycete heterologous clean host (20). When expressed in the heterologous host, the DEBS proteins folded correctly and were properly posttranslationally modified with the phosphopantetheine moiety from CoA. Hence, the *Streptomyces* heterologous host contained an endogenous phosphopantetheinyl (p-pant) transferase that converted the DEBS apo-ACP domains into their

holoforms. The heterologous host also contained adequate levels of required acyl-CoA substrates, propionyl-CoA and (2S)-methylmalonyl-CoA.

26.1.4. 6dEB Analogs

There is a linear correspondence between the order of polyketide chain assembly and the order of active sites in DEBS (and other modular PKSs). Consequently, analogs of modular polyketides can be produced by genetic reprogramming of the PKS genes—the “chemistry by genetics” approach (21, 24). Pioneering work in this area involved genetic engineering of the *ery* genes in the native host, *S. erythraea* (6, 9). The cloning strategy developed by Khosla and colleagues for manipulation and heterologous expression of the DEBS genes in *S. coelicolor* simplified the construction of mutated DEBS genes and facilitated the production of 6dEB analogs, many of which were intractable by traditional (chemical) synthetic routes. The construction of mutant genes was carried out in *E. coli*, after which the shuttle vector(s) containing the mutated PKS gene(s) was transferred into the heterologous production host CH999 or an analogous heterologous host, *S. lividans* K4-114 (63). This methodology was initially employed

to produce targeted analogs from the manipulation of a single DEBS module. For example, Liu et al. replaced the methylmalonyl-CoA-specific DEBS acyltransferase domain 6 (AT6) with AT2 (specific for malonyl-CoA) from the rapamycin PKS (RAPS) to produce 2-nor-6dEB (34) (compound 4) (Fig. 1C and 2). Analogs with changes at the starter-unit position were produced by a procedure known as chemobiosynthesis. This method involves supplying an exogenous starter unit in the form of a chemically synthesized diketide thioester to a polyketide-biosynthetic host in which the DEBS ketosynthase domain 1 (KS1) is inactivated, usually by mutation of the active-site cysteine to alanine. The synthetic diketide effectively mimics the ACP domain 1 (ACP1)-bound diketide and is incorporated at KS2, where it is subsequently elongated into the full-length polyketide analog. The Cys-to-Ala mutation was introduced into KS1 on plasmid pCK7, and CH999 was transformed with the resulting plasmid (19). When CH999 was cultured in R2YE medium containing (2S,3R)-2-methyl-3-hydroxyhexanoate-*N*-acetyl cysteamine thioester (propyl-SNAc), 15-methyl-6dEB (compound 5) (Fig. 1D and 2) was produced. Optimized diketide feeding protocols and further process modifications led to significant improvements in titers (to >1 g/liter) of 6dEB starter-unit analogs (8, 32, 58).

The technology for 6dEB analog production was further advanced by the development of a system for combining single alterations in DEBS domains to produce analogs with multiple substitutions in the 6dEB core structure (36). To facilitate domain manipulation, strategic restriction sites were introduced between domain boundaries, and the fragments containing the engineered restriction sites were subcloned into *E. coli*. The engineered restriction sites did not adversely affect 6dEB production. Domain cassettes from the RAPS gene were generated by PCR, with appropriate restriction sites incorporated at the domain boundaries. The DNA sequences comprising alternative PKS modules were introduced into the DEBS subclones via appropriate restriction sites. In the final cloning step, unique restriction sites were used to transfer the hybrid PKS DNA sequences into the expression plasmid pCK7. CH999 was transformed with the resulting plasmids for heterologous polyketide production and subsequent analysis. Over 50 6dEB analogs containing changes involving methyl substitution and/or β -carbon processing were produced by individual or combined DEBS-RAPS domain swaps. Compound 6 (Fig. 1E and 2), obtained from a triple substitution in DEBS module 2 (ketoreductase domain 2 [KR2] is replaced by dehydratase, enoylreductase, and KR1 from RAPS), module 5 (KR is removed by replacement of the coding sequence with a “stuffer” DNA sequence), and module 6 (methylmalonyl-specific AT is replaced with malonyl-specific AT), is an example of the type of analog accessible by this approach.

The combinatorial potential of the DEBS system was expanded by the development of a multiplasmid approach for DEBS expression in *S. coelicolor* CH999 or *S. lividans* K4-114 (61). The DEBS1 and DEBS2 genes were carried on separate pRM1-based plasmids with thiostrepton and hygromycin resistance markers, respectively, and the DEBS3 gene was carried on the integrating bacteriophage ϕ C31-based plasmid pSET152 with an apramycin resistance marker (4). In all cases, DEBS genes were expressed from the *S. coelicolor* *actI* promoter and *actII*-ORF4 transcriptional activator. The two pRM1-based plasmids, both with SCP2* origins of replication, were stably maintained when the culture medium contained appropriate antibiotic

supplementation, and the titer (50 mg/liter) of 6dEB produced by the strain expressing wild-type DEBS from three different plasmids was similar to that produced by the strain expressing DEBS from a single plasmid. The multiplasmid approach allows for the combination of single mutations by simple transformation, thereby eliminating the need to construct a separate plasmid for each desired analog. The combinatorial potential of this system arising from the combination of major elements is 262,144 polyketides (2 different ATs \times 4 different β -keto-modifying activities per module = 8 combinations per module; 8×8 per protein; $64 \times 64 \times 64 = 262,144$ per DEBS molecule). To generate such a library by the multiplasmid approach requires the construction of only 192 (64×3) different plasmids carrying single mutations. In contrast, the same number of genetic constructions using the single-vector combinatorial approach described above would yield only 192 different polyketides (36).

The utility of the multiplasmid approach was demonstrated by a proof-of-concept experiment: *S. lividans* K4-114 was transformed with eight variants of the DEBS3 gene (*eryAIII*) on the integrating vector. The resulting strains were cotransformed with four DEBS1 variants (*eryAI*) and two DEBS2 variants (*eryAII*) on the replicating plasmids. By starting with 14 different expression constructs, 64 transformants were generated. Among the 64 strains tested, 43 different polyketides were produced, 28 of which had been prepared previously using the single-plasmid approach (36) and 15 of which represented novel structures.

To convert the 6dEB analogs into corresponding erythromycin analogs, the aglycone product is purified from CH999 and fed to a bioconversion strain of the natural host, *S. erythraea* (5, 60), which contains a mutation in a DEBS gene that prevents 6dEB production, but harbors the downstream “tailoring” activities (glycosidation, oxidation, and methylation) necessary for completion of the biosynthesis pathway. The efficiency of bioconversion depends on the tolerance of the tailoring enzymes for the engineered change in the aglycone. Consequently, not all aglycone analogs are efficiently bioconverted by *S. erythraea*.

26.1.5. Epothilone

The epothilones are mixed polyketides/nonribosomal peptides that have microtubule-stabilizing activities similar to those of the taxanes but are active against Taxol-resistant tumors. The natural producer of epothilones, the myxobacterium *Sorangium cellulosum*, is not an ideal host for large-scale production due to its slow growth and genetic intractability. The large epothilone gene cluster (52 kb) comprises seven ORFs with products ranging in size from 47 to 765 kDa (yielding compound 7) (Fig. 1F and 2). Tang et al. expressed the epothilone gene cluster in *S. coelicolor* CH999 from two operons, each carried on a separate plasmid and each under the control of the *actI* promoter/*actII*-ORF4 transcriptional activator (54). The first operon, consisting of the EpoA to EpoD genes, was cloned into a pCK7 plasmid derivative, resulting in a 55-kb expression plasmid. The second operon, consisting of EpoE and EpoF genes and accessory genes, was introduced into a pSET152-based vector, giving a 30-kb expression plasmid. CH999 was transformed sequentially with the plasmids, and transformants were grown in R2YE medium. Following fermentation, ethyl acetate extracts were purified by high-performance liquid chromatography (HPLC) and epothilones A and B were detected by liquid chromatography-mass spectrometry (LC-MS); final titers were estimated to be about 50 μ g/liter. While achieving heterologous production of epothilones in *S. coelicolor* was

a major accomplishment, significant strain improvement would be required to develop a strain suitable for large-scale production of epothilone.

26.1.6. Boosting Polyketide Production in *S. coelicolor*

Many polyketides, including epothilone (54) and certain analogs of 6dEB (36), are produced at low levels in the *S. coelicolor* heterologous production system. Polyketide titers can potentially be increased by increasing the copy number of the SCP2*-based expression plasmid, normally present at 2 to 5 copies per cell. Hu et al. discovered a plasmid (SCP2@) that could recombine with the low-copy-number SCP2* (JRJ2) to form a cointegrate that has a 30-times-higher copy number (100 to 125 copies) and can be stably maintained (10, 17). Moreover, increased plasmid copy number correlates positively with product yield, resulting in ~25-fold-higher production of the polyketide analog 15-methyl-6dEB (compound 5) (Fig. 1D and 2). SCP2@ is identical to SCP2*, except for a 45-bp deletion upstream of *repl*. A plasmid called pBoost, containing SCP2@, a pBR322 replicon, and an apramycin resistance cassette, was constructed to provide a copy number boost to large pRM5 (SCP2*)-based expression plasmids upon cotransformation (17).

26.2. PRODUCTION OF POLYKETIDES IN *E. COLI*

26.2.1. 6-MSA

The polyketide 6-MSA was chosen as a paradigm for heterologous polyketide production in *E. coli* and *S. cerevisiae*, workhorse prokaryotic and eukaryotic hosts extensively employed in the biotechnology industry. The 6-MSAS ORF was excised as an NdeI-XbaI fragment from pDB106 (Table 1) and introduced into vectors for expression in *E. coli* or *S. cerevisiae* (22). The 6-MSAS ORF and *sfp*, encoding a heterologous p-pant transferase from *Bacillus subtilis* required for conversion of apo-6-MSAS to holo-6-MSAS, were coexpressed in *E. coli* from compatible plasmids with different antibiotic resistance markers. In *S. cerevisiae*, the 6-MSAS ORF and *sfp* were expressed from 2 μ m plasmids with different auxotrophic markers (22). Following induction of gene expression in the *E. coli* and *S. cerevisiae* production hosts, 6-MSA levels were determined by HPLC analysis of cell-free media by using UV detection (wavelength, 306 nm). The final titer of 6-MSA produced in *E. coli* was approximately 75 mg/liter, similar to that produced in *S. coelicolor* (2). The yeast host produced 1.7 g 6-MSA/liter in yeast extract-peptone-dextrose medium in unoptimized shake flask fermentations (22).

Since *E. coli* and *S. cerevisiae* do not naturally produce polyketides, the work on 6-MSA production in these hosts defined the minimum requirements for heterologous polyketide production.

1. *Soluble protein expression.* Production of 6-MSA in *E. coli* required that the cultivation temperature be reduced from 37°C (*E. coli* temperature optimum) to 30°C during heterologous protein expression, presumably to facilitate proper protein folding.
2. *Phosphopantetheinylation.* Coexpression of a heterologous p-pant transferase was required for phosphopantetheinylation of the apo-ACP domain of the PKS. The p-pant transferase from the *B. subtilis* surfactin biosynthetic pathway, Sfp, displays broad substrate specificity toward ACP domains (29) and therefore was chosen as a candidate heterologous p-pant transferase for activation of apo-6-MSAS. Since the first demonstration of its utility

for polyketide production in *E. coli* and *S. cerevisiae* (22), Sfp has been used extensively for heterologous activation of PKSs expressed in *E. coli* and/or *S. cerevisiae*. To construct *sfp* expression cassettes, the *sfp* gene (0.5 kb) is amplified from *B. subtilis* DNA by PCR using amplification primers that introduce convenient restriction sites. Alternatively, *sfp* can be synthesized from overlapping DNA oligonucleotides (see section 26.3). The *sfp* gene is placed under the control of an appropriate promoter (e.g., the T5, T7, or *lac* promoter) for expression in *E. coli*, and the expression cassette is introduced into the host strain on a plasmid vector or is integrated into the host genome. Other promiscuous p-pant transferases such as Syp (51) can be employed as well.

3. *Adequate levels of acyl-CoA substrates.* The substrates for 6-MSAS—acetyl-CoA, malonyl-CoA, and NADPH—are used for fatty acid biosynthesis and are therefore present in *E. coli* and *S. cerevisiae*. For 6-MSA production in *E. coli*, glycerol was included in the culture medium to increase intracellular malonyl-CoA levels (56), underscoring the importance of adequate provision of acyl-CoA substrates.
4. *Nontoxic products and/or intermediates.* 6-MSA is not toxic to *E. coli* or yeast. However, for heterologous production of other polyketides or natural products, introduced activities or pathways may cause the accumulation of intermediates or products that are toxic to host cells. In such cases, balancing pathway flux by overexpression of downstream enzymes can potentially relieve bottlenecks and decrease toxicity. For example, heterologous expression of the yeast mevalonate pathway in *E. coli* causes the toxic buildup of 3-hydroxy-3-methylglutaryl-CoA, which inhibits fatty acid biosynthesis (and results in an increase in the malonyl-CoA pool). Balancing pathway flux by increasing the expression of the downstream enzyme 3-hydroxy-3-methylglutaryl-CoA reductase relieves toxicity (47). Heterologous expression of the *Propionibacterium shermanii* methylmalonyl-CoA mutase/epimerase pathway in *E. coli* also results in elevated malonyl-CoA levels, suggesting that the introduced pathway likely impacts fatty acid biosynthesis (7) (see section 26.2.2). If the product itself is toxic, introduction of an appropriate resistance gene may be required. For example, in *E. coli* strains engineered for erythromycin production, the *ermE* resistance gene, encoding a 23S rRNA N-methyltransferase that confers resistance to erythromycin, was coexpressed (43) (see section 26.2.4).

26.2.2. 6dEB

Successful production of the simple polyketide 6-MSA in *E. coli* and *S. cerevisiae* demonstrated the feasibility of producing polyketides in non-polyketide-producing, user-friendly, genetically tractable heterologous hosts. Pfeifer and colleagues extended the work with *E. coli* by engineering a strain that produces the complex polyketide 6dEB (44). Like 6-MSA production in *E. coli*, successful heterologous production of 6dEB resulted when the minimal requirements, as outlined in section 26.2.1, were satisfied.

1. *Soluble protein expression.* Production of 6dEB in *E. coli* required that the postinduction cultivation temperature be reduced from 37 to ~22°C to facilitate proper folding of the megaenzymes.
2. *Phosphopantetheinylation.* The *sfp* gene, under the control of the T7 promoter, was integrated into the *prpC* locus in the *E. coli* chromosome, inactivating the 2-methylcitrate pathway and propionyl-CoA metabolism (13, 15). Concurrently, a T7 promoter was placed upstream of

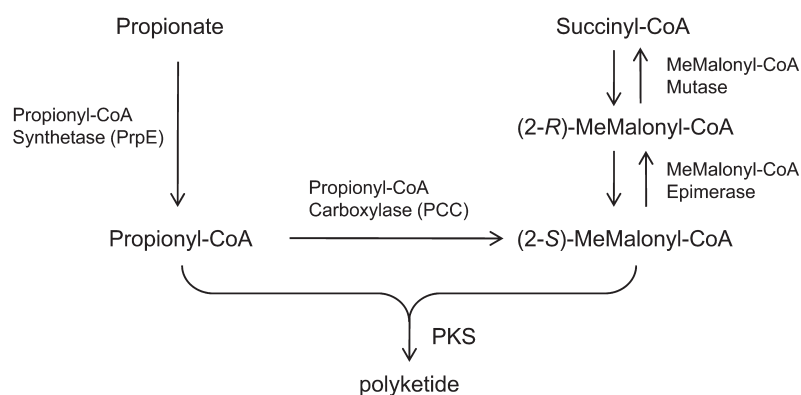

FIGURE 3 Heterologous biosynthetic pathways for (2S)-methylmalonyl-CoA introduced into *E. coli*.

prpE, a gene encoding propionyl-CoA synthetase, which catalyzes the conversion of propionate to propionyl-CoA (14). The genetic manipulation at the *prp* locus by Pfeifer et al. (44) illustrates a common strategy in metabolic engineering: knocking in genes with required functions while knocking out endogenous competing genes or pathways whose products may direct carbon flux away from engineered product pathways.

3. *Adequate levels of acyl-CoA substrates.* The starter unit for 6dEB biosynthesis, propionyl-CoA, was generated from propionate (included in the medium at the induction of gene expression) via propionyl-CoA synthetase. The (2S)-methylmalonyl-CoA extender unit was generated from

propionyl-CoA by the action of the *S. coelicolor* propionyl-CoA carboxylase (PCC), comprising a biotin carrier subunit and a transcarboxylase subunit (49) (Fig. 3).

4. *Nontoxic products and/or intermediates.* At the levels produced, there is no apparent toxicity of 6dEB to the *E. coli* host.

In the initial *E. coli* 6dEB production system developed by Pfeifer et al. (44), the DEBS1 and PCC genes were carried on a pET-based plasmid (pBP144) with kanamycin resistance, and the DEBS2 and DEBS3 genes were present on a second pET-based plasmid (pBP130) with ampicillin resistance (Table 2). An *E. coli* strain (BAP1) containing a single copy of *sfp* integrated at the *prpC* locus was cotransformed

with the plasmids, as described above. All introduced genes (and endogenous *prpE*) were under the control of the *lac*-inducible T7 promoter. Transformants were cultivated in LB medium with appropriate antibiotic supplementation. Upon induction of gene expression with IPTG (isopropyl- β -D-thiogalactopyranoside) at mid-log phase of growth (optical density at 600 nm of ~ 0.4 to 0.6), propionate was added to the culture medium. Although the BAP1 (pBP144, pBP130) strain produced 6dEB, the system suffered from plasmid instability. Murli et al. developed a second-generation stable *E. coli* strain that produced 6dEB at higher yields (40). In the second-generation strain, K-207-3, the *pcc* genes were integrated at *ygfG*, a gene encoding methylmalonyl-CoA decarboxylase. The DEBS1 gene was introduced into an RSF1010-based plasmid (pKOS207-129) such that it was compatible with the pET-based pBP130. In K-207-3 (pKOS207-129, pBP130), the plasmids were stably maintained without antibiotic supplementation and 6dEB was produced at high titers (~ 1 g/liter) in high-density *E. coli* fermentations (31). Recently, Wang and Pfeifer developed a plasmid-free *E. coli* strain for 6dEB production; however, this strain, YW9, produced low levels of 6dEB (≤ 0.52 mg/liter) (57).

As an alternative to the PCC pathway for the production of (2S)-methylmalonyl-CoA, the methylmalonyl-CoA mutase/epimerase pathway has been introduced into *E. coli* (Fig. 3) (7, 23, 40). Since mutase/epimerase produces methylmalonyl-CoA from succinyl-CoA, the extender unit can be produced independently of the starter unit, a potential advantage for the production of analogs of 6dEB with variations at the starter-unit position (see section 26.2.4 below). Moreover, the mutase/epimerase pathway generates the extender unit from an intermediate (succinyl-CoA) derived from central metabolism, potentially providing a more economical route to 6dEB by reducing or eliminating the propionate requirement.

Protocol 2. Quantification of 6dEB (and Analogs) Produced in *E. coli*

1. Plate *E. coli* transformants onto LB agar with appropriate antibiotics.
2. Pick at least two transformants for each strain analyzed. Inoculate single colonies into LB medium containing appropriate antibiotics and grow cultures overnight at 37°C in an incubator/shaker. Use an aliquot (1/50 final dilution) of each overnight culture to inoculate production flasks containing LB medium with appropriate antibiotic supplementation. Grow cultures at 37°C to mid-log phase (optical density at 600 nm, ~ 0.6) and then cool the cultures to 22°C. Induce the expression of regulated genes and add medium supplements (for example, add IPTG to a 0.5 mM final concentration and sodium propionate to 5 mM); continue shaking the cultures at 22°C.
3. After appropriate cultivation time, transfer 50 ml of fermentation culture into a 50-ml conical tube and collect cells by centrifuging at 3,500 rpm ($2,000 \times g$) for 15 min.
4. Transfer supernatant into a clean, 50-ml conical (Falcon) tube.
5. In a 15-ml conical tube, mix 5 ml of culture supernatant and 5 ml of ethyl acetate.
6. Shake vigorously for at least 15 min.
7. Centrifuge at 3,500 rpm ($2,000 \times g$) for 15 min.
8. Remove the upper (organic) layer and transfer it into a 16- by 100-mm glass tube.
9. Dry in a vacuum concentrator (approximately 1 h). Note that depending on the yield of polyketide, steps 1 through 7 can be performed in a 1.5-ml Eppendorf tube by mixing 0.5 ml of cell-free culture with 0.5 ml of ethyl acetate.

10. Resuspend the residue in 500 μ l of methanol (MeOH) and prepare samples of different concentrations by dilution in 50% MeOH. Analysis of several dilutions of the extract will ensure that the amount of 6dEB analyzed lies within the linear range for the assay. Analyze 6dEB by LC-MS and/or LC–evaporative light-scattering detection (ELSD). Prepare a serially diluted calibration standard of 6dEB. Dilute the standard to 2, 5, 10, 15, and 20 mg/liter in 50% MeOH. Perform analysis and quantitation by LC-MS-ELSD. A typical LC-MS system for analysis of 6dEB is an HPLC system with a C_{18} column (e.g., 5- μ m particle size; 4.1 by 150 mm) and a linear gradient from 35 to 100% methyl cyanide (0.1% acetic acid) at 1 ml/min over 10 min. The eluate is split 1:1 between ELSD and MS detectors. Under these conditions, 6dEB elutes at ~ 7.4 min. 6dEB titers from sample cultures are determined by comparing the integrated area of the ELSD response to a standard reference curve generated from authentic 6dEB.

26.2.3. Balancing Heterologous Expression

The *E. coli* production systems described above make use of T7 promoters for expression of genes involved in polyketide production. The exclusive use of the same promoters can result in unbalanced gene expression and reduction of polyketide titers. An extreme example of this phenomenon was described by Menzella et al. for an *E. coli* 6dEB production system that employed synthetic DEBS genes with codons tailored for *E. coli* tRNA frequency bias (39). Expression of the large plasmid-borne PKS genes from T7 promoters at high transcription and translation efficiencies effectively attenuated expression of the chromosomally localized PCC genes, each under the control of a T7 promoter. The resulting strain failed to produce 6dEB, due to inadequate acyl-CoA precursor levels. When the synthetic DEBS genes were expressed from alternative promoters (e.g., pBAD and *plac*) to better balance PKS and PCC expression, PCC expression increased and polyketide production was restored.

26.2.4. 6dEB Analogs and Erythromycin

The *E. coli* production system also was employed to produce analogs of 6dEB with changes at the starter-unit position. These analogs served as precursors for novel ketolides, a derivative class of macrolides with activities against macrolide-resistant pathogenic bacteria (62). Three approaches were used to produce 6dEB analogs in *E. coli*. The first involved chemobiosynthesis, as described in section 26.1.4, to produce compound 5 (Fig. 2) and related analogs. Synthetic diketides are “fed” to K-207-3 expressing DEBS2, DEBS3, and DEBS1 with nonfunctional KS1 (alternatively, module 2 of DEBS1 can be used in place of DEBS1 with a KS1 knockout). A similar construct has been successfully employed in *S. coelicolor* (58). A potential drawback to the chemobiosynthetic approach is the significant scale-up cost associated with chemical synthesis of the diketide raw material. Murli and coworkers developed an alternative chemobiosynthetic approach that involved feeding more economical monoketide acyl-thioester analogs to K-207-3 strains expressing DEBS2, DEBS3, and DEBS1 lacking the loading didomain (41). A third route to 6dEB starter-unit analogs such as compound 5 takes advantage of the relaxed substrate specificity of the DEBS loading domain toward alternative acyl-CoA starter units. Biosynthesis of polyketide analogs by incorporation of novel acyl-CoAs is cost-effective because the method does not require synthetic precursors, but the spectrum of

analogs that can be produced by this strategy is somewhat limited. Major challenges inherent to this methodology include (i) the ability to engineer a pathway to supply the desired acyl-CoA starter unit and (ii) efficient utilization of the alternative acyl-CoA by the DEBS loading domain. As an example of this approach, compound 5 was produced in *E. coli* through the incorporation of butyryl-CoA instead of propionyl-CoA as the primer unit (23). *E. coli* was engineered to produce high levels of butyryl-CoA from butyrate in a strain that generated the (2S)-methylmalonyl-CoA extender unit from the mutase/epimerase pathway (7). By producing (2S)-methylmalonyl-CoA from succinyl-CoA (and not propionyl-CoA via PCC), propionyl-CoA could be effectively removed from the system. Because the DEBS loading domain prefers propionyl-CoA over butyryl-CoA by at least a factor of 10 (23, 30, 33), eliminating competition between propionyl-CoA and butyryl-CoA for the DEBS loading domain was crucial for efficient utilization of butyryl-CoA by DEBS and successful heterologous production of compound 5.

As discussed in section 26.1.4, 6dEB analogs produced in *E. coli* or *S. coelicolor* are fed to a bioconversion strain of *S. erythraea* to produce the corresponding bioactive erythromycin analogs. As a step toward developing a single-host system for the production of erythromycin analogs, Gramajo and colleagues introduced into *E. coli* all of the downstream activities required to convert 6dEB into erythromycin (43, 44). The complete erythromycin production system consisted of 23 heterologous genes and five different plasmids in the K-207-3 strain background. Two plasmids (pBP130 and pKOS207-129) carried the DEBS genes; two other plasmids (pKOS452-53e and pKOS452-54) contained genes required for sugar biosynthesis and glycosyl transfer, P450-dependent hydroxylations, and erythromycin resistance (*ermE*). The fifth plasmid (pGro7) contained the *groEL* and *groES* chaperone genes, the products of which form a complex to promote proper folding of one or more of the heterologously expressed proteins (Table 2). Although the final erythromycin titers in this system were low (~0.4 mg/liter of erythromycin C), the demonstration of heterologous erythromycin production is a crucial first step toward the development of more efficient *E. coli* strains to accelerate the discovery of new antibiotics.

26.2.5. Epothilone

The successful heterologous production of epothilones C and D in *E. coli* serves an illustrative example of the application of synthetic biology to metabolic engineering (see also section 26.3 for further elaboration) (42). The entire epothilone gene cluster (55 kb) was redesigned and synthesized to allow for facile genetic manipulation and optimized gene expression in *E. coli*. Because it was not possible to express the largest epothilone protein, EpoD (765 kDa), this protein was divided into two parts (*epoD*₁ and *epoD*₂) containing cognate interaction domains. Such domains facilitate protein-protein interaction between the two halves of EpoD, thereby reconstituting the intact protein. The strategy is employed by natural PKS proteins (such as DEBS) to ensure that the correct molecular assembly line is formed (11, 12, 55). A similar strategy has been employed for production of the ansamycin polyketide precursor in *E. coli* (59). The complete *E. coli* epothilone expression system comprised four plasmids, including a plasmid that carried molecular chaperone genes *groES-groEL*, *dnaK*, *dnaJ*, *grpE*, and *tig* (encoding a trigger factor), in strain K431-37-2A (a derivative of K-207-3). Although the titers of epothi-

lones produced in *E. coli* were low (<1 µg/liter), the work demonstrates proof of concept and provides a basis for titer improvement, as well as a platform for further investigation of epothilone PKS biochemistry and enzymology.

26.3. APPLICATION OF SYNTHETIC BIOLOGY TO POLYKETIDE BIOSYNTHESIS IN *E. COLI*

Recently, custom gene synthesis (yielding >200 bp) has become more affordable, and the lead time for delivery of synthetic fragments has improved significantly. It is now practical to consider a totally synthetic route to the engineering of *E. coli* cell factories for the production of polyketides and other natural products. Indeed, as described above, DEBS and epothilone synthase are two examples of megaenzymes (encoded by DNA sequences of >30 kb) whose genes were resynthesized to facilitate genetic manipulation and expression. Advantages of the synthetic approach include (i) tailoring of the gene's codons to the host's tRNA and G+C biases, (ii) removal and/or addition of restriction sites to facilitate cloning and modular design, (iii) addition of epitope or fusion tags for protein purification and/or protein detection, (iv) the ability to clone any gene starting with only the protein coding sequence, and (v) avoidance of potential recombination between highly homologous sequences often found in PKS genes (for an example, see reference 16).

Custom gene synthesis, together with user-friendly *E. coli* expression systems, has been a powerful tool for studies of PKS specificity, modularity, and flexibility. In the work of Menzella et al., a library of PKS coding sequences were synthesized, unique common restriction sites were engineered in strategic locations between domains to facilitate cloning and modularity, and linker regions were added to mediate module-module assembly (38). Individual modules carried on compatible plasmids with unique antibiotic restriction markers were expressed in *E. coli* K-207-3 in pairwise combinations, and the functionality of bimodular pairs was assessed by measuring the formation of the expected triketide lactone. Those module pairs that were active in the first round of screening were combined with a third module in the next round of screening, and functional trimodular combinations were assessed by assaying for tetraketide formation (37). These experiments laid the foundation for the development of a generic strategy to produce complex polyketides in *E. coli* by modular assembly of novel PKSs.

26.4. SUMMARY AND PROSPECTS

The development of heterologous polyketide production systems in *S. coelicolor* and *E. coli* is a significant step toward establishing generic microbial cell factories for the production of therapeutically important polyketides. The versatility of the platform is underscored by the fact that a number of different polyketides have been successfully produced in these systems—from the simple polyketide 6-MSA to the complex hybrid polyketide/nonribosomal peptide epothilone. Progressing from a generic polyketide production system to one that is tailored to high-level production of an individual polyketide may require additional development, including process improvement, further strain engineering, and/or random mutagenesis. The iterative cycle of random mutagenesis and screening, followed by rapid whole-genome sequencing of improved clones to identify positive

causative mutations, is a potentially powerful approach for the rapid engineering of high-producing strains from generic predecessors. The random-mutagenesis/reverse-engineering approach is particularly attractive for hosts such as *E. coli*, a microorganism that is particularly amenable to high-throughput cultivation and rapid genome sequencing.

The availability of heterologous *E. coli* production systems, together with recent advances in synthetic biology, has accelerated studies of PKS modularity and specificity. In recent work, Menzella and coworkers have begun to build a library of synthetic PKS modules and to elucidate a basic set of rules or a code linking polyketide assembly with PKS module-module activity and connectivity (37, 38). With further refinement of the connectivity rules, it is anticipated that virtually any polyketide can be produced in *E. coli* by coexpression of a suitable set of synthetic PKS modules.

Genetic Engineering of Acidic Lipopeptide Antibiotics

RICHARD H. BALTZ, KIEN T. NGUYEN, AND DYLAN C. ALEXANDER

27

27.1. INTRODUCTION

Lipopeptide antibiotics are produced by actinomycetes, bacilli, and fungi. The clinically useful lipopeptide antibacterial agents include the basic or cationic polymyxins produced by *Bacillus* sp. (36) and the acidic, Ca^{2+} -dependent daptomycin produced by *Streptomyces roseosporus* (2, 9, 23), which acts as a cationic peptide when bound to Ca^{2+} (8, 59). The antifungal echinocandins are produced by several fungal species (64).

The biosynthesis of lipopeptides has been studied most extensively in the actinomycetes, where the gene clusters for daptomycin, A54145, calcium-dependent antibiotic (CDA), and friulimicin have been cloned, sequenced, and analyzed (6, 31, 44, 45, 48). Other related lipopeptide antibiotics produced by actinomycetes have been reviewed (9, 61) and will not be discussed here. Biosynthesis of the peptide portions of these molecules is carried out by nonribosomal peptide synthetases (NRPSs). The mechanisms of assembly of peptides by NRPSs are now fairly well understood (21, 56). NRPSs are often composed of several very large protein subunits that carry out multiple enzymatic functions. Each protein subunit often contains several modules comprising three or more enzymatic functions required for processing specific amino acids. Typical modules have three enzymatic domains: a condensation (C) domain for coupling amino acids, an adenylation (A) domain for binding and activating specific amino acids, and a thiolation (T) domain for tethering activated amino acids and growing peptides to a phosphopantetheine swinging arm. Some modules contain additional domains, such as an epimerase (E) to convert *L*-amino acids to their corresponding *D*-isomers or a methyltransferase (M) to *N*-methylate specific amino acids. Also, the final module often has a thioesterase (TE) domain to cleave and, in the case of cyclic peptides, cyclize the completed peptide chain. Typical extension modules are structured as C-A-T, C-A-T-E, C-A-M-T, or C-A-T-TE. Some starter modules have A-T didomains. The individual enzymatic domains are connected by interdomain linkers, and individual subunits of NRPS multienzymes are held together by interpeptide docking sequences (21, 56). In cyclic acidic lipopeptides such as daptomycin and A54145 (Fig. 1), the biosynthesis is initiated by the coupling of a long-chain lipid to the *N*-terminal Trp_1 by a special C^{III} domain (Fig. 2; 44), or F_{CL} , indicating that it couples a fatty acid to an *L*-amino acid.

Because there are no examples of genetic engineering of polymyxins in bacilli or of echinocandins in fungi, this chapter is restricted to the genetic engineering of the daptomycin and A54145 biosynthetic pathways. These two pathways are of particular note because their biosynthetic machinery may provide a means to generate novel lipopeptides to address the one currently understood shortcoming of daptomycin. Daptomycin is very effective at treating skin and skin structure infections (2) and bacteremia and right-sided endocarditis caused by *Staphylococcus aureus* (23), but is not effective at treating *Streptococcus pneumoniae* pulmonary infections (53) because it most likely becomes sequestered in surfactant in the lung (8, 57). Thus, improving the antibiotic activity in the presence of pulmonary surfactant can be addressed by combinatorial biosynthesis.

In this chapter, we use the terminology of “genetic engineering” and “combinatorial biosynthesis.” The latter term embraces a broad set of methodologies—including genetic engineering, the use of mutants blocked in specific biosynthetic steps, and the exploitation of natural variations in substrates and feeding unnatural substrates—to expand the numbers of compounds generated beyond what can be achieved by genetic engineering alone (4, 5). These approaches are particularly useful to generate derivatives of complex cyclic peptides that cannot be generated and scaled up economically by medicinal chemistry approaches.

27.2. CLONING OF LIPOPEPTIDE BIOSYNTHETIC GENES

A common method to clone antibiotic biosynthetic gene clusters is to construct a cosmid library and to screen for overlapping cosmids containing the genes of interest by using probes to conserved sequences as entry points. For relatively small antibiotic gene clusters, it is possible to isolate complete biosynthetic gene clusters on individual cosmids. Another approach is to clone antibiotic gene clusters in bacterial artificial chromosome (BAC) vectors, which can accommodate DNA inserts of >100 kb (24, 44; D. C. Alexander, J. Rock, X. He, V. Miao, P. Brian, and R. H. Baltz, in preparation).

27.2.1. Cosmid and BAC Cloning of Daptomycin Genes

S. roseosporus normally produces A21978C factors (Fig. 1). Daptomycin is the *N*-decanoyl derivative produced by

FIGURE 1 Structures of lipopeptide antibiotics and of NRPS subunits. (Top) A21978C factors naturally produced by *S. roseosporus* A21978.6 and A21978.65 (Table 1), and daptomycin, which is produced by feeding decanoic acid during fermentation. (Bottom) A54145 factors naturally produced by *S. fradiae* A54145.

feeding decanoic acid during fermentation (6, 9). The daptomycin biosynthetic gene cluster was localized to one end of the *S. roseosporus* linear chromosome by Tn5099 insertion mutagenesis (42, 43). Tn5099 (30) contains a hygromycin resistance gene (Hm^r) from *Streptomyces hygrosopicus* that can be expressed in streptomycetes and *Escherichia coli*. Thus the DNA segment flanking the Tn5099 insertions in the daptomycin gene cluster was readily cloned in *E. coli* and sequenced to confirm the localization in NRPS domains. The transposon insertions localized the

daptomycin gene cluster to a region centered ca. 450 kb from one end of the linear chromosome and established the direction of transcription of NRPS genes to the chromosome proximal end (43). A cosmid library of *S. roseosporus* DNA prepared in pKC1471 (see Table 1 for a list of key strains and plasmids) was screened using sequences flanking the transposon insertions, and overlapping cosmids were obtained (43). Two overlapping cosmids with large inserts were sequenced, but the inserts did not span the complete daptomycin gene cluster (44).

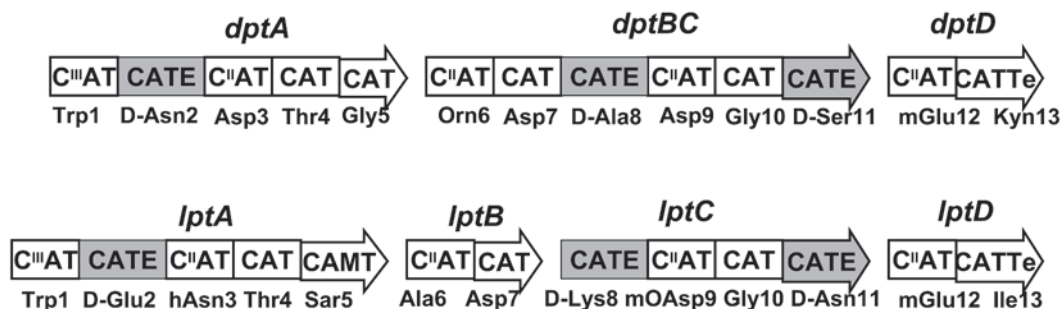

FIGURE 2 Functional organization of NRPS. The condensation domains designated as C (or $^L C_L$), C^{II} (or $^{D,C} C_L$), and C^{III} (or $^{F} C_L$) normally couple L-amino acids, D-amino acids, and long-chain fatty acids to L-amino acids, respectively. The shaded modules show CATE structures followed by C^{II} ($^{P} C_L$) condensation domains. A, adenylation domain; E, epimerase domain; M, methyltransferase domain; T, thiolation domain; TE, thioesterase domain. Figure modified from reference 6.

^cSubmitted, Nguyen et al., submitted.

To complete the sequencing and to facilitate the genetic engineering experiments described below, the complete daptomycin biosynthetic gene cluster was cloned in pStreptoBac V (44), which has the following features: pUC19 (which is removed during the cloning process) for high-copy-number replication in *E. coli*; *sacB* for selection of BACs containing inserts; *oriT* for conjugal transfer from *E. coli* to streptomycetes; *ϕC31 att/int* for stable insertion into streptomycete chromosomes; and an apramycin resistance (Am^r) gene to select for clones containing BACs in *E. coli* and streptomycetes. To prepare a BAC library, *S. roseosporus* cells were grown overnight in 25 ml of medium F10A (see section 27.7 for media composition), washed, and embedded in 1% Seakem GTG agarose. Agarose plugs were incubated in 2 mg/ml lysozyme for 2 h, then transferred to a solution of 0.2 mg/ml proteinase K and 1% sarcosine (wt/vol) and incubated at 50°C overnight to release high-molecular-weight genomic DNA. Agarose plugs were washed in 0.1 mM EDTA and treated with BamHI. Partially digested DNA was separated by pulsed-field gel electrophoresis, and 200 ng of DNA in the range of 75 to 145 kb was recovered by electroelution and then ligated to BamHI-digested, dephosphorylated pStreptoBAC V. The BamHI treatment of pStreptoBAC V releases the fragment containing pUC19, so clones containing large inserts can stably replicate in *E. coli* from the low-copy F replicon of the BAC. BAC clones were introduced into *E. coli* DH10B and screened for Am^r, and ca. 2,000 clones were archived in microtiter plates. Clones containing daptomycin (*dpt*) biosynthetic genes were identified by PCR amplification of segments containing published NRPS sequences from cosmid clones (43); pCV1 was determined to contain the complete *dpt* gene cluster (Fig. 3A), as confirmed by heterologous expression in *Streptomyces lividans* (44, 52; see section 27.4.1.1).

27.2.2. Cosmid and BAC Cloning of A54145 Genes

A cosmid library was prepared in pStreptoCos X (45). pStreptoCos X is derived from SuperCos (Stratagene) and carries *oriT* and *ϕC31 attP/int* functions to facilitate conjugal transfer from *E. coli* to streptomycetes and site-specific integration into streptomycete chromosomal *ϕC31 attB* sites.

Streptomyces fradiae cells were grown in F10A medium and incubated at 30°C with shaking at 200 rpm. Cells were harvested and genomic DNA was released in agarose plugs

as described in section 27.2.1 for *S. roseosporus* (44). DNA was partially digested with BamHI, and fragments of 30 to 60 kb were purified by gel electrophoresis, ligated in the BamHI site of pStreptoCos X, then packaged with Gigapack III Gold packaging extract (Stratagene). Packaged DNA was introduced into *E. coli* XL1-Blue-MR, and a library was screened using a PCR product amplified from an NRPS sequence from the daptomycin gene cluster (43). Cosmid clones flanking the original clone were obtained by walking, and the genes were sequenced and assembled (44).

A pECBAC1 (24) library of *S. fradiae* DNA was constructed in *E. coli* DH10B by Amplicon Express (Pullman, WA), using Sau3AI-digested genomic DNA purified from *S. fradiae* protoplasts embedded in agarose as described in section 27.2.1, and the DNA was inserted into the BamHI-digested pECBAC1. BAC clones believed to contain the complete *lpt* biosynthetic gene cluster were identified by PCR screening with primer sets specific for *orf21* upstream of the cluster and *lptI* gene at the downstream end of the cluster (45). pCB01 was chosen for further work because it had the largest insert (>100 kb; Fig. 3). It was further modified for conjugal transfer and site-specific insertion in streptomycetes by inserting a cassette containing the Am^r gene, *oriT* site, and *ϕC31 attP/int* functions, generating pDA2002 (Alexander, Rock, He, et al., in preparation) (see section 27.5.1). pDA2002 was used to produce A54145 factors in *Streptomyces ambofaciens* and *S. roseosporus* (see section 27.4.1.2) and as a starting vector to generate a number of additional vectors containing different sets of the A54145 biosynthetic genes (Table 1; Fig. 3). Similarly, pJR153 contains a cassette containing the Hm^r gene, *oriT* site, and *ϕBT1 attP/int* functions integrated into pCB01 (Fig. 3B).

27.3. ORGANIZATION OF DAPTOMYCIN AND A54145 BIOSYNTHETIC GENE CLUSTERS

In order to design methodology to carry out genetic engineering and combinatorial biosynthesis of novel lipopeptides related to daptomycin and A54145, it was important to understand how the gene clusters are organized and transcribed. Figure 1 shows the structures of daptomycin and A54145. Both are composed of cyclic tridecapeptides with 10 amino acid rings and three exocyclic amino acids coupled to long-chain fatty acids through the N-terminal

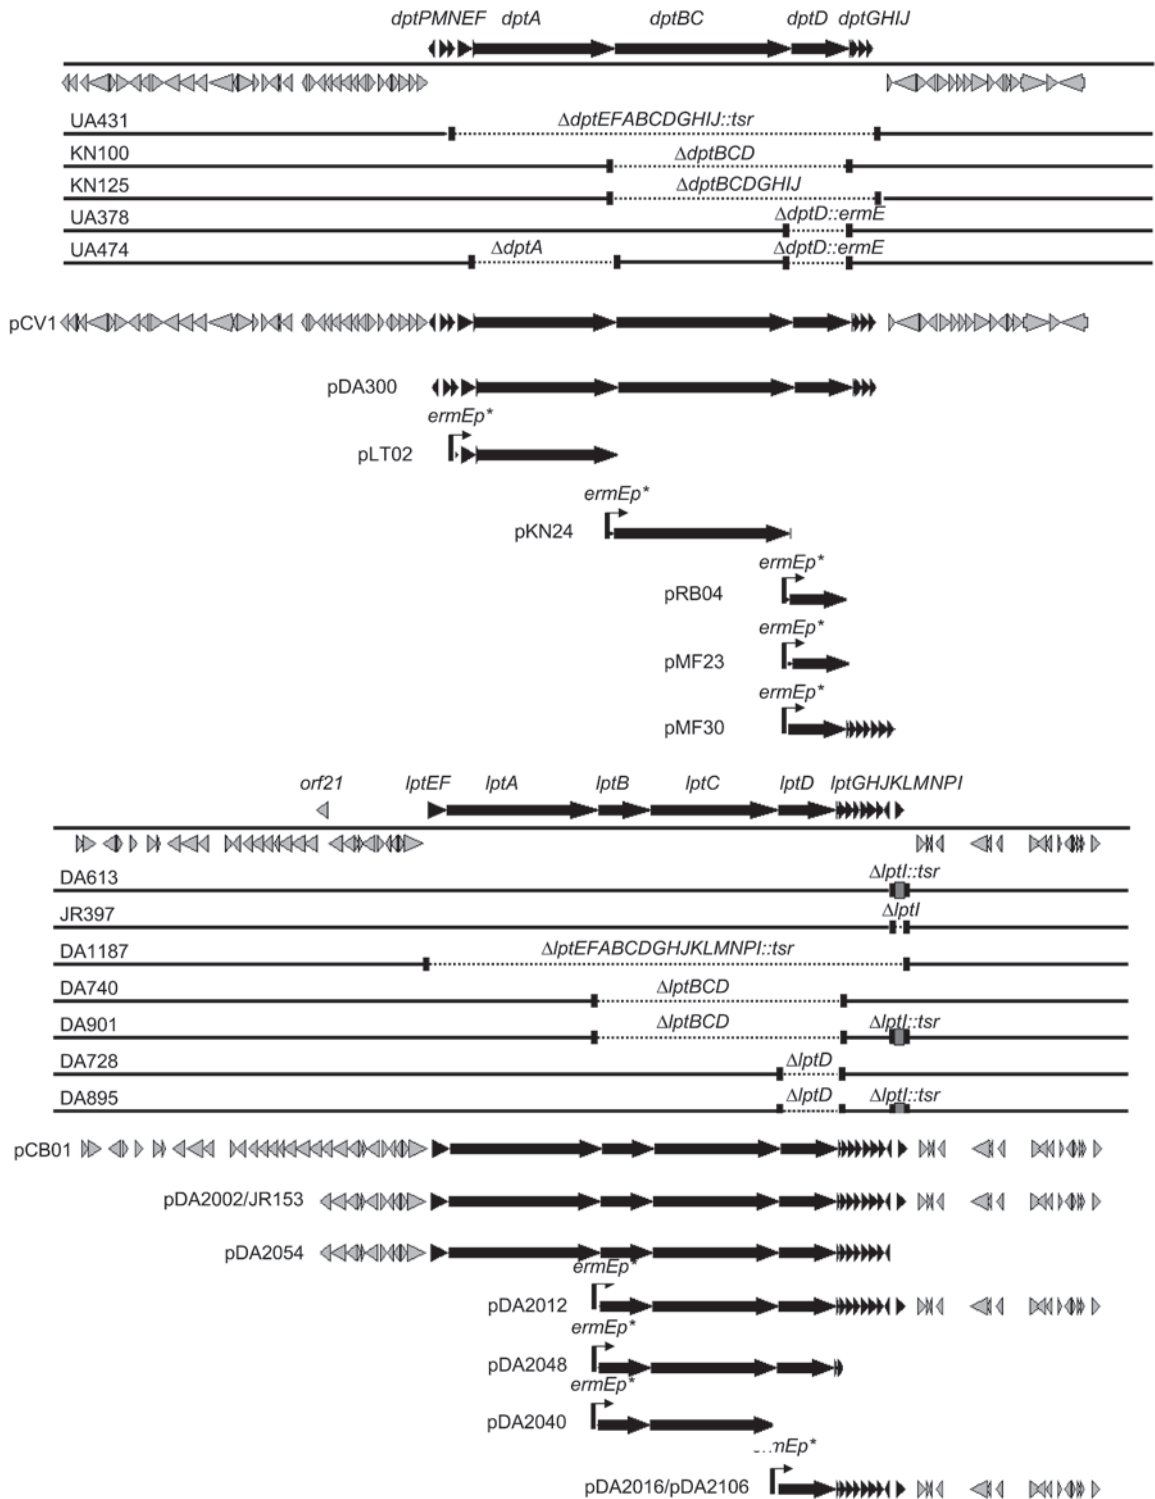

FIGURE 3 Ectopic *trans*-complementation systems for *S. roseosporus* and *S. fradiae*. (Top) The *dpt* genes on BAC pCV1 are shown in black. *S. roseosporus* strains deleted for different *dpt* genes (dotted lines) and plasmids containing different sets of *dpt* genes (pDA300, pLT02, pKN24, and pRB04), *cdaPS3* (pMF23), and *lptD* (pMF30) are also shown (see Table 1 for plasmid details). (Bottom) The *lpt* genes on BAC pCB01 are shown in black, and *S. fradiae* deletion mutants and plasmids for *trans*-complementation are shown below.

Trp₁. Both have D-amino acids at positions 2, 8, and 11 and achiral amino acids, Gly or sarcosine (Sar), at positions 5 and 10. They both have Ca²⁺ binding motifs DXDG at positions 7–10 and 3-methyl-glutamic acid (3mGlu) at position 12, and both cyclize through the hydroxyl group of Thr₄ to form depsipeptides. In spite of their similarities, daptomycin and A54145 have different amino acids at eight positions. In addition to 3mGlu₁₂, A54145 has the modified amino acids hydroxy-Asn₃ (hAsn₃), Sar₅, and methoxy-Asp₉ (mOAsp₉).

Figures 2 and 3 show the biosynthetic gene clusters for daptomycin (*dpt* genes) and A54145 (*lpt* genes). The key genes involved in lipopeptide biosynthesis begin with *dptE* and *dptF* and the fused *lptEF* genes, which encode acyl-coenzyme A ligase and acyl carrier protein functions involved in coupling the long-chain fatty acids to the N terminus of Trp₁ to initiate lipopeptide biosynthesis (6, 63). Immediately downstream are the NRPS genes, starting with *dptA* and *lptA*; both encode proteins containing five modules with the enzymatic functions required to incorporate the first five amino acids. Module 1 of each protein has a C^{III} (^FC_L) condensation domain required for coupling long-chain fatty acids to L-Trp₁. Both proteins have E domains in module 2 to convert L-amino acids to their corresponding D-isomers. LptA has an additional M domain to N-methylate Gly to Sar₅. The next genes are the related *dptBC* and the *lptB* and *lptC* genes that encode the incorporation of the next six amino acids. These genes have E domains appropriately placed for the D-amino acids at positions 8 and 11. Both DptBC and LptB proteins start with C^{II} (^DC_L) condensation domains, which normally follow upstream D-amino acids, even though these follow the achiral Gly and Sar. These ^DC_L domains may be vestiges from an ancestral NRPS pathway that encoded D-amino acids at this position in the ring, as observed in the CDA and friulimycin pathways (6). The final NRPS genes are *dptD* and *lptD*, which encode proteins with two modules for the incorporation of the final two amino acids. The modules for the coupling of 3mGlu₁₂ to the preceding D-amino acids start with ^DC_L condensation domains, and each module 13 terminates with a thioesterase (TE) domain responsible for cyclization and release of the completed lipopeptides. All of the other modules in the NRPS genes from both pathways required for the coupling of L-amino acids to L-amino acids have typical CAT domains starting with ^LC_L condensation domains.

Downstream of the *dptD* gene are *dptG*, *dptH*, *dptI*, and *dptJ*. DptG is a protein of unknown function required for normal production of daptomycin; DptH is an editing thioesterase; DptI is a methyltransferase involved in two-step conversion of α-ketoglutarate to 3mGlu (38); and DptJ is involved in the formation of Kyn. Deletion of *dptG*, *dptH*, *dptI*, or *dptJ* caused reduced lipopeptide production. Deletion of *dptI* also caused the production of daptomycin analogs containing Glu₁₂ and eliminated production of 3mGlu₁₂-containing lipopeptides (49).

Downstream of *lptD* are *lptG* and *lptH*, with functions similar to *dptG* and *dptH*. Further downstream are the *lptJ*, *lptK*, and *lptL* genes, involved in the modification of amino acids. The *lptJ* and *lptK* genes encode oxygenase and methyltransferase enzymes involved in biosynthesis of mOAsp₉, and the *lptL* gene encodes an oxygenase involved in biosynthesis of hAsn₃ (D. C. Alexander, J. Rock, J.-Q. Gu, C. Mascio, M. Chu, P. Brian, and R. H. Baltz, in preparation). LptL is related to the AsnO non-heme Fe²⁺/α-ketoglutarate-dependent L-Asn oxygenase involved in CDA biosynthesis (6, 60). Further downstream are the

lptM, *lptN*, and *lptP* genes, which have homologs *dptM*, *dptN*, and *dptP* located upstream of the *dptE* gene. These genes are likely to be involved in lipopeptide transport and/or resistance. Downstream of *lptP* is the *lptI* gene involved in methylation of α-ketoglutarate in the biosynthesis of 3mGlu. Deletion of *lptI* eliminated production of 3mGlu₁₂-containing lipopeptides and resulted in improved yields of Glu₁₂-containing lipopeptides (Alexander, Rock, He, et al., in preparation).

Much of the daptomycin biosynthetic gene cluster is transcribed as a single >50-kb mRNA molecule (15). This is supported by reverse transcription-PCR across the junctions of the *dptEFABCDGH* genes. The transcript is likely to include the *dptI* and *dptJ* genes, which are just downstream of *dptH* and transcribed in the same direction (44; Fig. 3) but were not included in the reverse transcription-PCR analysis (15). Furthermore, the *dptA*, *dptBC*, and *dptD* genes have overlapping stop and start codons, suggesting that they may be translationally coupled to assure the production of the NRPS proteins in stoichiometric amounts. For example, inspection of the region spanning the TGA stop codon in *dptA* and the GTG start codon in *dptBC* revealed a nucleotide sequence TGGTGAACCGC. The region spanning the TGA stop of *dptBC* and the ATG start of *dptD* has the sequence GGATGACGCAG.

The *lptEFABCDGHJKLMN* genes are transcribed in the same direction, and the *lptA*, *lptB*, *lptC*, and *lptD* genes have overlapping stop and start codons, all using TGA stop codons that overlap with GTG, ATG, and possibly CTG start codons. It is therefore likely that these genes are transcribed as a large multicistronic mRNA, as observed with the *dpt* genes. In this case, however, the *lptP* gene is transcribed in the opposite direction from a different promoter (Fig. 3) and *lptI* is expressed from its own promoter (Alexander, Rock, He, et al., in preparation). The transcriptional organization of the daptomycin and A54145 NRPS genes, with overlapping stop and start codons, poses tactical issues for ectopic expression of specific genes for combinatorial biosynthesis: it is important to excise specific NRPS genes without disrupting the natural transcriptional and translational relationships between the remaining genes.

27.4. EXPRESSION SYSTEMS FOR GENETIC ENGINEERING

There are at least three ways to set up genetic engineering systems for lipopeptides and other complex biosynthetic pathways. The first is to engineer the production of hybrid pathways in a heterologous host by preparing BAC clones containing the complete biosynthetic gene clusters in *E. coli*, engineering the pathway in *E. coli* in any of a number of ways, including λ Red-mediated recombination (18), then transferring the engineered pathway into a heterologous host by conjugation and site-specific integration into the chromosome. The second approach is to delete the complete pathway from a lipopeptide-producing host, engineer the biosynthetic gene cluster on a BAC in *E. coli*, transfer the engineered pathway into the homologous host lacking the genes by conjugation, and insert the genes by site-specific integration into an ectopic chromosomal site. A third approach is to engineer homologous lipopeptide-producing hosts to contain deletions of one or more of the lipopeptide biosynthetic genes, and to express engineered genes from ectopic loci in the chromosome using strong promoters to drive transcription. Each of these approaches is discussed below.

27.4.1. Heterologous Expression of Complete Gene Clusters

27.4.1.1. Daptomycin Production in *S. lividans*

The pStreptoBac V derivative pCV1 containing the complete daptomycin biosynthetic gene cluster was introduced into *S. lividans* strains TK23, TK64 (*str-6*), and TK23-521 (Δ act) by protoplast transformation (44, 52). *S. lividans* strains carrying pCV1 were grown on an A9 agar slant (44; see section 27.7) containing 100 μ g/ml apramycin (Am) for 7 to 10 days at 28°C. A mixed mycelial and spore suspension was made in 4 ml of 0.1% Tween 80, and 2 ml was inoculated into 40 ml of seed medium A345 (44) containing 25 μ g/ml Am in baffled flasks and shaken at 240 rpm and 5-cm orbit at 30°C for 24 to 28 h. Then, 2.5 ml of culture was added to flasks containing 50 ml of medium B (52). Replicate flasks were sampled for lipopeptide production by high-pressure liquid chromatography for 2 to 6 days.

S. lividans TK64 harbors *str-6*, an *rpsL* mutation that causes the K88E substitution in ribosomal protein S12 that enhances actinorhodin (Act) production in *S. lividans* TK24 (51). The introduction of pCV1 caused the production of A21978C factors in both TK64 and TK23, accompanied by high-level production of Act and CDA factors in both cases. The production of Act interfered with the quantification of A21978C factors. Part of the Act gene cluster was deleted, and the resulting strain, *S. lividans* TK23-521 (52) containing pCV1, produced about 20 mg/liter of A21978C_{1,3}. When medium B was supplemented with 3 g/liter K₂HPO₄, A21978C_{1,3} levels increased to 55 mg/liter at 72 h and were readily separated from the phosphorylated CDAs. Further development of this system would benefit from the deletion of the CDA gene cluster.

27.4.1.2. A54145 Production in *S. ambofaciens* and *S. roseosporus*

S. ambofaciens normally produces the 16-membered macrolide antibiotic spiramycin and the pyrrole-amidine oligopeptide antibiotic netropsin. *S. ambofaciens* is a potentially useful host for heterologous expression because it is relatively nonrestricting for bacteriophage and plasmid DNA (17, 39), and stable mutants defective in spiramycin production are available (22, 54; Table 1). *S. ambofaciens* BES2074, which is defective in spiramycin and netropsin biosynthesis (54), and *S. roseosporus* UA431, which is deleted for the daptomycin biosynthetic gene cluster (50), were used for heterologous expression of A54145.

S. roseosporus and *S. ambofaciens* strains were grown for 24 to 48 h in Trypticase soy broth (TSB), homogenized, centrifuged at 800 \times g for 10 min, resuspended in TSB, centrifuged again at 800 \times g for 10 min, then resuspended in TSB and chilled on ice. *E. coli* donor strains were grown overnight, diluted 1:40 into 10 ml of fresh LB broth plus appropriate antibiotics, and grown for 2 to 3 h. *E. coli* cultures were pelleted by centrifugation, washed with LB broth, pelleted by centrifugation, resuspended in 2 ml of LB broth, and mixed with mycelial fragments of *S. ambofaciens* or *S. roseosporus* in volume ratios of 1:4 and 4:1. Finally, 0.1 ml of the mix was plated onto AS-1 agar (section 27.7) supplemented with 10 mM MgCl₂ (12) for *S. roseosporus* or onto AS-1 agar supplemented with 10 mM MgCl₂ and 20 mM TES [N-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid] (pH 7.6) (1) for *S. ambofaciens*. Conjugation plates were incubated at 30°C for 18 to 24 h, then overlaid with 2.5 ml of NB soft agar (34) containing nalidixic acid (Nal) (50 μ g/ml final bottom agar concentration) to select against

E. coli and Am (50 μ g/ml final bottom agar concentration) to select for the *S. roseosporus* and *S. ambofaciens* strains containing pDA2002. Colonies were patched onto mR2YE agar plates containing Am (50 μ g/ml) and Nal (50 μ g/ml).

S. roseosporus and *S. ambofaciens* strains containing chromosomal insertions of pDA2002 containing the A54145 gene cluster were grown for 48 h in TSB as starter cultures, and for 48 h in A355 seed medium. Fermentations were carried out in DSF medium (13) plus 0.79% (wt/vol) L-Ile. Fermentations were harvested by centrifugation of whole broth at 24,000 \times g for 30 min at 4°C, and product yields were determined as described (Alexander, Rock, He, et al., in preparation). *S. roseosporus* DA1155 produced about 100 mg/liter of A54145 lipopeptides and *S. ambofaciens* DA1164 produced about 390 mg/liter, or 88% of the *S. fradiae* control (Alexander, Rock, He, et al., in preparation). These results indicated that either of these relatively easily manipulated strains would be a suitable host for the engineering of A54145 biosynthetic genes. It is likely that the yields can be further improved by fermentation medium development, as has been demonstrated with the *S. lividans* strain that produces daptomycin.

27.4.2. Expression of Individual Genes or Sets of Genes in Lipopeptide Producers

27.4.2.1. Genetic Manipulation of *S. roseosporus* and *S. fradiae*

Most streptomycetes produce restriction endonucleases that interfere with bacteriophage plaque formation, and often retard or block the introduction of plasmid DNA by protoplast transformation (3, 17, 39). *S. roseosporus* appears to exhibit relatively mild restriction of bacteriophage plaque formation. Ten of 11 broad-host-range streptomycete bacteriophages formed plaques on *S. roseosporus* (42). FP43 did not form plaques, but was able to transduce plasmid DNA containing the FP43 *pac* sequence (41) into *S. roseosporus* (42), indicating that FP43 can attach and inject DNA, but that FP43 phage DNA is restricted.

Because *S. roseosporus* expressed some restriction for double-stranded DNA, protoplast transformation was not pursued. Instead, conjugal transfer of plasmid DNA from *E. coli* was developed (42, 43). Plasmids were first introduced into *E. coli* S17-1 by standard transformation. *S. roseosporus* cells were grown at 29°C for 16 h in TSB from a 2% (vol/vol) inoculum of stationary-phase cells, washed by centrifugation, and resuspended in an equal volume of TSB. *E. coli* donor strains were grown overnight at 37°C in TY broth, diluted 1:10 into 10 ml of fresh TY broth plus appropriate antibiotics, and grown for 2 to 3 h. Cells were pelleted by centrifugation, washed with an equal volume of TY broth, pelleted again by centrifugation, and resuspended in 2 ml of TY broth. *E. coli* and *S. roseosporus* cells were mixed in ratios of 1:9, 5:5, and 9:1, spread on AS-1 agar, incubated at 29°C for 18 h, and overlaid with NB soft agar containing Nal plus Am or Nal plus hygromycin (Hm) to give final bottom agar concentrations of 20 μ g/ml Nal, 100 μ g/ml Am, or 400 μ g/ml Hm to select against *E. coli* (Nal) and for *S. roseosporus* transconjugants containing plasmids expressing Am^r or Hm^r. Maximum efficiency (>10⁻⁵ transconjugants per recipient) was obtained when equal volumes of donor and recipient (~10⁷ CFU each) were plated on AS-1 agar. Conjugations were also carried out on B agar with very poor results (42), emphasizing the importance of AS-1 agar for carrying out the intergeneric matings.

Plasmid DNA can also be introduced into *S. fradiae* spore germlings by conjugation from *E. coli* (Alexander, Rock, He, et al., in preparation). *S. fradiae* frozen spores were thawed and centrifuged at $800 \times g$ for 10 min, washed with 1 ml of spore germination medium (34), and recentrifuged. Spores were resuspended in 0.5 ml of germination medium, heat shocked at 50°C for 10 min, then added to 10 ml of germination medium and shaken at 30°C for 2 to 4 h. The spore suspension was centrifuged at $800 \times g$ for 10 min, washed with 10 ml of LB broth, centrifuged again, resuspended in 10 ml of LB broth, and placed on ice. *E. coli* cells grown in LB broth (section 27.4.1.2) were mixed with *S. fradiae* spore germlings in volumetric ratios of 1:4 and 4:1. The conjugation mix (0.1 ml) was plated onto ISP4 agar (Difco) supplemented with 10 mM MgCl₂. Plates were incubated at 30°C for 18 to 24 h, then overlaid with 3 ml of R2 modified soft agar (40) containing trimethoprim (Tmp), to select against *E. coli* donor strains, and thiostrepton (Tsr), neomycin (Nm), Am, or Hm to select for transconjugants. The final antibiotic concentrations in bottom agar were 50 µg/ml (Tmp), 10 µg/ml (Tsr), 10 µg/ml (Am), 10 µg/ml (Nm), or 150 µg/ml (Hm). *S. fradiae* colonies were picked after 4 to 6 days of incubation at 30°C and patched onto mR2YE agar plates (34) containing the appropriate antibiotics.

27.4.2.2. Isolation of Deletion Mutations in *S. roseosporus* and *S. fradiae*

The generation of mutants of *S. roseosporus* and *S. fradiae* deleted for one or more of the daptomycin (*dpt*) and A54145 (*lpt*) biosynthetic genes, respectively, was facilitated by the use of pRHB538 (Table 1), a vector that can be used for dominance selection (32). This method exploits the dominance of streptomycin susceptibility (*Sm*^s) over resistance (*Sm*^r). For instance, a strain carrying a chromosomal *Sm*^r mutation in the *rpsL* gene and a wild-type (*Sm*^s) allele on a plasmid is phenotypically *Sm*^s. If the wild-type *rpsL* gene is located on a temperature-sensitive plasmid containing cloned DNA segments flanking a gene to be deleted, then insertion of the plasmid into the chromosome by a single crossover can be facilitated by growing cells at the nonpermissive temperature and selecting for an antibiotic resistance marker on the plasmid. The second crossover, deleting the gene of interest, can be selected by growth on a medium containing *Sm* at the nonpermissive temperature for plasmid replication. This system has been used to isolate deletion mutations in the daptomycin and A54145 biosynthetic gene clusters. For example (44), a *dptD* deletion was generated in *Sm*^r *S. roseosporus* UA117 (*rpsL7*) by PCR amplifying 1.1- and 1.5-kb segments of DNA flanking the *dptD* gene and constructing a *dptD-ermE-dptD* cassette for deletion and insertion of the *ermE* (erythromycin resistance [*Erm*^r]) gene. The cassette was inserted into pRHB538, which has *oriT*, *rep*^{ts}, *rpsL* (*Sm*^s), and *Am*^r for selection. The plasmid was introduced into *E. coli* ML22 by electroporation, then transferred to UA117 by conjugation. Transconjugants were selected for *Am*^r, then grown at 38°C to cure the plasmid and plated on AS-1 agar containing *Sm*. *Sm*^r colonies were then screened for *Erm*^r (gene replacement) and *Am*^s (loss of plasmid) and strains with the correct phenotype were confirmed by Southern hybridization analysis and loss of daptomycin production. Other mutants containing markerless in-frame deletions of different sets of *dpt* genes (Fig. 3) were isolated directly from colonies containing single crossovers after growth at room temperature (49). In one case, the *dptA* gene was deleted and the strong constitutive promoter *ermEp*^{*} was inserted in front of the downstream *dptBC* gene (15).

S. fradiae mutants deleted for different combinations of *lpt* genes were generated in a similar manner, but without the use of positive selection. For example, *lptI* deletion mutants (Δ *lptI::tsr*) were generated using pJC12, a pRHB538 plasmid with ~2-kb DNA segments upstream and downstream of the *lptI* gene flanking the *Tsr*^r cassette. Recombinants containing pJC12 were grown in CSM broth plus *Tsr* and *Tmp* at 30°C. Strains were homogenized, inoculated into fresh CSM plus *Tsr*, grown at 38°C for 48 h, homogenized again, diluted, and grown for 48 h on mR2YE agar with *Tsr*. Colonies were screened for loss of pJC12 (*Am*^s) and presence of *lptI* replacement mutation (*Tsr*^r) by patching mycelia onto mR2YE agar containing *Tsr* or *Am*, and *lptI* deletions were confirmed by PCR. Mutants deleted for *lptD*, *lptBCD*, and *lptEFABCDGHIKLMNPI* (*lptEF-1*) were also generated by this procedure (Alexander, Rock, He, et al., in preparation) (Table 1 and Fig. 3).

27.4.2.3. Ectopic *trans*-Complementation in *S. roseosporus* and *S. fradiae* and Fermentation Analysis of Recombinants

To develop efficient systems for genetic engineering and combinatorial biosynthesis, it was desirable to engineer individual NRPS and other genes separately and to recombine the altered genes or gene cassettes in different combinations, using the *S. roseosporus* and *S. fradiae* deletion mutants (section 27.4.2.2) as expression hosts. Because the daptomycin and A54145 NRPS genes were both likely to be transcribed as single giant polycistronic mRNAs that are translated with overlapping stop and start codons, combinatorial biosynthesis required some additional steps to ensure success. These steps would not be necessary for smaller monocistronic genes each with its own promoter. Due to the possibility of a polar mutation affecting downstream gene function in the operon, markerless in-frame deletions were generated in most cases (50; Alexander, Rock, He, et al., in preparation). It was also necessary to engineer heterologous promoters in front of NRPS genes for complementation experiments because it was not likely that they possessed their own promoters. The individual genes were excised and expressed from different loci in the host chromosomes. To accomplish this, three different site-specific integrating plasmid vectors were used. Two of them utilize the *attP/int* genes from the streptomyces bacteriophages ϕ C31 and ϕ BT1 (12, 27, 35). The other uses the *att/int* functions from IS117 (34, 47). Another important element in the experimental design was to express the genes from the ectopic loci from the strong constitutive *ermEp*^{*} promoter (10, 11). This promoter has been used successfully to drive high-level expression of cloned genes in other streptomycetes (4, 5, 58).

To test the feasibility of expressing different daptomycin and A54145 genes at different chromosomal sites, reconstruction experiments were carried out with the lipopeptide genes being expressed at up to three different loci. *S. roseosporus* recombinants were tested for the production of A21978C factors after fermentation. Fermentations were carried out in 20 ml of broth in 125-ml baffled flasks at 30°C and 200 rpm, 5-cm orbit. Starter cultures were grown in TSB for 48 h, and then 1 ml of culture was transferred to medium A355 (44) and grown for 24 h. One milliliter was transferred to F10A or A346 production medium, and fermentations were carried out for 6 days. Lipopeptide yields were determined by high-pressure liquid chromatography analysis (44). *S. fradiae* strains were grown for 24 h in CSM broth (32) containing the appropriate antibiotics. One milliliter of culture was

TABLE 2 *Trans*-complementation systems in *S. roseosporus* and *S. fradiae* to express daptomycin and A54145 biosynthetic genes from different chromosomal sites

	–	<i>lptABCD</i> ⁺	–	–	107	In prep
	–	–	<i>lptABCD</i> ⁺	–	122	In prep
	<i>lptA</i>	<i>p*lptBCD</i> ⁺	–	–	82	In prep
	<i>lptA</i>	<i>p*lptBC</i>	<i>p*lptD</i> ⁺	–	85	In prep

^aAll lipopeptide genes other than those expressed at ectopic loci are expressed from the native locus for daptomycin. For A54145, the complete set of *lpt* genes (–) or all genes downstream of *lptA* (+) were deleted from the native locus and present on complementing plasmids. Genes were expressed on native or *ermEp*^{*} (*) promoters.

^bControl daptomycin and A54145 lipopeptide yields were 340 mg/liter (15) and 480 mg/liter (Alexander, Rock, He, et al., in preparation), in *S. roseosporus* UA1117 and *S. fradiae* XH25, respectively.

^cIn prep, Alexander, Rock, He, et al., in preparation.

transferred to a 125-ml baffled flask containing 25 ml of A355 medium (44) and grown at 30°C for 24 h at 200 rpm, 5-cm orbit. Two milliliters of culture was transferred to a 250-ml baffled flask containing 50 ml of DSF production medium (14) plus 0.79% L-Ile. A54145 factor yields were determined by high-pressure liquid chromatography analysis (Alexander, Rock, He, et al., in preparation). Table 2 shows that the strain that expressed the *dptD* gene from the IS117 site under the control of the *ermEp*^{*} promoter produced about 96% of the control yield. The strain that expressed the *dptBC* gene from the native locus and the *dptA* and *dptD* genes from the ϕC31 and IS117 sites, respectively, each transcribed from the *ermEp*^{*} promoter, produced about 79% of the control yield. Likewise, when *dptA* was expressed from the native site and *dptBC* and *dptD* from the ectopic sites, all three under the control of *ermEp*^{*}, the recombinant produced 50% of control. These results indicate that it is feasible to express the three NRPS genes from three different loci without sacrificing substantial yield, thus providing a system to express independently engineered NRPS genes combinatorially.

In *S. fradiae*, it was shown that the complete A54145 biosynthetic pathway can be deleted from the native locus and expressed from the ϕC31 or ϕBT1 *attB* sites without sacrificing lipopeptide yield (Alexander, Rock, He, et al., in preparation). In both cases, the recombinants produced more than 100% of the control yield (Table 2), indicating that both insertion sites are neutral if not positive for lipopeptide production. The suitability of using these sites for combinatorial biosynthesis was confirmed by expressing the *lptA* gene from the native locus and the *lptBC* and *lptD* plus downstream genes from the ectopic loci. The recombinant produced 85% of control lipopeptides (Table 2). The ability to express the complete A54145 biosynthetic pathway efficiently from three different chromosomal sites also suggests the possibility of making pathway duplications and triplications for yield enhancement.

27.5. GENETIC ENGINEERING AND COMBINATORIAL BIOSYNTHESIS OF NOVEL LIPOPEPTIDES

27.5.1. Engineering BAC Clones by λ Red-Mediated Recombination in *E. coli*

Over the past 3 decades, the ability to manipulate antibiotic-producing actinomycetes has become significantly easier and faster, allowing for more sophisticated strain constructions. Some early key milestones were the development of (i) bifunctional plasmids and resistance markers for use in both *E. coli* and actinomycetes; (ii) site-specific integration plasmids; and (iii) intergeneric conjugation from *E. coli* to actinomycetes. All of these properties were represented in a series of plasmids generated at Eli Lilly and Co. (12). The ability to do the majority of the cloning work in *E. coli* allows for significant gains in efficiency because of the much faster growth rate, very robust methods of transformation, and an expanded repertoire of molecular genetic tools (55).

No *E. coli* tool has changed the way actinomycete strain engineering is currently carried out more dramatically than has high-frequency homologous recombination of PCR products using the λ Red or RecET systems (18). Traditional gene replacement experiments in *E. coli* rely on *recA*-dependent homologous recombination, which requires ~1 kb of homologous sequences flanking the region to be exchanged for efficient recombination. This is time-consuming because DNA sequencing is required to confirm the accuracy of cloned PCR products, and multiple steps at nonpermissive growth temperatures or with counterselections are needed to generate mutants with double crossovers. With λ Red-mediated recombination, the number of steps is reduced dramatically, allowing for gene replacements to be completed in *E. coli* within a week. An antibiotic resistance marker is PCR amplified with primers containing 40- to 50-nucleotide extensions that are

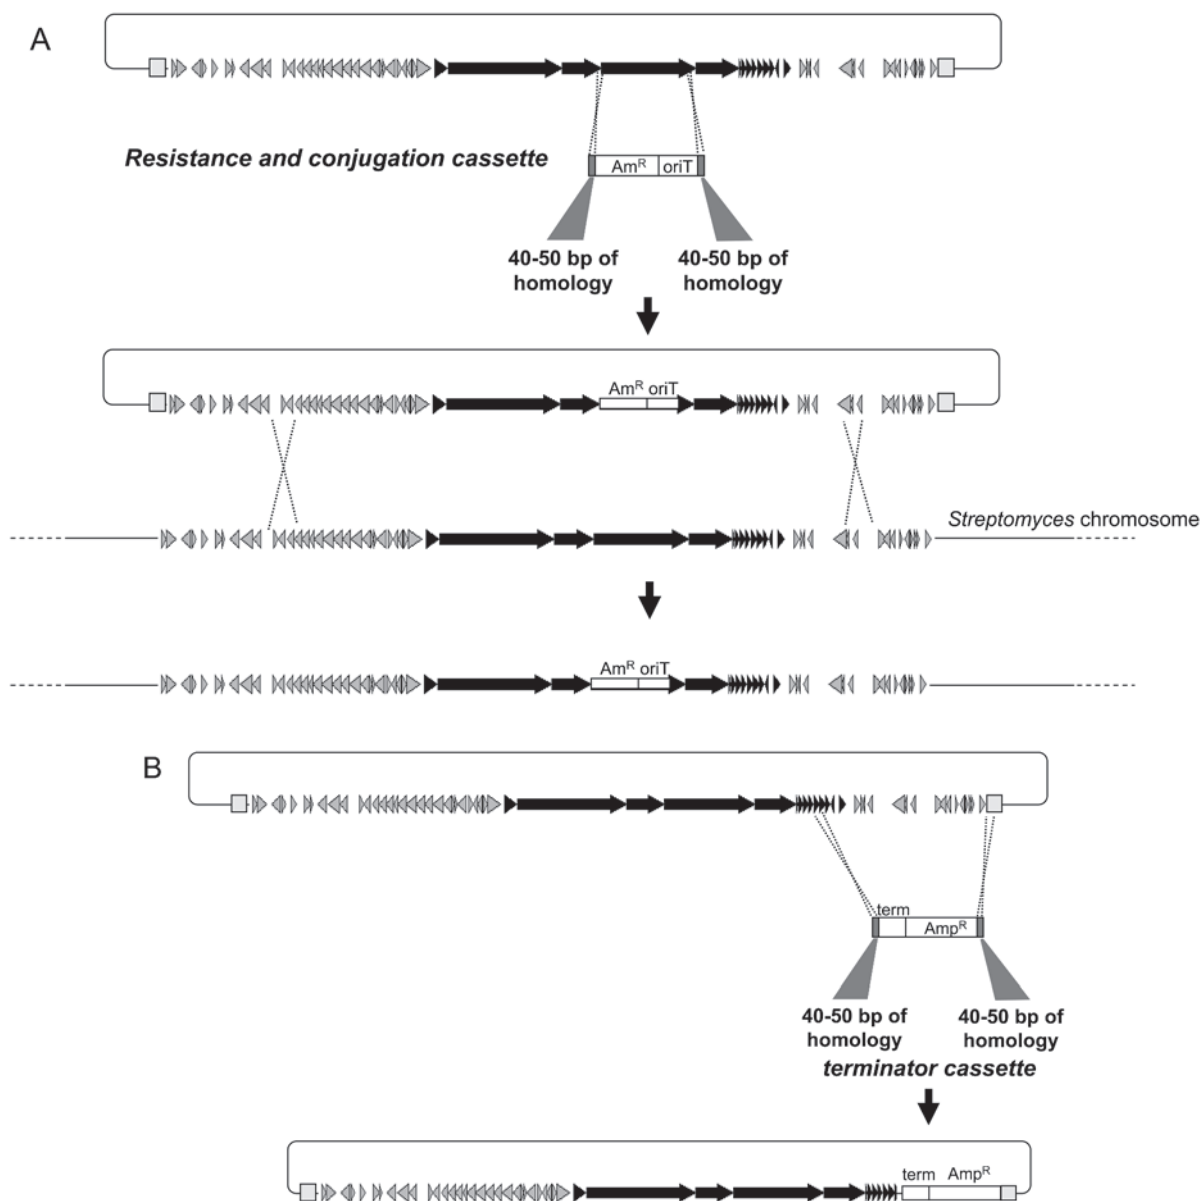

FIGURE 4 λ Red-mediated recombination in *E. coli*. (A) BAC pCB01 containing the complete *lpt* gene cluster is engineered to delete *lptC* by λ Red-mediated insertion of an Am^R -*oriT* cassette. The recombinant BAC can be transferred to *Streptomyces* by conjugation via *oriT*, and recombinants can be selected for Am^R . Other manipulations include (B) the insertion of a terminator cassette, (C) deletion and insertion of a promoter, and (D) insertion of a conjugation/integration cassette. (continued)

homologous to the gene to be disrupted. The PCR product is introduced by electroporation into cells induced for λ Red expression, and colonies are selected for antibiotic resistance. Recombination can be carried out in a strain that contains cosmid or BAC vectors containing parts or all of a biosynthetic gene cluster, so it provides a simple and efficient way to disrupt or modify specific genes. For example, λ Red recombination was used to trim BAC pCV1 to generate pDA300, which contains the minimal daptomycin gene cluster (Fig. 3). The first recombination event utilized the Am^R gene flanked by regions of homology for genes downstream of the daptomycin cluster to remove ~ 26 kb of DNA, thus generating pDA299. The second recombination utilized a spectinomycin resistance (Spc^R) gene flanked by

regions of homology for genes upstream of the daptomycin cluster to remove ~ 46 kb of DNA, generating pDA300.

Gust and colleagues (29) capitalized on this technology to rapidly generate gene disruptions in *Streptomyces* using cosmids. Their method required the PCR amplification of a bifunctional resistance gene and the origin of transfer (*oriT*) with extensions of homology targeting a specific gene present on a cosmid. This technology has been extended to BAC clones (as illustrated in Fig. 4A, which shows how the resistance cassette was inserted into the *lptC* gene to generate a deletion mutant). The resulting engineered BAC is introduced into *Streptomyces* by conjugation from *E. coli*, but since the BAC lacks *Streptomyces* replication and site-specific insertion functions, it can only confer antibiotic

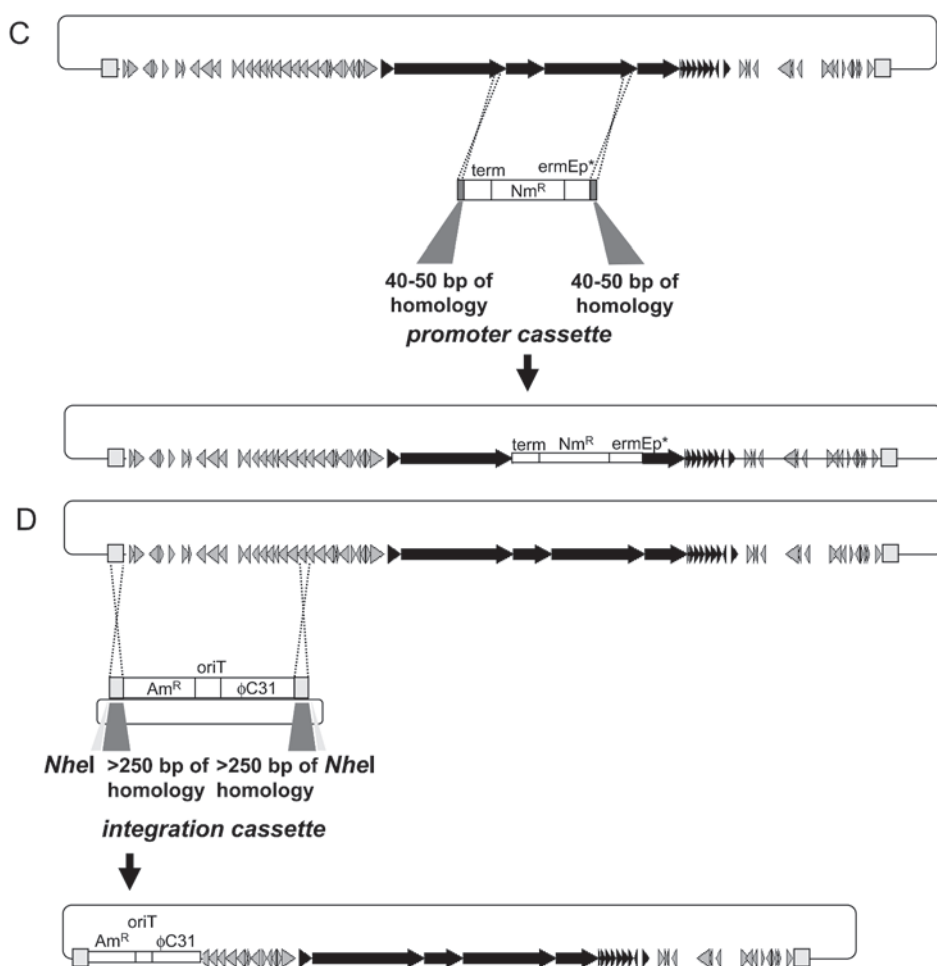

FIGURE 4 (Continued)

resistance by recombination between the regions of homology flanking the antibiotic resistance marker in the BAC and the chromosome. A large percentage of the Am^r *Streptomyces* colonies have undergone double crossovers resulting in allelic exchange; these can be identified by loss of the BAC (or cosmid as in reference 29) resistance marker. This system relies on antibiotic resistance as a selection for allelic exchange and cannot be used directly to generate markerless deletions.

The ability to clone entire biosynthetic pathways in *E. coli* in BAC vectors allows for the complex manipulation of genes needed for pathway engineering or module exchanges. For pathway engineering, a number of tools were created to modify BACs containing antibiotic gene clusters, using λ Red-mediated recombination, beyond the simple insertion of a disrupting antibiotic resistance marker. We designed a terminator cassette containing the λ t_o terminator and the Am^r gene, which is flanked by P1 (TGTGTAGGCTGGAGCTGCTTC) and 1233 (AGCG-GATAACAATTCACACAGGA) primer binding sites (Alexander, Rock, He, et al., in preparation). Primers were designed to contain 40- to 50-nucleotide regions of BAC insert or vector homology plus one of the primer binding sites. PCR-amplified products would recombine and delete genes and place a transcription terminator to stop transcrip-

tion of the biosynthetic gene cluster (Fig. 4B). The terminator cassette has been successfully used to precisely delete small or large regions of DNA for rapid engineering of the A54145 biosynthetic pathway to examine the functions of genes involved in amino acid modifications (Alexander, Rock, Gu, et al., in preparation).

To further extend this concept, a promoter cassette was constructed in which the Nm^r gene or other resistance genes were cloned between the fd phage terminator and the $ermEp^*$ promoter fragments, which are flanked by P1 (TGTGTAGGCTGGAGCTGCTTC) and P3 (CATATGTCCGCCTCCTTTGGTCAC) primer binding sites. The correct positioning of the homologous primer with the start codon in the P3 primer fuses the downstream *lptD* gene with the $ermEp^*$ promoter at the start codon (Fig. 4C). These promoter cassettes have been used successfully to create complementing plasmids for the daptomycin gene cluster (15, 50).

The pCB01 BAC was identified from the *S. fradiae* BAC library by PCR screening and was believed to contain the entire biosynthetic gene cluster. Functional validation of the *lpt* gene cluster on this BAC was not possible because the pECBAC1 vector lacks functions to drive conjugal transfer and chromosomal insertion in *Streptomyces*. To introduce pCB01 into streptomycetes required the addition

of an integration cassette containing the *Am^r* gene, *oriT* site, and ϕ C31 *attP/int* functions (Alexander, Rock, He, et al., in preparation). The large size of the integration cassette (~4.2 kb) prevented the efficient PCR amplification required to generate a template for λ Red-mediated recombination. As a result, we constructed a recombination cassette by cloning regions of homology needed for recombination on alternate ends of the integration cassette. To generate a BAC containing the entire *lpt* cluster, the integration cassette was flanked with regions of homology to the pECBAC1 backbone (0.26 kb) and the *orf21* region (1.4 kb), both upstream of the *lpt* gene cluster. The entire integration cassette was released from the cloning vector by digestion with *NheI* followed by gel purification before being used as a template for recombination. Successful λ Red-mediated recombination generated pDA2002 (Fig. 4D), containing the *lpt* cluster that could be transferred to *Streptomyces* by conjugation and site-specific integration. The use of compatible markers on these cassettes allows them to be used in combination to generate BAC vectors modified in very complicated ways.

By using this system, multiple constructs of NRPS domain and module exchanges were rapidly generated. Many of these may not have been feasible using *recA*-dependent recombination. Domains or modules of an NRPS pathway are typically 3 to 5 kb in length and share a high degree of sequence homology, especially in the condensation domains. This sequence homology results in problems for PCR amplification, yielding multiple different products of similar sizes, and *recA*-dependent recombination may also target alternate sites. The application of the λ Red system has simplified and accelerated the genetic manipulation of NRPSs by module and multidomain exchanges (Fig. 5). A specific module(s) present in the BAC can be replaced by

an antibiotic resistance marker flanked by rare restriction sites. The BAC DNA is digested to remove the resistance marker, treated with shrimp alkaline phosphatase, and used directly in a ligation with a replacement DNA fragment containing the new module. The replacing module is cloned directly from the BAC by using the λ Red system in a process called gap repair (37). A PCR product is generated from pBR322 using primers that are homologous with the ends of the module. When electroporated into cells induced for λ Red expression, the pBR322 PCR product will recombine with the BAC to pick up the module fragment and circularize the plasmid, thus allowing for stable replication (Fig. 5). The compatible rare restriction sites are incorporated into primers used for amplification of the pBR322 fragment. Only end sequencing of the cloned 3- to 5-kb module is necessary to check for errors, as the "cloned" module is not exposed to the low level of misincorporation mutagenesis associated with PCR. During the ligation of the module into the BAC, at least one restriction site is destroyed by combining compatible cohesive or blunt ends that are not resealed upon ligation (e.g., *AvrII* and *NheI*), and the resulting ligation mix can be digested with that restriction enzyme to remove BACs resulting from ligation of the original antibiotic resistance gene insert before transformation into *E. coli*. BACs containing the desired module exchanges are identified by PCR screening, restriction mapping, and sequencing of the fusion junctions.

27.5.2. NRPS Subunit *trans*-Complementation

The similarities in size and function of the terminal subunits of the NRPSs of daptomycin, A54145, and CDA made them attractive candidates for subunit exchanges. The *dptD*, *lptD*, and *cdaPS3* genes appear to have evolved from a common ancestral NRPS gene (6). The DptD, LptD, and

FIGURE 5 λ Red-mediated recombination to generate a C-A-T tridomain exchange and gene fusion in *lptB* and *lptC*.

CdaPS3 proteins share ~50% amino acid identities, and they show some conservation of N-terminal interpeptide docking sequences. The *lptD* and *cdaPS3* genes were cloned into pHM11a under the transcriptional control of *ermEp**, generating pRB04 and pMF26, respectively (Table 1). The plasmids were introduced into *S. roseosporus* UA378 (Δ *dptD::ermE*) by conjugation from *E. coli* and inserted into the IS117 *attB* site. Recombinants containing the *lptD* and *cdaPS3* genes produced A21978C_{1,3} derivatives containing Ile₁₃ or Trp₁₃ at about 25 and 50% of control levels, respectively (15, 46). Similar experiments have been attempted in an *S. fradiae* strain deleted for the *lptD* genes, but recombinants containing the *dptD* or *cdaPS3* genes inserted in the ϕ C31 site did not produce hybrid lipopeptides (D. C. Alexander, J. Rock, C. Mascio, C. Li, A. Van Praagh, L. Mortin, J.-Q. Gu, M. Chu, J. A. Silverman, P. Brian, and R. H. Baltz, in preparation). These mixed results suggest that subunit exchanges may have limited applicability.

27.5.3. NRPS Domain and Module Exchanges

27.5.3.1. Flexibility of Module Fusions at T-C Linkers

The production of A21978C_{1,3} derivatives containing Ile₁₃ or Trp₁₃ in *S. roseosporus* can also be achieved by module exchange by fusing the 3mGlu₁₂ module from *dptD* with the Ile₁₃ or Trp₁₃ modules from *lptD* and *cdaPS3*, respectively, as C-A-T::C-A-T-TE fusions (20). In this way, the homologous protein-protein docking relationship between DptBC and DptD is preserved. As a control, the homologous DptD C-A-T::C-A-T-TE fusions were made in the intermodule T-C linker region by inserting a restriction enzyme cleavage site to facilitate subsequent fusions. The flexibility of the system was tested by making three different double-amino-acid substitutions, a four-amino-acid insertion, and a four-amino-acid deletion in the linker region. The reconstructed *dptD* genes were cloned into pHM11a and expressed ectopically from the *ermEp** promoter at the IS117 *attB* site as described above, and all recombinants produced A21978C_{1,3} factors at control yields. Heterologous C-A-T::C-A-T-TE module fusions between *dptD* 3mGlu₁₂ and *lptD* Ile₁₃ or *cdaPS3* Trp₁₃ were constructed, and the recombinant strains produced A21978C_{1,3} derivatives containing Ile₁₃ or Trp₁₃ in higher yields (~100% of control) than observed with the whole subunit exchanges. The success in this system may be due in part to the maintenance of efficient protein-protein interactions between homologous interpeptide docking sites. Therefore, module fusions that preserve the natural protein-protein docking relationships may provide the most robust approach to generate hybrid NRPSs.

27.5.3.2. Didomain Fusions at A-T Linkers (C-A::T-TE)

Since few C-A-T-TE modules were available to further explore amino acid substitutions at position 13, the ectopic *trans*-complementation system in *S. roseosporus* was used to generate hybrid C-A-T-TE modules retaining the homologous TE for ring closure. The C-A-T or C-A domains from the LptC C-Ad-Asn₁₁-TE module were exchanged for the C-A-T or C-A domains from the C-A_{Kyn13}-T-TE module of DptD. The recombinant expressing the C-A-T::C-A::T-TE double fusion produced A21978C_{1,3} derivatives containing Asn₁₃ at ~43% of control. The strain expressing the C-A-T::C-A-T::TE double fusion produced no lipopeptides. These results point out the importance of maintaining the

homologous interaction between native T and TE domains (25, 62, 65). A C-A-T::C-A_{Kyn}::T-TE double fusion in *lptD* in *S. fradiae* was used successfully to generate A54145 analogs containing Kyn₁₃ from the daptomycin pathway (Alexander, Rock, Mascio, et al., in preparation) (Table 3).

27.5.3.3. Module and Domain Fusions Facilitated by λ Red-Mediated Recombination

Exchanges of C-A-T tridomains and C-A-T-E modules have been carried out at positions 8 and 11 in DptBC at splicing sites in interdomain linkers (20, 28, 50). Recombinants produced the predicted A21978C_{1,3} derivatives (50). The production yields were highest (10 to 50% of control) with the C-A-T exchanges, leaving the homologous E domains intact to interact with downstream ^DC_L domains. These changes have been coupled with subunit exchanges and deletion of the *dptI* gene to generate larger sets of hybrid compounds (49, 50; Table 3).

In *S. fradiae*, the λ Red-mediated recombination system (18) was used to exchange single or multiple modules, or multidomains in plasmids containing different sets of A54145 biosynthetic genes, using splicing sites located in the interdomain regions (K. Nguyen, X. He, D. Alexander, L. Chen, J.-Q. Gu, C. Mascio, A. Van Praagh, L. Mortin, M. Chu, J. A. Silverman, P. Brian, and R. H. Baltz, submitted) similar to those used above (49, 50). Exchanges at position 8 eliminated the stop codon of *lptB*, generating fused *lptBC* hybrid genes. Exchanges at positions 8 or 11 in the fused *lptBC* gene were carried out in plasmid pDA2048 (Fig. 3) and introduced into strains DA740 (Δ *lptBCD*) and DA901 (Δ *lptBCD* Δ *lptI::tsr*) at the ϕ C31 *attB* site, generating lipopeptides containing 3mGlu₁₂ and Glu₁₂. Exchanges at positions 2, 2 and 3, or 2–8 were made in plasmid pDA2054 and introduced into strain DA1187 at the ϕ C31 *attB* site to produce novel compounds containing Glu₁₂. These amino acid substitutions were coupled with 3mGlu₁₂ by introducing plasmid pKN55 containing the *dptI* genes into the ϕ BT1 *attB* site in recombinants. Hybrid lipopeptides containing one to three amino acid changes were produced in yields of 3 to 48 mg/liter, whereas the lipopeptides with five or six changes were produced at ~1 mg/liter (Nguyen et al., submitted).

27.5.4. Disruption of Genes Involved in Modification of Amino Acids

As already mentioned, disruption of the *dptI* and *lptI* genes in *S. roseosporus* and *S. fradiae* strains caused the production of lipopeptides containing Glu₁₂ rather than 3mGlu₁₂. These simple changes doubled the number of potential novel compounds generated by combinatorial biosynthesis. Importantly, as discussed in more detail below, disruption of *lptI* provided a means to generate derivatives of A54145 with low mammalian toxicity and substantially increased antibacterial activity in the presence of surfactant. A54145 has four modified amino acids, and the genes involved in the modifications have been disrupted singly and in combinations (Alexander, Rock, Gu, et al., in preparation), some by the insertion of a terminator cassette via λ Red-mediated recombination of pDA2002. Disruption of the *lptL* asparagine oxygenase gene caused the production of lipopeptides containing Asn₃ instead of hAsn₃. Disruption of the *lptK* O-methyltransferase gene caused the production of lipopeptides containing hAsp₉ rather than mOAsp₉, and *lptJ* aspartic acid oxygenase mutants produced Asp₉. The properties of mutants containing one or more mutations blocking amino acid modifications are summarized in Table 3 and are discussed in section 27.5.5.

TABLE 3 Lipopeptide antibiotics generated by combinatorial biosynthesis

^aDaptomycin has an *n*-decanoyl side chain. All others compounds have *anteiso*-undecanoyl side chains. MICs against *S. aureus* were determined with and without the addition of 1% bovine surfactant. Data from references 28, 46, 49, 50; Alexander, Rock, He, et al., in preparation; Alexander, Rock, Gu, et al., in preparation; Alexander, Rock, Mascio, et al., in preparation; and Nguyen et al., submitted.

27.5.5. Incorporation of Multiple Fatty Acid Side Chains

All of the manipulations described above are coupled with the natural propensity to initiate lipopeptide assembly with three different preferred fatty acids. During A21978 biosynthesis, the three major fatty acid side chains are *anteiso*-undecanoyl, *iso*-dodecanoyl, and *anteiso*-tridecanoyl, and during A54145 biosynthesis the major fatty acids are *n*-decanoyl, *iso*-decanoyl (8-methylnonanoyl), and *anteiso*-undecanoyl (8-methyldecanoyl) (Fig. 1). The heterologous pathway expression experiments (44, 52; Alexander, Rock, He, et al., in preparation) demonstrated that the fatty acid precursor specificity is inherent in the lipopeptide biosynthetic enzymes and not in the streptomycete host. The daptomycin pathway incorporates preferentially fatty acids that are two carbons longer than those preferred in the A54145 pathway. It is not known whether the specificity resides within the acyl-coenzyme A ligase and acyl carrier proteins (DptE and DptF or LptEF), in the $^{\text{F}}\text{C}_L$ condensation domain of the Trp₁ modules, or in both. The fatty acid preferences can be preempted by feeding high levels of other fatty acids (6, 9, 14, 33), and many more novel compounds can be produced by feeding different fatty acids, thus expanding the numbers achievable by combinatorial biosynthesis.

27.5.6. Properties of Novel Lipopeptides

Table 3 shows the amino acid substitutions and antibacterial properties of a subset of novel lipopeptides produced by genetic engineering and combinatorial biosynthesis in *S. roseosporus* or *S. fradiae*. Antibacterial activities against *S. aureus* were determined with and without 1% bovine surfactant to identify candidates that might be efficacious in *S. pneumoniae* pulmonary infections. For simplicity, only compounds containing *anteiso*-undecanoyl (8-methyldecanoyl) side chains are compared with daptomycin (which has a decanoyl side chain) and CB-181,220 (which has an 8-methyldecanoyl side chain). The *in vitro* antibacterial activities varied by 256-fold when the core peptides of daptomycin and A54145 were modified, and the magnitude of inhibition by bovine surfactant varied by 128-fold, with daptomycin and CB-181,220 showing the highest level of surfactant inhibition. These data demonstrate that combinatorial biosynthesis can be used to change the fundamental properties of complex cyclic lipopeptide antibiotics. Several observations from Table 3 are worth noting. (i) The presence of Kyn₁₃ is important for the antibacterial activity of daptomycin, but it also contributes substantially to surfactant inhibition. (ii) Substitutions for Kyn₁₃ reduce surfactant inhibition, but they cause reduced antibacterial activity against *S. aureus*. (iii) Substitution of Glu₁₂ for 3mGlu₁₂ in the context of daptomycin reduces surfactant inhibition by fourfold, but increases the MIC in the absence of surfactant 16-fold, leading to no net gain. (iv) Substitutions of D-Ala or D-Asn at position 11 in the daptomycin core peptide reduced surfactant inhibition about fourfold, but increased the MIC in the absence of surfactant twofold. (v) A54145 factor E is twofold less active than daptomycin in the absence of surfactant, but twofold more active in the presence of surfactant. (vi) Last, and importantly, A54145 factor D, which has Glu₁₂, is fourfold less active than daptomycin without surfactant, but 16-fold more active in the presence of surfactant. Also, the natural A54145 factors containing 3mGlu have higher levels of acute toxicity in mice than those containing Glu (16; Nguyen et al., submitted).

The properties of A54145D suggested that it might be possible to mitigate the surfactant inhibition encountered by

daptomycin while maintaining good antibacterial activity and low mammalian toxicity. This prompted the development of molecular engineering tools to carry out combinatorial biosynthesis in *S. fradiae* focused on modifying the A54145 core peptide (section 27.4.2). The following observations were made from these studies. (i) Substitution of D-Asn for D-Glu at position 2 (CB-182,575), or Asp for mOAsp at position 9 (CB-182,443), while maintaining 3mGlu₁₂, had the same effect on antibacterial properties as substituting Glu for 3mGlu at position 12. (ii) Disruption of three genes involved in modifying Asn₃ and Asp₉ generated a very active lipopeptide (CB-182,390) that showed no surfactant inhibition. (iii) Exchanging the D-Asn₂ and Asp₃ from the daptomycin pathway for D-Glu₂ and hAsn₃ generated CB-182,561 with MICs of 1 and 2 μg/ml in the absence and presence of surfactant. (iv) Finally, coupling Kyn₁₃ with Glu₁₂ in the A54145 core peptide generated CB-183,298, with the same improved properties as CB-182,561. The three most active compounds (CB-182,561, CB-182,390, and CB-183,298), with three distinctly different peptide core modifications, had MICs of 2 μg/ml and were 32-fold more active than daptomycin in the presence of 1% bovine surfactant.

27.6. CONCLUSIONS AND PROSPECTS

It is now feasible (i) to clone complex lipopeptide antibiotic biosynthetic pathways in BAC vectors that can be rapidly manipulated in complex ways in *E. coli* by λ Red-mediated recombination (recombineering); (ii) to transfer partial or complete pathways from *E. coli* to homologous or heterologous streptomycete hosts by conjugation; (iii) to insert partial or complete biosynthetic pathways into bacteriophage or insertion element integration/attachment sites in streptomycete chromosomes; and (iv) to express complete pathways from native promoters and partial pathways from native or other promoters in homologous and heterologous streptomycetes. Conjugal transfer from *E. coli* is a key element for successful introduction of very large BAC vectors, and the efficiency is media dependent. AS-1 agar and derivatives work well for conjugal transfer to *S. roseosporus* and *S. ambofaciens*. The concepts summarized above comprise the basic elements for successful genetic engineering and combinatorial biosynthesis in streptomycetes. The specific versatile tools that have facilitated genetic engineering in *S. roseosporus* and *S. fradiae* are (i) pStreptoBAC V, which has *oriT* and $\phi\text{C31 att/int}$ functions, Am^r for selection in streptomycetes and *E. coli*, and other features that facilitate the process; (ii) other vectors with *oriT* and *att/int* functions from ϕC31 , ϕBT1 , or IS117 for conjugal transfer and site-specific integration in streptomycetes; (iii) λ Red-mediated recombination in *E. coli*; and (iv) *ermEp** for driving transcription of cloned genes inserted at ectopic locations in streptomycete chromosomes. The methods discussed in this chapter include some that are specific to NRPS engineering, including (i) splicing at intermodule or interpeptide linker sites; (ii) recognizing and exploiting the correct type of C domain when coupling fatty acids to L-amino acids ($^{\text{F}}\text{C}_L$), D-amino acids to L-amino acids ($^{\text{D}}\text{C}_L$), or L-amino acids to L-amino acids ($^{\text{L}}\text{C}_L$); and (iii) maintaining the integrity of T-TE didomains when engineering terminal modules. It is probably important to maintain the integrity of C-A didomains (25, 62, 65), but this was not addressed specifically in the current studies. However, successful examples of transplanting C-A didomains were demonstrated.

This chapter has pointed out that both *S. roseosporus* and *S. fradiae* can be readily manipulated by the genetic

engineering methods described above. As such, they may be useful hosts for the expression and engineering of other secondary metabolic pathways, particularly other NRPS pathways. For example, the A54145 gene cluster was expressed successfully in an *S. roseosporus* strain deleted for daptomycin biosynthetic genes. Of particular note was the high-level expression of the complete A54145 biosynthetic pathway in a mutant of *S. ambofaciens* blocked in spiramycin production, yielding nearly 400 mg/liter of A54145 lipopeptides. *S. ambofaciens* BES2074 was specifically selected for stability and high-level spiramycin production (22) followed by the disruption of a key regulatory gene, *smrR* (26, 54), required for spiramycin biosynthesis. This strain is also defective in netropsin biosynthesis, making it a good host for the expression of antibiotic biosynthetic pathways. *S. ambofaciens* is easily manipulated genetically and thus may be a useful strain for the genetic engineering of pathways cloned from genetically recalcitrant strains. It might also be useful for the expression of cryptic pathways identified in genome sequencing projects (7).

Genetic Engineering To Regulate Production of Secondary Metabolites in *Streptomyces clavuligerus*

SUSAN E. JENSEN

28

Streptomyces clavuligerus is a filamentous soil bacterium originally isolated from a South American soil sample in a screening program targeting β -lactamase-resistant β -lactam antibiotics (34, 48, 66). The antibiotics for which it was originally isolated, cephamycin C and 7-demethoxycephamycin C (Fig. 1), were soon overshadowed in importance when rescreening of the organism for production of β -lactamase inhibitory compounds led to the discovery of clavulanic acid (12, 76). While cephamycin antibiotics are valuable clinical agents in their own right, clavulanic acid is recognized as the most important product of *S. clavuligerus* today. Clavulanic acid is a powerful irreversible inhibitor of many serine active site β -lactamases. Since these β -lactamases are responsible for much of the clinical β -lactam resistance, clavulanic acid is used in combination with conventional penicillin or cephalosporin-type antibiotics to restore the effectiveness of these agents against otherwise resistant strains.

S. clavuligerus NRRL 3585 (ATCC 27064) is the original, and was for many years the only known, strain of this species. Clavulanic acid for clinical use is still produced only by fermentations using the descendants of this original strain. Very recently, a second strain, *S. clavuligerus* CKD1119, was isolated from a Korean soil sample in a screen for immunosuppressive compounds (51, 52) and found to produce tacrolimus (also known as FK-506). Analyses showed that this strain also produces clavulanic acid, but no comparative information on productivity relative to the original strain is available. No other information is available on this new strain, and so the remainder of this article will refer to studies on the original *S. clavuligerus* NRRL 3585 strain.

In addition to cephamycin C and clavulanic acid, *S. clavuligerus* is known to produce two non- β -lactam metabolites, holomycin and tunicamycins (48), as well as at least four other clavam compounds (13, 75) (Fig. 1). Superficially, these other clavams resemble clavulanic acid in structure, but they differ in the side chains attached at C-2 and in the stereochemistry of the fused ring system. These other clavam metabolites have an S configuration at C-5, and so are referred to as 5S clavams, whereas clavulanic acid has a 5R configuration. β -Lactamase inhibitory activity is associated with the 5R configuration, and so none of the 5S clavams has this property; instead, they display a variety of weak antibacterial and antifungal activities. In the cases of alanylclavam and 2-hydroxymethylclavam, antibacterial activity is manifest only against organisms growing on

defined medium and is due to inhibition of the methionine biosynthetic enzyme homoserine succinyltransferase, resulting in methionine antimetabolite properties (77). In contrast, the antifungal activity of the 5S clavams is not due to this antimetabolite property, but to an effect on RNA synthesis. Clavam-2-carboxylate is toxic, but its mechanism of toxicity has not been described.

As well as small-molecular-weight metabolites, *S. clavuligerus* also produces a β -lactamase inhibitor protein, BLIP, which, unlike clavulanic acid, is a very narrow-range inhibitor affecting only a handful of class A type β -lactamases, but with very high affinity (K_i in the sub-nanomolar range) (22, 87). While there is no obvious connection between the production of clavulanic acid or the 5S clavams and BLIP, mutants of *S. clavuligerus* defective in production of the pathway-specific regulator, CcaR, that regulates both clavulanic acid and cephamycin C production, also produce lower levels of BLIP than does the wild type (93). Furthermore, production of BLIP proteins is quite restricted within *Streptomyces* spp., and so its occurrence in a species that also produces both cephamycin C and clavulanic acid seems unlikely to be just coincidence.

Many early studies on penicillin and cephamycin biosynthesis were carried out in *S. clavuligerus*, but because of the commercial importance of clavulanic acid, most recent studies have focused on that compound. In particular, genetic engineering to generate improved clavulanic acid producer strains has been a main interest. Although the bioactivity of the 5S clavams has no clinical value, the structural variation seen in this family of metabolites offers the possibility of biological routes to structural variants of clavulanic acid once the full biosynthetic details of their production are known. Finally, the cross-regulation seen between the β -lactam metabolites makes understanding the production of this entire family of metabolites of great interest.

28.1. PRACTICAL CONSIDERATIONS FOR GENETIC ENGINEERING OF *S. CLAVULIGERUS*

Genetic engineering of *Streptomyces* spp. in general is made challenging by the slow growth and filamentous nature of the organisms, the limited selection of genetic tools available, and the lack of natural competence in the genus, among other factors. In addition, *S. clavuligerus* has its own particular characteristics which add complexity.

FIGURE 1 Secondary metabolites produced by *S. clavuligerus*.

28.1.1. Basic Biological Features

S. clavuligerus is unusual among *Streptomyces* spp. in that it cannot use simple sugars such as glucose or sucrose as sole carbon sources (34), but it does grow well on glycerol, starch, maltose, or dextrin. Appropriate substitutions to growth media developed for other *Streptomyces* spp. will typically allow these media, and any genetic protocols with which they are associated, to be applied to *S. clavuligerus*. However, *S. clavuligerus* is fastidious about conditions supporting sporulation and will sporulate poorly if at all on most rich complex media. Good sporulation can usually be obtained on ISP-4 (Difco) or tomato oatmeal agar media. *S. clavuligerus* grows and produces secondary metabolites optimally at 28 to 30°C, but it is unusually sensitive to elevated temperature and will not grow above 31 to 32°C.

Liquid media employed by research groups studying the production of the various types of β -lactam metabolites produced by *S. clavuligerus* vary widely. Both clavulanic acid and cephamycin C can be produced reliably at high levels on a complex soy flour–starch-based medium (Soy medium; 78) as well as on a defined starch–asparagine-based medium (SA medium; 46). Other groups report using Trypticase soy broth for clavulanic acid production (81), but in our hands, production is poor and cultures lyse extensively in stationary

phase, so we use this medium only for staging seed cultures. Similarly, glycerol–sucrose–proline–glutamate (GSPG) medium supports only poor growth in our experience, although others report good results (74). Numerous bioprocess-type studies examining growth medium optimization as a means of improving production of clavulanic acid have appeared in recent years, typically reinforcing the association of soy-based growth medium constituents with high productivity (30, 68, 82, 97).

In contrast to clavulanic acid, reproducible production of 5S clavams is difficult to achieve in any liquid medium for reasons not understood at present. Soy medium is the only liquid medium that we have encountered that supports good 5S clavam production, and even then, variations in culture-to-flask volume ratio and aeration can greatly affect production (unpublished observations). Furthermore, despite careful attention to such details, amounts and relative proportions of the various 5S clavams vary widely from one experiment to the next. Surprisingly, liquid SA medium, which does not support 5S clavam production, will support production when solidified with agar, with metabolites recovered by a “freeze and squeeze” procedure. We have also encountered similar liquid-solid discrepancies with respect to production of 5S clavams on media employing soy protein extracts in place of soy flour (30).

28.1.2. Genetic Features

28.1.2.1. Introduction of Foreign DNA

Despite its lack of natural competence, *S. clavuligerus* is amenable to introduction of foreign DNA by polyethylene glycol-mediated transformation of protoplasts using standard techniques (27, 40, 50), although with some provisos. *S. clavuligerus* protoplasts are unusually sensitive to lysis even in osmotically supportive concentrations of sucrose unless appropriate levels of Ca^{2+} and Mg^{2+} are provided. *S. clavuligerus* protoplasts also regenerate at low rates, and that, combined with their powerful DNA restriction system(s), makes introduction of foreign DNA by polyethylene glycol-mediated transformation inefficient. Transformation with DNA constructs prepared in *Escherichia coli* directly into *S. clavuligerus* is also typically unsuccessful, even if methylation-defective host strains of *E. coli* are employed to prepare the DNA. Passage of *E. coli*-derived plasmid constructs through a nonrestricting *Streptomyces* sp. such as *S. lividans*, and from there into *S. clavuligerus*, can be used to overcome the restriction barrier. However, this precludes the use of integrative vectors that would insert into the intermediate host.

For all of these reasons, intergeneric conjugation has largely replaced transformation in recent years as a means of introducing both integrative and freely replicating plasmid and cosmid vectors into *S. clavuligerus*. Such constructs, so long as they include an origin of transfer such as *ori*_{TRK2}, can be transferred directly from methylation-deficient *E. coli* hosts carrying the necessary transfer functions into *S. clavuligerus*. Standard techniques developed for conjugative transfer from *E. coli* into *S. coelicolor* are generally applicable (50). However, while recovery of *S. clavuligerus* exconjugants using mannitol soy agar plates has been described by others (79), in our experience, conjugation is only successful when exconjugants are recovered on AS-1+Mg agar plates (6).

28.1.2.2. Plasmid Vectors Used in *S. clavuligerus*

Many plasmid vectors have been developed for use in various *Streptomyces* spp., but relatively few have been tested in *S. clavuligerus*, and so the following is not intended to be a complete list of all useful plasmid vectors. Multicopy vectors based on the pIJ101 replicon, such as pIJ486 (41, 64, 98) and pUWL-KS (99), typically work well in *S. clavuligerus* and have been widely used. Unlike the situation in *S. coelicolor*, however, they show segregational instability in *S. clavuligerus* in the absence of antibiotic selection. As a result, sporulation in the absence of antibiotic selection routinely gives near-complete loss of these plasmids, which can be useful for delivery of gene disruption constructs. Resistance to apramycin, encoded by the *apra* cassette and mediated by the *aac(3)IV* gene (50), is particularly useful as a selectable marker because spontaneous resistance is rarely encountered, and resistance can be selected in both *Streptomyces* spp. and *E. coli*. The thiostrepton resistance gene (*thio*; 50) is another widely used marker that gives resistance to thiostrepton with little background of spontaneous resistance in *S. clavuligerus* (although at the unusually low level of 2 to 5 $\mu\text{g}/\text{ml}$), but with the limitation that resistance cannot be selected in *E. coli*. Neomycin resistance due to *neo* (Tn5) is another useful marker (21) that is selectable in both *S. clavuligerus* and *E. coli*, but hampered by a greater tendency to show some spontaneous background resistance. Hygromycin, viomycin, streptomycin, and spectinomycin all have very high natural MIC values in *S. clavuligerus* that limit the usefulness of their resistance genes, although transformants showing hygromycin resistance (65) have been selected using levels of 250 $\mu\text{g}/\text{ml}$.

The segregational instability of pIJ101-based vectors makes them suitable delivery vectors for gene disruption constructs, since they are easily lost from the cell. The partition-defective vector pJV326 (33) also works well in *S. clavuligerus* for delivery of gene disruption constructs. In contrast, the low maximum growth temperature of *S. clavuligerus* precludes the use of temperature-sensitive plasmid vectors for delivery of gene disruption constructs (10).

Providing that antibiotic selection is maintained, plasmid vectors based on the pIJ101 replicon can also be used for complementation or protein expression purposes, but in practice, such high-copy-number vectors can have deleterious effects on cell growth and antibiotic production. Furthermore, in *S. clavuligerus*, attempts to use freely replicating plasmids for complementation or overexpression of native genes can promote integration of the plasmid into the chromosome via homologous recombination. For this reason, integrative plasmids such as pSET152 (8) and pHM8a (65) are preferred for protein overproduction or complementation studies. Furthermore, pSET152 and plasmids derived from it transfer into *S. clavuligerus* with unusually high efficiency by conjugation or transformation, and so they have become widely used vectors for such studies.

E. coli-derived promoters are usually nonfunctional in *Streptomyces* spp., but heterologous promoters from other actinomycete species such as the strong, constitutively expressed *ermE** promoter (83) have proven useful for expression studies in *S. clavuligerus*. Useful regulatable promoters include the *thio*-inducible *tipA* promoter (19, 50, 81) and the glycerol-inducible *gylP₁P₂* promoters (35, 41, 94), but the Ni^{2+} -regulatable *sodF1* promoter from *S. coelicolor* proved to be weak and unregulated in *S. clavuligerus* (unpublished observations).

Cosmid libraries based on *E. coli*-derived SuperCos-type vectors (Stratagene) have proven useful, both for general-purpose cloning of *S. clavuligerus* genomic DNA fragments and for gene disruption as part of the REDIRECT[®] PCR-targeted system (see below). The *E. coli*-*Streptomyces* shuttle cosmid pOJ436 (8) has also been used to prepare a library of genomic DNA for integration of large fragments of *S. clavuligerus* DNA into the chromosome of other *Streptomyces* spp.

28.1.2.3. Gene Disruption in *S. clavuligerus*

Gene disruption in *S. clavuligerus* is readily achievable, either by preparing gene disruption constructs and delivering them on pIJ101-based plasmid vectors, or by employing PCR-targeting techniques as part of the REDIRECT[®] system to introduce mutations (31). Of the various cassettes available for use in PCR-targeted mutagenesis, the *apra* cassette carried on pIJ773 is the only one that has been widely used for *S. clavuligerus* because the viomycin and spectinomycin cassettes do not provide useful levels of resistance in this species. Alternative resistance markers are desirable because creation of double mutants typically requires that two different selectable markers be employed. The availability of differently marked single mutants also makes possible their combination into double mutants by the simple expedient of protoplast fusion. Using established techniques for protoplast fusion (39), we were able to fuse BLIP single mutants (*bli::apra*) with BLIP-like protein (BLP) single mutants (*blp::neo*) to generate *bli::apra-blp::neo* double mutants with relative ease (unpublished observations). Alternatively, the REDIRECT[®] system allows single mutants to be rendered unmarked by using FLP/FLP recombination target (FLP/FRT)-based recombination to remove antibiotic resistance cassettes, making it theoretically possible to create double mutants by sequential use of the *apra* cassette. As originally designed, use of the FLP/FRT system relies on the ability to deliver *E. coli*-derived mutant cosmids by transformation,

but the restriction barrier prevents this in *S. clavuligerus*, requiring that alternative techniques be used to remove the resistance cassette. A recently developed *Streptomyces*-based vector carrying a synthetic *flp* gene optimized for expression in *Streptomyces* (25) should streamline this procedure by enabling in vivo excision of the FRT-flanked resistance cassettes in *Streptomyces* hosts, although this has not yet been tested in *S. clavuligerus*. Alternatively, we have just developed a vector which supports expression of the native *flp* gene in *S. clavuligerus* and *S. coelicolor*, allowing direct in vivo excision of the resistance cassette (103).

In vitro transposon mutagenesis of cosmid-based libraries of genomic DNA can be used as an alternative means to introduce mutations into the chromosome of *S. clavuligerus* using the modified Tn5-type transposon Tn5062 (11, 104). However, in our hands, a number of instances (about 20% of genes) were encountered where mutations carried on cosmids could not be successfully transferred into the *S. clavuligerus* chromosome, despite subsequent proof that the genes were not essential (104).

28.2. APPLICATIONS OF GENETIC ENGINEERING TO THE PRODUCTION OF β -LACTAM COMPOUNDS

28.2.1. Genetics of Production of β -Lactam Compounds in *S. clavuligerus*

Like the sequenced *Streptomyces* spp., *S. clavuligerus* is assumed to have a linear chromosome of about 8 to 9 Mb. A complete genome sequence for *S. clavuligerus* is currently not available, but a preliminary draft genome sequence, available through the NCBI site (<http://www.ncbi.nlm.nih.gov/sites/entrez?db=genomeprj&cmd=search&term=clavuligerus%20genome>), comprising 6.7 Mb of genomic sequence information distributed in 597 contigs and encoding 5,981

proteins, has been obtained by the Broad Institute Genome Sequencing Platform. The Korean Research Institute of Bioscience and Biotechnology continues to work to complete this genome sequence. In addition to its chromosome, *S. clavuligerus* is also known to carry three extrachromosomal linear plasmids, ranging in size from 11.2 kb to greater than 450 kb (67). The plasmids are stably maintained, and no reports of "cured" strains have appeared in the literature.

Genes associated with the production of the β -lactam metabolites are distributed across three separate locations in the genome of *S. clavuligerus*. Studies of the resident linear plasmids have shown them not to carry any genetic information required for the production of the β -lactam metabolites (90). This discontinuous arrangement of the β -lactam-producing genes is unusual and goes against the established paradigm that genes associated with antibiotic production are clustered in the chromosomes of producer bacteria. Clustering would facilitate horizontal gene transfer, which is presumed to be a common route for acquisition of antibiotic production ability, consistent with the sporadic distribution of antibiotic production ability across taxonomically unrelated species.

Clavulanic acid production is limited to a handful of species (43) and is accompanied by the production of cephamycin C, suggesting that the same grouping of clavulanic acid and cephamycin C biosynthetic genes into separate but adjacent gene clusters (the cephamycin C-clavulanic acid supercluster, Fig. 2) may also exist in other clavulanic acid producers. Production of 5S clavam metabolites is a trait shared with a larger number of species (43), but *S. clavuligerus* is unique among 5S clavam producers in its ability to produce both clavulanic acid and 5S clavam metabolites. Because the biosynthetic pathways to clavulanic acid and the 5S clavams overlap, enzymes encoded by genes located in the cephamycin C-clavulanic acid supercluster contribute to the production of the 5S clavams as well as clavulanic acid despite their separate locations. This leads

to a complex and overlapping regulatory situation that affects attempts to undertake genetic modifications aimed at improving cephamycin C or clavulanic acid production or modifying the array of metabolites produced.

28.2.2. Cephamycin C-Clavulanic Acid Supercluster

Genes involved in the production of cephalosporins and cephamycins have been studied from several species, and the details of cephamycin C biosynthesis are quite well understood (for reviews see references 20, 44, 55, and 56). In *S. clavuligerus*, biosynthesis begins with the amino acids L-lysine, L-cysteine, and L-valine and proceeds through the synthesis of penicillin and cephalosporin intermediates to give the

final cephamycin product (Fig. 3). In the first step of the pathway, L-lysine is converted to piperideine-6-carboxylate by the enzyme lysine- ϵ -aminotransferase, and from there to L- α -aminoadipic acid. Once α -aminoadipic acid is formed, it condenses with cysteine and valine through the action of a nonribosomal peptide synthetase, δ -(L- α -aminoadipyl)-L-cysteinyl-D-valine synthetase, and the resulting tripeptide is cyclized by isopenicillin N synthase to give a penicillin intermediate. The thiazolidine ring structure of penicillin N is then expanded by deacetoxycephalosporin C synthase to give the dihydrothiazine ring system characteristic of cephalosporin and cephamycin antibiotics. Other gene products from the cluster modify these intermediates to form the final cephamycin C product. Penicillin, cephalosporin, and cephamycin

FIGURE 3 The biosynthetic pathway to cephamycin C in *S. clavuligerus*. Enzyme names are followed by the corresponding gene designation shown in italics.

metabolites can therefore all be thought of as cyclized and highly modified nonribosomal peptide antibiotics.

Despite their superficially similar bicyclic β -lactam nuclear structure and adjacently located gene clusters, cephamycin C and clavulanic acid do not share any common biosynthetic elements except for the pathway-specific transcriptional activator, CcaR, encoded by *ccaR*, located within the cephamycin arm of the supercluster (Fig. 2). Clavulanic acid biosynthesis is less well understood than cephamycin C biosynthesis, but the clavulanic acid gene cluster is believed to contain all of the genetic information required for the production of clavulanic acid, with *ceaS2* shown to be the first, and *orf17* the most distant, gene of the cluster essential for clavulanic acid production (2, 36, 41, 45, 54, 59, 61, 62, 70, 71, 73, 74, 84, 98, 102). Mutation of genes beyond *orf17* has only limited or no effect on clavulanic acid production, although some conditional regulators may be encoded there. However, clavulanic acid producing capability has never

been transferred to a nonproducer species, and the late steps of clavulanic acid biosynthesis are not understood, making it hard to establish that all of the genes required for these steps have been identified. Therefore, the completeness of the cluster remains an assumption pending further proof.

The early steps of clavulanic acid biosynthesis convert the primary metabolites L-arginine and D-glyceraldehyde-3-PO₄ into clavaminic acid, the last known common intermediate for clavulanic acid and 5S clavam biosynthesis (Fig. 4). This conversion is accomplished in six steps by four enzymes, carboxyethylarginine synthase, β -lactam synthetase, proclavaminic amidinohydrolase, and clavaminic synthase (which catalyzes three independent steps). Genes encoding each of these activities make up the first four genes of the clavulanic acid gene cluster. Each of these genes has been expressed in *E. coli*, and the resulting proteins have been characterized and their structures examined by X-ray crystallography (14, 24, 63, 105).

FIGURE 4 The biosynthetic pathway to clavulanic acid and the 5S clavams in *S. clavuligerus*. Enzyme names are followed by the corresponding gene designation shown in italics. Parts of the pathway shown with broken arrows represent pathway steps that are proposed but not yet demonstrated.

While these early steps of clavulanic acid biosynthesis are now well understood, the late steps are not. Twelve more open reading frames (ORFs), *oat2-orf17*, complete the minimal clavulanic acid gene cluster. Gene disruption studies have shown that all of the ORFs in this region, with the exception of *oat2*, are essential or important for clavulanic acid production, although the nature of their involvement is often not clear. *oat2* encodes an ornithine aminotransferase (OAT) shown to catalyze the reversible transfer of acetyl groups from *N*-acetylornithine to glutamate (23, 49, 95). Since this step is part of the arginine biosynthesis pathway, *oat2* may serve to provide additional precursor for clavulanic acid production, a function consistent with its dispensable nature. Alternatively, although OAT acetylates glutamate in vitro, its actual role in clavulanic acid biosynthesis may be to acetylate some other substrate, in much the same way that clavamate synthase can hydroxylate *N*-acetylarginine in vitro even though that is not its natural substrate in vivo (58). ClaR is a transcriptional activator essential for expression of the genes involved in the late, post-clavaminic acid stages of clavulanic acid biosynthesis, and clavaldehyde dehydrogenase (Cad) catalyzes the final step of the pathway, the reduction of clavaldehyde to clavulanic acid. The only other characterized step in the late pathway is that catalyzed by Orf17, an enzyme that converts clavaminic acid to *N*-glycylclavaminic acid (4). This activity was observed in Orf17 enzyme produced in *E. coli*, and trace amounts of *N*-glycylclavaminic acid were also identified as a metabolite accumulating in *S. clavuligerus* mutants with defects in *orf15* or

orf16 (41), suggesting that production of *N*-glycylclavaminic acid may represent the first step beyond clavaminic acid on the clavulanic acid-specific branch of the pathway. Since this *N*-acylated derivative of clavaminic acid retains the 3*S*,5*S* configuration of clavaminic acid, the question of how the double inversion of stereochemistry needed to form clavulanic acid is achieved remains open, as do the roles played by the other unassigned and yet essential ORFs. Beyond *orf17* is a series of ORFs with less clear-cut relationships to clavulanic acid production (41). *orf18* and *orf19* encode apparent penicillin binding proteins, yet their disruption either is impossible (*orf18* is an essential gene) or has no effect on clavulanic acid production or on antibiotic resistance (*orf19*). *orf20* encodes an apparent cytochrome P450, but once again disruption studies suggest no direct involvement in clavulanic acid production. Beyond *orf20* lie three genes encoding apparent regulatory proteins, a sigma factor and the elements of a two-component regulatory system (84). While disruption studies suggest the possibility of conditional effects on clavulanic acid production, these effects are relatively minor compared to disruption of genes central to the cluster.

28.2.3. The Clavam and Parologue Gene Clusters

From the time of its discovery, the gene encoding clavamate synthase, *cas2*, from the clavulanic acid gene cluster was known to be only one of a pair of *cas* genes encoding two isozymes of clavamate synthase. The second of these, *cas1*, is located in a separate region called the clavam gene cluster (Fig. 5) because it is flanked on both sides by genes

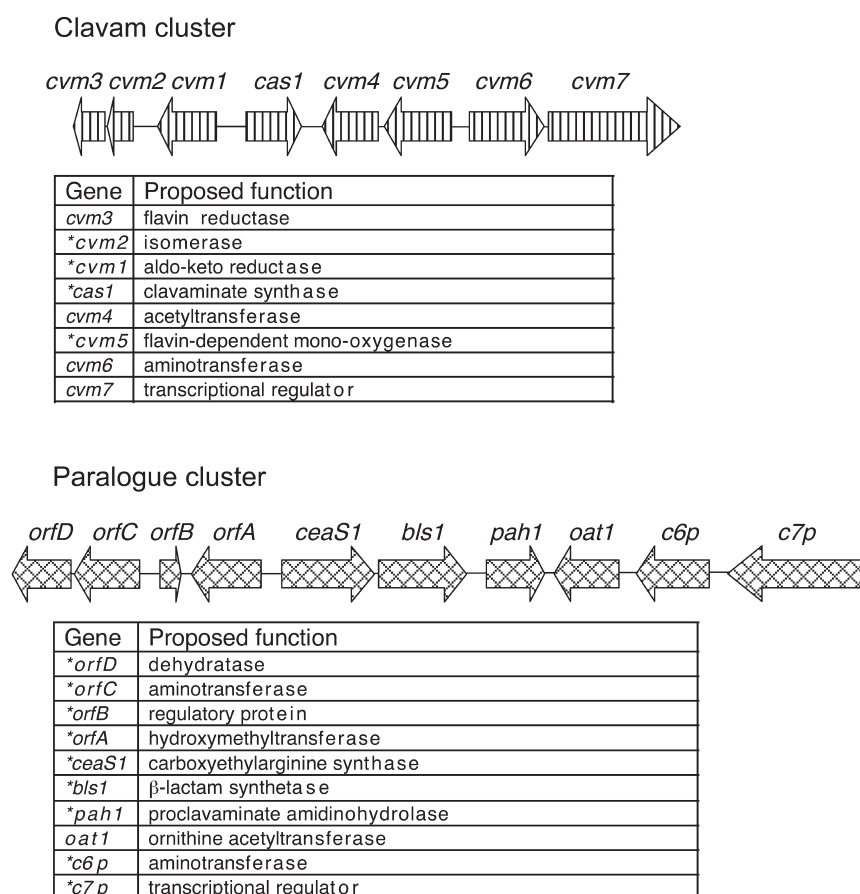

FIGURE 5 The clavam and parologue gene clusters in *S. clavuligerus*. Genes marked with asterisks are essential or important for 5*S* clavam production.

involved specifically in the production of 5S clavam metabolites (64, 88). Clavulanic acid and the 5S clavams share a common pathway to the level of clavaminic acid, but the genes of the clavam cluster, except for *cas1*, are involved in the late, 5S clavam-specific stages of biosynthesis.

In the same way that *cas2* has a paralogue, *cas1*, residing in the clavam cluster, the other early genes of clavulanic acid biosynthesis have paralogues located in yet another region of the chromosome called the paralogue gene cluster (42, 89) (Fig. 5). This cluster includes *ceaS1*, *bls1*, *pah1*, and *oat1*, paralogues of genes for early shared steps of the pathway, but also includes *c6p* and *c7p*, paralogues of the *cvm6* and *cvm7* genes of the clavam gene cluster. Upstream of *ceaS1*, the paralogue cluster includes a group of four genes, *orfA* through *orfD*, that are specifically involved in the biosynthesis of alanylclavam (104). Mutants with defects in any of these genes fail to produce alanylclavam but continue to produce both clavulanic acid and the other 5S clavams.

28.2.4. Regulatory Systems Influencing Production of β -Lactam Compounds in *S. clavuligerus*

Antibiotic production is not uniform throughout the growth cycle of an organism, and it is usually associated with the late, non-growth stages of a culture. In the model species *S. coelicolor*, a complex network of interacting factors has been shown to control both physiological and morphological differentiation (7). While *S. clavuligerus* has not been investigated to the same extent, elements of a similar regulatory network are apparently involved in this species as well.

The first antibiotic regulatory protein identified in *S. clavuligerus* was CcaR, encoded by the *ccaR* gene in the cephamycin arm of the cephamycin-clavulanic acid gene cluster (3, 9, 53, 72, 81, 95, 96). This protein shows a winged helix structure typical of the *Streptomyces* antibiotic resistance protein (SARP) family of transcriptional regulators that frequently serve as pathway-specific activators of antibiotic production (101). CcaR coregulates the expression of genes for two pathways, cephamycin C and clavulanic acid biosynthesis, and thereby ensures that β -lactamase inhibitor and β -lactam antibiotics are produced simultaneously in this species. Molecular studies to identify direct targets of CcaR have produced contradictory results. SARP-type regulators frequently control expression of most or all of the structural genes of their antibiotic gene clusters, but binding studies have identified few promoter regions that bind CcaR. Confirmed targets include the *ccaR* promoter itself and the bidirectional *cmcl-cefD* promoter controlling expression of genes involved in the middle stages of cephamycin C biosynthesis (81). Data for binding of CcaR to the *lat* promoter, controlling the first step of cephamycin C biosynthesis, are contradictory (53, 56). Although not all promoter regions have been examined, no evidence for binding of CcaR to any promoters of the clavulanic acid gene cluster has yet been obtained. SARP-type transcriptional regulators typically bind characteristic heptameric repeat sequences in the promoter regions of target genes. Such heptameric repeats can be identified in the *cmcl-cefD* intergenic region, but not in the *ccaR* promoter. On the other hand, suggestive, appropriately spaced pentameric repeat sequences are evident in the promoter regions of both the *lat* and *clavR* genes despite the lack of clear-cut binding by CcaR.

Whether or not DNA binding has been observed, mutation of *ccaR* does abolish the expression of the tricistronic *lat-pcbAB-pcbC* operon (3) and also prevents expression

from the *ceaS2* promoter in the clavulanic acid gene cluster (89). Furthermore, mutation of *ccaR* blocks production of ClaR, a transcriptional regulator encoded by the *clavR* gene contained within the clavulanic acid gene cluster (74). ClaR is a LysR-type transcriptional activator that controls expression of the genes specific for the late (post-clavaminic acid) stages of clavulanic acid biosynthesis (70, 74). Therefore, although an understanding of the molecular mechanism may be lacking, it is clear that CcaR controls expression of genes involved in the biosynthesis of cephamycin C and the early stages of clavulanic acid biosynthesis. It also controls expression of *clavR*, which in turn regulates the late stages of clavulanic acid biosynthesis. No other regulatory genes are evident within the cephamycin-clavulanic acid gene cluster.

One possible explanation for the inability to demonstrate direct binding of CcaR to more target genes is that other binding factors may be required to recruit CcaR to the promoters. In this regard, autoregulatory small molecules are commonly produced by *Streptomyces* spp. (92) and *S. clavuligerus* is known to produce IM-2-type γ -butyrolactone compounds (32). Correspondingly, an autoregulator binding protein, ScaR (also called Brp), has been described (38, 80), which has a repressive effect on antibiotic production since disruption of *scaR* increases both cephamycin C and clavulanic acid production. Autoregulatory binding proteins such as ScaR bind to characteristic DNA sequences referred to as autoregulatory elements (ARE), and one such sequence has been identified in the intergenic region upstream of *ccaR* (26, 80). Furthermore, this ARE region upstream of *ccaR* also simultaneously binds a second protein, AreB, a regulatory element related to leucine biosynthesis, and binding of AreB requires the participation of a small molecule, perhaps a γ -butyrolactone (79). This demonstrates how complex the interplay of regulatory factors governing gene expression can get, and explains why failure to observe binding to DNA by a purified regulatory protein in vitro may not rule out the possibility of involvement of the protein in regulation.

Just as CcaR and ClaR are the pathway-specific regulators governing clavulanic acid production, C7p (91) may perform the same function for the 5S clavams. Disruption of C7p (from the paralogue cluster) abolishes production of 5S clavams specifically without affecting clavulanic acid production. No molecular studies have yet been performed on C7p to define its regulons. It is also not clear whether any cross-regulation exists between the regulators of clavulanic acid production and those of the 5S clavams. However, evidence for cross-regulation between antibiotic regulatory pathways has been reported between clavulanic acid and holomycin production (19). While these two classes of compounds are completely unrelated in structure and biosynthesis, mutations in genes for the late steps of the clavulanic acid biosynthetic pathway resulted in strains that overproduced holomycin. Reciprocal experiments have not been done since the elements of the holomycin gene cluster have not yet been identified.

Pathway-specific regulators are themselves generally subject to higher levels of regulation, thus making a cascade or network of regulation. In *S. coelicolor*, an array of higher-level regulators have been identified that control the production of the pathway-specific regulators, including the global "bald" (Bld) regulators that affect both morphological differentiation and antibiotic production. A similar system exists in *S. clavuligerus*, although only a few of the elements have been examined to date. Studies have shown that the *S. clavuligerus* homologue of *bldG* controls both sporulation

and antibiotic production in *S. clavuligerus*, just as it does in *S. coelicolor* (9). *bldG* mutants do not sporulate, nor do they express *ccaR* or produce cephamycin C, clavulanic acid, or the 5S clavams. BldG encodes an anti-anti-sigma factor, and while its cognate sigma factor has not been identified, the adjacent anti-sigma factor encoding gene, *orf3*, is presumably part of this partner-switching mechanism, controlling utilization of an alternative sigma factor specific for sporulation and secondary metabolism.

The only other *bld* gene that has been studied in *S. clavuligerus* is *bldA*, encoding the leucyl-tRNA that recognizes the rare UUA anticodon. Genes containing TTA codons are very restricted in high-G+C organisms such as *Streptomyces* spp., and they are distributed asymmetrically. Genes containing TTA codons are overwhelmingly associated with secondary metabolism, sporulation, or utilization of secondary nutrient sources. Genes encoding pathway-specific regulators of antibiotic biosynthesis are commonly found to contain TTA codons, and so when *ccaR* was found to contain a TTA codon, it was fully expected that a *bldA* mutant of *S. clavuligerus* would fail to produce cephamycin C and clavulanic acid. However, antibiotic production was unaffected in the *bldA* mutant and CcaR protein production continued unabated although the mutant was unable to sporulate (94). A proposed explanation for this unexpected result is that the consequences of a *bldA* mutation on expression of TTA-containing genes depend on the context of the TTA codon, with TTA codons followed by pyrimidine nucleotides giving the phenotype of a null mutation, while codons followed by purine nucleotides show little or no effect. Consistent with this theory, in *ccaR* the TTA codon is followed by a purine residue. Interestingly, the *orfA* gene of alanylclavam biosynthesis represents just the second TTA codon-containing gene found in *S. clavuligerus*. In *orfA* the TTA codon is followed by a pyrimidine residue and alanylclavam biosynthesis is abolished in the *bldA* mutant.

Antibiotic production is also regulated at even higher levels in *Streptomyces* spp., and in particular, availability of amino acids, as detected by the stringent response, seems a point of control. At its simplest level, the stringent response is activated in response to an accumulation of uncharged tRNA molecules and is mediated by an accumulation of guanosine polyphosphate [ppGpp(p)] compounds formed by the RelA enzyme. In several *Streptomyces* spp., nutritional shift-down stimulates production of ppGpp and triggers antibiotic production. Recent studies have shown that *S. clavuligerus*, like other *Streptomyces* spp., has two *relA* homologues, *relA* and *rsh*, both encoding enzymes capable of synthesizing ppGpp (47). Mutation of *relA* was found to abolish ppGpp synthesis under conditions of starvation for amino acids, resulting in a bald phenotype and inability to produce either cephamycin C or clavulanic acid, whereas mutation of *rsh* affected only antibiotic production and not sporulation. Thus antibiotic production in *S. clavuligerus* is governed by the stringent response mediated by both RelA and Rsh. How the stringent response interfaces with other elements of the regulatory system, and whether intermediaries such as BldG or the γ -butyrolactone signaling system are involved, remain to be determined.

28.3. GENETIC ENGINEERING TO MODIFY PRODUCTION OF β -LACTAM COMPOUNDS BY *S. CLAVULIGERUS*

As an example of the use of genetic manipulations as described earlier to bring about changes in *S. clavuligerus* metabolite

production, the steps involved in generation of an in-frame *c7p* deletion mutant are described in more detail.

From a library of *S. clavuligerus* genomic DNA fragments carried in the *E. coli* cosmid vector SuperCos, a recombinant cosmid carrying a ~45-kb stretch of genomic DNA encompassing the *c7p* gene was selected (88). This cosmid, 14E10, served as the vehicle for PCR-mediated mutagenesis using the REDIRECT[®] system (31), which resulted in removal of the *c7p* gene and replacement with an *apra* cassette comprising the *apra* resistance gene and an *ori*_{TRK2} region (supports plasmid transfer by conjugation). The cassette was also flanked on both ends by *frt* sites to allow eventual removal of the resistance marker. As a first step (Fig. 6), two hybrid primers (59 nucleotides [nt] and 58 nt)—one primer consisting of 39 nt from the start codon and upstream of *c7p* fused to 20 nt specific for the 5' end of the *apra* cassette, and the second primer consisting of 39 nt from the stop codon and downstream of *c7p* fused to 19 nt specific for the 3' end of the *apra* cassette—were designed and used to amplify the *apra* cassette, with plasmid pIJ773 (31) as template. The resulting PCR product consisted of the *apra* cassette but with 39-nt sequences on each end to target the cassette to the *c7p* gene.

In order to achieve the replacement of the *c7p* gene, first the 14E10 cosmid and then the *apra* cassette were introduced sequentially by electroporation into the recombinogenic *E. coli* host strain BW25113/pIJ790 (31), with selection for kanamycin (*kan*) and ampicillin resistance (from the 14E10 cosmid) and then for apramycin resistance (from the cassette). The *apra* cassette could only persist in *E. coli* to give resistance if it recombined with the 14E10 cosmid, and the *c7p* specific sequences on the ends of the cassette ensured that it recombined to delete the *c7p* gene. The resulting mutant version of the cosmid (14E10 Δ *c7p::apra*) was transferred into the methylation-deficient *E. coli* host strain ET12567/pUZ8002 (31), which carries the transfer functions necessary to allow this strain to act as donor for interspecies conjugation between *E. coli* and *Streptomyces*. When cells from a mid-log-phase culture of *E. coli* ET12567/pUZ8002/14E10 Δ *c7p::apra* were combined with heat-shocked spores of wild-type *S. clavuligerus*, and then the conjugation mixture was plated on AS-1+Mg agar plates, transfer of the 14E10 Δ *c7p::apra* cosmid into *S. clavuligerus* occurred at some frequency. After overnight incubation in the absence of selection, plates were overlaid with nalidixic acid to counterselect the donor *E. coli* strain, and with apramycin to select for the incoming mutant cosmid. Since the SuperCos-based 14E10 Δ *c7p::apra* cosmid has no origin of replication for *Streptomyces*, it could only persist to give apramycin resistance if it recombined into the *S. clavuligerus* chromosome via the long stretches of *S. clavuligerus* genomic DNA flanking the now-deleted *c7p* gene. A single recombination event would result in insertion of the entire cosmid into the chromosome to give both apramycin and kanamycin (from the cosmid) resistance, but the tandem duplication of the region of the chromosome carried on the cosmid makes the cells prone to a second recombination event. To encourage this second recombination, apramycin-resistant exconjugants were plated onto ISP-4 agar and allowed to sporulate. Resulting spores were then diluted and plated on ISP-4 medium to obtain colonies derived from single spores and then replica-plated to identify the desired cosmid-free apramycin-resistant, kanamycin-susceptible Δ *c7p::apra* mutants.

While useful for many purposes, the presence of the *apra* cassette in the Δ *c7p::apra* mutants may have polar effects on expression of downstream genes, and it also precludes the use of the *apra* marker for introduction of other complementation

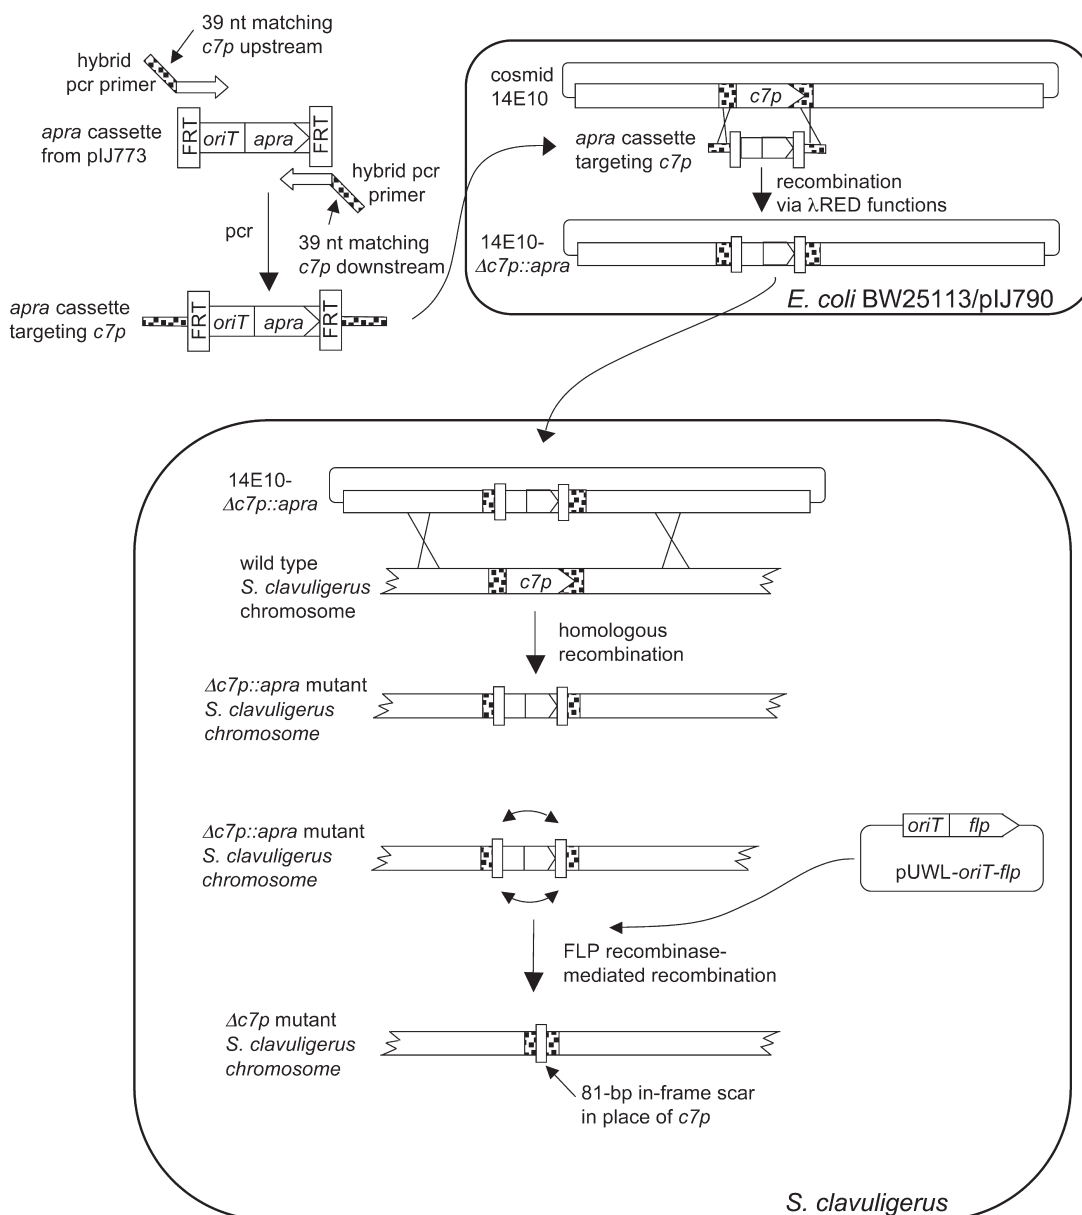

FIGURE 6 Generation of an *S. clavuligerus* $\Delta c7p$ mutant via PCR-mediated mutagenesis using the REDIRECT[®] system. An *apra* cassette targeting the *c7p* gene was prepared in vitro via PCR and then electroporated into *E. coli* BW25113/pIJ790 for recombination with cosmid 14E10. The resulting mutant 14E10- $\Delta c7p::apra$ cosmid was then transferred by conjugation to *S. clavuligerus*, where it exchanged with the resident *c7p* gene to give a $\Delta c7p::apra$ mutant strain of *S. clavuligerus*. Introduction of plasmid pUWL-*flp-oriT* to the $\Delta c7p::apra$ mutant resulted in loss of the *apra* cassette, leaving an unmarked $\Delta c7p$ mutant.

or expression plasmids. To remove the *apra* cassette, the plasmid pUWL-*oriT-flp* (103), carrying the gene encoding FLP recombinase, was conjugated from *E. coli* ET12567/pUZ8002 into the $\Delta c7p::apra$ mutant with selection for thiostrepton resistance, wherein the FLP protein promoted recombination at the FRT sites to excise the *apra* cassette from the $\Delta c7p::apra$ mutant. The resulting exconjugants were freed of the pUWL-*oriT-flp* plasmid by sporulation in the absence of antibiotic selection to promote loss of the segregationally unstable pUWL-*oriT-flp* plasmid, followed by replica-plating to identify the desired plasmid-free apramycin-susceptible, thiostrepton-

susceptible $\Delta c7p$ mutants. In place of the *apra* cassette, the $\Delta c7p$ mutants retain only an 81-bp in-frame “scar.”

Other applications of techniques such as these to modify metabolite production in *S. clavuligerus* are described in the following sections.

28.3.1. Manipulation of Genes Encoding Pathway Enzymes

While *S. clavuligerus* is not used for industrial production of cephamycin C, it does serve as a useful model organism for studies aimed at improving or modifying the production of

penicillins and cephalosporins. In particular the demonstrations that isopenicillin N synthase can accept unnatural peptide precursors to form novel penicillins (5, 18), and deacetoxycephalosporin C synthase can ring-expand unnatural penicillins to form high-value cephalosporins (15–17), have attracted interest. While native enzymes carry out these unnatural conversions with low efficiency, site-directed mutagenesis of the genes encoding the enzymes can improve conversion rates. Development of high-throughput assays for these enzymes should facilitate these mutational studies (86). The demonstration that it is possible to convert aromatic penicillins such as penicillin G directly into aromatic cephalosporins via enzymatic processes has been of special interest and has led to intensive mutational studies on *cefE* (1, 57, 100). In addition to studies aimed at altering the native enzyme activity, increasing the dosage of the *lat* gene (encoding the first dedicated enzyme of cephamycin C biosynthesis) was shown to increase cephamycin C production two- to fivefold in *S. clavuligerus* (60).

Although cephamycins can be valuable metabolites, *S. clavuligerus* is primarily of interest as a producer of clavulanic acid, and for this purpose, production of cephamycin C is a liability. Cephamycin C and clavulanic acid production are tightly linked and coregulated in *S. clavuligerus*. Since the two metabolites arise from separate pathways that share no common steps, it was anticipated that clavulanic acid production might be improved by mutating a gene essential for cephamycin C production, thereby diverting metabolic resources into clavulanic acid production. With this in mind, the *lat* gene was disrupted in a wild-type strain of *S. clavuligerus*, resulting in two- to threefold improvement in clavulanic acid production. A similar improvement, although of lesser magnitude, was also noted when the mutation was introduced into a strain of *S. clavuligerus* used for industrial production of clavulanic acid (69). The industrial strain was the product of years of intensive mutation and selection as part of a strain improvement process, demonstrating that targeted mutation through genetic engineering is useful both for initiating a strain improvement process in a wild-type organism and for effecting additional improvements in a strain already exposed to intensive mutation and selection programs.

Just as cephamycin C production is undesirable in a clavulanic acid producer strain, so too production of 5S clavam metabolites represents an unwanted drain of metabolic resources away from clavulanic acid production. Furthermore, the need to ensure complete removal of these structurally similar 5S clavams from the final product can complicate downstream processing. Mutation of the *cvm1* gene (from the clavam cluster) was shown to completely abolish production of all 5S clavams, and when *lat* and *cvm1* mutations were combined in the production strain, a 10% improvement in clavulanic acid production persisted through scale-up to the pilot plant scale with no production of 5S clavams (69).

While gene knockouts can be used to improve antibiotic production by eliminating competing pathways, further improvements can be made by increasing dosage of genes encoding critical enzymes of the biosynthetic pathway. *ceaS2* encodes the first enzyme of the clavulanic acid pathway, and since the early steps of the pathway are shared between clavulanic acid and the 5S clavams, it also contributes to 5S clavam production. *ceaS2* is the lead gene in an operon comprising *ceaS2*, *bls2*, *pah2*, *cas2*, and *oat2*, although internal promoters also drive expression of some genes. When additional copies of *ceaS2* were introduced into *S. clavuligerus* on a multicopy plasmid, earlier formation and higher levels of production of clavulanic acid (73) resulted. Since other genes from the operon or the cluster were not included in

the expression construct, this implies that clavulanic acid production in the wild-type cell must be limited by availability of *CeaS2*. Consistent with this theory, increasing copy number of the *cad* gene, encoding the enzyme for the last step of clavulanic acid biosynthesis, had no beneficial effect on metabolite production (74). However, other studies have since shown that introduction of an additional copy of the *pah2* gene increased clavulanic acid productivity (85), and similarly, increased copy number of *cas2* was reported to increase clavulanic acid production (37). Since each of these studies increased the dosage of one enzyme only, this raises the question of what the rate-limiting step for this pathway may be. The situation is further confused because of the duplication of these elements of the pathway that already exists naturally. Perhaps increasing copy number of the elements from one set of genes can result in unanticipated effects on expression of the other set of genes, making prediction of effects of increasing gene dosage difficult. However, increased copy number of genes other than *cad*, from the late uncharacterized stages of clavulanic acid biosynthesis (*orf10* through *orf14*), has also been reported to increase clavulanic acid production, and these genes are present at single copy only (62). The different growth conditions employed and different units used to express clavulanic acid productivity in the various studies make it hard to compare clavulanic acid productivity directly from one study to the other, but clearly the matter of the rate-limiting step for clavulanic acid production remains to be determined.

Despite this confusion, it is clear that overproduction of pathway enzymes offers yet another route for increasing productivity of the pathway, particularly once the rate-limiting step can be identified.

28.3.2. Manipulation of Genes Encoding Regulatory Proteins

While improvements in productivity can be achieved by increasing production of pathway enzymes, in the absence of a full understanding of pathway flux this becomes a trial-and-error approach to strain improvement. An alternative approach to achieving the same end is to identify genes encoding critical regulatory proteins and increase their expression levels. Although our understanding of the regulatory networks that affect production of β -lactam compounds by *S. clavuligerus* is still incomplete, manipulation of known regulatory genes can simultaneously affect expression of whole clusters of genes.

Knockout mutation of *ccaR* was found to simultaneously abolish both cephamycin C and clavulanic acid production in *S. clavuligerus* (3, 72), and conversely, introduction of extra copies of *ccaR* improved production of both cephamycin C and clavulanic acid by two- to threefold when they were introduced on a freely replicating multicopy plasmid. In a separate study, the effects of overexpression of *ccaR* alone, or together with the *cas2* gene on an integrative vector with expression driven by the *ermE** promoter, were examined (37). Clavulanic acid production was improved for all of the expression constructs, and in the case of the *ccaR-cas2* expression construct, the resulting strain showed a 24-fold increase in productivity compared to the wild-type background, with clavulanic acid production levels approaching 1 g/liter. No data on effects on cephamycin C production levels were provided.

Increased production of ClaR resulting from overexpression of *claR* on a multicopy plasmid has also been shown to result in a threefold increase in clavulanic acid production, whereas cephamycin C production was decreased (74). Surprisingly, alanylclavam production was also reported to increase in the ClaR-overproducing mutant, a contradictory result since

increased production of clavulanic acid would be expected to channel intermediates away from the 5S clavams.

Pathway-specific regulators for the 5S clavam arm of the clavam biosynthetic pathway are just now being identified and so no studies to define their regulons at the molecular level have yet been reported. Gene knockout studies have however established that disruption of *c7p* generates a mutant able to produce only clavulanic acid and cephamycin C, and not any of the 5S clavams (88). *cvm1* and *cvm5* mutants show this same phenotype, but the *c7p* mutation may be a more desirable route to take if abolishing all production of 5S clavams is the goal, rather than targeting only one gene encoding a biosynthetic enzyme. Conversely, if increased production of 5S clavams is desired, a strategy of knocking out *ccaR* and/or *claR* combined with overexpression of *c7p* might be expected to promote increased levels of 5S clavam production. Although impressive improvements in productivity are possible, pathway-specific regulators are typically expressed at relatively low levels in wild-type cells, and so very high expression levels can be potentially deleterious or toxic to the cell, in our experience.

More global approaches to improvement of antibiotic production could also be coupled with strategies aimed at the pathway-specific regulators. Although the γ -butyrolactone-based quorum sensing system of *S. clavuligerus* is not fully characterized, it does affect antibiotic production, and inactivation of the repressor-like product of the *scaR* gene of *S. clavuligerus* resulted in up to threefold increases in production of cephamycin C and clavulanic acid (80). Although no studies have yet been undertaken, improvements in antibiotic production through altered induction of ppGpp synthesis or alteration of the ribosomal proteins with which it interacts (28, 29) should also hold promise.

In contrast, regulation by *bldA* may at first glance suggest only opportunities for reducing rather than increasing antibiotic production. However, the observed nonuniform effect of the presence of TTA codons on gene expression depending on sequence context may offer the means for selectively modifying metabolite productivity. For example, fermentation of a *bldA* mutant specifically favors production of 5S clavams other than alanylclavam, which is specifically eliminated (unpublished observation). In contrast, BldG mutants show loss of productivity of all antibiotics, suggesting that overproduction of BldG may hold promise for improving productivity (9).

28.4. CONCLUSIONS

Genetic engineering of antibiotic pathways to promote production of unnatural products or to increase levels of production of natural end products is being intensively investigated for many classes of antibiotics. These approaches also have demonstrated value in manipulating the production of β -lactam antibiotics, although in the case of clavulanic acid and the 5S clavams, an understanding of the late stages of the biosynthesis of these products is needed to allow a fully rational approach to be taken. Simple overproduction of pathway enzymes has provided improvement in production levels, but without a better understanding of pathway flux to identify rate-limiting steps, this approach can offer only unpredictable results. Effects of greater magnitude are seen when pathway-specific regulators are targeted for overproduction, and combination approaches targeting both global and specific regulators along with individual pathway enzymes for overproduction, together with elimination of competing pathways, will likely yield

even greater results. Such approaches offer the promise of yielding vigorous, high-producing strains uncompromised by the effects of repeated rounds of random mutagenesis.

Genetic Engineering of Myxobacterial Natural Product Biosynthetic Genes

BRYAN JULIEN AND EDUARDO RODRIGUEZ

29

29.1. INTRODUCTION

Plants and microbes have been a rich source of bioactive natural products, some of which have been developed for medical or animal health uses (17). The importance of natural products is highlighted by the fact that 34% of all small molecule drugs developed over the last 25 years have been derived from natural products or their semisynthetic derivatives (32). Of the microbes, actinomycetes are the largest known producer of natural products. Recently, myxobacteria have been identified as an alternative source of natural products through the work of the group led by Hans Reichenbach at Gesellschaft für Biotechnologische Forschung. From ~7,500 strains of myxobacteria isolated, many novel bioactive compounds have been discovered (35).

Myxobacteria are gram-negative soil bacteria that, under adverse environmental conditions (36), have the ability to form complex fruiting bodies, which can be simple mound structures as seen in *Myxococcus xanthus* or elaborate multibranching, stalked structures as in *Chondromyces crocatus*. These fruiting bodies house dormant spores that are resistant to many environmental stresses.

Natural products produced from myxobacteria have gained wide interest recently. To date, more than 100 new structures and some 500 variants have been identified (3). The majority of myxobacterial natural products have been isolated from strains of *Sorangium cellulosum* (48%), *Myxococcus* (20%), and *Chondromyces* (10%) (12). Most of these natural products are hybrid molecules consisting of polyketides and non-ribosomally made peptides in a linear or cyclic form. Although the addition of modified sugars to natural products from *Streptomyces* is common, they are rarely found on myxobacterial natural products. Less common but noteworthy features of myxobacterial natural products are two compounds with chlorinated amino acids (19, 20), one with a cyclopropane ring (39), and compounds that complex with boron (18). Finally, a few terpenoid compounds have been identified (12).

Of all myxobacterial natural compounds identified, only one compound, the lactam version of epothilone B (Ixemptra®) (Fig. 1), is currently marketed as a human drug. The epothilones were originally identified by their antifungal activity against the zygomycete *Mucor hiemalis* (11). They were later rediscovered in a screen to identify compounds that stabilize microtubules, similar to the

mechanism of paclitaxel (4). The advantage of epothilones over paclitaxel is their ability to inhibit tumors that exhibit multidrug resistance (28). Ixemptra® is currently approved for treatment of metastatic or locally advanced breast cancer.

Because the majority of the natural products from myxobacteria are synthesized by type I polyketide synthases (PKSs) and nonribosomal polypeptide synthetases (NRPSs) (Fig. 1), they are amenable to structure modification through genetic engineering using the information gained over the years on the structure and biochemistry of the polyketide and nonribosomal peptide megasynthases. Genetic engineering of PKSs and NRPSs is aimed at producing novel analogs of natural products for drug development (30, 41, 52).

In order to engineer PKS genes, one must be able to genetically manipulate the producing host. Alternatively, expression and engineering of the genes in a heterologous host is required. However, several challenges with engineering myxobacteria are present. The most prolific producers, *Sorangium* spp., grow relatively slowly, can be difficult to grow as a dispersed culture, and have limited molecular and genetic tools for engineering. Advancements have been made in using heterologous hosts for expression and production of myxobacterial natural products.

In this chapter we summarize progress made with engineering novel analogs of epothilone and ambruticin, an antifungal compound isolated from *S. cellulosum* more than 30 years ago (39). We describe the cloning of the gene clusters from *S. cellulosum*, the development of *M. xanthus* as a heterologous expression host, and the development of tools and techniques to genetically manipulate the natural producer for generating new analogs. The reader is also directed to several reviews of myxobacterial natural products (3, 12, 35, 51, 54).

29.2. HETEROLOGOUS EXPRESSION OF PKS/NRPS GENES IN MYXOBACTERIA

29.2.1. Cloning and Identification of PKS/NRPS Gene Clusters

After identification of a natural product as a lead candidate for drug discovery, limited material supply can be a major obstacle to clinical evaluation. Chemists usually resolve

FIGURE 1 The PKS/NRPS assembly line for epothilone biosynthesis. The six polypeptides of the megasynthase are shown at the top (EpoA to EpoF) as arrows (N to C terminus). The domain composition is shown schematically. The numbered domains on the polypeptides were targets for genetic engineering as described in section 29.5.1. The *epoK* gene encodes a cytochrome P450 protein which adds an epoxide to epothilones C and D to produce epothilone A and B, respectively.

this by developing methods for chemical synthesis from commercially available materials. However, for polyketides and peptides, the number of steps required for synthesis excludes this approach as a long-term economical method of production. A good example is epothilone. The Danishefsky and Nicolaou research groups completed the synthesis of epothilone and numbers of analogs (2, 33, 46, 55), but given the complexity of the 20-step synthetic process, chemical synthesis would be more costly than if a final molecule or an intermediate could be made by fermentation and then modified chemically.

Fermentation production of natural products can be costly in the beginning if titers are low. However, a classical strain improvement program involving mutagenesis and screening for higher-producing strains is the proven route to bring fermentation costs down. For example, an *S. cellulosum* strain was improved 500-fold to increase soraphen titers from 3 to 1,500 mg/liter (12), and more recently epothilone B titers were increased 130 times from 0.8 to 104 mg/liter by using a combination of classical mutagenesis and genome shuffling techniques (14).

An alternative method, especially for compounds produced by microorganisms that are difficult to grow at large scale or where techniques are not available for genetic manipulation, is heterologous expression of the natural product biosynthetic genes. The first step in this process is their identification. To identify the epothilone biosynthetic genes, two approaches were taken (22, 43). Both resulted in

generating DNA fragments for screening a library of DNA fragments. Because of the common biosynthetic nature of all type I PKSs, there are conserved protein regions that can be used for making DNA probes. Of these homologous protein regions, the β -ketoacyl acyl carrier protein (ACP) synthase domain (KS) of a PKS, which is found in all extension modules, was used to design degenerate primers which were then used to amplify genomic DNA from the epothilone-producing strain *S. cellulosum* SMP44. The putative KS sequences were cloned, sequenced to verify their identity, and then used to probe a cosmid library of genomic DNA from the producing strain (Fig. 2A). Thirteen cosmids were identified and further analyzed by restriction mapping, hybridization with an enoylreductase probe, and end-sequencing of the DNA cloned into each cosmid. Using the information gained from the analysis of the cosmids, four were identified for sequencing (22). The complete sequence of the cosmids revealed a modular type I PKS, and analysis of the enzymatic functions encoded in each module correlated well with those required for the synthesis of epothilone.

The second approach taken was to generate a more random set of probes for identifying PKS gene clusters. This entailed constructing a library of 1- to 2-kb DNA fragments and sequencing the ends of the cloned fragments. From this library approximately 500 DNA sequences were produced and then analyzed for homology to PKS or NRPS sequences. From these sequences, 16 showed

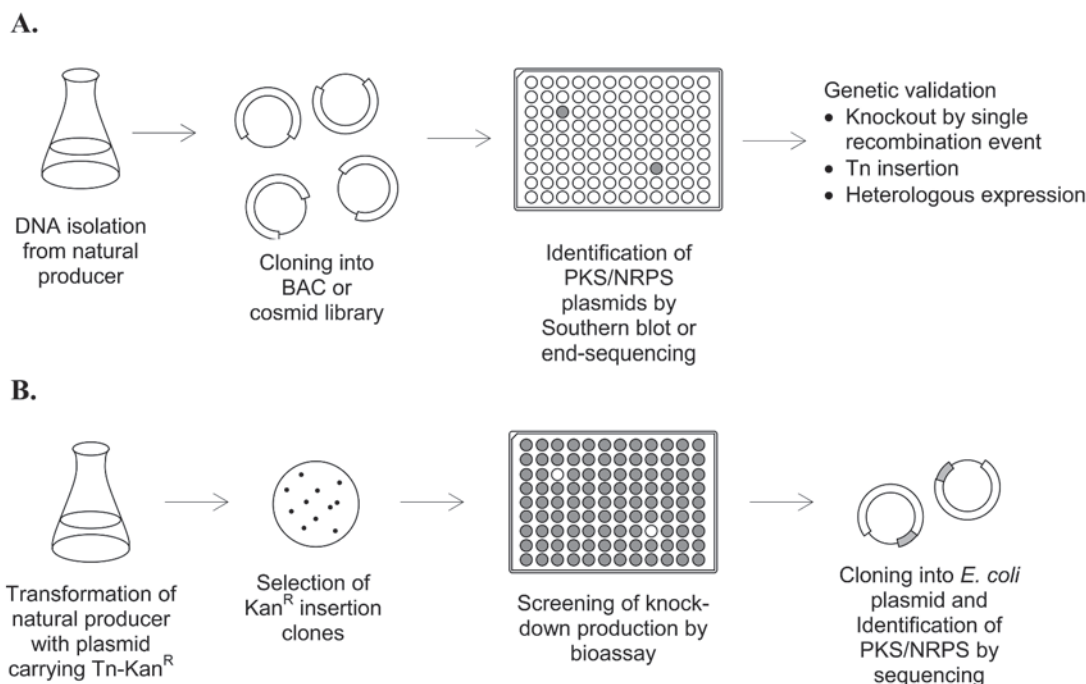

FIGURE 2 (A) Schematic representation of cloning and identification of the PKS/NRPS gene cluster from a *Myxobacterium* natural producer. (B) Schematic steps for using the *mariner* transposon derivative for identification of PKS/NRPS in myxobacteria.

homology to PKS sequences and 4 showed homology to NRPS sequences. Although these PKS/NRPS DNA fragments were never used to probe a library, they did provide the first glimpse at the large number of natural product gene clusters encoded by *S. cellulosum*. The data indicate that approximately 4% of the genome is PKS/NRPS sequence (43); assuming a genome size of approximately 10 Mb (13), then 400 kb of DNA encodes PKS/NRPS sequences. With an average size of approximately 40 to 50 kb per biosynthetic gene cluster, then six to eight different gene clusters are present in SMP44. The large number of natural product gene clusters in myxobacteria have been verified from the genome sequencing of *M. xanthus* DK1622 and *S. cellulosum* So ce56 (13, 44).

Another method of identifying natural product biosynthetic gene clusters in myxobacteria was later developed for isolation of the ambruticin biosynthetic genes. This method uses a transposon to insert and tag a gene cluster of interest. The insertion inactivates the biosynthetic genes, and the loss of production can be screened for by a simple bioassay or by analyzing culture extracts by high-pressure liquid chromatography (HPLC) or liquid chromatography/mass spectroscopy (LC/MS) (Fig. 2B). A detailed protocol for using the transposon is described in section 29.3.1. Using the techniques described for identifying natural product biosynthetic genes, 23 complete gene clusters have been sequenced from myxobacteria (51).

29.2.2. A Bacterial Host for Heterologous Production of Myxobacterial Natural Products

The first myxobacterial natural product to be produced in a heterologous host was epothilone (48). The gene cluster, consisting of nine PKS modules, one NRPS, and a cytochrome P450 spanning 56 kb (Fig. 1), was cloned onto two compat-

ible *Streptomyces* plasmids and transformed into *Streptomyces coelicolor*, a widely used host for expression of polyketide biosynthetic genes from actinomycetes (see chapter 26 by Kealey, this volume). In *S. coelicolor*, epothilones A and B were produced, but at a low level due to an apparent toxicity. This prompted a search for an alternative host.

Such an alternative host would ideally be one similar to *S. cellulosum*. Examination of research on myxobacteria revealed that *M. xanthus* is a good host for several reasons. First, it is well characterized and has the most developed engineering tools among the myxobacteria. It has a shorter doubling time than *S. cellulosum* (5 versus 16 h). Several promoters from other myxobacteria function properly in *M. xanthus*; we have shown the functionality of the myxothiazole promoter from *Stigmatella aurantiaca* and the epothilone and ambruticin promoters from *S. cellulosum* in *M. xanthus* (24; B. Julien, unpublished data). Also, the genome sequence of *M. xanthus* is known. Other requisites, such as precursor supply and posttranslational modifications of PKS/NRPS, have been demonstrated in *M. xanthus*, proving it to be a suitable host for heterologous production of myxobacterial natural products (24).

The epothilone biosynthetic gene cluster was built in the genome of *M. xanthus* in a two-step process due to its large size (24). The first step required introduction of fragments of the epothilone gene cluster for use as recombination sites. Subsequent steps introduced large fragments of the gene cluster from cosmids into the chromosome. Although this work involved time-consuming techniques, it proved the viability of using the myxobacterium *M. xanthus* as a heterologous host for production of myxobacterial natural products, and led the way for combinatorial biosynthesis of novel epothilone analogs (section 29.4). Also, the genetic manipulation of the epothilone PKS cluster allowed an

easy method to inactivate the *epoK* gene for production of epothilones C and D in *M. xanthus* (24). The *epoK* gene encodes a cytochrome P450 protein, which adds an epoxide moiety to epothilones C and D to produce epothilones A and B, respectively (Fig. 1) (48).

With the complete epothilone biosynthetic gene introduced into *M. xanthus* host, initial production of epothilone B was 0.3 mg/liter. Unexpectedly, the ratio of epothilone B to epothilone A is significantly higher in *M. xanthus*, 6:1, than in *S. cellulosum*, which has a ratio of 1:2. Through media optimization, this was quickly raised to 25 mg/liter by using a fed-batch process (29). Finally, with a classical strain improvement program, titers over 100 mg/liter were reached, which provided a production host for epothilone D that provided material for phase I and phase II clinical trials. Although *Escherichia coli*, *Streptomyces venezuelae*, and *Pseudomonas putida* have been engineered with the epothilone biosynthetic genes, none has reached the titers obtained from *M. xanthus* (9, 31, 34).

29.3. GENETIC TOOLS FOR MYXOBACTERIA

29.3.1. *mariner*-Based Transposon for *Sorangium* spp.

Because a single strain of myxobacteria can harbor multiple PKS/NRPS gene clusters for natural products, it can be challenging to identify the proper gene cluster for a product of interest. For epothilone, PCR-based amplification of conserved regions in the KS sequence and sequencing of a library of genomic fragments eventually led to the identification of the biosynthetic genes (section 29.2.1). However, this process is time-consuming because it requires the identification of all PKS/NRPS gene clusters, usually by partial sequencing of cosmids, to determine which ones are correct.

To facilitate the identification of the biosynthetic gene cluster in *S. cellulosum*, a transposon based on the *mariner* transposon from eukaryotes was developed. For use in *S. cellulosum*, a conjugative plasmid was constructed that harbored both a *mariner tnp* gene encoding the transposase and the *mariner* inverted repeats flanking the antibiotic resistance gene for bleomycin. Using a conjugation procedure (described in chapter 18, this volume), a transposition frequency of 10^{-4} to 10^{-5} per cell was obtained with *S. cellulosum* So ce90 (25). Additionally, a *tnp* gene harboring two point mutations allowed a fourfold increase in the transposition frequency relative to wild type. Since the transposase only requires the dinucleotide TA to insert into DNA, the modified *mariner* transposon essentially inserts randomly throughout the genome (40).

The utility of such a transposon was demonstrated by isolation of an *epoK* knockout from a library of approximately 12,000 mutants of the *S. cellulosum* strain So ce90 (25). In addition, this transposon was used for mutagenesis of *S. cellulosum* So ce10 and *S. cellulosum* So ce12 for the rapid identification of the ambruticin and disorazole biosynthetic genes (Fig. 2B) (5, 26). For identification of the ambruticin biosynthetic genes, the transposon mutagenesis technique proved superior to the sequencing of random cosmid inserts. Thus, the *mariner* transposon provides a valuable tool for generating random mutations in *Sorangium* spp., and it has been shown to work in other myxobacteria as well (27, 42, 57).

29.3.2. Gene Replacements in *M. xanthus*

The major advantage of using *M. xanthus* over other myxobacteria is the ability to introduce stable genetic

modifications into the chromosome by double homologous recombination. This process can be accelerated by the use of a counterselectable marker. For *M. xanthus*, two markers have been used, *sacB* (encoding a levansucrase) and *galK* (encoding a galactokinase) (50). Both genes, when integrated into the *M. xanthus* chromosome, provide selective conditions for their subsequent loss: for *sacB*, growth in the presence of sucrose, and for *galK*, growth in the presence of 2-deoxygalactose. Because 2-deoxygalactose is expensive, it was later found that galactose can be used in the *galK* counterselection system (Julien, unpublished data). This substitution is possible because *M. xanthus* does not metabolize galactose. Expression of *galK* in *M. xanthus* results in the phosphorylation of galactose where there is no pathway to convert or export it. This results in an accumulation of phosphogalactose inside the cell, causing death. Similar results have been seen with *E. coli* mutants that are blocked after the phosphorylation of galactose (56).

29.3.3. Protocol for Performing Gene Replacements in *M. xanthus*

1. In a plasmid carrying the *galK kan^r* genes, clone both flanking regions of the target gene at each side of the gene. PCR, DNA synthesis, or λ Red recombineering technology (54) can be used to construct the DNA. Design of restriction enzyme sites or overlap extension PCR can help to stitch the fragments together.
2. Transform the plasmid into the strain using electroporation or conjugation (see chapter 18, this volume) and select on Casitone-yeast extract (CYE) plates containing 50 μ g/ml kanamycin. Verify insertion into target location by PCR or Southern blot.
3. Inoculate the *kan^r* strain, containing the integrated replacement plasmid, in CYE without kanamycin until cells are in mid-log to early stationary phase.
4. Dilute cells to 10^{-3} and 10^{-4} , add 2.5 ml of CYE top agar, and pour onto CYE plates supplemented with 1% galactose.
5. Incubate plates at 32°C for 7 to 10 days.
6. Restreak colonies and confirm the loss of the *kan^r* marker by the lack of growth on CYE with 50 μ g/ml kanamycin.
7. Confirm presence of the mutation by PCR or Southern blot.

In cases where several replacements need to be tested, as was performed in module 4 replacements of the epothilone gene cluster (section 29.4.2), an additional step in the gene replacement protocol can be included as follows:

1. Replace the target gene with the *galK kan^r* genes using a plasmid carrying these genes cloned between the two flanking regions of the target gene.
2. Transform the linearized plasmid into the strain using electroporation. Select on CYE plates containing 50 μ g/ml kanamycin. Verify the replacement into target location by PCR or Southern blot.
3. Construct a new plasmid containing the bleomycin resistance (*ble^r*) gene and the same flanking regions of the target gene at both sides of the new version of the gene, and transform into the above *kan^r* strain, selecting for bleomycin-resistant colonies.
4. Inoculate the *kan^r ble^r* strain, containing the integrated replacement plasmid, in CYE without kanamycin until cells are in mid-log to early stationary phase and then follow step 4 of the previous protocol.

This additional step generates a nonproducing Kan^r strain which allows the possibility of using a bioassay for screening the positive clones after the replacement.

29.3.3.1. Media

CYE medium: (per liter) 10 g of Casitone, 5 g of yeast extract, 1 g of MgSO₄·7H₂O. After autoclaving, add 10 ml of 1 M morpholinepropanesulfonic acid (MOPS) adjusted to pH 7.6.

CYE plates: CYE medium containing 15 g of Bacto agar.

CYE top agar: CYE medium containing 7.5 g of Bacto agar.

29.3.4. Integration of Large Fragments of DNA into *M. xanthus* Using Mx9 Site-Specific Integration System

As mentioned above, the introduction of the epothilone biosynthetic genes into *M. xanthus* was time-consuming. However, it was the most efficient method at the time given its size. More efficient methods of introducing large DNAs have been developed. Recently a technique using a transposon to move large pieces of DNA into the chromosome was used for introduction of the epothilone gene cluster into *M. xanthus* and *P. putida* (9, 53). Because of the size of the epothilone gene cluster, the technique required "stitching" large pieces of DNA together on the transposon by Red/ET recombination. Although the authors were successful at building the transposon with the epothilone cluster, the recombination was less efficient, due to the large size of the gene cluster, and there was a high frequency of intermolecular recombination due to the high homology of the DNA sequence encoding each module. Furthermore, the results showed size-dependent transposition frequency: the larger the transposon, the lower the transposition frequency. Thus, very large DNA pieces can be problematic with this technique.

A new method has been developed that enables large fragments of DNA, >100 kb, to be integrated into the chromosome of *M. xanthus*. This technique uses a modified bacterial artificial chromosome (BAC) with large DNA inserts which can be transferred by conjugation and then integrated into the chromosome. This modified BAC contains an *oriT* for conjugation into *M. xanthus* from *E. coli*, and the site-specific recombination system from the myxophage Mx9, to integrate the DNA into the chromosome (Julien, unpublished data). The Mx9 site-specific recombination system was used because integration at the Mx9-*attB* site does not interfere with gene expression, unlike integration at the Mx8 integration sites (23).

This method was validated using a BAC containing a DNA fragment greater than 100 kb which harbored the complete ambruticin biosynthetic gene cluster. Through the use of the *loxP* site for specific recombination carried on the BAC, the *oriT* for conjugal transfer, the bleomycin resistance gene for selection in *M. xanthus*, and the Mx9 *int* gene and Mx9-*attP* site for integration into the *M. xanthus* chromosome were added. The modified BAC was successfully conjugated into six different *M. xanthus* strains, and production of ambruticins varied from 0.1 to 10 mg/liter depending on the *M. xanthus* strain used (Julien, unpublished data).

This technique of integrating large pieces of DNA into *M. xanthus* provides a method to identify new natural product biosynthetic genes from any myxobacteria by first constructing a library of large DNA fragments on this integrating BAC and then conjugating the individual BAC

clones into *M. xanthus*. Since the genomes of myxobacteria are in the range of 10 Mb in size, 100 clones from a BAC library with an average insert size of 100 kb should give one genome size worth of coverage.

29.4. ENGINEERING NOVEL ANALOGS OF EPOTHILONE

29.4.1. Inactivation of KR, DH, and ER Domains in the Epothilone Gene Cluster

An important advantage of using *M. xanthus* as a heterologous host is the possibility of applying combinatorial biosynthesis. Thus, the heterologous expression of the epothilone gene cluster in *M. xanthus* provided the opportunity for making novel analogs and understanding novel enzyme mechanisms. This technology makes use of genetic engineering of the assembly line of a PKS through addition, deletion, or mutation of catalytic domains or the reorganization of whole modules aimed at generating novel analogs (Fig. 3).

After the condensation of a carboxylic residue into the carbon skeleton, the β -ketone can be sequentially reduced first by the actions of a ketoreductase (KR), then a dehydratase (DH), and finally an enoylreductase (ER) domain. Thus, one method to alter polyketide structures is through inactivation of one or more of these reductive reactions so that the corresponding step in the synthesis is bypassed, resulting in a novel compound. Our ability to inactivate these domains comes from molecular modeling combined with mutational studies that have led to the identification of key amino acid residues that participate in the catalysis of the KR, DH, and ER domains. In addition, the amino acids required for setting the stereochemistry of the alcohol group by the KR domain were determined (7, 37).

For abolishing the activity of KR domains, it was shown that a conserved active site tyrosine was important for activity, and that changing this amino acid to phenylalanine resulted in a loss of activity (37). In addition, mutation of the conserved glycine in the Rossmann fold important for NADPH binding is predicted to prevent KR activity (7). Using this information, replacement of the corresponding residues in the KR in modules 4 and 6 of the epothilone gene cluster in *M. xanthus* strain was attempted.

For the KR domain in module 4, single amino acid substitutions of the tyrosine or glycine did not inactivate the KR, as evidenced by the production of epothilone D and not the expected 13-oxoepothilone. However, combining both mutations resulted in complete inactivation of the KR domain and production of the expected compound 12,13-dihydro-13-oxoepothilone C, in trace amounts, and the unexpected compound 11,12-dehydro-12,13-dihydro-13-oxoepothilone D as the major product (Fig. 3A) (50). Complete deletion of the KR₄ domain and insertion of a linker region resulted in the same products as the double mutants. For KR₆ the two point mutations were constructed. This strain produced the expected compound 9-oxoepothilone D and its isomer 8-*epi*-9-oxoepothilone D as the major products (Fig. 3B) (47).

In addition to inactivating KR modules, mutations were made in the DH or ER domains of module 5. To inactivate ER₅, the NADPH binding site was targeted, similar to the KR point mutations. Mutation of two adjacent glycine residues to an alanine and serine in the NADPH binding site and introduction into the epothilone D-producing *M. xanthus* strain resulted in the production of the predicted 10,11-didehydroepothilone D (1).

FIGURE 3 Novel epothilone analogs generated by manipulation of the *epo* PKS. Most of the successful changes were produced through inactivation of domains involved in the reductive cycle. (A) KR₄. (B) KR₆. (C) DH₅. (D) ER₅.

In addition to making novel epothilone compounds by engineering the biosynthetic gene cluster, important biochemical information was obtained on the formation of the *cis* double bond between C12 and C13. For this double bond to form, a DH domain is required. However, there is no DH activity encoded in module 4 of the epothilone PKS. Inactivation of DH₅ revealed its role in *cis* double bond formation. Mutations were constructed in DH₅ that replaced eight highly conserved amino acids with three amino acids, or replaced the entire DH/ER/KR segment with a KR domain from another module (49). In both mutants the major product was 10,11-didehydro-12,13-dihydro-13-hydroxyepothilone D (Fig. 3C). The presence of a hydroxyl group at C13 strongly connects the activity of DH₅ with the dehydration and formation of the 12,13 double bond (48). However, the unanticipated 10,11 double bond must have been produced by another DH domain, potentially DH₆. Thus, DH₅ performs an unprecedented series of two reactions, one for *cis* double bond formation and the other for dehydration of the C13 hydroxyl, resulting in the formation of a *trans* double bond (49). Thus, besides being able to make 10,11-didehydroepothilone D in *M. xanthus*, this procedure uncovered the mechanism by which the C12-C13 *cis* double bond is formed (Fig. 3D).

29.4.2. AT Domain Replacement in the Epothilone Gene Cluster

In addition to modification of the reductive domains within the epothilone biosynthetic enzyme, modifications of the specificity of ATs were attempted. The AT of each module recognizes either a malonyl or methylmalonyl extender unit to be added to the growing polyketide chain. Changing the

specificity of an AT will create novel molecules. Modifications of several of the ATs in the epothilone PKS were attempted, but only one yielded a functional replacement (E. Rodriguez and L. Tang, unpublished data). Thus the epothilone PKS is less amenable to changes in the extender unit, likely due to a stricter structure requirement to be recognized by each module as the polyketide chain is lengthened.

The only module that was amenable to changes of specificity of its AT was module 4 (AT₄), which is able to use either malonate or methylmalonate. The two major products made by the epothilone PKS are epothilones A and B. The difference between the two is the presence of a methyl group at C12. Labeling studies have confirmed that this methyl group is derived from propionate (10), the precursor for methylmalonate; thus, to make epothilones A and B, AT₄ must be able to utilize both extender units, malonate or methylmalonate. Because the epothilones with the C12 methyl group are more potent, a strain was engineered to produce only epothilone B or epothilone D in an *epoK* mutant strain.

To engineer this strain, the AT₆ from the soraphen gene cluster from *S. cellulosum* So ce26 and the AT₇ from the epothilone gene cluster were chosen for the replacement, based on their similar domain organization to the module 4 of EpoD protein and their preference for methylmalonyl-coenzyme A (CoA) (E. Rodriguez and B. Julien, unpublished data) (Fig. 4). Three unique junction boundaries between the KS and AT domains in combination with three boundaries between the AT and KR domains were designed based on protein alignments. The gene replacements were performed according to the protocol described in section 29.3.3. The results showed that both the soraphen AT₆ and epothilone AT₇ could be used to increase the ratio of epothilone D to

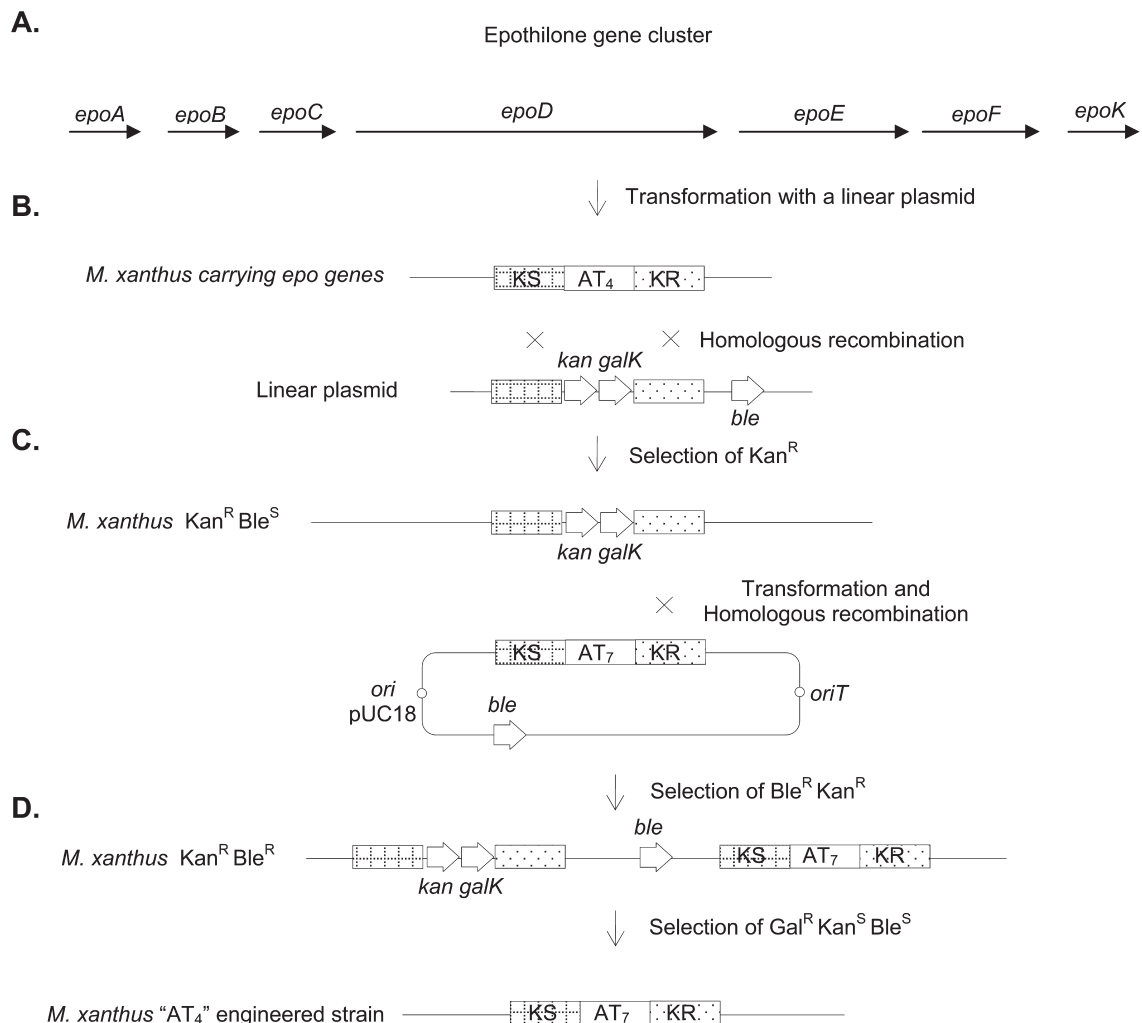

FIGURE 4 Scheme for engineering an AT replacement in the chromosome of *M. xanthus* carrying the epothilone gene cluster. (A) Schematic representation of the epothilone gene cluster. (B) Step 1: replacement of AT₄ with the *kan*^r *galk* genes through double recombination using a linear delivery vector. (C) Step 2: a cassette, consisting of a heterologous AT flanked by upstream and downstream regions, is introduced into the *M. xanthus* strain constructed in step 1. The first crossover can occur with either of the flanking regions. (D) Step 3: the second crossover is selected using plates containing galactose, resulting in the recombination event to remove duplicated regions and segments with the kanamycin resistance and *galk* genes. Fermentation of the Gal^r Kan^s Phle^s strain allows selection of the correct construct.

epothilone C 50-fold in the *epoK* mutant *M. xanthus* strain. These results were obtained using only one of the KS-AT boundaries in combination with any of the three AT-KR boundaries. In addition, a twofold increase in overall titers was obtained by use of the epothilone AT₇ domain.

29.5. MODULATION OF EPOTHILONE PRODUCTION IN MYXOBACTERIA

29.5.1. Protocol for Production of Epothilone in *M. xanthus*

M. xanthus presents a special challenge for development of a production medium for secondary metabolites. It does not metabolize simple sugars, but relies on amino acids and oils to provide its carbon source. Using amino acids as a carbon source results in the accumulation of ammonium, which

has a negative impact on secondary metabolite production. To circumvent this, the oil methyloleate is used as a carbon source. Because methyloleate disrupts the cell membrane if added at high concentrations, the cells are adapted to the oil before inoculation into production medium. The following protocol has been established for production of secondary metabolites in *M. xanthus* (29).

1. *Inoculum preparation.* Inoculate *M. xanthus* into 3 ml of CYE medium supplemented with 3 μ l of methyloleate in a 50-ml glass tube. Incubate at 32°C and 175 rpm until culture is saturated. Slow agitation is critical to prevent too much mixing of the oil and subsequent lysis of the cells. After 3 days, transfer into a 250-ml Erlenmeyer flask containing 50 ml of CYE supplemented with 100 μ l of methyloleate, and grow for 2 days at 32°C and 175 rpm.

2. **Production medium.** In a 250-ml Erlenmeyer flask, add 1 g of XAD-16 and enough water to immerse the resin, and autoclave to sterilize. Remove water from sterile flask and add 50 ml of CTS fermentation medium supplemented with 350 μ l of methyloleate and 200 μ l of trace elements.
3. **Fermentation conditions.** Inoculate medium with 2.5 ml (5%, vol/vol) of the saturated culture. Grow cultures at 32°C. For simple batch fermentations, grow the cultures for 5 days, then remove the XAD-16 resin and extract the compounds. For fed-batch fermentation, which results in increased secondary metabolite production, feed the cultures daily, starting after day 2, with 150 μ l of methyloleate and 100 μ l of a 1-g/liter solution of Casitone. After 10 days, remove the XAD-16 resin and extract the compound.
4. **Analysis of the products.** To extract the product from the resin, allow the culture to sit for several minutes for the resin to settle to the bottom of the flask, and then pour off the culture broth. Wash the resin twice with several volumes of water, and remove the final few milliliters of water by aspiration. To the resin, add 25 ml of methanol and incubate at room temperature for a couple of hours, preferably with shaking. Analyze the methanol extract by HPLC or LC/MS for desired products.

29.5.1.1. Media

CTS medium: (per liter) 5 g of Casitone, 2 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$. After autoclaving, add 50 ml of 1 M HEPES (pH 7.6).

Trace element solution: (per liter) 10 ml of concentrated H_2SO_4 , 14.6 g of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, 2 g of ZnCl_2 , 1 g of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$, 0.43 g of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, 0.31 g of H_3BO_3 , 0.24 g of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$, and 0.24 g of $\text{Na}_2\text{MO}_4 \cdot 2\text{H}_2\text{O}$.

29.5.2. Altering Epothilone Congener Production through Medium Design

Epothilones A and B are the major fermentation products of *S. cellulosum* So ce90 and of the *M. xanthus* strain engineered to contain and express the epothilone biosynthetic genes. However, the ratios of the compounds produced in the two organisms are dramatically different. For *S. cellulosum*, the ratio of A to B is 2:1, but for *M. xanthus* it is 1:6. The difference in ratio is likely due to the available pools of malonyl- or methylmalonyl-CoA, providing the hypothesis that modulating the levels of these two extender units can result in altering the ratio of the two major products.

To change the ratio of epothilones, the intracellular concentrations of malonyl-CoA and methylmalonyl-CoA were altered by the addition of acetate or propionate to the basal production medium. Supplementation of increasing concentrations of acetate resulted in decreases in the epothilone D:C ratio (8). Conversely, addition of propionate to the basal medium resulted in a higher epothilone D:C ratio. The growth rates and cell densities of these cultures were also markedly decreased as the propionate concentration was increased in the basal medium, indicating a potential toxicity associated with high levels of propionate in the media or high levels of propionate, propionyl-CoA, or methylmalonyl-CoA.

In addition to epothilones A and B, *S. cellulosum* has been shown to make small amounts of 37 additional epothilone variants due to the incorporation of different

precursors or alterations in the biosynthetic steps by the epothilone NRPS/PKS enzymes (16). One of the variants contains an oxazole ring in place of the thiazole that results from the utilization of serine rather than cysteine by EpoB, the NRPS. To increase the production of the oxazole-containing compounds by the engineered *M. xanthus* strain, the fermentation medium was supplemented with serine in concentrations ranging from 2.3 mM to 168 mM (8). At a serine concentration of 71 mM, the maximum production of the oxazole-containing compound was achieved, producing roughly equal amounts of the thiazole- and oxazole-containing epothilones. However, the overall epothilone titers were decreased by 75%. Thus, in addition to modification of the PKS enzyme, fermentation conditions can aid in making novel compounds or increasing the production of minor ones.

29.5.3. Metabolic Engineering

In addition to modifications of the PKS enzyme or media optimization to increase production of target molecules, engineering biochemical pathways can prove valuable. One example in *S. cellulosum* is the engineering of the pathway for methylmalonyl-CoA to produce more epothilone B. Because AT_4 is able to utilize either malonyl-CoA or methylmalonyl-CoA, increasing the intracellular pool of methylmalonyl-CoA would favor the production of epothilone B. To achieve this, the propionyl-CoA synthase gene, *prpE*, from *Ralstonia solanacearum* was heterologously expressed in *S. cellulosum* (15). PrpE converts propionate into propionyl-CoA, which then is subsequently converted to methylmalonyl-CoA. This engineered *S. cellulosum* strain exhibited a significant increase in the epothilone B:A ratio of 127:1, which was 100-fold higher than that of the parental strain.

29.6 ENGINEERING NOVEL ANALOGS OF AMBRUTICIN

29.6.1 Inactivation of Post PKS Enzymes

The first myxobacterial natural product was isolated from *S. cellulosum* by researchers at Warner-Lambert in the 1970s (39). The compound, ambruticin S (Fig. 5), exhibited potent activity against many fungal strains, in particular the pathogens *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*. It was also shown to be active against *C. immitis* and *H. capsulatum* infections in murine models. However, its development was halted due to its lack of activity against *Candida albicans* (38).

Interest in ambruticins resurfaced as other fungal infections became more problematic, particularly aspergillosis in immunocompromised people. Kosan Biosciences, Inc., began a development program testing new ambruticin analogs that were derived from chemical modification of the basic ambruticin scaffold. Several of these analogs showed efficacy in murine models for coccidioidomycosis and aspergillosis (6, 45).

To make analogs that were inaccessible through facile chemical modification, the biosynthetic genes for ambruticin were identified (26). Analysis of the biosynthesis genes revealed novel enzymatic reactions for PKSs. One is the use of a separate methyltransferase for capturing an enolate to form the first pyran ring. The most intriguing is a Favorskii-like rearrangement that results in the excision of a carbon atom from the growing polyketide chain and the formation of the internal cyclopropane ring. Because of the unique chemistries required for the biosynthesis of

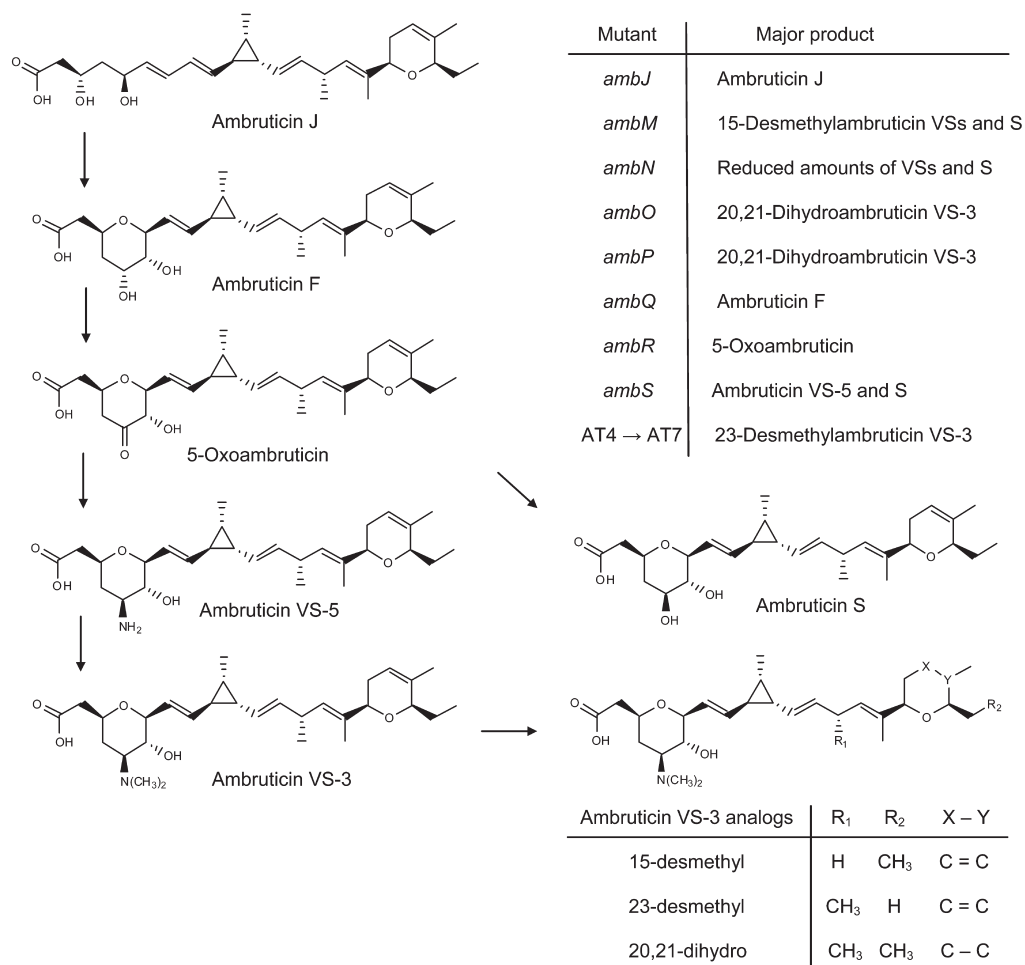

FIGURE 5 Pathway proposed for the biosynthesis of ambruticin. Inactivation of genes from the ambruticin gene cluster allows the isolation of intermediates in the biosynthesis of ambruticins.

ambruticin, the ability to engineer novel analogs from our current understanding of the PKS is limited. However, eight genes downstream of the last PKS gene, *ambH*, were identified that played a role in the biosynthesis of ambruticin. Inactivation of each of them provided strains that made novel analogs or resulted in strains that made greater quantities of minor products.

A summary of the mutants and the products that are made by each is shown in Fig. 5. Four novel compounds were identified: ambruticin J, 20,21-dihydroambruticin S and VSs, 5-oxoambruticin, and 15-desmethylambruticin S and VSs. Two mutant strains produced previously identified minor compounds as major products; the *ambS* mutant strain made predominantly ambruticin VS5; and the *ambQ* mutant strain made ambruticin F as a major component. Initial testing of these compounds for antifungal activity revealed that all were active (L. Vetcher and B. Julien, unpublished data).

29.6.2. AT Domain Replacement in the Ambruticin Gene Cluster

The classical procedure to make a domain replacement in PKS genes is by homologous recombination, requiring two steps. Because currently it is not possible to perform gene replacement in *Sorangium*, a strategy was devised that allowed for integration of a plasmid by a single homo-

logous recombination that inactivated the native *ambA* gene of the ambruticin gene cluster and expressed a new, engineered version of *ambA* (Rodriguez and Julien, unpublished data) (Fig. 6).

AmbA initiates the synthesis of ambruticin by decarboxylation of a methylmalonyl unit specified by the loading acyltransferase (*AT*₀) domain (26). To alter the specificity of *AT*₀, the *AT* from module 7 was used because its domain organization is identical to the loading module. The junctions between the *KS*, *AT*₀, and *ACP* were based on the engineering of the *AT*₄ in the epothilone biosynthetic genes (section 29.5.2) (Rodriguez and Julien, unpublished data).

For this engineering approach, the *ambA* gene was inactivated by truncation of the 5' end of *KS*₀. The malonate specific *AT*₇ domain was cloned along with the truncated *KS*₀ under the transcriptional control of the *epoA* promoter. Isolation of a recombinant that integrated this engineered loading module within the *KS*₀ sequence in the chromosome resulted in a recombinant strain that produced 23-desmethylambruticin VS3 (Fig. 6). This result represents the first successful example of polyketide engineering in an *S. cellulorum* strain, showing the potential for engineering this important microorganism. However, this approach can only be employed at the beginning or end regions of the PKS gene cluster.

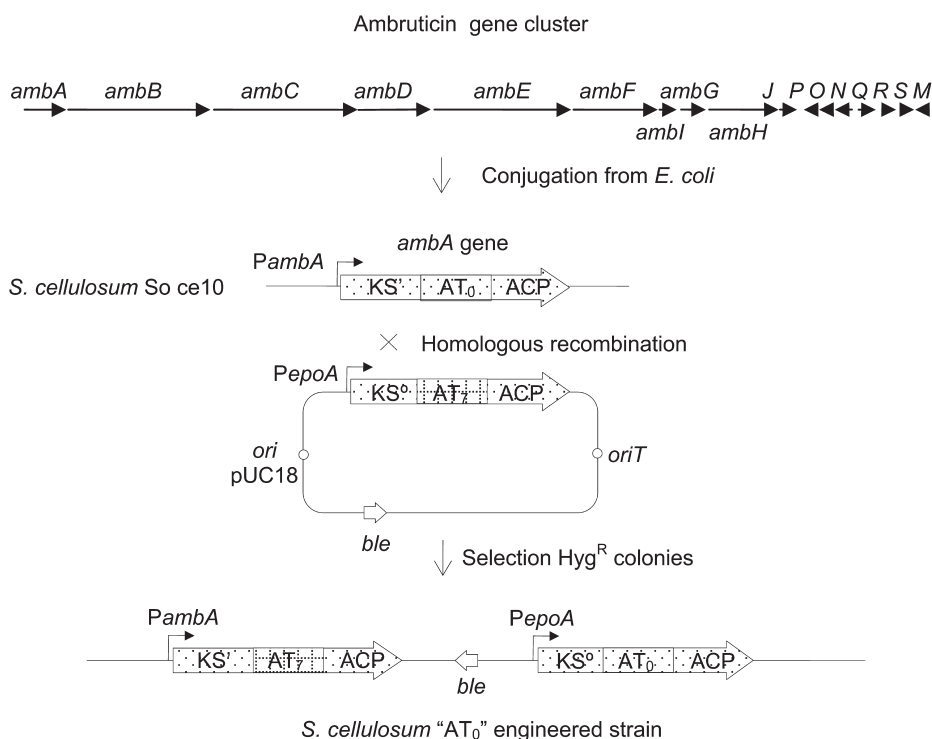

FIGURE 6 PKS engineering in *S. cellulosum* using a single crossover event. The first PKS gene, *ambA*, encodes the loading module consisting of KS', a methylmalonyl-CoA specific AT (AT₀), and an ACP. A plasmid is constructed carrying an in-frame deletion at the 5' end of the KS (KS⁰), an AT domain replaced with one specific for malonyl-CoA (AT₇), and an ACP under the expression of a heterologous promoter, *PepoA*. Isolation of a transformant in which crossover has occurred at the KS' sequence allows the expression of the engineered loading module gene carrying the malonyl-CoA-specific AT₇ domain under the *PambA* promoter, while the expression of remaining downstream PKS genes is under the heterologous promoter *epoA*. The expression of the 5' truncated loading module gene carrying the AT₀ domain is maintained to avoid a polar effect over the downstream PKS genes.

29.6.3. Protocol for Production of Ambruticin from *S. cellulosum* So ce10

Unlike *M. xanthus*, *S. cellulosum* uses a variety of sugars as carbon sources. As its name implies, it is able to metabolize cellulose and starches to their monomeric subunits. The following fermentation protocol has been developed for high-level production in shake flasks and can be scaled into fermentors.

1. Prepare seed culture by inoculating 25 ml of CF9 medium into a 250-ml shake flask.
2. In a 250-ml flask, add 1 g of XAD-1180 (for ambruticin S) or 1 g of XAD-16HP (for VS series of ambruticins) and enough water to immerse the resin, and autoclave to sterilize.
3. Remove water from sterile flask and add 50 ml of Medium F (batch fermentations) or SF1-P medium (fed-batch fermentations).
4. Once the seed culture reaches saturation, use a 10% (vol/vol) inoculum to inoculate the production flask. Incubate the culture at 32°C at 190 rpm. For batch fermentation, grow the cultures for 7 to 8 days. For fed-batch fermentations, initiate feeding on day 3 with the addition of 1 g/liter fructose and continue until harvest on day 7.
5. To extract product from resin, allow the culture to sit for several minutes for the resin to settle to the bottom

of the flask, then pour off the culture broth. Wash the resin twice with several volumes of water, and remove the final few milliliters of water by aspiration.

6. Add 25 ml of methanol to the resin, and incubate at room temperature for about 2 h, preferably with shaking. Analyze the methanol extract by HPLC or LC/MS for desired products.

For large-scale production in fermentors, Medium F is used and the culture is fed with maltodextrin DE18 (1.5 g/liter/day) starting on day 7. The pH is maintained at 7.1 and the dO₂ is maintained at 40%. The XAD resin is recovered after 20 days of fermentation.

29.6.3.1. Media

CF9 medium: (per liter) 9 g of Casitone, 6 g of fructose, 0.5 g of CaCl₂·2H₂O, 0.5 g of MgSO₄·7H₂O, 0.008 g of ferric citrate, 25 ml of 1.0 M HEPES (pH 7.6). Ferric citrate and HEPES should be filter sterilized and added after autoclaving.

SF1-P medium: (per liter) 3 g of soy peptone, 6 g of fructose, 1 g of CaCl₂·2H₂O, 1 g of MgSO₄·7H₂O, 0.008 g of ferric citrate, 50 ml of 1.0 M HEPES (pH 7.6). Ferric citrate and HEPES should be filter sterilized and added after autoclaving.

Medium F: (per liter) 10 g of maltodextrin DE18, 4 g of soy grits, 4 g of skim milk, 5 g of Pharmamedia, 1 g of $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 1 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 4.3 ml of glycerol, 0.008 g of ferric citrate, 50 ml of 1.0 M HEPES (pH 7.6). Ferric citrate and HEPES should be filter sterilized and added after autoclaving.

29.7. SUMMARY

Myxobacteria have been proven to be an alternative source of natural products, with more than 100 novel structures and 500 structural variants. One natural product from *S. cellulosum*, Ixemptra®, is currently marketed for treatment of metastatic or locally advanced breast cancer. With 23 complete biosynthetic clusters sequenced, combinatorial biochemistry is possible to generate a variety of new molecules. Using the techniques described in this chapter with the epothilone and ambruticin biosynthetic genes, many new analogs have been made. This technology paves the way for developing more natural products from myxobacteria.

INDUSTRIAL ENZYMES, BIOCATALYSIS, AND ENZYME EVOLUTION

BIOCATALYSIS MAY BE BROADLY DEFINED AS THE USE OF ENZYMES OR WHOLE cells as biocatalysts for industrial synthetic chemistry. Compared to chemical catalysts, biocatalysts generally offer several advantages such as high selectivity, high catalytic efficiency, and mild reaction conditions. Thanks to its association with reduced energy consumption, greenhouse gas emissions, and waste generation, biocatalysis is increasingly used in pharmaceutical, chemical, food, and agricultural industries. For example, glucose isomerase is used to produce high-fructose corn syrup at an industrial scale. Subtilisins and lipases are widely used as additives in laundry detergents. More recently, biocatalysis has become an indispensable and powerful tool for production of biofuels and chemicals from renewable plant materials.

There are a wide variety of biocatalysts capable of catalyzing numerous biological reactions. However, naturally occurring biocatalysts are often not optimal for many specific industrial applications, due to characteristics such as low stability and low activity. Moreover, naturally occurring biocatalysts may not catalyze the reaction with the desired non-natural substrates or produce the desired products. To address these limitations, many molecular techniques have been developed to create improved or novel biocatalysts with altered industrial operating parameters.

In this section, chapter 30 by Yasuhisa Asano describes a number of molecular tools for enzyme discovery. Louis A. Clark emphasizes the synergy between computational protein design tools and directed evolution approaches in chapter 31, whereas Manfred T. Reetz, in chapter 32, provides insightful discussions on various directed evolution methods used in enzyme engineering. In chapter 33, Nikhil U. Nair et al. provide a comprehensive overview of the applications of enzyme catalysts in various industries, including chemical, pharmaceutical, food, textile, and pulp and paper industries, and chapter 34 by Feng Xu provides a comprehensive survey of the enzymes involved in biomass conversion and their applications in biofuels production. Chapter 35, by Elton P. Hudson et al., discusses the use of enzymes for chemical transformations in nonaqueous organic solvents. In chapter 36, Bert Van Loo and Florian Hollfelder discuss enzyme promiscuity and its role in creation of new protein functions, which is not only scientifically interesting but also practically important since novel biocatalysts are highly desirable in biocatalysis. Chapter 37, by Daniel J. Sayut et al., discusses various aspects involved in the high-level production of enzymes in the bacterium *Escherichia coli*, such as gene regulation, vector design, host selection, inducible gene expression, and high-cell-density fermentation. Finally, Lutz Hilterhaus and Andreas Liese deal with various aspects of bioprocess development, such as bioreactor design, process modeling, optimization, scale-up, and product separation and recovery, in chapter 38.

It is clear that the integration of all the above-mentioned tools and approaches will make biocatalysis even more powerful and more broadly applicable.

Tools for Enzyme Discovery

YASUHISA ASANO

30

30.1. INTRODUCTION

Success in microbial transformation has been based on screening for microbial enzymes catalyzing new reactions, or screening known enzymes for an unknown activity with synthetic substrates. Since the advantages of the use of enzymes in organic synthesis have been fully illustrated (2, 23, 44), more and more attention has been paid to the systematic exploitation of microorganisms producing new enzymes, and how to obtain enzymes with desired activities from various enzyme sources and databases (2, 18, 44, 45).

In screening enzymes, it is extremely important to clarify the purpose of the experiment. One would screen microorganisms or databases for an enzyme when (i) nothing is known about the specific reaction, but a homologous enzymatic reaction of the same category is known; (ii) the same enzyme is known only in another biological source; (iii) not enough enzyme is produced by a certain organism for a practical transformation; (iv) improved function, such as better productivity, stability, etc., for practical use is required; and even when (v) almost no information is available for the desired reaction, etc.

One might just like to have an enzyme to see how the reaction proceeds, and further to have a new enzyme. In such a case, one can buy an enzyme from the suppliers or clone the known gene by PCR according to the information given in the database on the Internet (e.g., DBGET Search, <http://www.genome.jp/dbget/dbget.html>), and express the gene for the enzyme in a versatile heterologous host such as *Escherichia coli*. Knowing the reaction, one might then start further screening. In some cases, a starting material is a new drug intermediate to be converted by known enzymes. In such a case, it would be convenient to have libraries of wide varieties of known enzymes from different sources catalyzing the expected reactions so as to identify the chemical reaction more quickly and selectively, instead of starting random screening from microbial stock cultures (31). If one would like the challenge of establishing an entirely new enzymatic industrial process, no similar case should exist in the world; the enzyme reaction should be unique, without a previous publication or a patent. Interestingly, basic studies such as this result not only in finding new enzymes, but also in discovering unknown biological phenomena and new materials hidden in nature. Thus, a successful screening should focus on what is new in the screening: substrate, product, gene, protein, property, screening source, method, etc.

In this chapter, recent remarkable examples in the screening for new enzymes, biocatalysis, and enzyme evolution are introduced and their merits are discussed. Figure 1 shows a flow chart of the use of tools for discovery and the development of industrial enzymes. The different steps are identified by letters, which are cited below in the text to indicate the various tools being utilized in the process under discussion. Other possibilities of creating proteins by RNA display technique, etc., will be covered in other chapters of this volume.

30.2. SCREENING FOR ENZYME ACTIVITIES

This section will discuss screening for enzymes by enrichment culture technique from stock cultures, followed by enzyme purification and characterization, coupled with gene cloning. Examples will include the discovery of nitrile hydratase and industrial production amides, aldoxime dehydratase and nitrile synthesis, ω -lauro lactam hydrolase for enzymatic transcrystallization, and hydroxynitrile lyase from plants. These traditional approaches often yield primary information that can be industrialized successfully.

30.2.1. Nitrile Hydratase in Acrylamide Production (Fig. 1: a, d, i, r, q, s)

Enrichment culture is a technique to isolate microorganisms having special growth characteristics. (Please note: letters in section heads as above correspond to the labels in Fig. 1, indicating the tools used in each section.) Some microorganisms grow faster than others in media with limited nutrients, high temperature, extreme pH, etc. Microorganisms that grow faster than other species become dominant after several transfers of the culture. An acclimation technique is applied when a toxic or unnatural compound is used as a substrate; such a technique is usually run long term to isolate microorganisms that are not easily isolated by enrichment culture. An adaptation to a synthetic medium containing a target compound often results in the isolation of microorganisms having a new enzyme. A typical example of the acclimation procedure is the successful isolation of an acrylonitrile-utilizing bacterium, *Rhodococcus rhodochrous* (formerly *Arthrobacter* sp.) I-9 (K-22, AKU 629) (61). Activated sludge obtained from sewage disposal facilities was suspended in an acclimation

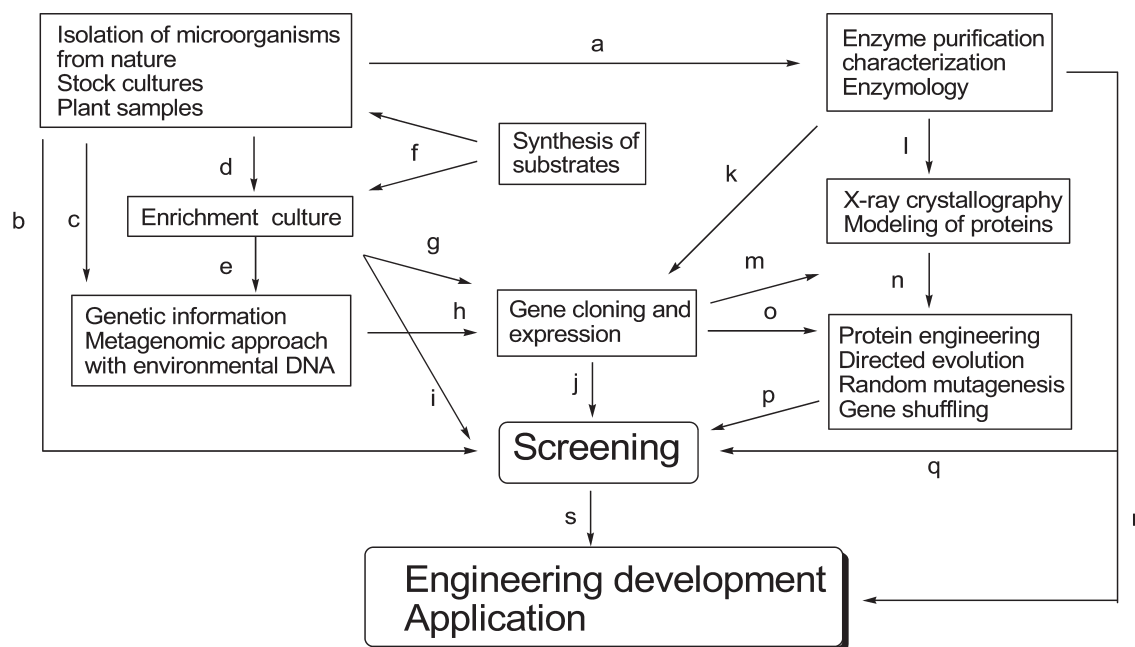

FIGURE 1 Discovery of industrial enzymes, biocatalysis, and enzyme evolution. These various steps in discovery and development are cited by their respective letters throughout this chapter.

medium containing 0.0008% acrylonitrile. After 3 months, *R. rhodochrous* I-9 was isolated for the first time as a degrader of toxic acrylonitrile as carbon and nitrogen source. By the enrichment culture technique, *R. rhodochrous* (formerly *Arthrobacter* sp.) J-1 (12) and *Pseudomonas chlororaphis* B23 (16), etc., were isolated as acetonitrile and isobutyronitrile utilizers, respectively. From *R. rhodochrous* J-1, nitrile hydratase was discovered, purified, named, and characterized (4, 12). Two pathways of nitrile hydrolysis were also discovered to coexist in *R. rhodochrous* J-1; one combines nitrile hydratase and amidase and the other

involves nitrilase (16) (Fig. 2). *P. chlororaphis* B23 was isolated as an industrial acrylamide producer by differential screening from non-acrylonitrile-degrading microorganisms, since acrylonitrile is highly toxic, and the degradation of acrylonitrile by *R. rhodochrous* I-9 was unexpectedly found to be catalyzed by a nitrilase. Nitrile hydratase has become one of the most important industrial biocatalysts, used for the microbial production of acrylamide, nicotinamide, 5-cyanovaleramide, etc., on an industrial scale. Acrylamide synthesis is now the largest enzyme-catalyzed organic synthesis in the world (2, 16, 62).

FIGURE 2 Plant and microbial aldoxime-nitrile pathway.

30.2.2. Aldoxime Dehydratase in the First Enzymatic Synthesis of Nitriles (Fig. 1: a, d, g, i, l, s)

There has been no report concerning the microbial biosynthesis of nitriles and the physiological function of such enzymes. It is also not known whether aliphatic and aromatic nitriles are biological compounds or just petrochemicals. Asano and Kato and their colleagues discovered the coexistence of aldoxime dehydratase and nitrile-degrading enzymes and elucidated their role in aldoxime metabolism in microorganisms. Nitrile hydratase has been found to be linked with aldoxime dehydratase both genetically and physiologically.

Asano, Kato, and their coworkers have been successful in the enzymatic synthesis of nitriles from aldoximes by using the new microbial enzyme "aldoxime dehydratase." They acclimated soil samples for about 4 months to isolate *Bacillus* sp. strain OxB-1, a degrader of *Z*-phenylacetaldoxime (6). The strain possessed an inducible enzyme catalyzing the formation of phenylacetone nitrile from *Z*-phenylacetaldoxime. Microorganisms converting *E*-pyridine-3-aldoxime to the corresponding nitrile were screened, and *Rhodococcus* sp. strain YH3-3 was also isolated from soil. The cells catalyzed a dehydration reaction of various aryl- and alkyl-aldoximes to form the corresponding nitriles, but did not act on arylalkyl- and substituted alkyl-aldoximes (7). Various nitriles, such as 3-cyanopyridine, 2-cyanopyridine, and cyanopyrazine, were synthesized at preparative scales from 10 to 100 mM aldoximes under optimized reaction conditions (pH 7.0, 30°C). This is the first report on the enzymatic synthesis of nitriles (32, 59).

The *oxd* gene coding for the enzyme was cloned, and an open reading frame coding for 351 amino acid residues was identified (33). A nitrilase, which participates in aldoxime metabolism in the organism, was found to be encoded by the region just upstream from the *oxd* gene. These findings provide genetic evidence for a novel gene cluster that is responsible for aldoxime metabolism in this microorganism. It was found that the occurrence of aldoxime dehydratase is as wide as that for nitrile-degrading enzymes such as nitrile hydratase, amidase, and nitrilase. Most of the nitrile degraders hitherto isolated contain aldoxime dehydratase activities (34). In addition, Asano and Kato and their colleagues proposed that the pathway in which aldoximes are successively degraded via nitrile be termed the "aldoxime-nitrile pathway" (2) (Fig. 2). Thus, such exploratory studies yield richer basic knowledge on enzymology and microbial physiology; they are not just tools for enzyme discovery.

30.2.3. A New Enzymatic Process for the Synthesis of 12-Aminolauric Acid by Enzymatic Transcrystallization of ω -Laurolactam Using ω -Laurolactam Hydrolase (Fig. 1: a, d, f, g, i, k, s)

Asano et al. proposed a new enzymatic method for the production of 12-aminolauric acid by hydrolyzing

ω -laurolactam (Fig. 3), a chemical widely used in the synthesis of nylon, adhesives, and hardening agents (5, 25). Although there are some harsh chemical processes for the preparation of 12-aminolauric acid in industry, no report has appeared on mild, e.g., enzymatic production of this chemical. Hydrolysis of the intramolecular amide bond of ω -laurolactam has been possible with 6 N HCl at high temperature.

Recently, Asano et al. (5) isolated from soil samples several ω -laurolactam-degrading microorganisms that were capable of growing in a medium containing ω -laurolactam as a sole source of carbon and nitrogen. Five bacterial strains were selected according to their unique activities: *Cupriavidus* sp. strain T7, *Acidovorax* sp. strain T31, *Cupriavidus* sp. strain U124, *Rhodococcus* sp. strain U224, and *Sphingomonas* sp. strain U238. The primary structure of the enzymes from these five isolates was revealed and shown to be significantly similar to that of 6-aminohexanoate-cyclic-dimer hydrolase from *Arthrobacter* sp. strain KI72 (formerly *Flavobacterium* sp. strain KI72), known as a nylon oligomer-degrading microorganism.

The enzyme from *Acidovorax* sp. strain T31 was most successfully expressed in *E. coli*. Cell-free extract of the recombinant strain was used for the synthesis of 12-aminolauric acid from ω -laurolactam by a process termed "enzymatic transcrystallization," because crystalline ω -laurolactam added into the enzyme solution was converted to crystalline 12-aminolauric acid (>97.3% yield). Under optimum conditions, 208 g/liter of 12-aminolauric acid was produced in 17 h. The synthesized product could be purified by filtration and washed by water; thus, there is no other purification step such as column chromatography (25).

30.2.4. Plant Hydroxynitrile Lyase for Synthesis of Cyanohydrins (Fig. 1: a, b, r, s)

More than 2,000 plants are considered to be cyanogenic, and more than 60 cyanoglycosides made from aliphatic and aromatic cyanohydrins are known. The cyanohydrin aglycones of the cyanoglycosides are considered to be synthesized from hydrophobic amino acids such as *L*-tyrosine, *L*-phenylalanine, *L*-valine, *L*-isoleucine, etc.

Asano et al. (11) established a simple high-performance liquid chromatography method to determine the activity and stereochemistry of the chiral mandelonitrile synthesized from benzaldehyde and cyanide, and applied it to screen for hydroxynitrile lyase (HNL) activity of plant origin. In a similar manner, in screening for microorganisms with a desirable enzyme activity, they screened plants for new HNLs. A total of 163 species of plants among 74 families were examined for (*R*)- and (*S*)-HNL activities. Asano et al. discovered that the homogenate of leaves of *Baliospermum montanum* shows (*S*)-HNL activity, while leaves and seeds from *Passiflora edulis*, *Eriobotrya japonica*, *Chaenomles sinensis*,

FIGURE 3 Synthesis of 12-aminolauric acid from ω -laurolactam.

Sorbus aucuparia, *Prunus mume*, and *Prunus persica* show (*R*)-HNL activity. Thus, 30% of HNLs were discovered within a few years in Japan, while others were found over 100 years of history of studies on HNL. Some of the newly found HNLs are used for chiral synthesis of cyanohydrins (43) (Fig. 3).

30.3. APPROACHES WITH MOLECULAR TOOLS

In section 30.2, we explained that the isolation of microorganisms and direct screening for an enzyme in natural organisms are very important steps to initiate the study of the enzymatic transformation of chemicals and to exploit new enzymes, because of the wide biological diversity that exists. In this section we discuss molecular and “omics” approaches, such as databases, whole-genome sequencing, metagenomic approaches, and library construction of genes for industrially important enzymes. There is much more diversity in metagenomes found in the environment, since it is estimated that there are 10 times more species of “unculturable” microorganisms than culturable ones. Since most microorganisms in the environment are difficult to cultivate, scientists have been prompted to clone useful genes directly from environmental metagenomes. An average environmental sample will contain 3,000 to 11,000 genomes per g of soil, with less than 1% of these accessible through cultivation techniques (51). Thus, metagenomes are considered to be a very important

likely source of useful enzymes (19, 21, 51, 53). Chitinases, lipases, esterases, nitrilases, amylases, nucleases, alcohol oxidoreductases, etc., are some examples. Metagenomic approaches include sequence-based screening after shotgun large-scale sequencing of environmental DNA, enzyme activity-based screening of expressed libraries of environmental DNA, and a recent methodology called substrate-induced gene expression screening approaches (SIGEX).

30.3.1. Biodiversity of Nitrilases for Enantioselective Catalysis (Fig. 1: d, e, f, g, h, j, k, s)

Nitrilases are attractive catalysts for forming chiral centers by kinetic resolution reaction. It is reported that about 20 nitrilases have been described. Recently, 137 unique nitrilases, discovered from DNA libraries processed from more than 651 environmental samples collected worldwide from terrestrial and aquatic microenvironments, were characterized (49). The genes were expressed in *E. coli* and tested for the hydrolysis of three nitrile substrates in terms of substrate specificity and stereoselectivity. These enzymes, discovered using a high-throughput, culture-independent method, provide a toolbox for enantioselective hydrolysis of carboxylic acid derivatives from nitriles. The enzymes were tested for their abilities to catalyze stereoselective hydrolysis of three nitrile substrates, 3-hydroxyglutaronitrile, mandelonitrile, and phenylacetaldehyde cyanohydrins (Fig. 4). One of the products of the desymmetrizing hydrolysis on the

FIGURE 4 Reactions catalyzed by nitrilases.

prochiral substrate 3-hydroxyglutaronitrile, (*R*)-4-cyano-3-hydroxybutyric acid, is an intermediate in the synthesis of the cholesterol-lowering drug Lipitor. The most selective enzymes generated products with enantiomeric excesses (e.e.s) of 90% for (*S*)-4-cyano-3-hydroxybutyric acid and 95% for (*R*)-4-cyano-3-hydroxybutyric acid. On mandelonitrile, the highest e.e. was 99% for (*R*)-mandelic acid and up to 30% for (*S*)-mandelic acid. On phenylacetaldehyde cyanohydrins, (*S*)-specific enzyme (e.e. 77%), and (*R*)-selective enzyme (e.e. 76%) were found among libraries constructed for genes from all over the world.

It is noteworthy that the desymmetrization of the prochiral substrate 3-hydroxyglutaronitrile was made possible by newly found nitrilases yielding (*S*)-4-cyano-3-hydroxybutyric acid in 90% e.e., and (*R*)-4-cyano-3-hydroxybutyric acid in 95% e.e. As for mandelonitrile, it was already known that (*S*)-specific nitrilase usually acts on mandelonitrile with low e.e. (56). However, the collection of a large and diverse group of sequences and the characterization of their activities provide an opportunity to explore principles of protein structure and evolution and their relationship to catalytic activity. It was surprising that enzymes with opposite stereochemistry have sometimes shared high structural similarities. The desymmetrization of the prochiral substrate 3-hydroxyglutaronitrile has been of interest in enzyme-catalyzed organic synthesis, although there has been limited success in the preparation of (*S*)-4-cyano-3-hydroxybutyric acid of 22% e.e. by immobilized whole cells of *Rhodococcus* sp. (20). The starting material for Lipitor synthesis, (*R*)-4-cyano-3-hydroxybutyric acid, has also been found by screening single-site mutagenesis of the known nitrilases, containing 10,528 variants. Ala190 and Phe191 were found to be effective for synthesis of (*R*)-4-cyano-3-hydroxybutyric acid with increased e.e. (22). It was possible to load up to 3 M of the substrate, yielding the product with 99% e.e. (17).

Thus, this work on high-throughput enzyme discovery from metagenomes has shown very clear benefits both for substantially expanding protein sequence space and for solving problems in industrial catalysis.

30.3.2. Isolation of a Phenol-Induced Enzyme System from Metagenomes by the SIGEX Approach (Fig. 1: c, d, e, g, h, i, s)

Current metagenome approaches use either nucleotide sequence-based or enzyme activity-based screening for isolation of catabolic genes. Nucleotide sequence-based screening by hybridization is highly efficient when PCR is used for direct retrieval of target DNA fragments. However, PCR screening can access only homologs of known genes in the environmental gene pool. Catechol 2,3-dioxygenase genes were isolated from DNA of microbial cultures enriched with phenol and crude oil. In such

enzyme activity-based screening, clones expressing a desired enzymatic activity have to be selected from a vast quantity of clones from a metagenome library (48), and it is difficult for some enzymes to be expressed as active forms in cloning hosts such as in *E. coli*.

Considering the limitations associated with current screening methods, Uchiyama and Watanabe introduced a third option for the metagenome approach, the SIGEX method for screening (57). This method takes advantage of the induction of a set of genes by a substrate. In the above-mentioned metagenomic approaches, it has been necessary to establish a method to concentrate useful genes or clones from candidates of genes from a metagenomic library of DNA for the purpose of application, because the conventional microbial enrichment culture technique is very powerful in concentrating desirable microorganisms from a huge number of microorganisms in the environment by their autocatalytic growth ability. The SIGEX method is based on the knowledge that catabolic gene expression is generally induced by substrates and controlled by regulatory elements proximate to catabolic genes. Uchiyama et al. used green fluorescent protein as an indicator of expression detected, and the *E. coli* transformants were screened with a cell sorter. With the SIGEX method, it was possible to clone aromatic hydrocarbon (benzoic acid and naphthalene)-induced genes from a groundwater metagenome library very efficiently. Uchiyama et al. found operons for benzoate and catechol degradation and gene homologs of xenobiotic reductase, tyrosine-phenol lyase, ubiquinone precursor hydroxylase, etc.

30.3.3. Comparison of Conventional and In Silico Screening Approaches: Discoveries of Two New Enzymes for the Production of Functional Dipeptides

30.3.3.1. Conventional Approach (Fig. 1: b, f, s)

Yokozeki and Hara reported efficient enzymatic production of *L*-Ala-*L*-Gln—a dipeptide of significant industrial interest by virtue of its widespread use in infusion therapy—from *L*-Ala methyl ester (acyl donor) and *L*-Gln (nucleophile) by a new microbial enzyme, such as from *Empedobacter brevis*, screened by a conventional approach from culture collections (65) (Fig. 5a). They eventually succeeded in the industrial production of *L*-Ala-*L*-Gln (64). The newly found enzyme purified from *E. brevis* facilitates significantly high production yields of *L*-Ala-*L*-Gln in an aqueous solution—more than an 80% yield based on *L*-Ala methyl ester. The enzyme has wide substrate specificity, both for acyl donors and nucleophiles, and can catalyze peptide-forming reactions, not only to produce various dipeptides, but also to produce various oligopeptides from the corresponding amino acid esters and peptides.

FIGURE 5 Enzyme-catalyzed peptide synthesis. (a) A peptidase from *E. brevis* catalyzing aminolysis reaction. (b) LAL.

30.3.3.2. *In Silico* Screening Approach (Fig. 1: h, j, s) On the other hand, dipeptide-forming enzymes in the presence of ATP, as shown in Fig. 5b, may rarely be detected by activity-based screening when activities are weak and products are liable to degradation. One might hesitate to screen for such an enzyme, because no enzyme synthesizing α -dipeptides of L-amino acids by an ATP-dependent manner has been known. Discovery of L-amino acid ligase (LAL) enabled the microbial production of dipeptides such as L-Ala-L-Gln, which is a useful ingredient of infusion.

Tabata and Hashimoto attempted to find such an enzyme by *in silico* screening based on the consensus sequence of the superfamily, followed by an *in vitro* assay with purified enzyme to avoid the degradation of the peptide(s) synthesized (55). *ywfE* of *Bacillus subtilis* was found to code for an activity forming L-Ala-L-Gln from L-Ala and L-Gln with hydrolysis of ATP to ADP (Fig. 5). The enzyme accepted a wide variety of L-amino acids. Among 231 combinations of L-amino acids tested, reaction products were obtained for 111 combinations and 44 kinds of α -dipeptides were synthesized; no tripeptide or longer peptide was detected, and the D-amino acids were inert (55, 60).

30.3.4. An Alternative Menaquinone Biosynthetic Pathway Operating in Microorganisms (Fig. 1: h, i, s)

Menaquinone (MK; vitamin K) is an essential vitamin because it is a critical factor of blood coagulation in humans and an obligatory component of the electron transfer pathway in microorganisms, respectively. MK has been shown to be derived from chorismate by seven enzymes, designated MenA, -B, -C, -D, -E, -F, and -G, in *E. coli*. Recently, Dairi et al. ascertained, by bioinformatic analyses

of whole-genome sequences, that some microorganisms, such as *Helicobacter pylori* and *Campylobacter jejuni*, do not have the homologs of most of the *men* genes, although they biosynthesize MK (26). A novel MK biosynthetic pathway was investigated by using *Streptomyces coelicolor* A3(2), which also possesses the novel pathway. The ^{13}C -labeling pattern of MK purified from *S. coelicolor* A3(2) grown on $[\text{U-}^{13}\text{C}]$ glucose was quite different from that of *E. coli*, suggesting that a novel pathway was operating in the strain. Candidate genes participating in the novel pathway were searched by *in silico* screening, and the involvement of these genes in the pathway was confirmed by gene-disruption experiments. Mutants that required MK for their growth were also isolated by mutagenesis and used as hosts for shotgun cloning experiments. Metabolites accumulated in culture broth of these mutants were isolated and their structures were determined (52). Taking these results together, the outline of this pathway, which branched at chorismate in a manner similar to that in the known pathway but then followed a completely different pathway, was proposed. Since human cells and some useful intestinal bacteria such as lactobacilli do not have this pathway, it would be an attractive target for the development of novel chemotherapeutics. This biosynthetic pathway is a good source of new enzymes (Fig. 6).

30.4. FINE-TUNING OF ENZYMES BY DIRECTED EVOLUTION

Here we discuss the fine-tuning of enzymes with regard to optimal temperature, substrate specificity, and yield of the reaction. Examples will include the following: mutation of

FIGURE 6 Biosynthesis of menaquinone in microorganisms.

FIGURE 7 Industrial dynamic kinetic resolution of hydantoin by hydantoinase and DCase to produce *p*-hydroxy-*D*-phenylglycine.

N-carbamoyl-*D*-amino acid decarbamoylase (DCase) to a thermostable form for the industrial production of *p*-hydroxy-*D*-phenylglycine, and directed evolution of acid phosphatase for the industrial production of 5'-IMP (inosine 5'-monophosphate) and 5'-GMP (guanosine 5'-monophosphate). The use of software for molecular modeling of the enzyme structure, followed by protein engineering, is also described, with creation of *D*-amino acid dehydrogenase from *meso*-diaminopimelate dehydrogenase as an example.

30.4.1. DCase in *p*-Hydroxy-*D*-Phenylglycine Production (Fig. 1: a, f, k, o, p, s)

D-Amino acids are used for the starting materials for semi-synthetic penicillin and bioactive peptides. For example, *p*-hydroxy-*D*-phenylglycine is an important *D*-amino acid produced on a 2,000-tons/year scale by an enzymatic method, as a component of the wide-spectrum β -lactam antibacterial amoxicillin. These studies were begun in 1980 by a collaboration of Kyoto University and Kaneka Corp. (Fig. 7) (44, 45). The reaction involves *D*-stereospecific hydrolysis of synthetic *DL*-5-substituted hydantoins to *N*-carbamoyl-*D*-amino acid, with spontaneous racemization of hydantoins. Thus, all of the racemic hydantoins will be converted to *N*-carbamoyl-*D*-amino acids by the “dynamic kinetic resolution” reaction. *N*-Carbamoyl-*D*-amino acid is decarbamoylated to form *D*-amino acid. The process was improved to a two-step bioreactor reaction by changing the latter chemical decarbamoylation reaction to an enzymatic reaction. By improving DCase to a much more thermostable enzyme, it was possible to change the whole process from a batch to a bioreactor system with immobilized enzymes catalyzing the two-step reactions.

Since the existence of DCase with high stability was not known, soil samples were screened for a wild-type enzyme, and *Agrobacterium* sp. strain KNK712 was isolated. The enzyme from this organism showed good reactivity toward the substrates, although it was necessary to improve its operational stability. The gene for the enzyme was cloned and subjected to random mutagenesis by chemical treatment with hydroxylamine and NaNO₂. The mutants were screened by replication to filter paper, heat treatment, and screening for the remaining activity by a color formation. Of 34,000 colonies, 16 clones were isolated (27). Their gene analyses revealed that three amino acid residues caused the stabilization against heat.

They are His57Tyr, Pro203Leu/Ser, and Val236Ala. Next, saturation mutagenesis was carried out in the three sites, and some other mutants were found to stabilize the enzyme as well. Furthermore, the mutations were combined, with interesting results. A His57Tyr/Pro203Glu mutant caused about 12°C increase in thermostability, His57Tyr/Val236Ala caused about 14°C increase, and Pro203Glu/Val236Ala caused about 17°C increase. His57Tyr/Pro203Glu/Val236Ala showed the highest thermostability at 75°C, approximately 10°C higher than the wild-type enzyme. There was no loss of stereoselectivity, nor a change in the substrate specificity. The *K_m* increased 50%, and the *V_{max}* decreased 16%, although these changes were negligible for production (28, 42). The crystal structure of the mutant was analyzed and the cause of the stabilization was rationalized (41).

30.4.2. Creation of *D*-Amino Acid Dehydrogenase from *meso*-Diaminopimelate Dehydrogenase (Fig. 1: h, m, n, p, s)

The production of *D*-amino acids is mainly conducted by enzymatic methods, with the exception of the fermentative production of *D*-Ala. The enzymatic methods include (i) dynamic kinetic resolution of hydantoin derivatives by hydantoinase (EC 3.5.2.2), followed by DCase reaction; (ii) optical resolution of *N*-acyl amino acids by *N*-aminoacylase (EC 3.5.1.14) in the possible presence of *N*-acyl *D*-amino acid racemase; (iii) asymmetric synthesis from α -keto acids in the presence of *D*-amino acid transaminase (EC 2.6.1.21), alanine dehydrogenase, formate dehydrogenase, and alanine racemase; and (iv) dynamic kinetic resolution of amino acid amide by *D*-aminopeptidase and amino acid amide racemase (3, 14) (Fig. 8).

Novik et al. (58) have created an NAD⁺-dependent *D*-amino acid dehydrogenase with broad substrate specificity by rational and random mutagenesis. By the asymmetric reductive amination reaction from the corresponding α -keto acid and ammonia, as has been well studied in *L*-amino acid dehydrogenases (13), the enzyme was evolved by three rounds of mutagenesis, and screening was performed on *meso*-diaminopimelate *D*-dehydrogenase. The first round targeted the active sites by the previously studied X-ray crystal structure of the wild-type enzyme and produced mutants (Arg196Met, Thr170Ile, and His245Asn) which were active only on a substrate *D*-lysine, but no longer on *meso*-diaminopimelate, the original substrate. The screening was

FIGURE 8 Enzymatic synthesis of D-amino acids.

done by monitoring color formation with nitrotetrazolium dye. The second mutation was carried out randomly by error-prone PCR on the entire gene, and a fourth mutation, Gln51Leu, was added. The third round of mutagenesis produced mutants that had an increased substrate range including straight- and branched-aliphatic amino acids and aromatic amino acids, and a fifth mutation, Asp155Gly, was added. Very high selectivity toward the D-enantiomer (95 to >99% e.e.) was shown to be preserved even after the total of five mutations were found in the three rounds of mutagenesis and screening. Reductive amination reaction of α -keto acid to form D-amino acid was made possible with this new enzyme. D-Isoleucine, D-glutamic acid, D-phenylalanine, and D-4-chlorophenylalanine were the substrates on which the wild-type enzyme was completely nonactive.

30.4.3. A New Industrial Enzymatic Method of Selective Phosphorylation of Nucleosides for 5'-IMP and 5'-GMP Production (a, j, k, l, m, n, o, p, s)

5'-IMP and 5'-GMP are important nucleotides because they give "Umami" taste in foods. There is no taste in other isomers such as 2'- and 3'-inosinic acids. Two phosphorylation methods have been reported. One is a chemical phosphorylation process that uses phosphoryl chloride (POCl_3), and the other is an enzymatic process that uses inosine kinase.

A "greener" and newer enzymatic method to produce 5'-IMP was sought. Microorganisms that phosphorylated nucleosides using pyrophosphate (PP_i) as the phosphate

donor regioselectively at the 5' position were screened from 3,000 strains (Fig. 9) (9). Although many of the microorganisms screened were able to phosphorylate inosine, phosphotransferase activity specific to the 5' position was found to be distributed among the bacteria belonging to the family *Enterobacteriaceae*. *Morganella morganii* NCIMB 10466 was selected as a 5'-IMP producer (10).

A selective nucleoside phosphorylating enzyme was purified to homogeneity from *M. morganii* NCIMB 10466 crude extract. The enzyme appeared to consist of six subunits identical in molecular weight (M_r 25,000). It phosphorylated various nucleosides at the 5' position to produce nucleoside 5'-monophosphates using PP_i as the phosphate source. Energy-rich compounds, such as carbamoyl phosphate and acetyl phosphate, were also very effective phosphate donors. The enzyme also exhibited phosphatase activity and dephosphorylated various phosphate esters, but had a weak effect on nucleoside 3'-monophosphates. The *M. morganii* gene encoding a nucleoside-phosphorylating enzyme was isolated by a shotgun-cloning strategy. It was identical to the *M. morganii* PhoC acid phosphatase gene. With use of the purified enzyme, 32.6 mM 5'-IMP was synthesized from inosine with a 41% molar yield, but the synthesized 5'-IMP was hydrolyzed back to inosine because of its phosphatase activity as the reaction time was extended.

To suppress the dephosphorylation reaction and increase the efficiency of the transphosphorylation reaction, a random mutagenesis approach was used. By error-prone

FIGURE 9 Acid phosphatase-catalyzed 5'-monophosphorylation of nucleoside with PP_i as a phosphorylating agent.

FIGURE 10 Directed evolution of acid phosphatase as an industrial biocatalyst to produce 5'-IMP and 5'-GMP. ○, wild type; ●, mutant.

PCR, one mutated acid phosphatase that increased in phosphotransferase reaction yield was obtained (38–40). With the *E. coli* overproducing the mutated acid phosphatase, 101 g/liter (191 mM) of 5'-IMP was synthesized from inosine in an 85% molar yield (Fig. 10). This improvement was achieved with two mutations, Gly to Asp at position 92 and Ile to Thr at position 171. A decreased K_m value for inosine was responsible for the increased productivity.

Ile151Thr caused improvement of the affinity toward inosine, and the mutation at Gly72Asp, together with Ile151Thr, caused not only an increase in affinity toward inosine but also a decrease in the dephosphorylating activity. On the basis of X-ray analysis of the enzyme crystal, two mutation sites are located near the active site, and Thr151 seems to form hydrogen bonds with inosine, enhancing the affinity toward inosine (29, 30, 54). Since 2003, 5'-IMP and 5'-GMP have been produced at multiple thousands of tons per year by Ajinomoto Co. Inc., Japan.

30.5. FINDING NEW FUNCTIONS OF KNOWN ENZYMES BY LABORATORY EXPERIMENTS

An example of obtaining the desired enzyme without screening, or directed evolution, is introduced. Several dynamic kinetic resolutions of synthetic substrates have been developed for the industrial production of chiral amino acids. The use of *L*- α -amino- ϵ -caprolactam (*L*-ACL) hydrolase in the presence of α -amino- ϵ -caprolactam (ACL) racemase is a

typical example of *L*-lysine production (24). *L*-Cysteine is produced by hydrolases acting on amino-2-thiazoline-4-carboxylic acid in the presence of a racemase (50). As described in section 30.3, DCase catalyzes the hydrolysis of *N*-carbamoyl-*D*-amino acids to form *D*-amino acids when used in combination with *D*-specific hydantoinase, either with spontaneous racemization of hydantoin or with hydantoin racemase. *N*-Acyl-*D*-amino acid amidohydrolase and *N*-acyl amino acid racemase are used together to form *D*-amino acids.

Asano and Yamaguchi (14, 15) discovered amino acid amide racemizing activity in ACL racemase (EC 5.1.1.15) from *Achromobacter obae*. They reported the discoveries, properties, and structures of the new enzymes *D*-aminopeptidase (EC 3.4.11.19) (8), *D*-amino acid amidase (EC 3.5.1.-) (35), and alkaline *D*-peptidase (EC 3.4.11.-) from *Ochrobactrum anthropi* C1-38, *O. anthropi* SV3, and *Bacillus cereus* DF4-B, respectively (3). These *D*-stereospecific hydrolases can be applied to kinetic resolution of racemic amino acid amides to yield *D*-amino acids. By this route, *D*-amino acid may be prepared in three steps from an aldehyde. The amino acids can only be obtained in 50% yield, because the enzyme accepts one of the *D*-enantiomers as a substrate. If amino acid amide racemase were used together with these *D*-stereospecific hydrolases, the remaining *L*-amino acid amide could be racemized and *D,L*-amino acid amide would be completely hydrolyzed to form *D*-amino acid (36). It would also be possible to synthesize *L*-amino acids when amino acid amide racemase is used with *L*-stereospecific hydrolases (37).

Amino acid amide-racemizing activity in ACL racemase (EC 5.1.1.15) from *A. obae* was discovered. Previously, Soda et al. did pioneering work on ACL racemase and reported that the substrates for ACL racemase are only ACL, α -amino- δ -valerolactam, and α -amino- β -thia- ϵ -caprolactam, but the enzyme does not act on amino acid amide (1). The result of construction of an efficient system to produce *D*-amino acid from *L*-amino acid amide by a combination of ACL racemase and *D*-aminopeptidase is demonstrated in Fig. 11. This is the first report of the enzymatic synthesis of stoichiometric amounts of *D*-amino acid from *L*-amino acid amide by a combination of a new amino acid amide-racemizing enzyme and *D*-stereospecific amino acid amide hydrolase (Fig. 12) (3, 63). The X-ray crystal structures of the enzymes have been solved (46, 47).

30.6. CONCLUSION

In this chapter, I have discussed how new enzymes have been discovered and improved, with the following examples: nitrile hydratase, aldoxime dehydratase, ω -laurolactam hydrolase, *L*-amino acid ligase, DCase, *D*-amino acid dehydrogenase, acid phosphatase, amino acid amidases, and amino acid amide racemase. Half of these are industrial

FIGURE 11 Dynamic kinetic resolution of amino acid amide.

FIGURE 12 Dynamic kinetic resolution of alanine amide with D-aminopeptidase and ACL racemase. ●, L-alanine; ○, D-alanine amide; □, D-alanine.

enzymes. Furthermore, the discovery of a new biosynthetic pathway of MK by in silico screening was introduced.

Traditional approaches, with isolation of microorganisms and characterization of the enzyme, followed by gene cloning, etc., have had a huge impact on current enzyme engineering. Discoveries, however, sometimes needed serendipitous work.

The resource of genome information, including the metagenome, is in our hands and could certainly be utilized more in the future. A new SIGEX metagenome approach was invented to screen inducible enzymes efficiently, since the metagenome approaches are based on higher-fidelity discovering methods such as hybridization and PCR. The discoveries of LAL and the new MK biosynthetic pathway are good examples of in silico screening for enzymes and the biosynthetic pathway. There is no doubt that microbiology will be involved in this search, including metagenomic information, as seen in the successful exploitation of nitrilase genes from environmental DNA.

A tremendous amount of information is available from the databases, and it is now possible to predict the function of enzymes from the similarity of their primary structures. This has helped to accelerate the exploitation of genetic resources, as seen in the discovery of LAL for dipeptide synthesis. The discovery of the new MK biosynthetic pathway also used the database to find missing information. Research on the use of ACL racemase in the dynamic kinetic resolution of amino acid amide was made possible by information from accessible databases, although it has been shown that data accumulation in the “wet” laboratory was the key factor in finding the new function of those enzymes. It should be emphasized that the counterpart enzymes such as D-aminopeptidase and D-amino acid amidases have been discovered by screening from nature by enrichment culture technique (see Fig. 1, steps a, d, g, i, j, k, and s).

The directed evolution of enzymes has proved to be a very powerful technique, as can be seen in the development of the new enzyme D-amino acid dehydrogenase, a thermostable DCase, and industrial production of nucleic acids with umami flavor by the evolved acid phosphatase.

The mutated acid phosphatase is probably one of the first examples of the use of directed evolution in the industrial production of useful materials. It seems that there should be no limit to the evolution of proteins for the benefit of human beings; these tremendous possibilities should be utilized to the fullest.

Looking at the history of the development of new drugs, discoveries have been a major factor. How do the readers of this chapter think about the future of enzyme discovery? Do they judge that the 99% of total microbial DNA from unculturable microorganisms is a huge or a modest resource, compared with the already known 1%? As we have seen here, many more advances may be made in the development of industrial enzymes, biocatalysis, and enzyme evolution with the aid of rational approaches combining the information from databases with actual experiments in the laboratory.

Enzyme Engineering: Combining Computational Approaches with Directed Evolution

LOUIS A. CLARK

31

31.1. INTRODUCTION

It is increasingly being recognized that the most effective way to evolve proteins, and especially enzymes, involves the use of both screening and rational design. This chapter seeks to give a cursory overview of how one might use rational or semirational design techniques to guide an evolution project. The goal is to give scientists who are not experienced in rational protein design, but who may have experience with the necessary experimental techniques, a view of what one can achieve. Emphasis is placed on practical evolution goals and the determination of what is reasonable. Large modifications in substrate range, enantioselectivity, and enzyme stability are routinely, if not easily, achievable. In addition, it now appears possible to switch catalytic mechanism and to design active sites from first principles in some cases. Support for these claims and details of techniques are provided solely by examples from the open literature. There are now many convincing and instructive examples of rational and semirational enzyme design.

There are many aspects of an evolution project that will not be covered here, but which are essential. Perhaps the two most important such aspects are the DNA manipulation techniques and the activity assays. Without effective methods to construct desired variants, rational design cannot be practiced. Likewise, without a fast assay sensitive to any pertinent chiral products, evolution is restricted or impossible (95). It will be argued that the throughput of the assay is the most critical factor in choosing to use rational design and selecting an approach. Beyond making that choice and a few mentions to the literature, strategy aspects will not be discussed, in part because they are best learned through experience.

It is useful to examine some reasonable evolution goals for the industrial usage of enzymes. Substantial progress has been made in incorporating enzymes into pharmaceutical processes where high regioselectivity and stereoselectivity are critical (94). Biocatalysts are typically used as crude lysate and exposed to the substrate under nonphysiological conditions. For the pharmaceutical industry, goals of 100 g/liter substrate, 1 g/liter enzyme, 99% enantiomeric excess, and 98% conversion in less than 24 h of reaction are reasonable and necessary (81). These conditions often require extensive evolution for activity, selectivity, and stability. Emerging uses of exogenous enzymes as part of *in vivo* systems may be less stringent.

This chapter begins with an overview of the synergy between rational design and screening or selection. The choice of a rational design approach requires consideration of the number of enzyme variants that can be evaluated experimentally. A review of fundamentals of enzyme catalysis from an energy landscape point of view is presented to illustrate why and where rational design could be applied. The bulk of the chapter follows with many examples from the literature of techniques that have worked. Throughout the discussion, mention of basic computational techniques needed to support design is made. It will be seen that it is often quite feasible to adapt an enzyme to many chemical process or organism-engineering needs. From these collective examples, an assessment of what is reasonable to expect from evolution will emerge. Finally, a brief attempt to foresee applications of emerging computational techniques will be made.

31.2. SYNERGY BETWEEN DESIGN AND SCREENING

It is useful to examine the bounds of screening and rational design combinations. If one can make an exhaustive library of all possible sequences and pull the desired phenotype out of it using a selection method, then there is little or no need to bother with design. There is a sole example in the literature of a selection system developing *de novo* (from the beginning) enzyme activity (105). That being said, such a situation is very rare. It can be very time-consuming to develop an *in vivo* selection system, and in many cases, it may be impossible. For example, it would be quite difficult to tie production of a nonnatural product with a distinct chirality to organism fitness.

For many cases, a versatile practical approach is to intelligently construct as many enzyme variants as possible and screen them in high throughput. High throughput may mean ten reactions mixed and injected onto a chiral column by hand, or it may be tens of thousands handled only by robotics and assayed spectroscopically. Once an assay is developed, it is foolish not to take advantage of whatever throughput it can offer. The more variants one tests, the more chances of success. It is throughput that determines how many variants one can test and therefore what type of rational design one could use.

Figure 1 attempts to show the range of likely combinations between rational design and screening. For a given

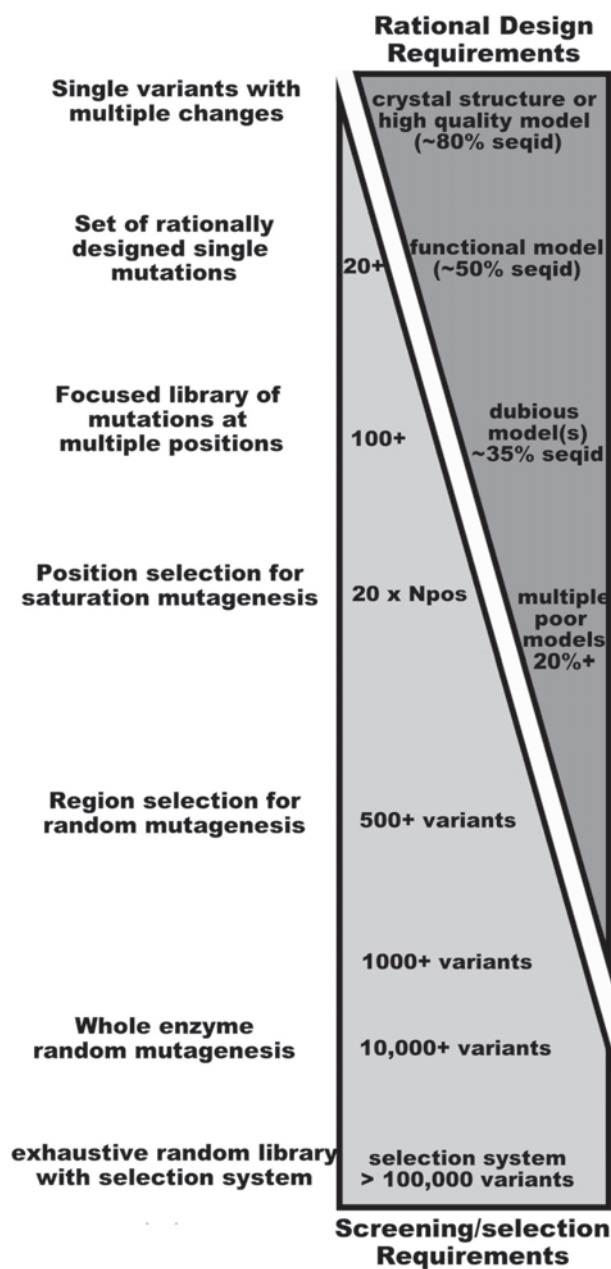

FIGURE 1 Possible choices of rational design methods for a given level of screening capacity. The upper triangle gives approximate requirements for structural information in the form of percentage of sequence identity (seqid) of the homology model template to the enzyme sequence. The lower triangle specifies the corresponding screening requirements for each approach Npos, number of positions targeted.

screening capacity (lower triangle), a possible design approach is listed in the left column. Corresponding minimum requirements to support that structure-based design approach are given in the upper triangle. Many of these scenarios will be seen in the examples provided in later sections.

There is always a trade-off between incorporating multiple potentially beneficial mutations into a design and risking destabilization of the enzyme. A balance must be

made when considering a mix of screening and rational design. Stability can be engineered by selecting mutations that are likely to improve protein-stabilizing interactions or at least be neutral (see later section). The ability to rationally pick such mutations depends in part on the quality of the structural information. If the quality is high, it may be possible to make more than one mutation per tested variant. This is represented in the top level of Fig. 1. Conversely, if structural information is poor or not present, the chance of each mutation decreasing stability is higher and multiple mutations are more likely to waste screening resources.

The quality of structural information is the accuracy at which atoms are present and properly positioned in the computer representation of the structure. High-resolution crystal structures reflect reality best, and models are best if they are based on crystal structures with fewer sequence differences. Models are made by first aligning a crystal structure sequence (the template) with a sequence from the protein to be modeled, then replacing residues that do not match. They are called "homology models" under the assumption that the template is a homologous protein. Various software is available for performing this common procedure. Swiss Model is freely available on the Web (4). MODELLER is one of the most established packages and is free to academic users (102; MODELLER software available at: <http://www.salilab.org/modeller/>). The most reliable homology models are those made by using a template that has high (ca. 80% or more) sequence identity to the modeled sequence and no gaps in the sequence alignment. Trustworthiness decreases approximately with sequence identity until even the overall fold becomes unreliable (perhaps ca. 20% sequence identity).

31.3. RATIONAL DESIGN IS A COST-EFFECTIVE METHOD

The more difficult it is to develop a screening assay for your enzyme reaction, the more rational design is likely to be useful. If one is limited to testing only a few variants, it makes sense to use any available methods to improve the chance that those variants will be productive. At this extreme, any amount of in silico screening and validation is worthwhile.

Rational design itself costs little to implement. The literature contains much information on enzyme mechanisms, and crystal structures for many common classes of enzymes are available. In most cases, it is possible to make at least a low-quality homology model. With that model and the mechanistic knowledge, it should be possible to identify the catalytic residues and the binding pocket. Even without modeling the substrate in the active site, the scientist can return to the laboratory and focus any mutagenesis experiments at residues near or in the binding pocket. This semirational design scenario is exemplified in the middle of Fig. 1, where many positions are chosen for saturation mutagenesis.

As an example of why directed evolution alone is not ideal, consider random mutagenesis. Even if it were truly random, mutations resulting in amino acids coded by the greatest number of codons would be more favored. Residues coded by a single codon (methionine and tryptophan) would be six times less likely than those coded by six codons (arginine, leucine, and serine). Random mutation introduced by polymerase errors occurs almost exclusively by single base changes. Simple calculations show that it is not possible to access all amino acid types from a given

FIGURE 2 Probability of mutating from a given residue type to another during a single-base change. Random mutations are inherently biased on a residue level, and 42% of all residue-to-residue type changes are impossible. Residues are ordered approximately by hydrophobicity. The figure is read from left to right (row index to column index). Example: the probability of mutating from M to I is higher than mutating from I to M.

starting amino acid codon. Figure 2 shows the probability of making a given amino acid type change by random mutagenesis. Forty-two percent of all amino acid type changes are not accessible. In some cases (e.g., phenylalanine), drastic changes in hydrophobicity are impossible or very unlikely. When interfacing rational design with traditional evolution, it may be useful to use this information to suggest mutations that will not occur via random mutagenesis.

31.4. REVIEW OF THE ENERGY LANDSCAPE VIEW OF CATALYSIS

Biocatalysts accelerate and determine which chemical reactions occur. The rate acceleration results in part from reducing the free-energy barrier of the rate-limiting reaction step. From this perspective, enzyme function may appear simple. The relative free energies of the substrates, transition states, intermediates, and products make up the reaction *energy landscape* and determine much of the rate and selectivity of reaction (56). Computational methods can give estimates of these free energies (51, 68, 74). Catalytic effects that do not fall well into a thermodynamic viewpoint, such as vibrations (47) or tunneling (84), are generally smaller, but could also be treated computationally with more development effort. For engineering, it is beneficial to have as much knowledge as possible of the relative energies of these reaction states in the context of

the reaction mechanism. While not all aspects of enzyme catalysis fit well into an energy landscape view, much can be rationalized and it provides a convenient basis for discussion of engineering approaches.

It is useful to partition enzyme catalysis into binding and chemical transformation. Under the Michaelis-Menten description of kinetics, reaction is first order in bound substrate concentration, which is in turn determined by adsorption equilibrium (see reference 50 for greater depth). Stronger binding translates to a lower equilibrium dissociation constant (K_d , which is conceptually related to the Michaelis constant, K_m), a higher concentration of prereactive substrate, and often higher reaction rate. Improving substrate binding is thus a reasonable goal, especially when substrate concentrations in solution are expected to be low. However, substrate binding is just the first step in catalysis.

A simplistic example of an enzymatic reaction energy landscape beginning with binding is given in Fig. 3. In this example, the reaction in the enzyme (black lines) is compared with reaction in solution (gray dotted lines). Catalysis is achieved here by lowering the energy gap between the reactants and the relevant transition state. In solution phase, the reactants (E+S state) must proceed directly to a high-transition state (TS0). This hypothetical enzyme lowers the first energy barrier (TS1 – ES) by providing a more accessible intermediate state. It could be a covalently bound species such as the acyl intermediate formed by the reactive serine in serine proteases (see reference 119 for

FIGURE 3 A hypothetical energy landscape for an enzyme-catalyzed reaction (black line) compared with the uncatalyzed reaction (gray dotted line). The overall reaction is thermodynamically favorable ($\Delta G_{\text{rxn}} < 0$). Notice that, in this case, the catalyzed reaction has only a slightly more favorable activation energy (ΔG_{cat}) than the uncatalyzed reaction (ΔG_{uncat}) due to strong binding to the substrate (ΔG_{bind}). E, enzyme; S, substrate; P, product.

examples of covalent effects). The enzyme may also catalyze by binding the reactants in a configuration that is more likely to lead to reaction. Other theories hypothesize enzyme residue arrangements that provide interactions that preferentially stabilize the transition state, perhaps by electrostatics (10). In any case, the enzyme provides a lower energy barrier path to reaction. If one can improve the energetics of the path or provide an alternative lower energy path by rational mutagenesis, then design is possible.

The reaction path is determined in part by the preference of the enzyme to accept certain substrates (specificity) or produce certain products (selectivity). It results from variation in the relative energy levels for possible species at any of the points at or bordering the rate-determining transition state. In Fig. 3, substrate specificity could manifest as the lack of an ES energy minimum (no binding) for one possible substrate. Alternatively, it could be that one substrate cannot approach the reactive transition state geometry because of steric clashes. In that case, TS1 for that substrate could be very high.

Although it is often assumed that the bond-forming or bond-breaking step in catalysis is rate-limiting, there are plenty of counterexamples. Often a product must be released before the active site is regenerated and able to accept another substrate. If the product is bound too tightly, release could become rate-limiting. Halohydrin dehalogenase HheC from *Agrobacterium radiobacter* provides one example. Tang et al. (110) showed that destabilizing the halide (product)-binding pocket by removing a hydrogen bond could accelerate the reaction rate for some substrates.

31.5. PHYSICOCHEMICAL CONTRIBUTIONS TO FREE ENERGY

A number of basic physicochemical effects provide a convenient framework for thinking about what determines the free energy of a reaction state. Interatomic interactions modify the potential energy of a collection of atoms and are enthalpic in nature. Rather than attempt to review the

computational methods for calculating these various interactions, the reader is directed toward recent reviews (14). In many cases, it is most important to understand what type of interactions could be important. *Electrostatic interactions* are one type. They occur between charged atoms and formally decay only gradually with distance ($1/r^2$). In the absence of dielectric shielding from solvent, and less so from bulk protein, they would be significant well beyond 10 Å. Electrostatic stabilization is often hypothesized as a major contributor to transition state stability and catalysis. *Steric repulsion* results from close approach of two atoms to the point where electron clouds begin to overlap and strongly repel. It is the easiest to calculate and most conceptually powerful interaction. If a substrate cannot be fit in the necessary reactive configuration without steric clashes, it will not react. If experiment shows that it does react, then one needs to refine the model and rework assumptions.

Hydrogen bonding and *van der Waals forces* are attractive interactions that can be manipulated by protein engineering. As any two atoms approach, there is a relatively minor attraction due to electronic effects that is often called van der Waals forces or London interactions. This electronic effect increases with the number of electrons on the atoms and their polarizability. It is difficult to calculate from first principles and is always treated empirically for systems as complex as proteins. Hydrogen bonding is also a complex electronic effect between a hydrogen atom and an acceptor atom such as oxygen, but it can be reduced to geometric rules for great engineering benefit. At the optimal configuration between donor and acceptor, and in a low dielectric environment, a hydrogen bond can contribute multiple kilocalories per mole of stabilization. Hydrogen bonds are critical for stabilizing proteins and binding reactants.

Solvation effects are the most complex and difficult interactions to compute and are sometimes even difficult to predict qualitatively. The absence of explicit water molecules in many simulations and visualizations

of enzyme structure makes solvation effects easy to forget. Despite its comparatively small size, each water molecule can act as donor for two hydrogen bonds and as acceptor for two. Other molecules with less ability to hydrogen bond are, to varying degrees, hydrophobic. Water molecules avoid them to maximize water-water hydrogen bonding and minimize free energy. The hydrophobic effect wherein nonpolar molecules are effectively attracted to each other can be thought of as a consequence of surrounding water molecules squeezing them together. At about room temperature, water molecules can adopt some greater degree of order around a hydrophobe to maintain good hydrogen bonding. Because the partial ordering of the surrounding water decreases the entropy, the hydrophobic effect has a strong entropy component. When two hydrophobes come into contact, the partially ordered water molecules between them are released and the total free energy decreases (30). As the temperature increases, fluctuations increase and the surrounding water is less able to form all the hydrogen bonds present in bulk water. The hydrophobic effect *increases* with temperature. Hydrophobicity is often cited as the main driving force behind protein folding.

31.6. EXAMPLES OF STABILITY ENGINEERING

The resistance of an enzyme to thermal or solvent conditions is an integral part of almost any application. Most natural enzymes do not have ideal stability characteristics. They may not function at pH extremes, form aggregates at higher temperature, or simply lose activity with time under even mild conditions. Stability characteristics are loosely transferable across different challenge conditions. For example, mutations that improve thermostability may also promote solvent stability (111). However, folding

stability as measured by the free energy of folding may not translate to solubility (see reference 20 for an example). Protein stability engineering is a broad topic in the literature (46), and only the aspects most relevant for enzyme evolution are mentioned below.

There is growing evidence that higher enzyme stability promotes evolvability. In work directly addressing this question, it was shown that stabilizing mutations in a bacterial P450 enzyme were required before necessary destabilizing active-site mutations could be made (13). Global stability must be maintained to keep the enzyme folded. The active site can be viewed as a necessary pocket of instability in the near-optimal background of bulk protein. In support of this concept, Shoichet, Matthews, and coworkers have shown that enzymes can easily be stabilized at the sacrifice of their enzymatic activity by making mutations in the active site (9, 106). Properties necessary for biocatalysis, such as maintenance of a hydrophobic water-filled cavity or burial of uncompensated charged residues, are detrimental to protein stability.

It is worth asking what the chances are of finding a single mutation in an enzyme that will increase thermostability. Certainly, the answer depends on the origin of the enzyme. Enzymes from mesophilic organisms experience less selective thermostability pressure than those from thermophilic organisms. One can also examine published data giving folding free-energy changes due to mutations. Figure 4 shows the distribution of mutation effect on protein stability for all single mutations with known structure in the Protherm database (8). Although the data set is not a random sample, it is large (ca. 3,000 entries). It can be seen that mutations tend to be destabilizing (1.1 kcal/mol) on average. Mutations on the surface are significantly less (0.4 kcal/mol) destabilizing, and those buried in bulk protein are more destabilizing (1.5 kcal/mol) on average. The more confined and tightly packed the environment is, the

FIGURE 4 Distribution of mutation effect on the ΔG of protein folding. Data are taken from the Protherm4.0 data set and restricted to single mutations where the protein structure is known (8). Buried residues are $<20\%$ exposed relative to exposure in an alanine-X-alanine tripeptide. Surface residues are defined as having at least 60% relative exposure.

fewer alternative amino acid types that can be accommodated. This destabilizing effect of pseudorandom mutations and the previously mentioned destabilization of the active site implies that unchecked evolution for only activity may result in destabilization.

While random amino acid substitutions are unlikely on average to lead to stabilization, rational design can improve the chances of making stabilizing changes. A model of the structure and the basic physicochemical principles discussed in the last section can be used for rational selection of stabilizing mutations. Insights into what stabilizes enzymes from hyperthermophiles can also be useful (112). Repacking of side chains in enzyme cores in pursuit of stabilization can be performed using ROSETTA software version 3.0 (<http://www.rosettacommons.org/>) (36, 76). Other freely available software packages, such as PoPMuSiC (20) and FoldX (58), that use side-chain repacking or less-structure-based approaches have also been used for stabilization.

Mutations that decrease conformational flexibility are often used to stabilize proteins. One may view such constraints as decreasing the entropy of the unfolded state or as hindrances to unfolding. Disulfide bonds are the most effective because they provide covalent constraints on folding and unfolding. Several studies demonstrate that adding disulfide bonds to proteases (73, 109, 110a) and xylanases (49, 66, 114) may increase thermostability, sometimes by more than 10°C (69). Mutations to proline place a kink in the backbone that can also be stabilizing. Matthews et al. (85) made mutations to proline as well as glycine-to-alanine mutations, then used crystal structures to show that backbone conformations were unchanged during stabilization. The procedure of finding proline mutations can be automated by use of side-chain repacking software (29). Readers interested in structural stabilization are directed to a particularly instructive review by DeGrado et al. (37) for further insights on the design of protein secondary structure.

31.7. CONSENSUS APPROACH

The use of similar sequences to suggest mutations during the evolution of an enzyme is one of the more effective and easiest approaches to stabilization of proteins. Although it may also be used for selectivity engineering, its origins are in stability engineering (108), to which it is well suited. The basic idea is that nature has already explored variations on a given enzyme sequence or fold of interest and arrived at a “consensus” sequence that may have good stability properties. Variants similar to the sequence of interest (sometimes called “homologs”) are often present in public databases. If the sequences are similar enough (>50% sequence identity), then the fold and many of the local residue environments will be the same. The similar sequences can be aligned to the sequence of interest and, at positions where the sequence of interest differs from the most common residue, change can be made. If the similar sequences are taken from thermophilic organisms, then chances of finding stabilizing mutations are further improved.

There are many applications of the consensus approach in the literature. It has worked well in the hands of many researchers on many different protein scaffolds. The thermostability of commonly used glucose dehydrogenase was increased substantially to allow utilization at 65°C (110c). Consensus-based libraries were used to increase the T_m of β -lactamase by 9.1°C (2). A consensus approach emphasizing local sequence alignment quality increased the T_m of

subtilisin E by 13°C (42). In an extension of the approach, Larson et al. (78) included pair correlation effects and used the method to stabilize an SH3 fold.

31.8. EXAMPLES OF SELECTIVITY ENGINEERING

In contrast to conventional heterogeneous or homogeneous catalysts, high chiral selectivity from enzymes is the rule, not the exception. In fact, it is generally difficult to make an enzyme nonselective. Enantioselectivity is a consequence of the arrangement of the catalytic residues in a geometrically constrained active site. Active sites will often be shaped to accommodate only a certain arrangement of bulky or small substituents at a chiral center, meaning that it is also common for a given enzyme to retain its *R* or *S* selectivity, even if the substrate is changed. In some cases, binding site pockets can be altered in size or shape to accommodate different chirality-determining side groups. Substantial changes in selectivity can be made. Directed evolution experiments show that it is possible to invert enantioselectivity (86). The examples here are chosen to demonstrate the range of modifications that can be achieved.

True rational design involves formulation of a hypothesis concerning how the enzyme function could be changed by mutagenesis, followed by construction and testing of the predicted variants. Semirational design uses logic to focus variant construction to fewer, but still many possibilities, which are then screened for activity. This section is divided by the approach taken. The semirational approaches will be covered first, moving roughly from the bottom of Fig. 1 to the top.

31.8.1. Targeted Random Mutagenesis for Selectivity Engineering

Very little or no structural information is required to target random mutagenesis libraries to large sequence regions. For multidomain proteins, the catalytically active domain(s) can often be identified by sequence-based classification. If a homology model can be built, it is likely that the active site can be identified and libraries further focused. There are many examples of selectivity-changing mutations occurring far from the active site, but logic and experimental evidence support targeting mutations for selectivity to the active site (87). Targeted random mutagenesis has been advocated and reviewed by Chica et al. (28). It is the least rational of the approaches in Fig. 1.

Random mutagenesis and rational or semirational mutation strategies can work well together. For example, Cheon et al. (27) followed up on consensus-guided and structure-based mutations at four positions with random mutagenesis of a D-hydantoinase to give a 280-fold shift in selectivity.

When random mutagenesis is focused to a specific residue position, it is called saturation mutagenesis, which refers to the construction and testing of all possible amino acids at a single-residue position. It has long been the favored technique for exhaustive exploration of function arising from small regions of proteins. More recently, effective evolution strategies have been built around repeated application of saturation mutagenesis at the same sites (96) and blanketing the whole enzyme with saturation mutagenesis (41).

There are examples of semirational saturation mutagenesis on several different enzyme classes in the literature. Rui et al. (100) used a library of saturation mutagenesis at four sites to improve both k_{cat} and K_m of an epoxide hydrolase, resulting in

a fivefold improvement in k_{cat}/K_m . Park et al. (91) used a homology model of an esterase to pick four active-site positions for individual saturation mutagenesis. They found mutations improving enantioselectivity by as much as fivefold and noted that saturation mutagenesis in the active site produced more selectivity than random mutation in the whole protein.

Although most reports in the literature deal with the construction of only a single set of saturation mutagenesis variants, evolution benefits from multiple rounds. Hill et al. (62) picked two active-site positions for simultaneous saturation mutagenesis by using a crystal structure of a phosphotriesterase, yielding a two-mutation variant with a 100-fold improvement in k_{cat}/K_m . They then followed up with saturation mutagenesis at another active-site position to gain an additional 10-fold.

For some catalytic mechanisms, the accessible transition states can determine the product selectivity of the reaction. Terpene cyclases utilize a high-energy carbocationic intermediate that can easily access many related structures before being quenched. Yoshikuni et al. (117) used product selectivity from saturation mutagenesis at 19 active-site positions in a sesquiterpene cyclase to guide rounds of rational mutations. A homology model was sufficient to pick the active-site residues. The final designed variants had at least 50% selectivity for seven different products.

31.8.2. Rationally Focused Libraries

As the number of library positions to sample increases or the screening resources decrease, it occasionally becomes prudent to explore less than all 20 amino acid types at each position. This type of focused library can explore concerted changes at multiple sites while keeping the number of variants to screen at a minimum. In general, one must suspect that synergistic mutations will be more beneficial than single mutations before this approach becomes effective. Reetz et al. (97) found the technique to be more effective than saturation mutagenesis or random mutagenesis. Schmitzer et al. (103) used rationally chosen degenerate codons at four active-site positions in a library format to achieve a sixfold activity improvement for the native substrate of a dihydrofolate reductase.

A focused library helped Koga et al. (75) invert the enantioselectivity of a lipase. They chose four leucine positions in the substrate-binding pocket by using a homology model and varied their residue identities within a hydrophobic set. The restriction drastically reduced the size of the library (from 20^4 to 7^4) while presumably increasing the fraction of variants with reasonable binding pockets. An interesting cell-free system was used for screening, and the best variants were found to also have beneficial random mutations.

As multiple-site libraries increase in complexity, so do the results from the screening. Truly beneficial mutations may occur only sparsely and in combination with neutral or even detrimental mutations. Random unintentional mutations are a common side effect of many library construction techniques. Statistical methods such as regression analysis can be very helpful to separate the good mutations from the bad (2, 54, 55). Interested readers might also examine the work from Ranganathan and coworkers that seeks to infer mutation energetics from multiple sequence alignments (101).

31.8.3. Single-Variant Design

The design of single variants is the most “rational” of the selectivity change categories. Much of the earliest work on rational enzyme design was done without the assistance of

libraries. Without libraries, other approaches must be taken to increase the chances of maintaining stability and finding improved activity. This is especially true when the variants contain more than one mutation. A number of researchers have used either a consensus approach or structural information to guide mutations.

Proteases were one of the first enzyme classes to receive substantial engineering attention. A minor glycine-to-alanine mutation in trypsin gave a 20-fold change in specificity (34). Carter et al. (21) used a modeled substrate in a subtilisin crystal structure to successfully design replacement of a catalytic histidine with a histidine from the substrate. Ballinger et al. (115) used comparison with eukaryotic homologs and electrostatic arguments to switch the subtilisin protease toward dibasic (6), and tribasic peptides (7). The specificity change was 60,000-fold for a tribasic substrate after three synergistic mutations (7). A single mutation in a hydrophobic pocket of the same enzyme was shown to give a specificity change of 200-fold for a different substrate (98).

Lipases are another class of enzymes that have received much engineering attention. Reetz's group tested several approaches, including random mutagenesis and site saturation mutagenesis on a *Pseudomonas aeruginosa* lipase (80). They later found focused libraries based on previous knowledge to be most effective (97). In a strictly rational approach, Magnusson et al. (83) chose a tryptophan on the base of the binding site of *Candida antarctica* lipase B (CALB) for size reduction. As hypothesized, enlarging the binding pocket allowed the enzyme to accommodate larger alcohols. Docking of the substrates showed steric clashes for the larger alcohols in the wild-type active site and explained specificity changes of more than 5 orders of magnitude for some substrate comparisons. In an opposite approach, Ema et al. (48) increased the size of a hydrophobic residue in the binding pocket of a *Burkholderia cepacia* lipase to constrain reaction of one enantiomer.

If done carefully, it is possible to make more than one rational mutation in a single variant. Multiple mutations will tend to destabilize proteins more than single mutations (see arguments presented with Fig. 4), so it is important to work with good information. The most useful guidance comes from a crystal structure of a related enzyme with the desired function. There are several examples of using a related enzyme structure to transplant function and/or selectivity.

Mutations at four positions designed from direct structure comparison helped convert an isocitrate dehydrogenase to an isopropylmalate dehydrogenase, although it was subsequently shown that random mutagenesis was more effective (43). A homology model was used to pick six active-site residues in an aspartate aminotransferase for substitution from tyrosine aminotransferase. Substitution improved activity on the intended substrate by 1,000-fold, but fell short of donor enzyme activity by 10-fold, providing evidence that effects outside the first sphere of residues are important (89). Structure comparison was used to rationally invert enantioselectivity of a vanillyl-alcohol oxidase with two mutations (110b). With use of a related crystal structure for information, a catalytic residue was moved to the opposite face of the active site. The best resulting enzyme had an enantiomeric excess of 80%, but lost approximately 100-fold in k_{cat}/K_m relative to wild type. Cheon et al. (27) used structure-guided mutations at four positions in a D-hydantoinase followed by random mutagenesis to give a 280-fold shift in specificity.

It is beneficial, but not strictly necessary, to use a related structure for comparison. The same consensus-guided approach used for stability enhancements can be used to sample selectivity variants. However, because it lowers the success rate, this is best done through a library approach. Chen et al. (26) used residue substitutions from related sequences in a consensus-type approach and specific structure-based pocket mutations to change the specificity of strictosidine synthase to accommodate larger substrates.

Successful structure-based enzyme engineering can be done without the aid of a related structure with the desired function. Crystal structure availability for a coenzyme A ligase complexed with a 4-chlorobenzoate substrate enabled rational expansion of substrate specificity (116). An isoleucine residue in the binding pocket was selected for replacement with a smaller alanine residue. After engineering, crystal structure evidence established that the mutation had the desired effect of accommodating another substituent on the substrate ring. A second round of mutations was beneficial; more structure-based mutations were made and a wide variety of substrates were tested, and selectivity changed by as much as 100-fold.

31.8.4. Substrate Docking for Selectivity Engineering

An accurate model of how the substrate fits into the active site and approaches the transition state is critical for rational engineering. In a rare example, Karimäki et al. (72) produced a crystal structure of a nonnative substrate bound to xylose isomerase and used it for redesign. They modeled the *L*-arabinose into the electron density at the active site and rationally selected two mutations that increased the reaction rate with the smaller C5 sugar by 2.8-fold. One mutation was selected to push the reacting oxygen closer to a catalytic metal. In typical circumstances, one is very unlikely to have crystal structure information for the substrate of interest.

Computational docking of the substrate into a crystal structure or a good homology model is a viable alternative. Gocke et al. (57) used previous modeling results and examination of an *R*-selective benzoylformate decarboxylase active site to locate and enlarge a small *S*-substrate pocket. Resulting enzymes were as much as 99% *S*-selective and a crystal structure of one mutant verified the mutation strategy.

Docking and design around transition state analogs (TSAs) is a logical and successful technique for selectivity design. It is based on the theory that molding the enzyme to best bind the transition state will decrease the activation energy (see Fig. 3). Selection for binding to TSAs has been used experimentally to engineer catalytic activity into antibodies. The technique produces catalytic antibodies, but may be limited because binding affinity rather than activity is directly selected (63). Improving binding to a TSA will decrease the energy level of the transition state, but it may decrease the bound substrate energy level similarly, resulting in no net decrease of the activation energy.

TSA docking has been used to make rational mutations to a carbonic anhydrase that increase the esterase rate for bulky substituents by 3,000-fold (64). It may also be used to rationalize known mutation effects. Bocola et al. (15) used a model TSA taken from more rigorous quantum chemical calculations to carefully explain the function of lipase mutations found by using random mutagenesis and other techniques. They were able to propose a mechanism for

the effect of both a mutation to glycine and one to proline. Mutations involving glycine and proline are more likely than others to alter the secondary structure and complicate modeling. Later the same group built on the modeling and used it to guide experiments that further improved the enzyme (96).

Once docking of the substrate or TSA has been performed, it is possible to use computer algorithms to search for side-chain possibilities (rotamers) at selected positions. This repacking of the side chains is typically done on a fixed protein backbone. Side-chain repacking around an alternative DNA substrate was used to redesign the specificity of an endonuclease at a single base (5). In a related example, a DNA-binding antibody was converted to a ribonuclease by strategic introduction of a histidine without repacking, but with the help of a crystal structure (52). Lassila et al. incorporated a rigorous TSA and internal ligand flexibility into the repacking-driven redesign of an *Escherichia coli* chorismate mutase (79). They observed small but measurable improvements in both k_{cat} and K_m on the native substrate.

31.8.5. Grafting from Similar Enzymes

Grafting or change of substantial sequence sections at once produces large jumps in sequence and potentially function space. The downside is that the resulting enzymes tend to be destabilized because of incompatibilities at the interface of new and old sequence (see references 43 and 70 for examples). Destabilization can also result in unexpected effects such as domain swapping (31). However, library-based approaches have shown that swapping of large regions can be successful some fraction of the time (35, 88), especially when breakpoints are chosen to minimize broken or changed contacts (113). Despite the low likelihood of producing a stable functional protein, many interesting examples of loop grafting are available in the literature.

Loop grafting requires high-quality structural information, good modeling, and as much screening throughput as possible. In keeping with the expected power of a selection system, Park et al. (90) showed that it is possible to use extensive consensus-based loop changes to change the mechanism of an enzyme. A glyoxylase was converted to a metallo- β -lactamase using the guidance of a very dissimilar metallo- β -lactamase structure from the same fold family. Library sizes of ca. 10^7 kept the evolution on track while 81 of the 198 amino acids were changed. In contrast to the suggestion in Fig. 1, structural information and rational design was useful in this case even when a selection system was available.

In a successful effort to switch specificity of cofactor binding, Chen et al. (25) grafted a 13-residue stretch from an isocitrate dehydrogenase into an isopropylmalate dehydrogenase. The structures were superimposed, the stretch transplanted into the donor enzyme, and the resulting hybrid enzyme energy minimized to investigate the fit. During this process steric clashes were noticed and three mutations were introduced into the final design to eliminate them.

Using a crystal structure of their starting enzyme and sequence from a related enzyme with the same mechanism and different specificity, Ma and Penning (82) found that grafting three long loops produced a stable enzyme with the target specificity. They also noted that making only residue substitutions predicted to contact the substrate was insufficient to change the selectivity. Even long loop grafts can result in stable enzymes if the scaffold is similar enough.

In another encouraging report, Bocola et al. (16) removed an active-site loop in a phenylacetone monooxygenase

to accommodate a larger substrate. This may be a generally applicable strategy for situations when the desired substrate would make steric clashes with the backbone. Conversely, it may be possible to insert residues into an active site that is too open. Boersma et al. showed that inserting two- or three-residue-long loops from related crystal structures resulted in an inversion of enantioselectivity (17). Further site-directed saturation mutagenesis improved the enantioselectivity to almost 60%.

31.9. EXAMPLES OF COFACTOR ENGINEERING

Enzymatic cofactors enable many important reaction types by providing labile chemical elements such as hydrides and electrons. The type and orientation of an enzymatic cofactor can be critical in determining the activity and selectivity of an enzyme. There have been clear successes in the design of metal binding sites and the alteration of cofactor binding specificity that will be useful to those contemplating rational enzyme design.

31.9.1. Design of Metal Binding Sites

Several examples of spectroscopically verified metal binding sites have been introduced by rational design. An informational wealth of residue type and configurations that support metal binding sites are available in crystal structures and organized in accessible databases (22, 38). The strategy typically involves locating a site in a given protein fold where the backbone positions are compatible with the desired side-chain placement. Copper centers (11, 107) have been introduced by copying known sites. Loop grafting from a homolog also achieved the same goal (59). Iron binding sites have been successfully designed (12), as well as cuboidal iron-sulfur centers, using the DEZYMER program (32).

31.9.2. Interconversion of NADH and NADPH Cofactor Binding

With the emergence of rational enzyme engineering for *in vivo* applications and the continued importance of cofactor cost in pharmaceutical processes, it can be quite advantageous to control the nicotinamide adenine dinucleotide (NADH) cofactor usage. NADH and NADPH differ by a single phosphate group, which carries a formal -2 charge and provides a handle for recognition. An early example of structure-guided mutations was given by Scrutton et al. (104), who succeeded in switching the cofactor specificity of a glutathione reductase from NADPH to NADH. They used related enzymes to make consensus-style mutations.

Curiously, Flores and Ellington (53) were able to switch the cofactor specificity for a lactate dehydrogenase from NADH to NADPH by using consensus-guided mutations *outside* the phosphate binding pocket. Chen et al. (24) also found two mutations outside the phosphate binding pocket which, in combination with six other mutations, shifted selectivity by $>10^6$ -fold from NADPH to NADH. They later used loop grafting to achieve the opposite selectivity change in another enzyme (25).

Kristan et al. (77) used comparative homology modeling to choose mutations in a 17β -hydroxysteroid dehydrogenase. Single mutations gave improvements of twofold to fivefold, and a single Y to D mutation switched cofactor specificity from NADPH to NAD. The most common effective strategy behind all the reports in the literature is the introduction of a negatively charged residue to mimic the phosphate charge

or removal of positively charged phosphate binding residues. For the NAD to NADPH change, the opposite is done.

31.9.3. Active-Site de Novo Design

Design of enzyme active sites from first principles is beginning to be possible. Clever researchers have shown that it is sometimes possible to rationally redesign an enzyme to use a related mechanism (see references 19 and 92 for reviews). However, even when they exist, recognizing such engineering opportunities may be difficult. The *de novo* design work covered here uses generally applicable approaches to introduce catalytic activity. It introduces a number of intriguing possibilities. In its simplest form, it can be used to graft known active sites into a protein scaffold of interest. Still more promising in terms of applications is the possibility of introducing novel or nonnatural catalytic reaction mechanisms that enable useful transformations. It is an area where the benefits of rational design are clear and where almost any amount of effort spent *in silico* is worthwhile. For now, the primary practical goal of *de novo* active-site design should be to provide several proteins with measurable starting activity for further evolution.

Active-site design and introduction of *de novo* activity are difficult. The field has a history of failed validations (1, 33, 44) which seem to stem from difficulties in distinguishing low activity from background activity. Promising structure-based approaches use various search methods to match a desired active-site geometry with possible sites in known protein backbones (60, 118). The approach is flexible because the active-site geometry may include the catalytic residues, cofactors, and even neighboring residues. In this way, the proposed transition state of even nonnatural reactions can be specified.

Some of the earliest *de novo* design successes involved the introduction of catalytic metal centers. An active-site conformation for an iron superoxide dismutase was derived from known structures and used to redesign a thioredoxin. The single tested design had four mutations, three of them mutations to histidine for metal binding. Superoxide dismutase activity was observed and noted to be approximately 10^4 lower than natural enzymes (93). The same system was later revisited, and five separate superoxide dismutase designs in thioredoxin were characterized more extensively. Apparent correlations between redox potential or surrounding positive charge with activity were observed (12). The researchers also note that the deepest active site had the most shifted pK_a , confirming general expectations for shifts due to hydrophobic burial. These additional characterizations beyond activity are essential to further the rational design field and inform continued design on similar enzyme classes.

Similar successes at introducing known activity into a nonenzyme scaffold have been achieved with dock-and-design methods. Hydrolysis activity was introduced into thioredoxin by docking a TSA near a known histidine and molding the active site around it (18). A number of designs were tested, and two to four mutations were required to accommodate a *para*-nitrophenylacetate substrate. The researchers made use of the solvent accessibility of the TSA to choose designs for construction and testing. Some solvent accessibility is necessary to allow binding, but too much and the active site lacks the order it needs to function. Kaplan and DeGrado (71) took the dock-and-design approach further by applying it to a scaffold that itself had been designed to fold and form a helical bundle. They docked a 4-aminophenol TSA with two catalytic iron atoms and made accommodating mutations in the center of the bundle.

It has recently been demonstrated that active sites catalyzing nonnatural mechanisms can be designed into nonenzyme scaffolds. Researchers from the Baker group have been successful in constructing nonnatural enzymes that catalyze both the Kemp elimination (99) and retro-aldol reactions (67). These designs were made possible by a generalized approach combining hashing methods used in ligand docking with rotamer-based protein design methods (118). Two methods were developed to deal with the problem of side-chain position variability on the fringe of the active-site geometry specification. One matches a large set of variations on the same active site geometry to scaffolds and the other seeks to match independent placements of the catalytic residue rotamers to the transition state geometry.

For each of the two reaction mechanisms, multiple designs were constructed and tested in multiple scaffolds: 20 designs in 4 scaffolds for Kemp elimination and 72 designs in 10 scaffolds for the retro-aldol reaction. This work illustrates the benefit in trying many approaches to the same reaction. Our understanding of what makes a good enzyme is not complete and multiple trials are required to achieve evolution starting points with reasonable starting activity. The researchers also tested variations on the same mechanism involving different catalytic and binding residues: two for the Kemp elimination and four for the retro-aldol reaction. For the retro-aldol reaction, 32 of 72 designed constructs had measurable activity, putting the success rate over 40% for a reaction that requires multiple substrate-enzyme catalytic interactions. Quality assurance was provided by crystal structures of the tested variants and the resulting good superposition with the intended design.

31.10. CONCLUSIONS AND OUTLOOK

It should be clear from the examples provided in this chapter that rational computational-based design can play a strong role in evolving enzyme activity, especially when screening is difficult. As argued in other reviews, there are clear synergies between screening and rational design (3, 23, 28).

From the full set of selectivity engineering examples above, it is possible to draw some conclusions concerning what can be expected from rational and semirational approaches. A wide range of enzymes have been rationally engineered (more than 25 classes in more than 50 examples). Most of the efforts were focused in the active sites and resulted in substantial improvements by as much as several orders of magnitude in specificity or selectivity. Activity improvements were seen with substantial increases over wild type for nonnative substrates and even one example of a sixfold increase for a native substrate. Although little attention has been paid in these primarily academic reports of finishing the evolution for process requirements, it should be clear that these rational design techniques can also support evolution for industrial processes (55).

What is the best way to get started with structure-based design? After reading some of the work cited above, consider downloading a free or low-cost structure viewer such as PyMOL (39) and look at crystal structures related to your enzyme of interest. Pay attention to what the current most accepted mechanism implies for substrate positioning. Learn as much as possible from the literature and model the mutations you think might be beneficial.

31.10.1. Outlook for Future Advances

One area where one can expect improvements are contributions from more sophisticated calculations. The difficulty in achieving

activities as high as natural enzymes is an ever-present theme in enzyme engineering. Improvements in potential energy calculations and configuration sampling could address this gap. None of the examples cited in this chapter use mixed quantum mechanical and molecular mechanical methods, molecular dynamics, or high-level ab initio quantum chemistry calculations. The only mention of free-energy perturbation methods was in the postexperimental validation of a design (72). The low usage presumably indicates that these methods are simply not yet easily accessible to the people who do the design, construction, and testing.

The area of de novo design also holds significant promise as both a tool to refine our understanding of enzymes and as a source for starting activity for enzyme evolution. Improvements in conformational sampling that have already been successful in loop design (65) can be expected to make contributions to active-site design. Authors of some recent successes have speculated that improvements in backbone flexibility handling (99) and discrimination during handling of polar networks (67) will be important factors in achieving high reaction rates common to natural enzymes. Jiang et al. (67) noted that their designed enzymes had low binding affinities. More sophisticated free-energy prediction methods, perhaps from the ligand-docking field, may play a useful role. For some reaction mechanisms, it will be necessary to incorporate negative design techniques to avoid side reactions. In any case, it is clear that interested readers can expect significant developments before the next edition of this manual.

Enzyme Engineering by Directed Evolution

MANFRED T. REETZ

32

32.1. INTRODUCTION

Enzymes have been used as catalysts in synthetic organic chemistry and in biotechnology for at least a century, but it was not until the past few decades that the chemical community has finally accepted biocatalysis as a truly useful tool in synthetic endeavors. To some researchers it may seem surprising that many enzymes not only accept numerous nonnatural substrates, but also turn them over with high degrees of chemo-, regio-, and/or stereoselectivity (11). Moreover, the discovery that many enzymes are also active in organic solvents (although at much lower rates than in the usual aqueous medium) originally came as a surprise, but is now state of the art. Progress in bioreactor design and process engineering has also been instrumental in making biocatalysis a viable option in industry, including the use of whole cells (26). Nevertheless, until the mid-1990s, many limitations to biocatalysis remained.

1. Numerous (if not the majority of) synthetic substrates of interest to chemists and/or biotechnologists are not accepted by enzymes, or react so slowly that enzyme catalysis is not feasible.
2. Enantioselectivity may well be poor, even if activity is acceptable.
3. Some enzymes, although active and enantioselective in a given transformation, may not be thermally stable enough for practical applications.
4. Many enzymes do not survive well enough in hostile organic solvents to be of practical use.

Traditional approaches to solve these problems include immobilization techniques, posttranslational modification, the use of additives, and/or protein engineering utilizing site-specific mutagenesis based on rational design, but unfortunately these methods are far from general (11, 26). In contrast, directed evolution, meaning Darwinian evolution in the test tube, has emerged during the past 15 years as the method of choice for addressing these problems (1, 21, 28, 40). The roots of directed evolution go back to the contributions of such researchers as Spiegelman and Eigen, but it was not until the mid-1980s that molecular biologists began to develop reliable gene mutagenesis methods required for the overall process.

Today, directed evolution of proteins comprises the following steps. The gene of the wild-type (WT) enzyme is used as a template for producing a library of mutated genes, which is then inserted into an appropriate bacterial host needed for

(over)expressing the corresponding enzyme variants. Upon plating out on agar plates, the bacterial colonies containing the transformants are harvested by a colony picker and placed in the wells of microtiter plates containing nutrient broth. Since each colony originates from a single cell, undesired mixtures of mutants never form. Following another step, the enzyme variants are tested as catalysts in a given reaction of interest by using an appropriate high-throughput screen (or selection method). The gene of the best enzyme variant (hit) is then used as a template for another cycle, and the Darwinian process is repeated as often as necessary until the desired degree of catalyst improvement has been achieved (Fig. 1). The most commonly used mutagenesis methods are error-prone polymerase chain reaction (epPCR), saturation mutagenesis, and DNA shuffling (section 32.3).

The problems in putting this form of laboratory evolution into practice revolve around the need to devise optimal gene mutagenesis methods and strategies for probing protein sequence space efficiently (1, 28, 40), and the necessity to develop fast and reliable methods for high-throughput screening or selection (52). Because of the screening problem, laboratory evolution of enantioselective enzymes constitutes a special challenge (40). In any directed evolution study of proteins, it is necessary to ensure the linkage between genotype and phenotype, the former referring to the information stored by the gene in the form of nucleic acids (which can be replicated), and the latter referring to the corresponding protein variants. In the case of nucleic acid libraries of ribozymes, aptamers, and DNAszymes, a well-developed research area (22), genotype and phenotype are the same. However, such biocatalysts are not as versatile or as stable as protein-based enzymes, and nature itself uses the latter in the vast majority of catalytic processes. This chapter treats exclusively directed evolution of proteins, the primary focus being on recent methodology developments.

32.2. SCREENING VERSUS SELECTION

The need to develop high-throughput screening methods (or selection) in directed evolution relates to the vast extent of protein sequence space (39, 52). The number of enzyme variants N at the theoretically maximum degree of diversity is traditionally described by the algorithm $N = 19^M X! / (X - M)! M!$, where M denotes the total number of amino acid substitutions per enzyme molecule

FIGURE 1 Individual steps in directed evolution.

and X is the number of residues in the enzyme molecule. When considering an enzyme composed of 300 residues, for example, 5,700 mutants are possible if one amino acid is substituted randomly, but 16 million in the case of two simultaneous substitutions, and about 30 billion if three amino acids are exchanged simultaneously. In practice, the size of libraries of enzyme variants ranges typically between 10^3 and 10^6 transformants. Screening using some sort of an analytical technique follows the expression of enzyme variants, whereas selection, in the strict sense of the word, relies on the survival of the host organism that harbors an improved enzyme variant, thereby allowing for very large gene libraries. The concepts are sometimes confused in the literature.

In most directed evolution studies some sort of screening is applied, often in combination with a crude pretest that assesses activity and thereby automatically eliminates “dead” variants (52). An example of an efficient pretest is the traditional tributyrin assay for lipase activity in which the agar plates are charged with tributyrin undergoing lipase-catalyzed hydrolysis, active variants being indicated by the appearance of halos on the agar plates. Such tests are important because directed evolution produces enzyme libraries in which the vast majority of variants are inactive.

Many different high-throughput screening systems have been developed (52), including those that assess enantioselectivity (39). Conventional chiral gas chromatography or high-performance liquid chromatography can handle only a few dozen samples per day, but cleverly designed assays based on UV-visible, infrared, or nuclear magnetic resonance spectroscopy, mass spectrometry, fluorescence or circular dichroism have been devised, allowing typically the determination of 800 to 5,000 ee-values per day (ee = enantiomeric excess), depending upon the nature of the substrate. In favorable cases automated gas chromatography or high-performance liquid chromatography can be used to assay up to 400 to 500 samples. Pooling strategies can also be used to alleviate the screening problem (37), which to this day constitutes the bottleneck in directed evolution.

In nature, compartmentalization of genes in cells ensures the genotype-phenotype linkage. Inspired by this phenomenon, droplet-based strategies for *in vitro* compartmentalization have been developed (16). By use of oil, detergents, and emulsifiers, emulsions with droplets having diameters of approximately $2\ \mu\text{m}$ are easily constructed, “mimicking” natural cells. The members of a gene library are then partitioned into microscopic compartments in such a way that one copy comes to exist in each droplet, and *in vitro* protein expression is used to synthesize multiple copies of the encoded protein. Since the droplets are so small, large libraries (10^6 to 10^8 members) can be generated and handled. Several variations of this technique have been reported, including systems in

which the droplets are the sole connection between genotype and phenotype and DNA display in such droplets using covalent or noncovalent links or even beads (16). It remains to be seen how this technique will develop in the future, as for example in the directed evolution of enantioselective enzymes, and how it compares with other approaches.

Various systems for genotype-phenotype linkages have been reviewed (1, 4, 16, 28), including display techniques such as ribozyme display, phage display, bacterial surface display, and yeast surface display. Sometimes the desired mutants are isolated or enriched directly from a suspension of the corresponding display species, while in other systems analytical instruments such as the fluorescence-activated cell sorting (FACS) need to be invoked. The numbers describing the size of the libraries in all of these systems are high (10^6 to 10^{10}), and, indeed, successful examples of directed evolution of proteins have been reported (1, 4, 16, 28). Nevertheless, the question of generality and ease of performance needs to be addressed. For example, phage display is primarily suited to handle the binding properties of proteins. That is probably why attempts to apply phage display in the directed evolution of enantioselective enzymes (as in the case of a lipase) have not been exceedingly rewarding so far (12). In contrast, a promising approach to yeast surface display for selecting horseradish peroxidase variants as catalysts in the stereoselective dimerization of tyrosinol has been devised, the synthesis of fluorescence-labeled enantiomeric tyrosinol substrates being necessary (27). One was immobilized on the surface of live yeast cells (together with the library of enzyme variants), and the other was supplied in solution and used by the active variants to label those cells that express the active enzyme variants. A library of approximately 2×10^6 horseradish peroxidase variants was generated by saturation mutagenesis at five positions next to the binding pocket. The library was subjected to FACS analysis, once for enantioselectivity favoring D-tyrosinol over the L-enantiomer, and once favoring the reverse. Variants with up to eightfold-altered enantioselectivity toward L/D-tyrosinol were identified, including those with reversed stereoselectivity (27).

A system for single-cell, super-high-throughput screening to identify enantioselective esterase mutants as catalysts in the hydrolytic kinetic resolution of chiral esters also deserves mention (3). The FACS-based concept requires the two enantiomeric esters to be labeled, each with a different fluorescent dye (green/red). Appropriately labeled (R)- and (S)-tyramide esters as substrates were subjected to hydrolytic kinetic resolution, peroxidase-mediated radical formation ensuring the immediate covalent attachment of the reaction products to the surface of an esterase-proficient bacterial cell (*Escherichia coli*) (3). The system allows 10^8 cells, and thus this number of clones is screened within a few hours. The goal was to reverse

FIGURE 2 Genetic selection system for laboratory evolution of enantioselectivity in a kinetic resolution (43).

the sense of enantioselectivity. In a proof-of-principle study, epPCR was applied at an error rate corresponding to the introduction of two to four amino acid substitutions per enzyme molecule. The best hit was found to display a selectivity factor of $E = 16$ in favor of the (*R*)-enantiomer [WT: $E = 1.2$ in favor of the (*S*)-substrate]. More work is required here, especially to see how far enantioselectivity can be boosted with epPCR or with other gene mutagenesis methods.

As already stated, selection systems can handle larger libraries than conventional screening assays, meaning libraries of gene mutants versus libraries of protein variants (21, 52). The question of whether the generation of super-large libraries is really desirable, certainly relative to the use of small but super-high-quality protein libraries, will be addressed in section 32.4. Here, a short discussion regarding selection is in order. Experimental platforms that link microbial survival as detected by growth rate with a catalytic parameter of an enzyme are needed. Growth conditions are required so that, from libraries comprising 10^6 to 10^{10} gene mutants, only those cells that express improved enzyme variants appear on the agar plates. In most successful examples of selection systems, the necessary physiological effects are straightforward and easy to predict (1, 21, 28). In most cases, substrate mimics are used for a defined reaction to be catalyzed in a way that fulfills the metabolic requirement. Further requirements concern the necessity of water solubility of the substrates and the prerequisite that the substrates and reaction products do not interfere with the cellular environment. Many systems regarding the evolution of activity, substrate acceptance, or stability are based on the use of antibiotics. However, this limits the scope of applications.

The question whether selection can be harnessed in the directed evolution of enantioselective enzymes is a particularly difficult one. Why should an organism experience a growth and thus survival advantage just because it harbors an enzyme that is enantioselective for a given substrate? Two recent studies have shown that, in principle, this is possible, although generalization has yet to be achieved. In one approach, a selection system for enantioselective lipase variants of *Bacillus subtilis* was devised using a mutant library in an aspartate auxotroph *E. coli* (5). This was supplemented with an aspartate ester of a chiral alcohol, namely isopropylidene glycerol in the enantiomeric (*S*)-form. Such a step alone does not ensure any growth advantage. Therefore, the researchers added an enzyme inhibitor consisting of (*R*)-isopropylidene glycerol covalently bonded to a phosphonate ester. Since phosphonate esters are known to be lipase inhibitors by undergoing covalent attachment to serine of the catalytic triad Asp/His/Ser, the combined effects were expected to induce selection. Saturation mutagenesis using an appropriate cassette for amino acid positions 132 to 136 was used to construct a library, and after three selection rounds in which the concentration of the inhibitor was successively raised, a lipase variant was indeed identified having improved enantioselectivity ($ee = +73.1\%$ at 28.9% conversion versus $ee = -29.6\%$ at 23.4% conversion of the WT) (5).

In another study describing a selection system for evolving enantioselectivity, a more general approach was taken that does not require such surrogate diastereomeric substrates or the use of inhibitors (43). The basic concept is to mimic kinetic resolution in such a way that “positive” and “negative” components are used in a single system according to the absolute configuration of the chiral compounds under study. This ensures simultaneous selection for activity and enantioselectivity (Fig. 2). For the evolution of (*R*)-selectivity, the (*R*)-substrate needs to contain a positive component that serves as a potential energy source for the host organism, thereby promoting growth following the desired enantioselective cleavage reaction. In contrast, the (*S*)-substrate is designed so as to contain a negative component, in this case the cleavage reaction generating a toxic component as a poison for the organism. This dual-selection system requires the use of a mixture of isosteric pseudo-enantiomers, the ratio of the two starting substrates serving as a convenient way to optimize selection pressure (43).

The concept was illustrated in the directed evolution of *Candida antarctica* lipase B as a catalyst in the kinetic resolution of the acetate of isopropylidene glycerol (43). The WT is slightly (*R*)-selective ($E = 1.9$). The (*S*)-acetate was used as the “positive” component, the cleavage reaction generating acetic acid as an energy source. The enantiomeric (*R*)-fluoroacetate served as the “negative” component, leading to fluoroacetic acid as the toxic agent, which means that with this choice reversal of enantioselectivity was programmed. After saturation mutagenesis, the use of a 1:100 ratio of this mixture led to the appearance of bacterial colonies that harbor almost exclusively (*S*)-selective *C. antarctica* lipase B variants [$\geq 90\%$ active variants favoring the (*S*)-substrate with E -factors up to 8]. In this proof-of-principle study, only a relatively small gene library was generated (43), and it is therefore of interest to see how this and related selection systems for enantioselectivity will perform when studying 10^6 - to 10^{10} -sized gene libraries.

32.3. GENE MUTAGENESIS METHODS

During the past 25 years, numerous gene mutagenesis methods have been developed. It is difficult even for experts to make the optimal choice, because comparative studies focusing on relative efficiency are rare. Since the methods have been summarized in previous reviews and monographs (1, 28, 40), only a few basic facets are repeated here. It should be pointed out that although many gene mutagenesis methods were already available in the 1980s, the idea that repetitive cycles of mutagenesis/screening constitute the crucial tool for exerting evolutionary pressure was rarely practiced at this time (25).

32.3.1. epPCR and Related Methods

To this day the mutagenesis method used most often is epPCR (1, 28, 40). By adjusting such parameters as the concentration of $MgCl_2$ (or $MnCl_2$) or using unbalanced

concentrations of nucleotides, the error rate can be adjusted empirically so that on average one, two, three, or more amino acid substitutions occur in the protein. epPCR is often designated as random mutagenesis, but this is only a rough first approximation, and, in fact, several sources of serious bias have been reviewed (33, 57, 59). Due to the degeneracy of the genetic code, *inter alia*, amino acid bias occurs. The full potential diversity is hardly reached, on average, only about one-third (57). It is unlikely that two or even three point mutations will occur at neighboring residues in the protein. Bias can also arise because of the exponential nature of the amplification process (33). A detailed statistical analysis of these limitations has been performed (57).

Some of these problems can be reduced by combining libraries generated by Tag-based PCR and those obtained by application of the Stratagene GeneMorph kit which is characterized by a different bias (33). A very different way to reduce amino acid bias is sequence saturation mutagenesis, comprising four steps (60). It is independent of the mutational bias of DNA polymerases, and also has the advantage that the fragment distribution of a DNA library can be controlled by the use of different concentrations of the individual Sp-dNTP α S or a combination thereof. The mutation rate can be tuned by varying the concentration of NaCl and/or NaOH in the DNA-melting step. It remains to be seen whether the advantages inherent in these alternatives outweigh the increased labor effort relative to the use of standard epPCR.

Despite the limitations of standard epPCR, the introduction of point mutations by this method is easy to perform, and it is particularly appropriate if no structural information is available. In an early publication the stability and activity of aspartase, catalyzing the industrially important addition of ammonia to fumarate with formation of *L*-aspartic acid, were improved by a notable margin as a result of screening a library of enzyme mutants produced by epPCR (63). Another early study concerns the enhancement of activity of subtilisin E in dimethylformamide as a hostile solvent, which constitutes a landmark contribution, because for the first time sequential rounds of epPCR were shown to be effective in directed evolution, such a strategy providing a means to exert evolutionary pressure (7). Since then, many if not most

studies in directed evolution have utilized successive rounds of epPCR.

32.3.2. Saturation Mutagenesis

The generation of focused libraries can be achieved by saturation mutagenesis, which requires some structural knowledge to make an appropriate decision regarding where in the enzyme amino acid randomization should take place (1, 28, 40). In the simplest case a single residue is targeted, meaning the introduction of all of the other 19 amino acids by using the appropriate codon degeneracy. It is also possible to randomize sites composed of two or more amino acid positions, in which case the term "combinatorial cassette mutagenesis" is sometimes used. Since in such a process the individual point mutations may influence each other, the simultaneous introduction of amino acids at more than one position makes synergistic effects possible (not just additivity).

Since the mid-1980s many methods for saturation mutagenesis, usually as variations of the general approach based on the use of appropriate oligodeoxynucleotides, have been reported. Accordingly, primers need to be designed and prepared that carry the genetic information encoding the desired mutational changes. The most widely used procedure is the so-called QuikChange protocol of Stratagene (19), which is based on previous work. It was originally developed for traditional site-specific single-amino-acid introduction, but can also be used for randomization at up to five amino acid positions in the enzyme (Stratagene's QuikChange® Multi Site-Directed Mutagenesis Kit). The general sequence of events required in the QuikChange protocol is summarized in Fig. 3.

Unfortunately, the extended protocol is not general, e.g., problems related to the primer length and design were noted. Therefore, various improvements were proposed, e.g., the use of partially overlapping or even nonoverlapping oligonucleotides, the resulting amplicon being employed as a megaprimer that completes the synthesis of the plasmid in a second PCR (30). Nevertheless, difficulties were still encountered in the case of recalcitrant targets such as large plasmids, as in the case of *P450-bm3* from *Bacillus megaterium* (55). Extending the idea of using nonoverlapping oligonucleotides (23, 66), a highly improved two-stage PCR-based method

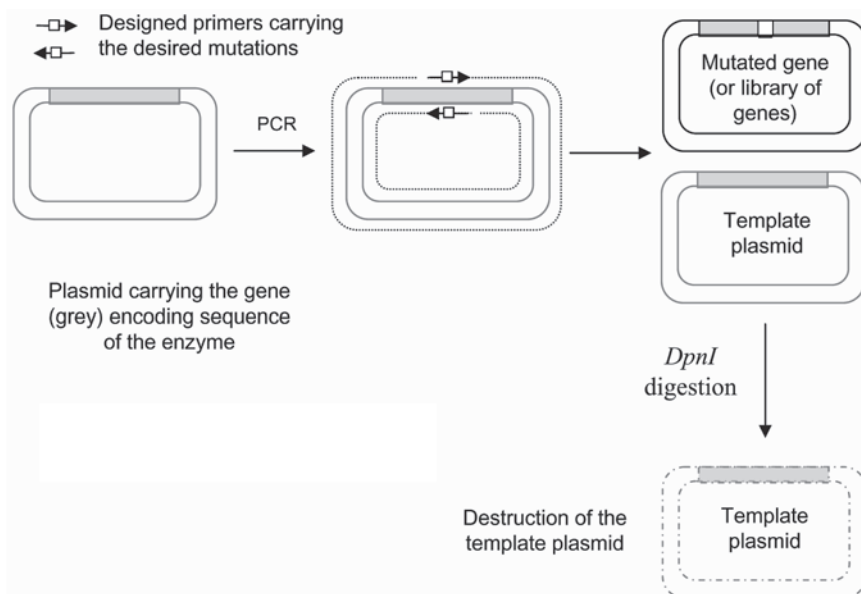

FIGURE 3 Schematic illustration of QuikChange (Stratagene) (19).

for the creation of saturation mutagenesis libraries was recently developed specifically for difficult-to-amplify templates (Fig. 4) (55). In the first stage, both the mutagenic primer and the antiprimer that are not complementary anneal to the template. The amplified sequence is then used in the second stage as a megaprimer. In this straightforward process, sites composed of one or more residues can be randomized in a single PCR reaction, irrespective of their location in the gene sequence. In a carefully performed comparative investigation, the virtues of the new method relative to QuikChange and related protocols were demonstrated by use of four different enzymes (55).

The optimal use of saturation mutagenesis requires the consideration of oversampling (44, 53). Fortunately, algorithms have been developed which are useful in the design of libraries (6, 10, 36), and indeed these have been applied in assessing the degree of oversampling as a function of the nature of the codon degeneracy and of the percentage of coverage of the respective protein sequence space (44). As a result of a systematic study addressing the numbers problem in directed evolution, practical recommendations were made (44). NNK degeneracy is usually applied in directed evolution based on saturation mutagenesis, which means that all

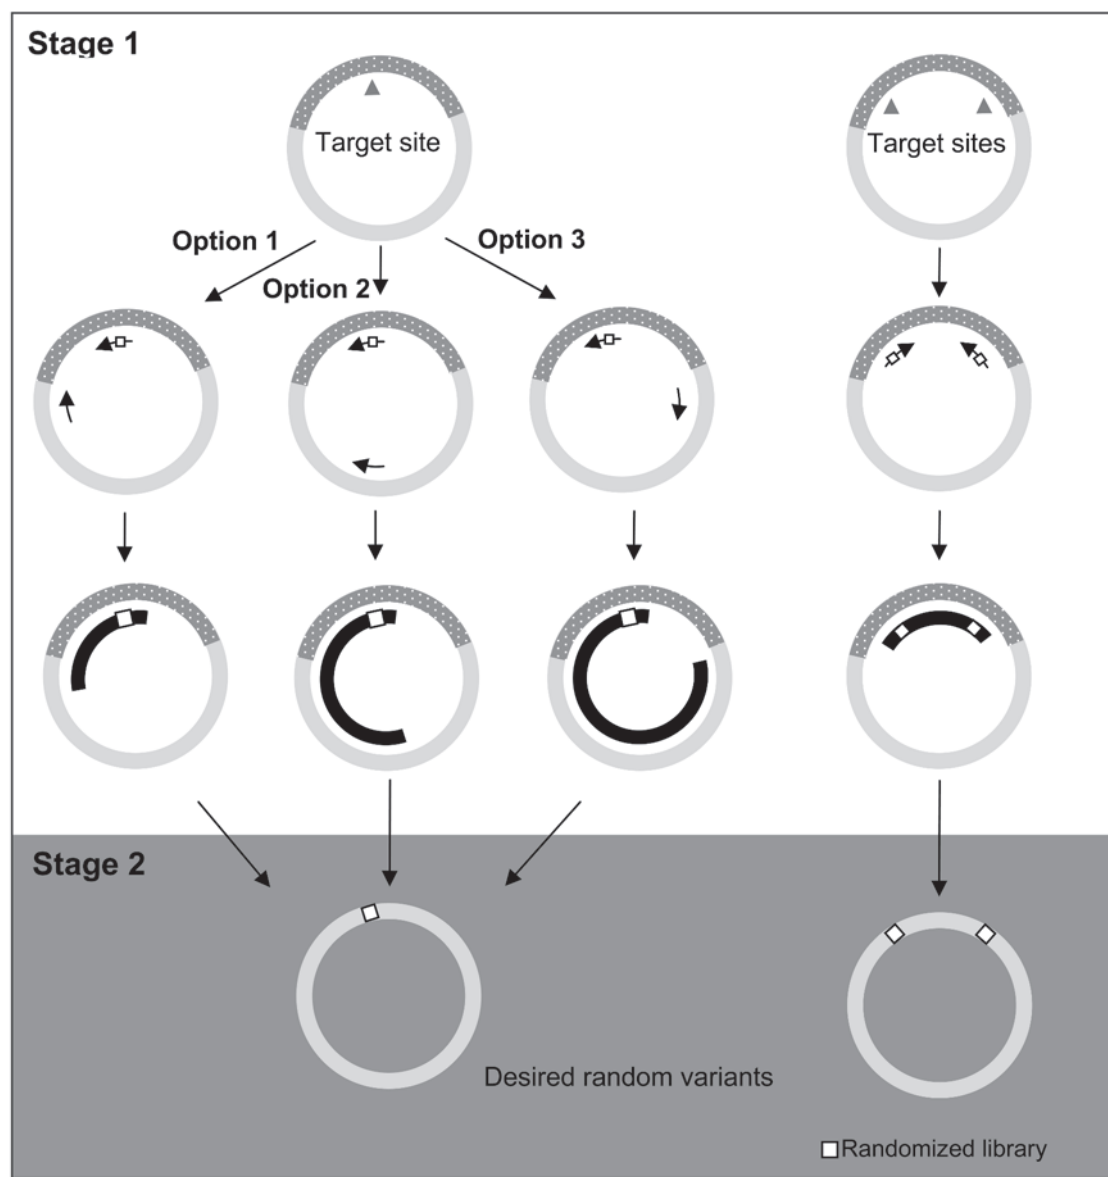

FIGURE 4 Scheme illustrating the improved method for PCR-based saturation mutagenesis useful in the case of difficult-to-amplify templates (55). The gene is represented by the dotted section, the vector backbone is shown in light gray, and the formed megaprimer in black. In the first stage of the PCR both the mutagenic primer (positions randomized represented by a white square) and the antiprimer (or another mutagenic primer, shown to the right) anneal to the template, and the amplified sequence is used as a megaprimer in the second stage. Finally, the template plasmids are digested by use of DpnI and the resulting library is transformed in bacteria. The scheme on the left illustrates the three possible options in the choice of the megaprimer size for a single-site randomization experiment. The scheme to the right represents an experiment with two sites simultaneously randomized.

TABLE 1 Oversampling necessary for 95% coverage as a function of NNK and NDT codon degeneracy assuming the absence of amino acid bias (44)

No. ^a	Codons	NNK transformants needed	Codons	NDT transformants needed
1	32	94	12	34
2	1,028	3,066	144	430
3	32,768	98,163	1,728	5,175
4	1,048,576	3,141,251	20,736	62,118
5	33,554,432	100,520,093	248,832	745,433
6	$>1.0 \times 10^9$	$>3.2 \times 10^9$	$>2.9 \times 10^6$	$>8.9 \times 10^6$
7	$>3.4 \times 10^{10}$	$>1.0 \times 10^{11}$	$>3.5 \times 10^7$	$>1.1 \times 10^8$
8	$>1.0 \times 10^{12}$	$>3.3 \times 10^{12}$	$>4.2 \times 10^8$	$>1.3 \times 10^9$
9	$>3.5 \times 10^{13}$	$>1.0 \times 10^{14}$	$>5.1 \times 10^9$	$>1.5 \times 10^{10}$
10	$>1.1 \times 10^{15}$	$>3.4 \times 10^{15}$	$>6.1 \times 10^{10}$	$>1.9 \times 10^{11}$

^aNumber of amino acid positions at a given site.

20 proteinogenic amino acids are used as building blocks (N, adenine/cytosine/guanine/thymine; K, guanine/thymine). However, reduced amino acid alphabets are also possible by applying the appropriate codon degeneracy, NDT being one of many options (D, adenine/guanine/thymine; T, thymine). In this case only 12 amino acids are encoded (Phe, Leu, Ile, Val, Tyr, His, Asn, Asp, Cys, Arg, Ser, and Gly), reducing structural diversity but having strong ramifications regarding the quality of saturation mutagenesis libraries. In a comparative investigation regarding the relative merits of NNK versus NDT codon degeneracy, the respective oversampling necessary for 95% coverage of the respective libraries was first calculated for randomization sites comprising different numbers of amino acid positions (Table 1) (44). These calculations are only rough approximations since amino acid bias is neglected. Bias can be avoided by the use of appropriate mixtures of oligonucleotides, but such a procedure is more expensive and

time-consuming; however, it is being studied for comparison in the author's laboratory. In the discussion that follows, bias is neglected. For example, in the case of a site composed of three amino acids, NNK requires almost 100,000 clones, whereas NDT needs only approximately 5,000 clones for 95% coverage. This raises the question as to which codon degeneracy is optimal, especially when the screening problem forces the experimenter to restrict the library size, e.g., to 5,000.

The results of the calculations over the whole range of coverage (0 to 95%) for sites composed of one, two, three, four, and five amino acid positions as a function of NNK versus NDT are shown in Fig. 5 and 6 (44). Here again, the pronounced differences in NNK and NDT libraries become apparent. For example, if, in the case of a three-amino-acid site, the experimenter restricts screening to 5,000 transformants for practical and economical reasons, the use of an NDT library correlates with approximately 95% coverage,

**FIGURE 5** Library coverage calculated for NNK codon degeneracy at sites composed of one, two, three, four, and five amino acid positions (aa, amino acids) (44).

FIGURE 6 Library coverage calculated for NDT degeneracy at sites composed of one, two, three, four, and five amino acid positions (aa, amino acids) (44).

whereas the same number of screened clones in an NNK library allows for only 15% coverage.

Other codon degeneracies, which may be more suitable for a given task, can be analyzed analogously. It was concluded that it is best to choose systems in which the number of codons is equal to the number of amino acids, which helps to reduce the inherent bias and overrepresentation of certain amino acids (44). These statistical analyses were used as the basis for evolving substrate acceptance (rate) and enantioselectivity of an epoxide hydrolase (section 32.4). In particular, it was demonstrated that the quality of a size-limited enzyme library (5,000 transformants) produced by saturation mutagenesis at a site made up of three amino acid positions, using NDT codon degeneracy, is dramatically higher than that of a 5,000-membered library generated on the basis of the conventional NNK codon degeneracy. NDT is not the only alternative to a reduced amino acid alphabet, and indeed the use of more than one codon degeneracy in a given saturation mutagenesis experiment is possible.

The use of focused libraries in directed evolution has been practiced successfully many times (1, 28, 40), as, for

example, in the successful quest to enhance the enantioselectivity of a lipase, in which a site composed of four amino acid positions aligning the binding pocket was randomized (49). In a later study it was suggested that whenever substrate acceptance or enantioselectivity need to be improved, sites closer to the active center are liable to be more important than remote positions (20).

It was not until systematization and iterativity were implemented that saturation mutagenesis was really exploited to its full potential, specifically in the form of iterative saturation mutagenesis (ISM) (41, 42, 48). The experimenter systematically identifies all relevant “hot” sites with the help of structural data (X-ray data or homology model), a given site being composed of one or more amino acid positions. After the generation and screening of the respective saturation mutagenesis libraries, the genes of the respective hits are then used as templates for performing further rounds of randomization at the other sites. Consider the case of four sites, A, B, C, and D (Fig. 7) (41, 48). If each site is “visited” only once in a given upward pathway, convergence is reached after preparing

FIGURE 7 ISM using four sites, A, B, C, and D, each site in a given upward pathway in the fitness landscape being visited only once (48).

and screening a total of 64 libraries. As will be seen in section 32.4, complete scanning of such a defined and limited section of protein sequence space is not necessary, i.e., any one of the 24 pathways can be chosen. If a “dead end” as a consequence of a local minimum is encountered, backtracking is possible. In all applications of ISM, it is crucial to develop reliable criteria for choosing the appropriate randomization sites.

Thus far, several enzyme properties important in practical biocatalysis have been addressed when applying ISM, namely, enantioselectivity/substrate acceptance (48) and thermostability (41, 42). In the case of enantioselectivity and/or substrate acceptance (rate), the criterion is defined in the combinatorial active-site saturation test (CAST) (48). All sites next to the binding pocket are systematically identified on the basis of X-ray data or homology model, a site being composed of one or more amino acid residues. Second-sphere residues may also be considered (41). Rather than focusing just on a select site as done in previous saturation mutagenesis experiments (1, 20, 28, 40, 49), CASTing constitutes systematization, setting the stage for iterativity (ISM). It is a relatively new approach, but it has already been applied to several different enzymes in the quest to broaden substrate scope and to enhance enantioselectivity (section 32.4) (2, 24, 48). Such a systematic method is a practical way to reduce the screening effort, which is the bottleneck of directed evolution.

When applying ISM in the enhancement of thermostability of proteins, a different criterion for choosing randomization sites needs to be applied (41, 42). Since it was well known that hyperthermophilic enzymes are more rigid than the mesophilic analogs (13), it seemed reasonable to introduce appropriate mutations at sites displaying high degrees of flexibility. To have a rough guide for identifying such sites, atomic displacement parameters obtained from X-ray data can be used, namely, B factors that reflect smearing of atomic electron densities with respect to equilibrium positions as a result of thermal motion and positional disorder.

On the basis of this physical phenomenon, the B-factor iterative test (B-FIT) was developed, according to which only those sites displaying the highest B factors are considered for saturation mutagenesis, the process being performed iteratively according to Fig. 7 (41, 42). This embodiment of ISM has likewise proved to be successful; unusual degrees of thermostabilization have been achieved (section 32.4). Moreover, B-FIT can also be used to enhance enzyme tolerance toward hostile organic solvents, since a rough correlation between thermostability and stability in organic solvents exists (13).

32.3.4. Recombinant Gene Mutagenesis Methods

Instead of introducing point mutations, as in the methods above, recombination can also be considered, meaning the breaking and rejoining of DNA in new combinations (1, 21, 28, 40). DNA shuffling is the most prominent method (38). In general, one or more genes are first digested with a DNase to yield double-stranded oligonucleotide fragments of 10 to 50 base pairs, which are then amplified in a PCR-like process. Repeating cycles of strand separation and reannealing in the presence of a DNA polymerase followed by a final PCR amplification result in the reassembly of full-length mutant genes. DNA shuffling was first applied to tumor endothelial marker β -lactamase, the goal being to achieve increased antibiotic resistance. DNA shuffling can be performed with one gene, with two or more natural genes, or with mutant genes (Fig. 8). In general, a relatively high degree of homology is necessary (at least 60%). A particularly efficient version is family shuffling (38), in which homologous genes from different species are chosen; such an approach provides high catalyst diversity. In all of these recombinant methods a certain degree of self-hybridization of parental genes occurs, thereby lowering the quality of the mutant libraries. Various improvements have been suggested (1, 21, 28, 40).

An alternative to the above-mentioned *in vitro* recombination is the so-called staggered extension process (StEP), which is based on cross-hybridization of growing

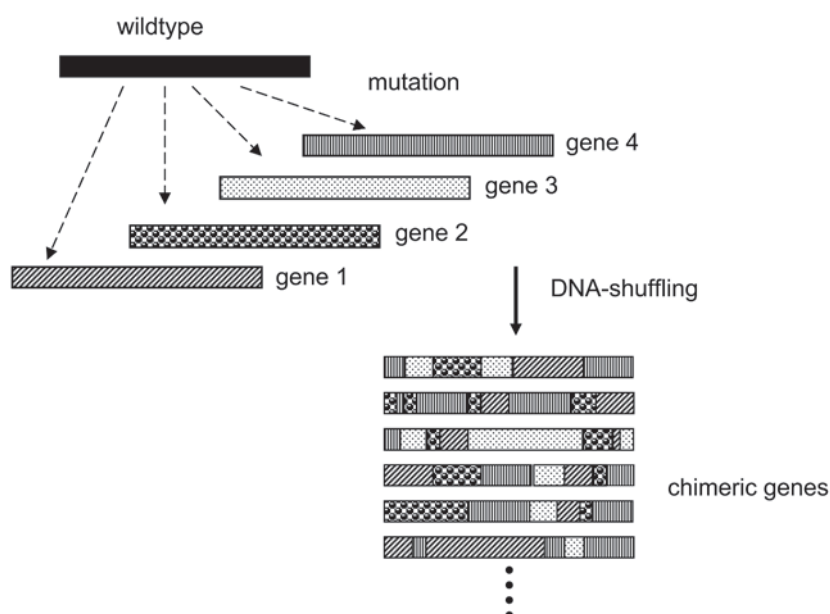

FIGURE 8 Scheme illustrating DNA shuffling for the case in which the parental genes originate from the WT by some sort of mutagenesis.

gene fragments as the DNA polymerase-catalyzed primer extension process (65). Subsequent to denaturation the primers anneal and extend under conditions that limit extension, allowing the primers to reanneal randomly to different parent sequences throughout the multiple cycles. Finally, the recombinant full-length gene products are amplified by PCR.

A number of homology-dependent and independent *in vitro* recombination methods have been summarized in reviews (1, 21, 28, 40), and only a few recent advancements are highlighted here. A prominent method is random chimeragenesis on transient templates (RACHITT), which constitutes a conceptually distinct alternative to sexual PCR for gene family shuffling (9). Accordingly, thermocycling, strand switching, or staggered extension are not necessary, the method relying on the trimming, gap filling, and ligation of parental gene fragments hybridized on a transient DNA template. This approach was applied successfully to the directed evolution of dibenzothiophene monooxygenase, which catalyzes the first step of the *dszABCD* diesel biodesulfurization pathway. Significantly increased reaction rate and a broadened scope of substrate acceptance were achieved (9).

Another advancement is random strand transfer recombination (RSTR), which is based on the ability of reverse transcriptases to undergo homology-independent template switches during the DNA synthesis (51). The method appears to be fairly general, involving spontaneous base-pairing-dependent recombination at high frequency between genes having low or high sequence homology. A different recombinant method is "biased mutation-assembly," in which a library is generated by overlap extension PCR with DNA fragments from a WT enzyme and phenotypically advantageous mutant genes (17). The number of mutations assembled in the WT gene is controlled stochastically by mixing ratio of the WT fragments to the mutant DNA fragments. In yet another approach, synthetic oligonucleotides are added to a mixture of gene fragments prior to assembly (56), a method that has been optimized and dubbed "incorporating synthetic oligonucleotides via gene reassembly" (ISOR) (18).

Insertion and deletion constitutes a different way to obtain mutant enzymes, but random versions of this approach have not been routinely applied. In addition to the first successful approach called random insertion/deletion (RID), which allows for the deletion of up to 16 consecutive bases at random positions and the insertion of a specific sequence or random sequences of an arbitrary number of bases thereat (31), a method based on gene shuffling termed "random insertional-deletional strand exchange" mutagenesis (RAISE) was recently proposed (15). It is composed of three steps, namely random DNA fragmentation by DNase I, attachment of a random short nucleotide sequence to the 3' terminus of the fragment using TdT, and finally reconstruction of each fragment with a tail of random nucleotides into a full-length sequence by self-priming PCR. The method was first applied to a tumor endothelial marker β -lactamase for improved antibiotic resistance.

In a different approach to recombination, the WT genes normally necessary for digestion are not needed, because the starting points are synthetic DNA fragments that are then simply assembled. Three versions have been reported, namely "degenerate homoduplex recombination" (8), "synthetic shuffling" (32), and "assembly of designed oligonucleotides" (61). These methods tolerate low homology, while undesired self-hybridization of parental

genes is minimized. However, they have not been exploited extensively thus far.

32.3.5. Computation-Guided Approaches to Mutagenesis

Some of these mutagenesis methods utilize computer aids, as for example, in the user-friendly design of saturation mutagenesis libraries (10, 41, 42, 44) or in strategies relying on sequence alignments (1, 28). In this section, the focus is on strategies in which computation is the primary tool; two select cases are highlighted. In one approach called SCHEMA, homologous recombination, guided by structure-based computation, is used to create libraries of protein sequences that are not only extensively mutated, but that also have a high likelihood of having the same folding as the parental structures (54). To adapt this to shuffling, the computational algorithm SCHEMA was developed, which allows the prediction of fragments that need to be inherited from the same parent. The algorithm computes all interactions between residues, and then predicts the number of interactions that are disrupted in the process of recombination, i.e., in the formation of new proteins. SCHEMA was originally developed by use of two distantly related β -lactamases, but has since been applied to cytochromes P450 as well (54).

In another *in silico* approach, recombination-based directed evolution was augmented by incorporating a strategy for the statistical analysis of protein sequence activity relationships (ProSAR) (14), in analogy to the well-known quantitative structure-activity relationships (QSAR) that have been used widely in drug design and peptide optimization. ProSAR is a multivariate optimization process composed of repetitive diversity generation and screening accompanied by a statistical analysis based on linear regression on "training sets" derived from one or more libraries per cycle. After the identification of a hit obtained at the end of a given round, the variant is used as a template for programming diversity in the next round. Statistical learning comes about by applying an algorithm that correlates mutations with protein function. In ProSAR, DNA shuffling and semisynthetic DNA shuffling are used as the mutagenesis methods. The method was applied in the directed evolution of a bacterial halohydrin dehalogenase, the goal being highly improved volumetric productivity (14). In this endeavor, one to four libraries were designed and constructed from a pool of 10 to 50 mutations; approximately 14,000 enzyme variants are typically screened per round. Each round required 3 to 4 weeks. After 18 rounds, a 4,000-fold improvement in activity was indeed achieved in the cyanation process relevant in the synthesis of a chiral intermediate useful in the preparation of the cholesterol-lowering drug Lipitor®. Studies are needed in which the performance of both ProSAR and SCHEMA are compared with other strategies being applied in directed evolution.

32.4. COMPARATIVE ENZYME EVOLUTION STUDIES

In this section a few select studies in directed evolution are reviewed, because they allow conclusions regarding the relative merits of different mutagenesis methods and strategies. However, the results should be viewed as possible trends, because the scarcity of comparative data regarding the vast majority of other studies does not allow for general conclusions.

32.4.1. Transforming a β -Galactosidase into a β -Fucosidase by DNA Shuffling and Saturation Mutagenesis

In a landmark study, single-gene DNA shuffling was applied to turn *E. coli* β -galactosidase (BGAL) into a β -fucosidase, thereby changing the substrate scope (62). The enzyme hydrolyzes β -galactosyl linkages such as the $\beta(1,4)$ -linkage in lactose. Following seven cycles of DNA shuffling and screening approximately 10,000 transformants in each round, an enzyme variant was obtained showing a 10-fold improvement in activity as measured by k_{cat}/K_m in the reaction of the model compound *p*-nitrophenyl- β -D-fucopyranoside (pNP-fuc), while exhibiting a 39-fold decrease in activity with the “native” substrate *p*-nitrophenyl- β -D-galactopyranoside (pNP-gal). A 2.7-fold preference for pNP-gal over pNP-fuc was maintained.

Later, the same system was used to systematically compare DNA shuffling with saturation mutagenesis (35). Using appropriate primer design, residues Asp201, His540, and Asn604 were randomized by using NNK codon degeneracy. These positions were chosen because the X-ray structure of the E537QB GAL/pNP-gal complex reveals a hydrogen bond between the C6 hydroxyl moiety and residues His540 and Asn604 with a fixed sodium, which is held in place by Asp201. Only approximately 10,000 transformants were screened using a color test that indicated the presence of approximately 250 possibly improved clones, 29 of which showed a particularly prominent color change (blue). These were studied more closely, leading to the discovery of 11 variants that exhibited greater activity and specificity in reactions with pNP-fuc than the WT does with pNP-gal, indicating that substrate specificity had inverted in a single round of saturation mutagenesis/screening. Several highly improved variants were identified, the combination His540Val/Asn604Thr (Asp201 remaining) being particularly efficient. It was shown to have a k_{cat}/K_m value ($s^{-1} M^{-1}$) of 179 for pNP-gal and 2,563 for pNP-fuc, which is an impressive result. The failure to realize that Asp201 is necessary to fix the sodium greatly reduced the efficiency of the combinatorial search, because only approximately 1/32 of the library contained Asp201. This means that a mere 300 transformants had any chance of harboring improved variants. Yet, this strategy outperformed the DNA approach, by far, in terms of the degree of catalyst improvement (kinetic data), labor intensity, and speed (35). The authors of this comparative study offer several explanations for the reason why DNA shuffling does not produce the crucial mutations His540Val and Asn604Thr, but they are careful not to generalize.

32.4.2. Increasing the Thermostability of an Esterase by epPCR

Increasing the thermostability of enzymes is an important endeavor in biotechnology for practical and theoretical reasons. Rational design using site-specific mutagenesis and directed evolution have been used successfully in many studies (13). In early reports, several rounds of epPCR, sometimes alternating with recombinant methods, were shown to be effective in the thermostabilization of such enzymes as esterases and proteases (64). Since then, most studies regarding thermostabilization have relied on epPCR (13), a recent example being highlighted here.

A case study concerns the esterase from *Burkholderia gladioli* (EstB) which belongs to a family of esterases related to β -lactamases and DD-peptidases (58). It catalyzes the chemoselective hydrolysis of the acetyl group at the

3 position of cephalosporin derivatives, which is of considerable industrial interest. To obtain a more stable variant, epPCR was applied corresponding to approximately five amino acid substitutions per enzyme molecule. By use of a crude but efficient colony filter pretest based on the pH change, approximately 10^6 transformants were screened in a process requiring 2,000 plates. This led to the identification of 11 moderately improved mutants showing ΔT_m values of up to 7.6°C. In the attempt to enforce further improvements, DNA shuffling was applied, which failed. Even after optimizing every stage of the recombinant process, including fragment sizes, elution protocols, DNA concentrations, and the PCR conditions, no product could be obtained after the final reassembly PCR step. The researchers postulated that the high GC content of EstB (74%) imposes a barrier to successful PCR gene assembly (58). Then the mutations of several of the previous variants were combined, followed by another round of epPCR involving 10^5 transformants, which led to the best variant displaying distinctly improved thermostability ($\Delta T_m = 13^\circ C$). High activity toward cephalosporin C was retained, underscoring the success of this study. Nevertheless, it would be interesting to subject this enzyme to directed evolution in a knowledge-guided manner such as the B-FIT method (sections 32.3.2 and 32.4.3).

32.4.3. Increasing the Thermostability of a Lipase by the B-FIT Method

In principle, epPCR and DNA shuffling are independent of structural data, whereas saturation mutagenesis generally needs such knowledge to make a decision regarding the randomization sites. Alternatively, saturation mutagenesis can be applied systematically at every single amino acid position, as was reported in the thermostabilization of a xylanase (34). This process provided nine improved mutants, eight of which showed enzymatic activity similar to the WT, but the thermally most stable variant exhibited only 35% activity. The mutations were subsequently combined, leading to a highly robust variant having $T_m = 95.6^\circ C$. This means an improvement of $\Delta T_m = 35^\circ C$, which constitutes a dramatic increase in thermostability. The best mutant showed similar initial rate/temperature optima at 70°C, but the WT had higher activity at lower temperatures (25 to 50°C). Another recent approach to saturation mutagenesis in the quest to increase thermostability is based on a two-step strategy, as demonstrated in the case of phosphite dehydrogenase (29). First, epPCR was performed with the identification of improved variants, followed by saturation mutagenesis at the observed mutation points. Improved variants displaying ΔT_m values of up to 25°C were obtained, demonstrating that they are potential candidates for practical cofactor regeneration.

In yet another approach, the B-FIT method (section 32.3.2) was applied to the mesophilic lipase from *B. subtilis* (Lip A) (41, 42). The 10 amino acids with the highest average B factors, as provided by the X-ray data and the B-FIT-TER computer aid, were chosen for saturation mutagenesis: Arg33 (B factor = 50.9), Lys69 (44.1), Gln164 (40.7), Asp34 (39.8), Lys112 (39.6), Lys35 (38.9), Met134 (38.5), Tyr139 (37.9), Ile157 (37.4), and Gly13 (37.0), and these were grouped as eight sites: site A (Gly13), B (Arg33, Asp34, Lys35), C (Lys69), D (Lys112), E (Met134), F (Tyr139), G (Ile157), and H (Gln164).

Thermostability was assessed by measuring the residual activity subsequent to the exposure to high temperature and ascertaining the T_{50} value, which is the temperature required

FIGURE 9 Thermostability diagram in the B-FIT-based evolution of Lip A (41, 42).

to reduce the initial enzymatic activity by 50% within a given time (in this case, as measured by the hydrolysis rate of *p*-nitrophenylcaprylate). For rapid screening, a 15-min heat treatment was applied (T_{50}^{15} values), but the final variants were subjected to a heat treatment of 1 h, providing T_{50}^{60} values (which are quite similar to T_{50}^{15}). The WT Lip A has a T_{50}^{60} value of 48°C. Of the many possible pathways, only one was actually tested, namely E→G→F→D→B, which provided the best Lip A hyperthermophilic variants, X and XI, having T_{50}^{60} values of 89 and 93°C, respectively, meaning an increase of 41 and 45°C, respectively, which have no precedence in the literature (Fig. 9). The overall effort required the screening of only 8,000 transformants (41, 42). In further experiments, it was shown that activity and enantioselectivity of variant XI at room temperature are essentially identical to those of the WT. The data speak for the unusual efficacy of the B-FIT method (45), but more case studies using other proteins are needed.

32.4.4. Enhancing the Enantioselectivity of an Epoxide Hydrolase by Iterative CASTing

Subsequent to the first directed evolution study regarding the enantioselectivity of enzymes (50), which involved four cycles of epPCR in the hydrolytic kinetic resolution of a chiral ester catalyzed by a lipase, numerous academic and industrial studies have appeared that contribute to the generalization of this new approach to asymmetric

catalysis (40). In most cases, epPCR, DNA shuffling, and/or saturation mutagenesis at select sites were applied. Efficiency was greatly increased by the development of iterative CASTing (48) (section 32.3.2). In a case study, the epoxide hydrolase from *Aspergillus niger* (ANEH) was used as the catalyst in the hydrolytic kinetic resolution of glycidyl phenyl ether, the WT showing slight (*S*)-selectivity ($E = 4.6$). The CAST analysis based on the X-ray structure of ANEH suggested six sites for saturation mutagenesis, namely A (amino acid positions 193/195/296), B (215/217/219), C (329/330), D (349/350), E (317/318), and F (244/245/249). An arbitrarily chosen pathway, B→C→D→F→E, led to a dramatically improved ANEH variant LW202 exhibiting a selectivity factor of $E = 115$ (48) (Fig. 10). Only 20,000 transformants had to be screened in the overall process, which happens to be the same number required in an earlier study based on epPCR leading to a maximum enantioselectivity of only $E = 11$ (47). This comparison illuminates the difference in efficiency of the two approaches.

Subsequent investigations addressed the reasons for the apparent efficacy of iterative CASTing as a form of ISM (45, 46). A deconvolution strategy was devised in which the five sets of mutations leading from the WT ANEH to the best variant LW202 were used to form all theoretically possible permutational combinations, leading to the construction of a fitness landscape comprising $5! = 120$ pathways. Of these 120 trajectories leading from WT ANEH to LW202,

FIGURE 10 Iterative CASTing in the enhancement of enantioselectivity of the hydrolytic kinetic resolution of glycidyl phenyl ether catalyzed by ANEH variants (48).

55 proved to be energetically favored, meaning the absence of any local minima (45, 46). Moreover, strong synergistic effects operating between the sets of mutations were uncovered, likewise shedding light on the nature of the ISM process. This is also an indication that ISM creates an amino acid network in which the residues communicate with one another. Finally, CASTing utilizing a reduced amino acid alphabet for the construction of ANEH libraries constitutes another important tool in directed evolution, because it points the way to handling the numbers problem in directed evolution (44) (section 32.3.2).

32.5. CONCLUSIONS

The past decade has witnessed the generalization of directed evolution of enzymes as a reliable protein-engineering technique for improving such catalytic parameters as

thermostability, stability in hostile organic solvents, substrate acceptance, and enantioselectivity. Numerous mutagenesis protocols and strategies for their application were applied successfully in the quest to achieve a practical result and/or to deepen our understanding of enzyme mechanisms. A certain degree of success can always be anticipated, irrespective of the mutagenesis method applied. It is not easy to make the optimal choice regarding the mutagenesis method, although trends are now visible. Fortunately, in recent years one of the important foci of research has centered on the development of user-friendly methods and strategies for probing protein sequence space more efficiently, making fast and reliable directed evolution possible (28, 45). This means that small but high-quality libraries are now accessible, as highlighted in this chapter. Hopefully, in the future more comparative studies focusing on relative efficiency will follow.

Industrial Applications of Enzymes as Catalysts

NIKHIL U. NAIR, WENG LIN TANG, DAWN T. ERIKSEN, AND HUIMIN ZHAO

33

33.1. INTRODUCTION

The industrial use of enzymes exploded in the late 1960s with the development of protease additives to detergents in the detergent industry and the use of a fungal glucoamylase (hydrolase) in the breakdown of starch into glucose in the food industry. Following the trend set by these pioneering efforts, the detergent and food industries have continued to dwarf all other industries in terms of total industrial enzyme usage and sales. Food-manufacturing processes, including starch hydrolysis and bread, cheese, and juice manufacturing, are responsible for an estimated 40 to 45% of all enzyme sales. Detergent additives such as proteases, lipases, and cellulases are responsible for 35 to 40% of total soluble enzyme sales. The growth of the enzyme industry, concomitant with a greater demand for enzymes, has been quite remarkable in the past 40 years, with a 3 orders of magnitude increase in total sales. For example, Novo Industri A/S (now Novozymes), the leading enzyme manufacturer in the 1960s, had enzyme sales of approximately US \$1 million in 1965. By 2007 the same metric had reached a value of over US \$1 billion.

While the aforementioned two industries may be quite capable of sustaining the burgeoning enzyme industry, applications have extended to other areas, including paper and pulp processing, textile manufacture, pharmaceutical syntheses, and now even the commodity chemicals business. Increased emphasis on sustainability and use of renewable resources is driving this trend further, because biocatalysts align very well with the current trend toward green chemistry (2). The Freedomia Group (Cleveland, OH) estimated that the global demand for enzymes will grow at a rate of 7.6% per year, to reach US \$6.1 billion by 2011. However, just because the potential exists does not mean it will be realized. The rate at which biocatalysis or principles of green chemistry will be adopted depends on whether or not it makes economic sense, which in turn greatly depends on the prices of the feedstock—be it oil or biomass.

Irrespective of the starting raw material or the process, biocatalysis offers several significant advantages over chemocatalysts. First, since enzymes function at moderate temperatures and pressures, they require less energy input. Second, enzymes can be highly selective (regio-, diastereo-, enantio-, or chemo-), and thus are able to replace multistep reactions or difficult purification schemes. This can circumvent the need for many blocking and deblocking steps that are required for stereo- or regioselective reactions. Third, enzymes can be

extremely fast, increasing reaction rates by 4 to 12 orders of magnitude. In some cases, enzymes can be so fast that their turnover rates are limited only by diffusion of substrate(s) and product(s) to and from the active site. Fourth, since biocatalysts are biodegradable and rarely contain heavy metals, waste streams are much more manageable, requiring minimal treatment. Fifth, since most biocatalysts function in aqueous media, effluent volatile organic compound emissions from production plants can be drastically reduced.

However, the above-mentioned secondary concerns are more relevant to bulk chemical industries where profit margins are low. In pharmaceuticals, or even the closely related fine chemicals, product purity is of greater concern. Selectivities of >95% are difficult to achieve by chemocatalysis and, if essential to synthesis, would require the use of biocatalysis. This can also be relevant when high enantiopurities are required by regulatory authorities. At present, 22 of 38 large-scale asymmetric syntheses have already incorporated biocatalysis (93). In industrial settings, whole cells are usually preferred over purified enzymes, even for single-step transformations. This makes more sense for enzymes such as oxidoreductases and lyases that are used for asymmetric syntheses, because such enzymes require cofactors in stoichiometric quantities. Hydrolases, however, do not require cofactors, yet the industry standard practice is to use whole cells to avoid enzyme purification costs. The following sections describe some of these industrial-scale applications of biocatalysis.

33.2. APPLICATIONS IN THE CHEMICAL INDUSTRY

Biocatalysts have been increasingly used in the chemical industry. However, because of their high overhead of production and purification costs, biocatalysts are usually not competitive for use in synthesis of most bulk-quantity, low-margin chemicals. Therefore, they are employed in a niche set of reactions that are either extremely difficult or uneconomical to perform by chemocatalysis. It is not surprising that manufacturers of fine chemicals that produce compounds with complex stereocenters have embraced biocatalysis. The following examples reveal that optimized biocatalytic processes are quite viable commercially, and provide further precedence for their application outside their forte in fine chemicals and pharmaceuticals.

33.2.1. Regioselective Catalysis

33.2.1.1. Acrylamide

Acrylamide **1** is a commodity chemical used industrially in coagulators, paper treatment, paper sizing, and soil conditioning, as well as for adhesives, polymers, paints, and petroleum recovery agents. The traditional route of producing acrylamide from acrylonitrile uses either an acid or a Raney-copper catalyst for regioselective hydration. While the Raney-copper process is superior to the former, it is plagued with issues such

as catalyst poisoning and leaching of copper ions. This necessitates not only the constant replenishment for fresh catalyst, but also wastewater treatment to remove the toxic heavy metal ions (50, 65). Mitsubishi Rayon Co. (formerly Nitto Chemical Industries, Japan) produces acrylamide by regioselective hydration of acrylonitrile at a scale of approximately 100,000 tons/year by use of biocatalysis (50, 97). The first-generation process commercialized in 1985 used whole cells harboring an iron-containing nitrile hydratase from *Rhodococcus* sp. N-774 (65) (Fig. 1). In 1988, a second-generation process

FIGURE 1 Schemes for use of biocatalysis to synthesize industrially important chemicals including acrylamide **1**, niacinamide **2**, 5-cyanovaleramide **3**, 6-hydroxynicotinic acid **4**, 1,5-dimethyl-2-piperidone **5**, (R)-mandelic acid **6**, and D-pantolactone **7**.

was developed using another iron-containing nitrile hydratase from *Pseudomonas chlororaphis* B23. The final upgrade in 1991 implemented a copper-containing nitrile hydratase from *Rhodococcus rhodochrous* J1 (64). This third-generation process can produce acrylamide titers of up to 700 g/liter (>50 wt%) with ~99.99% yield in an immobilized-cell bioreactor. In addition to being a highly productive (>7 g of product/g dry cell weight) and environmentally friendly process, the low operating temperature (10°C) ensures lower operating costs than the Raney-copper process and minimizes spontaneous polymerization of acrylamide (1, 38, 94). SNF Floerger (France) and Mitsui Chemicals (Japan) have licensed this process and built several acrylamide plants, each with capacity of 20,000 tons/year. Considering that biocatalysts have been typically viewed as stereoselective catalysts, it is ironic that this nonstereoselective Mitsubishi Rayon process is one of the most well-known industrial syntheses using a biocatalyst.

33.2.1.2. Niacinamide

Another well-known regioselective process was developed by Lonza (Switzerland) for the production of niacinamide **2** (also known as vitamin B₃ or nicotinamide), which is used against the skin disease pellagra in humans, and is also an additive to animal feed (6). Commercialized by Lonza Guangzhou Fine Chemicals (China) in 1999, the entire process involves a four-step chemoenzymatic synthesis, with the final step being an enzyme-catalyzed hydration (94) (Fig. 1). The process starts with catalytic conversion of a nylon-6,6 by-product, 3-methyl-1,5-diaminopentane (Dytek®), to 3-picoline by cyclization and dehydrogenation, followed by ammoxidation to 3-cyanopyridine. *R. rhodochrous* J1-immobilized cells expressing a nitrile hydratase are then used for hydration to niacinamide (37). The plant has a capacity of 3,400 tons/year and employs a three-stirred-tank reactor continuously fed with 10 to 20 wt% 3-cyanopyridine. The final amide is produced with >99.3% selectivity, >99.5% purity, and near-complete conversion. Due to the addition of the final enzymatic step, the entire process uses lower energy and has lower emissions than with the caustic hydration step used previously (1, 37, 94). Also, unlike the alkaline hydration, it does not produce any nicotinic acid, an unwanted by-product that causes diarrhea in cattle (6).

33.2.1.3. 5-Cyanovaleramide

Yet another commercialized process using a nitrilase for regioselective hydration is employed by DuPont (United States) for synthesis of 5-cyanovaleramide (5-CVAM) **3**, a precursor to the insecticide Milestone® (azafenidin) (61, 94) (Fig. 1). This process was developed because the previously used manganese dioxide-based catalysis was plagued by several issues. First, nonspecific reactivity of water in the presence of this catalyst resulted in hydration of the product 5-CVAM, yielding unwanted adipamide. Up to 5% of the total reacted adiponitrile was converted to adipamide at a total conversion of only 25%. Second, the separation of the product from the reactant involved a difficult extraction step. Finally, the rapid deactivation of the manganese dioxide catalyst resulted in the production of 1.25 kg of waste/kg 5-CVAM (94). The biocatalytic process used *P. chlororaphis* B23, the same organism used in the second-generation Mitsubishi Rayon process, immobilized in calcium alginate beads (6, 32). Using batch reactions with catalyst recycle, 13.6 tons of 5-CVAM were produced at 97% conversion with 93% yield and 96% selectivity (6). The total turnover for the biocatalyst was 3,150 kg of

5-CVAM/kg cell dry weight (6). With the biocatalytic process, the final step was made much more environmentally friendly, produced little waste and by-products, and had minimal purification steps.

33.2.1.4. 6-Hydroxynicotinic Acid

A derivative of niacin, 6-hydroxynicotinic acid **4** is a versatile building block in many modern insecticides such as imidachloprid (40). During chemical synthesis, nonspecific hydroxylations of the pyridine ring lead to side products (76), requiring extensive downstream processing. This renders the entire process prohibitively expensive. The discovery of a regioselective hydroxylase has alleviated many of the issues associated with synthesis. *Achromobacter xylosoxydans* LK1 (DSM 2783) is able to use niacin as its sole nitrogen and carbon source. The first step in niacin metabolism is exactly the regioselective hydroxylation required to produce 6-hydroxynicotinic acid. A unique property of *A. xylosoxydans* LK1 metabolism exploited by Lonza is that, at high concentrations (>1%) of niacin, its assimilation is stalled at 6-hydroxynicotinic acid because of inhibition of the next catabolic enzyme. Therefore, cells are induced with low concentrations of niacin (<1%) to express high levels of the hydroxylase, and then growth is quenched by addition of a high concentration of caustic soda-neutralized niacin. Incubation in well-aerated conditions at 30°C results in yields of >99% (43, 86). Ultrafiltration of the biomass followed by crystallization of product by sulfuric acid addition yields nearly pure precipitated 6-hydroxynicotinic acid crystals. After this downstream processing, the overall yield is >93% and purity is >99%. Lonza has produced more than 10 tons of 6-hydroxynicotinic acid by using this process since its implementation.

33.2.1.5. 1,5-Dimethyl-2-piperidone

Also known as Xolvone®, 1,5-dimethyl-2-piperidone (1,5-DMPD) **5** is a highly water-soluble, nonflammable, biodegradable cleaning solvent with low toxicity. Industrially, it is suitable for application in electronics cleaning, photoresist stripping, degreasing, and metal and resin cleanup (38). It is also used in the formulation of industrial adhesives and inks and as a reaction solvent for production of polymers and chemicals (15, 33). Initial production of 1,5-DMPD was performed by direct hydrogenation of precursor 2-methylglutaronitrile in the presence of methylamine. However, this produced a mixture of 1,5- and 1,3-DMPD. DuPont developed a two-step chemoenzymatic route to overcome the production of unwanted 1,3-DMPD (Fig. 1). Regiospecific hydration of 2-methylglutaronitrile by the nitrilase activity of immobilized *Acidovorax facilis* 72W cells gives 4-cyanopentanoic acid. This is subsequently nonenzymatically converted to the final product by direct hydrogenation in the presence of methylamine (15). The *A. facilis* step is carried out at high loadings (~200 g/liter) and has ~98% selectivity, even after catalyst recycling to give high turnovers (~1,000 kg of product/kg cell dry weight). A further improvement to this process using alginate-immobilized recombinant *Escherichia coli* expressing *A. facilis* 72W nitrilase has been reported (33).

33.2.2. Racemic Resolution

33.2.2.1. (R)-Mandelic Acid

(R)-Mandelic acid **6** [(R)-2-hydroxy-2-phenylacetic acid] has been used in the past as an antibacterial, in

particular to treat urinary tract infections (98), but it is now primarily used in cosmetics as an acne or wrinkle treatment (90). Starting with a racemic mixture of mandelonitrile, *E. coli* cells expressing an (*R*)-specific nitrilase are used to create enantiomerically pure (*R*)-mandelic acid (38) (Fig. 1). With use of classical chemical hydrocyanation, the unreacted mandelonitrile is racemized via aldehyde in situ. This enzyme-mediated dynamic resolution allows for enantiomerically pure (*R*)-mandelic acid to be produced on a multiton-per-year scale from a racemic mixture (84).

33.2.2.2. D-Pantolactone

Used in feed for pigs and poultry, D-pantolactone **7** is a chiral-building block for chemical syntheses, particularly for pantothenic acid (vitamin B₅) and coenzyme A (1, 38). A racemic mixture of pantolactones can be achieved by hydrocyanation of the formaldehyde/isobutanal aldol product followed by acidic lactonization. However, separation of the enantiomers is troublesome, and, as a result, a biocatalytic resolution to this problem was developed. Calcium alginate-immobilized *Fusarium oxysporum* AKU302 cells were employed to hydrolyze D-pantolactone to its corresponding acid (Fig. 1). The L-enantiomer is relatively unreactive in the presence of this fungal aldolactonase and is racemized after extraction, whereas the D-pantoic acid is chemically lactonized (81, 87). Since then several other chemical and enzymatic syntheses for both enantiomers have been developed and reviewed in detail for their merits (10).

33.2.2.3. 2,5-Hexanediol

Hexanediols are building block chemicals for synthesis of chiral acetals. Catalytic resolution using Chirazyme L2® (a lipase) in heptane with vinyl propionate esterifies only (*R*)-hydroxy groups (Fig. 2). This selectivity creates pure (2*S*,5*S*)-hexanediol **8**, which is easily extracted into water. The mono- and diesters remaining in the heptane can be rehydrolyzed chemically to (2*R*,5*R*)-hexanediol **9** (38). Both diols can be produced at 99% diastereomeric excess (d.e.) and 99% enantiomeric excess (e.e.) and the production has been scaled up to 40-kg batches.

33.2.3. Asymmetric and Enantioselective Synthesis

33.2.3.1. Aspartame

Holland Sweetener Company, a joint venture between Tosoh (Japan) and DSM (Netherlands), produced the low-calorie sweetener aspartame **10** (L- α -aspartyl-L-phenylalanine methyl ester) on a kiloton scale (Fig. 2) until 2006, when they shut down their production facilities. Aspartame is used extensively (12,000 to 15,000 tons per year), however, in soft drinks, salad dressing, and tabletop sweeteners, as well as in pharmaceuticals (31). Starting from fumaric acid and ammonia, aspartase (a lyase) catalyzes the formation of L-aspartic acid. After the addition of a protection group, thermolysin (a metalloprotease from the thermophile *Bacillus thermoproteolyticus*) catalyzes its coupling to L-phenylalanine methyl ester from a D,L-isomeric mixture. The protected dipeptide carboxylate has low solubility and precipitates, driving the equilibrium-disfavored reaction forward. Deprotection of precipitated product is done by traditional chemistry to yield aspartame.

33.2.3.2. Terminal Epoxides

Oxygenation of terminal alkenes to the corresponding epoxides with high enantiomeric purity is difficult by

traditional chemistry because of the insufficient activation of the terminal double bond. Such epoxides are particularly useful building blocks for various enantiopure syntheses (22). The alkene monooxygenase from *Nocardia corallina* B276 used by Nippon Mining Co. Ltd. (Japan) is capable of producing predominantly the (*R*)-enantiomer, starting from a wide range of C₃ to C₁₈ alkenes (Fig. 2). Depending on the starting olefin, the bioprocess is carried out in different configurations to cope with the varying levels of toxicity of the resulting epoxide **11**. Short-chain (C₃ to C₅) gaseous epoxides are highly toxic and must be quickly removed by high aeration, followed by an extraction to recover the low amounts of product. Medium-chain epoxides (C₆ to C₁₂) are liquid and less toxic, and are therefore produced in a two-phase bioreactor process. The aqueous phase contains resting cells expressing the monooxygenase, and the organic phase is used to continuously extract the epoxide, driving the reaction forward and also allowing for ease of product recovery. Finally, for long-chain epoxides (C₁₃ to C₁₈) that have very low toxicity, growing cells are used in a bioreactor (25–28, 38).

33.2.3.3. (*S*)-*m*-Phenoxybenzaldehyde Cyanohydrin

Cyanohydrins are useful building block chemicals, and (*S*)-*m*-phenoxybenzaldehyde cyanohydrin in particular is used in synthesis of a highly effective class of insecticides and repellents called pyrethroids. A biphasic system using an oxynitrilase as a catalyst for hydrocyanation has been studied extensively to demonstrate the enzyme's applicability to unnatural systems (19, 30, 44, 85). Of particular interest is the recombinant enzyme from the rubber tree, *Hevea brasiliensis*, which is used to produce (*S*)-*m*-phenoxybenzaldehyde cyanohydrin **12** by DSM and Nippon Shokubai (Japan) (Fig. 2).

33.2.3.4. D-Malic Acid

Used as a synthon, resolving agent, or as a ligand in asymmetric synthesis, D-malic acid **13** is a chiral hydroxy dicarboxylic acid produced by DSM. After screening 300 organisms for the ability to produce D-malic acid from maleic acid, permeabilized *Pseudomonas pseudoalcaligenes* NCIMB 9867, expressing the lyase malease, was found to be capable of producing the desired enantiomer with 99.97% purity (96).

33.3. BIOCATALYSIS IN THE PHARMACEUTICAL INDUSTRY

Chirality is a very important factor in the efficacy of many drug products. A survey of major pharmaceutical companies such as GlaxoSmithKline (United Kingdom), AstraZeneca (United Kingdom), and Pfizer (United States) showed that more than half of the drug compounds examined contained one or more chiral centers (11). Furthermore, an enantiomeric purity of at least 99.5% is often necessary to meet regulatory requirements. Recognizing its importance, many fine-chemical and pharmaceutical companies have started to focus on acquiring biocatalysis expertise (Table 1), and those that have already done so are trying to maintain their positions as technological leaders.

33.3.1. Production of Amino Acids

Chiral amino acids are important building blocks for a number of drug compounds. Industrial application of enzymes for production of L-amino acids began almost 40 years

FIGURE 2 Schemes for use of biocatalysis to synthesize industrially important chemicals including (2S,5S)-hexanediol **8**, (2R,5R)-hexanediol **9**, aspartame **10**, (R)-terminal epoxide **11**, (S)-m-phenoxybenzaldehyde cyanohydrin **12**, and D-malic acid **13**.

ago in Japan with the resolution of *N*-acetyl D,L-amino acids by immobilized acylase (14). Degussa (Germany) has established a large-scale process for the production of D- and L-amino acids via the enantiospecific hydrolysis of *N*-acyl amino acids by amino acylase I from *Aspergillus oryzae* (101). The broad substrate specificity of *A. oryzae* enables a wide range of proteinogenic and nonproteinogenic *N*-acetyl and *N*-chloroacetyl amino acids to be transformed by use of a continuous enzyme membrane reactor, with the enzyme retained by a hollow-fiber ultrafiltration membrane. Established in the early 1980s, this process enabled

the production of hundreds of tons of enantiopure amino acids each year. In more recent years, Degussa established a process which combines the use of the acylase with a novel racemase from *Amycolatopsis orientalis* subsp. *lurida*. Selective in situ racemization of *N*-acetyl amino acids greatly improved the acylase process by eliminating costly racemization and separation steps (60).

Meanwhile, the DSM process for the production of L-amino acids is based on the resolution of racemic amino acid amides. Although the amidase (aminopeptidase) is L-specific, both the D- and L-amino acids are obtained, and

TABLE 1 Biotransformations developed by the pharmaceutical industry (89)^a

Target compound	Company	Reaction	Biocatalyst

the undesired enantiomer is recycled. DSM's biocatalytic amidase toolbox consists of enzymes from *Pseudomonas putida*, *Mycobacterium neoaurum*, and *Ochrobactrum anthropi*, thus enabling a wide range of amino acid amides to be resolved (84).

The hydantoinase/carbamylase system has been used since the 1970s to produce D-phenylglycine and p-hydroxy-D-phenylglycine, which are building blocks for the semi-synthetic antibiotics ampicillin and amoxicillin. Today, it is commercially applied at a scale of >1,000 tons per year. Using directed evolution, the D-specificity of hydantoinases was switched to L-specificity (59). In addition, Degussa has also established a dynamic kinetic resolution of 5-monosubstituted hydantoins using evolved whole-cell biocatalysts coexpressing an L-carbamoylase, a hydantoin racemase, and a hydantoinase. The hydantoin-converting pathway was optimized by adjusting expression levels of the respective enzymes and by inverting the enantioselectivity of the D-selective hydantoinase by directed evolution. As a result, productivity was improved by 50-fold and biocatalyst cost was significantly reduced (60).

33.3.2. β -Lactam Antibiotics

Based on the condensation of the appropriate D-amino acid derivative with a β -lactam nucleus, processes for large-scale enzymatic production of antibiotics such as ampicillin 14, amoxicillin 15, cefaclor, cephalexin 16, and cefadroxil 17 have been well developed (Fig. 3a). With worldwide capacity exceeding 20,000 tons annually, 6-aminopenicillanic acid (6-APA, 18), 7-aminocephalosporanic acid (7-ACA), and 7-aminodesacetoxycephalosporanic acid (7-ADCA, 19) are important precursors for the semisynthetic β -lactam

antibiotics (1). In the 1980s, the chemical preparations of 6-APA and 7-ADCA were replaced with enzymatic routes that were found to be cheaper and environmentally friendly. The enzyme that removes the side chain from penicillin G 20, penicillin V, and phenacetyl-8-ADCA is penicillin G amidase. A high conversion rate of 98% is reported for the industrial production of 6-APA and 7-ADCA. 7-ACA, on the other hand, is produced in a three-step process using two enzymes. The starting material, cephalosporin C, is subjected to deamination by a D-amino acid oxidase, followed by spontaneous decarboxylation of the α -ketoamidyl-7-ACA into glutaryl-7-ACA. Its side chain is finally hydrolyzed by glutaryl-7-ACA acylase to form 7-ACA.

Penicillin amidases are also used to couple the precursor 7-ADCA with D-phenylglycine methyl ester (D-PGM) or D-phenylglycine amide (D-PGA) in a kinetically controlled enzymatic peptide synthesis to form cephalexin. Similarly, ampicillin is synthesized from 6-APA and excess D-PGA or D-PGM. Amoxicillin, on the other hand, is synthesized using high substrate concentrations by the enzyme-catalyzed reaction of 6-APA and D-4-hydroxyphenylglycine amide (D-HPGA) or D-4-hydroxyphenylglycine methyl ester (D-HPGM) using a semicontinuous reactor system. Despite several drawbacks such as solubility, difficulty in pinpointing an optimal process pH, and chemical degradation issues, the aqueous enzymatic synthesis of β -lactam antibiotics is indeed feasible with yields comparable to or even better than the chemical route. Scientists at DSM research and Gist-Brocades (Netherlands) have developed a biocatalyst that can be recycled many times and also improved the downstream process for better yield (8).

FIGURE 3 Schemes for use of biocatalysis to synthesize chiral intermediates for the production of pharmaceuticals, including β -lactam antibiotics (a), abacavir **21** (b), and omapatrilat **28** (c).

33.3.3. Antiviral Drugs

33.3.3.1. Abacavir

Abacavir **21** (ZiagenTM) is a 2-aminopurine nucleoside analog that functions as a selective reverse transcriptase inhibitor for the treatment of human immunodeficiency viruses (HIVs) and hepatitis B viruses. Its intermediate, γ -lactam 2-azabicyclo(2.2.1)hept-5-en-3-one **22**, is produced via the resolution of racemic γ -lactam **23** to

yield the desired product **22** and amino acid **24** using the γ -lactamase-containing organisms *Pseudomonas solanacearum* NCIMB 40249 and *Rhodococcus* NCIMB 40213 (57). An enzymatic process using a commercially available enzyme, Savinase[®], to hydrolyze the lactam bond of racemic *tert*-butyl-3-oxo-2-azabicyclo-(2.2.1)hept-5-ene-2-carboxylate **25** has also been developed (56). The hydrolysis of **25** yields the corresponding amino acid **26**, with the desired (1R, 2S)-**27** unreacted (Fig. 3b). The

reaction can be carried out at 100 g/liter substrate and gives a reaction yield of 50% and an e.e. of 99%.

33.3.3.2. BMS-186318

Inhibition of HIV protease stops the replication of the virus in vivo. Patel et al. (72) developed an enzymatic process to prepare the chiral intermediate (1*S*,2*R*)-[3-chloro-2-hydroxy-1-(phenylmethyl)propyl] carbamic acid, 1,1-dimethylethyl ester for the total synthesis of an HIV protease inhibitor, BMS-186318. The stereoselective reduction of (1*S*)-[3-chloro-2-oxo-(phenylmethyl)propyl] carbamic acid, 1,1-dimethylethyl ester is carried out using microbial cultures, among which *Streptomyces nodosus* SC 13149 efficiently reduced the ester to its corresponding (1*S*,2*S*)-alcohol. A reaction yield of 80% is obtained with product optical purity of 99.8% and diastereomeric purity of 99%.

33.3.3.3. Lobucavir

Lobucavir, a cyclobutyl guanine nucleoside analog, is a potential antiviral agent to treat herpes and hepatitis B. Synthesis of lobucavir *L*-valine prodrug, BMS 233866, requires regioselective coupling of one of the two hydroxyl groups of lobucavir (BMS 180194) with valine (35). This regioselective aminoacylation is difficult via chemical routes. Hence, an enzymatic route was developed. Selective hydrolysis of di-Cbz-valine ester with lipase M gives *N*-[(phenylmethoxy)carbonyl]-*L*-valine, [(1*R*,2*R*,4*S*)-2-(2-amino-6-oxo-1*H*-purin-9-yl)-4-(hydroxymethyl)cyclobutyl]methyl ester in 82.5% yield. Meanwhile, *L*-valine, [(1*R*,2*R*,4*S*)-2-(2-amino-1,6-dihydro-6-oxo-9*H*-purin-9-yl)-4-(hydroxymethyl)cyclobutyl]methyl ester monohydrochloride (87% yield), is obtained by hydrolysis of the divalinal ester dihydrochloride with lipase from *Candida cylindracea*. The final intermediate for the lobucavir prodrug, *N*-[(phenylmethoxy)carbonyl]-*L*-valine, [(1*S*,2*R*,4*R*)-3-(2-amino-6-oxo-1*H*-purin-9-yl)-2-(hydroxymethyl)cyclobutyl]methyl ester, is obtained by either transesterification of lobucavir using ChiroCLEC BL™ (cross-linked enzyme crystals of subtilisin Carlsberg) (61% yield), or more selectively by using an immobilized lipase from *Pseudomonas cepacia* (84% yield).

33.3.4. Anticancer Drug: Paclitaxel Semisynthesis

The anticancer drug Taxol® (paclitaxel) is an antimetabolic agent that inhibits the depolymerization process of microtubulin during mitosis. It has been used in the treatment of ovarian cancer and metastatic breast cancer with annual sales revenue of US \$1 billion (39). Paclitaxel was originally extracted and purified from the bark of the yew *Taxus brevifolia* in very low yield, with approximately 9,000 kg of yew bark (3,000 trees) required to produce 1 kg of purified paclitaxel. Semisynthetic approaches to obtain paclitaxel by coupling baccatin III (paclitaxel without the C-13 side chain) or 10-deacetyl baccatin II ([10-DAB], paclitaxel without the C-13 side chain and the C-10 acetate) to C-13 paclitaxel side chains have also been established. Baccatin III and 10-DAB can be obtained from renewable resources such as needles, shoots, and young *Taxus* cultivars, thus eliminating the cutting down of yew trees.

The C-13 paclitaxel side chain is obtained from the enantioselective hydrolysis of racemic acetate-*cis*-3-(acetoxy)-4-phenyl-2-azetidione to the corresponding (3*S*)-alcohol and the intact desired (3*R*)-acetate. The reaction is catalyzed by the lipase PS-30 from *P. cepacia* or Bristol-Myers Squibb (United States) lipase from *Pseudomonas* sp. SC 13856 which was immobilized on Accurel polypropylene

prior to use. Reaction yields of >48% and an e.e. of >99.5% are obtainable for (3*R*)-acetate. The process has been scaled up to 75 and 150 liters using immobilized enzymes. Finally, the (3*R*)-acetate is converted into (3*R*)-alcohol (C-13 paclitaxel side chain) via a chemical route (71).

33.3.5. Anti-inflammatory Drugs

33.3.5.1. Ibuprofen

Ibuprofen, or 2-(4-isobutylphenyl)propionic acid, is a non-steroidal anti-inflammatory drug that inhibits the binding of arachidonic acid to prostaglandin H2 synthase-1 and prevents the synthesis of prostaglandins acting on the inflammatory response. The (S)-ibuprofen molecule is 160 times more potent than the (R)-enantiomer (39). The resolution of racemic ibuprofen is achieved via a lipase-catalyzed esterification reaction with methanol or butanol in organic media. The (S)-ibuprofen is selectively esterified and is easily separated from the (R)-ibuprofen. The (S)-ester is then chemically hydrolyzed to obtain the (S)-ibuprofen. The production of (S)-ibuprofen has also been demonstrated through a lipase-catalyzed hydrolysis of its chemically synthesized ester (46).

33.3.5.2. Naproxen

The racemic resolution of the nonsteroidal anti-inflammatory drug (S)-naproxen or 2-(6-methoxy-2-naphthyl)-propionic acid has been developed by Chirotech (United Kingdom) (77). Widely used as a drug for human connective tissue diseases, the (S)-enantiomer is 30-fold more active than the corresponding (R)-enantiomer (52). Chirotech screened and cloned an efficient *Bacillus* esterase that is specific for the (S)-ester only. The enzyme can accept an initial ester loading of 150 g/liter and the (R)-ester and (S)-acid can be separated easily by centrifugation while the (R)-ester is recycled.

Over the past few years, various enzymatic kinetic resolution reactions have been developed for the preparation of (S)-(+)-naproxen involving *trans*-esterification and hydrolytic methods, using nitrilases (20) as well as lipases and esterases (7, 12, 52, 104). For example, Koul et al. (52) successfully used *Trichosporon* sp. whole cells or its cell-free ester hydrolase to selectively hydrolyze (±)-6-methoxy-α-methyl-2-naphthaleneacetic acid alkyl ester to yield (S)-naproxen (e.e. >99%, *E*~500). The whole-cell process has been scaled up to a multikilogram level. Further optimization of the process resulted in downstream processing at 80 to 100 g/liter substrate concentration with >90% recovery.

33.3.6. Anticholesterol and Antihypertensive Drugs

33.3.6.1. Lipitor

Atorvastatin is an active ingredient in Pfizer's Lipitor®, a cholesterol-lowering drug with annual sales exceeding US \$12 billion per year (91). Atorvastatin belongs to a class of drugs named statins that reduce levels of total cholesterol and low-density lipoprotein. Statins inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, an enzyme that catalyzes the conversion of HMF-CoA to mevalonate. This conversion is one of the initial steps in cholesterol biosynthesis. Therefore, by inhibiting the production of mevalonate, the production of cholesterol is also limited. HN, chemically named ethyl (R)-4-cyano-3-hydroxybutyrate, is the key chiral building block in the synthesis of atorvastatin. Scientists at Codexis (United

States) have developed a green HN process using a three-enzyme system obtained by directed evolution technologies. In the first step, two evolved enzymes, a ketoreductase and a glucose dehydrogenase, are used to catalyze the enantioselective reduction of a prochiral chloroketone (ethyl 4-chloroacetoacetate) by glucose to form an enantiopure chlorohydrin. In the second step, *Agrobacterium radiobacter* halohydrin dehalogenase, expressed in *E. coli*, is used to catalyze the conversion of ethyl (S)-4-chloro-3-hydroxybutyrate to HN at neutral pH, thus avoiding the side reactions associated with chemical cyanation. Using a protein sequence activity relationship-driven strategy, scientists successfully evolved a halohydrin dehalogenase that improves the volumetric productivity of the cyanation process by ~4,000-fold (23). This green HN process is currently being commercialized by Arch Pharmed (India), a Codexis production partner, and Lonza.

33.3.6.2. Omapatrilat

Omapatrilat **28** is an antihypertensive drug that inhibits angiotensin-converting enzyme and neutral endopeptidase. It is used not only in the treatment of hypertension but also in the management of congestive heart failure. (S)-6-Hydroxynorleucine **29** is an important intermediate and is synthesized through the complete conversion of 2-keto-6-hydroxyhexanoic acid **30**, in equilibrium with 2-hydroxytetrahydropyran-2-carboxylic acid sodium salt **31** (Fig. 3c), using beef liver glutamate dehydrogenase, in the presence of ammonia and NADH (34). NAD⁺ produced is recycled to NADH by the oxidation of glucose to gluconic acid by use of glucose dehydrogenase from *Bacillus megaterium*. A reaction yield of 92% and an e.e. of >99% for (S)-6-hydroxynorleucine are obtained from this process.

Alternatively, 2-keto-6-hydroxyhexanoic acid can be prepared by the treatment of racemic 6-hydroxynorleucine with porcine kidney D-amino acid oxidase and beef liver catalase or *Trigonopsis variabilis* whole cells (source of both the oxidase and catalase). Once the e.e. of the remaining (S)-6-hydroxynorleucine has risen to >99%, reductive amination procedure is used to convert the mixture containing 2-keto-6-hydroxyhexanoic acid to (S)-6-hydroxynorleucine with a yield of 97% and e.e. of 98% from racemic 6-hydroxynorleucine (70).

33.3.7. Calcium Channel Blocker: Diltiazem

Diltiazem is a benzothiazepinone calcium channel-blocking agent that inhibits influx of extracellular calcium through L-type voltage-operated calcium channels. Used widely in the treatment of hypertension and angina, diltiazem sales were reported to be \$250 million in 2002. Tanabe (Japan) manufactures 50 tons of diltiazem annually. Resolution of racemic epoxyesters is a key step in the production of an important intermediate in the synthesis of diltiazem. Catalyzed by a lipase from *Serratia marcescens*, the enantiospecific hydrolysis yields (2R,3S)-methyl-*p*-methoxyphenylglycidate with an e.e. of >98%. This key diltiazem intermediate has also been successfully produced by Sepracor (United States) in a multiphase membrane bioreactor at a multikilogram scale (39).

In searching for a more potent analog, (*cis*)-3-(acetoxyl)-1-[2-(dimethylamino)ethyl]-1,3,4,5-tetrahydro-4-(4-methoxyphenyl)-6-(trifluoromethyl)-2H-1-benzazepin-2-one was identified as a longer lasting and better antihypertensive agent. A key intermediate in the synthesis of this compound is (3*R*-*cis*)-1,3,4,5-tetrahydro-3-hydroxy-4-(4-methoxyphenyl)-6-(trifluoromethyl)-2H-1-benzazepin-2-one,

which is produced via the enantioselective reduction of 4,5-dihydro-4-(4-methoxyphenyl)-6-(trifluoromethyl)-1H-1-benzazepin-2,3-dione using *Nocardia salmonicolor* SC 6310. A reaction yield of 96% with 99.8% e.e. is obtained for this process (73).

33.3.8. Anti-Alzheimer's Disease Drugs

Several potential anti-Alzheimer's disease drugs that inhibit β -amyloid peptide release or its synthesis have been developed (83). (S)-2-Pentanol, an important intermediate in the synthesis of these drugs, is obtained from the enzymatic resolution of racemic 2-pentanol by lipase B from *Candida antarctica* (69). Various commercially available lipases were screened for stereoselective acylation of racemic alcohols in the presence of vinyl acetate as an acyl donor, and lipase B from *C. antarctica* gave a reaction yield of 43 to 45% with an e.e. for (S)-2-pentanol of >99% at a substrate concentration of 100 g/liter. Racemic 2-pentanol is used both as solvent and substrate. By use of 0.68 mol equivalent of succinic anhydride and 13 g of lipase B per kg of racemic 2-pentanol, an overall yield of 38% with an e.e. of >98% is obtained for (S)-2-pentanol.

In another approach, 2-pentanone is enantioselectively reduced to (S)-2-pentanol by using the 2-ketoreductase from *Gluconobacter oxydans* (66). On a pilot scale, 1.06 kg of (S)-2-pentanol was prepared from 2.3 kg of 2-pentanone by use of Triton X-100-treated *G. oxydans* cells with an e.e. of >99%.

33.3.9. Antituberculosis Drugs

5-Hydroxypyrazine-2-carboxylic acid, a versatile building block for the synthesis of new antituberculous agents, is prepared by a two-step biotransformation of 2-cyanopyrazine using whole cells of *Agrobacterium* sp. DSM 6336 (102). The biotransformation involves the hydrolysis of the nitrile group to pyrazonecarboxylic acid, followed by a regioselective hydroxylation to 5-hydroxypyrazinecarboxylic acid. A product concentration of 286 mM (40 g/liter), corresponding to a total yield of 80%, is achieved. Earlier studies demonstrated that various 5-chloropyrazine-2-carboxylic acid esters, prepared from 5-hydroxypyrazine-2-carboxylic acid, were up to 1,000 times more potent against *Mycobacterium tuberculosis* and other *Mycobacterium* strains than pyrazinamide, a drug commonly used in treating tuberculosis. This result indicated a great potential for 5-hydroxypyrazine-2-carboxylic acid as a building block for new antituberculous agents.

33.3.10. Conversions of Steroids and Oligosaccharides

Biotransformation of steroids for use in contraceptives and other steroid hormone derivatives is a well-established industrial application of biocatalysis. The world demand for these steroid drugs exceeds 1,000 tons per year (84). Basic building blocks for these drugs can be obtained from natural phytosterols from soya (typically a mixture of 40% β -sitosterol, 25% campesterol, and 25% stigmasterol), from conifers (tall-oil: 70% β -sitosterol, 10% campesterol, and 15% β -sitostanol), and from rapeseed (45% β -sitosterol, 35% campesterol, and 12% brassicasterol). Schering (Berlin and Bergkamen, Germany) utilizes these natural resources together with mutants of *Mycobacterium* sp. devoid of steroid-ring degradation activities for the large-scale production of androstenedione and androsta-dienedione. These steroids are used as basic substrates for the subsequent production of drugs. Among the biocatalytic

processes are hydroxylations (e.g., at the 11 α or 11 β positions with *Curvularia* sp.), dehydrogenations (Δ 1-position; hydrocortisone to prednisolone), and reductions (17-keto reduction).

Oligosaccharides play important roles in various types of biochemical recognition processes on the cell surface and are useful pharmaceuticals. Kyowa Hakko Kogyo Co. Ltd. (Japan) has developed a multistep whole-cell biocatalysis for the production of oligosaccharides with high yield, productivity, and product concentration (51). They implemented a large-scale production system of uridine 5'-diphosphogalactose (UDP-Gal) from inexpensive starting materials by using a combination of metabolically engineered recombinant *E. coli* and *Corynebacterium ammoniagenes*. *E. coli* was engineered to express the UDP-Gal biosynthetic genes galactose-1-phosphate uridylyltransferase (*galT*), galactokinase (*galK*), glucose-1-phosphate uridylyltransferase (*galU*), and pyrophosphatase (*ppa*). *C. ammoniagenes* was engineered to produce uridine 5'-triphosphate (UTP), a substrate for UDP-Gal biosynthesis, from orotic acid. By coupling the UDP-Gal production system with *E. coli* cells that expressed the α 1,4-galactosyltransferase gene (*lgtC*) of *Neisseria gonorrhoeae*, 372 mM (188 g/liter) globotriose (Gal α 1-4Gal β 1-4Glc), a trisaccharide portion of the verotoxin receptor, is produced from inexpensive starting materials including orotic acid, galactose, and lactose. No oligosaccharide by-products are observed in the reaction mixture because of

the strict substrate specificity of α 1,4-galactosyltransferase. It is interesting that the production of globotriose is much higher than that of UDP-Gal itself (72 mM). This system, combining *C. ammoniagenes* with metabolically engineered recombinant *E. coli* cells that overexpressed sugar nucleotide biosynthetic genes, overcame the drawbacks of enzymatic methods of sugar nucleotide synthesis that require expensive raw materials such as phosphoenolpyruvate and nucleoside 5'-phosphates (42, 103).

33.4. ENZYMES IN FOOD, TEXTILE, AND PULP AND PAPER INDUSTRIES

Enzymes have been used to make cheese, bread, and beer for thousands of years, long before the knowledge of their existence (49, 74). With the recent advancements in recombinant DNA technology and protein engineering, more efficient enzymes are being applied to these processes, as well as others in the food industry. In addition, enzymes are being applied to improve processes in the textile, pulp, and paper industries (Fig. 4). The following sections describe a few representative enzymes that are commonly used in these industries.

33.4.1. Amylases

The amylase family is a starch-degrading enzyme acting on the α -1,4- and α -1,6-O-glycosidic linkages of the

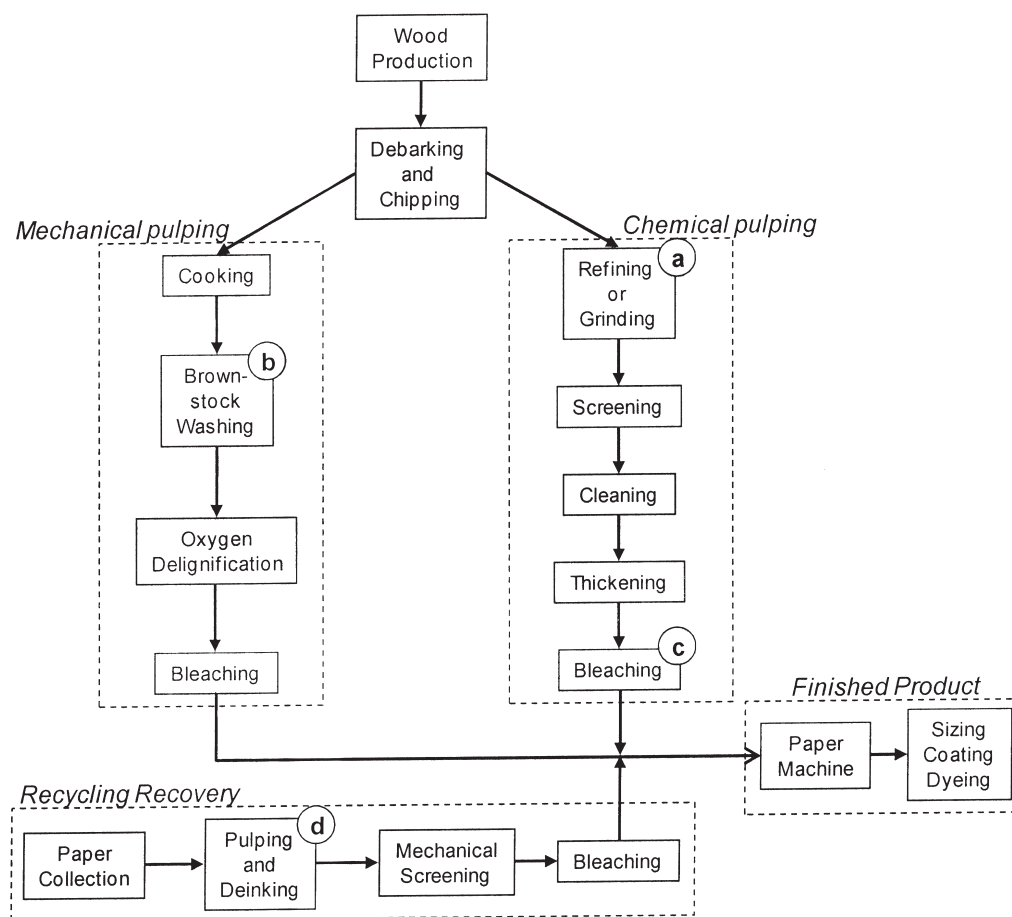

FIGURE 4 Flow diagram of the main processes in the pulp and paper industry, with indication of enzymes applied at an industrial scale. (a) Cellulases, (b) xylanases, (c) lipases, and (d) cellulases.

polysaccharide (68). The largest demand of amylases in the food industry is for the production of high-fructose corn syrups (13). The starch is pressure cooked, and thermostable α -amylases hydrolyze the internal glycosidic linkages of the starch molecule to form maltodextrins. β -Amylases are then applied to produce maltose by hydrolyzing only the nonreducing ends of the molecule, and a final treatment with glucose isomerase produces fructose (80). Protein-engineering techniques were used to produce thermostable enzymes that significantly increased the efficiency of the reaction and thus improved the process (17, 45, 55, 78). The thermostable *Bacillus licheniformis* α -amylase is one of the most widely used amylases in the bioindustry (99). The wild-type enzyme performs optimally at 90°C and a pH of 6, but requires the addition of calcium for high thermostability (100). Machius and coworkers (55) used directed evolution techniques on the protein to introduce five-point mutations (H133V, N190F, A209V, and Q264S), which increased the temperature of the unfolding of the enzyme by 13°C. The single-point mutations had a cumulative effect, resulting in a final mutant that unfolded 32 times slower than the wild type. Richardson et al. (78) used biodiversity studies to identify thermostable amylases from multiple organisms and applied DNA-shuffling techniques to produce protein chimeras. These chimeras not only had a 5°C increase in thermostability and required no additives for stability compared with the wild type from *B. licheniformis*, but were also tolerant to pH as low as 4.5.

Amylases have also been used as an additive to improve the quality of bread (75). During baking, the amylases decrease starch gelatinization, which decreases the dough viscosity (18). This improves the oven spring (ability of bread to rise when heated), thus enlarging the bread volume. Dogan (18) has shown that increased amylase activity improves gas production, which leads to enhanced crumb structure. Amylases are also known to improve the shelf life of baking products through their antistaling properties (29, 58, 62). During staling, a decrease in moisture level causes the amorphous starch structure to retrograde and crystallize. Palacios et al. (67) have shown that addition of thermostable amylases that remain active after baking hydrolyze chain segments in the amorphous regions near crystallites, which reduces crystallization.

Since the 1950s, the textile industry has also applied amylases to improve the process of producing cotton fabrics (3). To protect the product during weaving, the threads are coated with a starch called size that must subsequently be removed before dyeing and finishing. Conventionally, desizing was carried out by treating the fabric with chemicals such as acids, alkali, or oxidizing agents that can have damaging effects on the product. However, amylases have been applied to the process to selectively degrade the starch and not harm the product (41).

33.4.2. Pectinases

A main structural component of plant cell walls called pectins are polysaccharides, consisting of galacturonic acid residues linked by α -(1,4)-glycosidic linkages that are hydrolyzed by pectinases. In the food industry, pectinases from *Aspergillus niger* are used to increase the yield of fruit juice. When fruit tissue is ground, pectin is localized in the liquid phase and increases the viscosity of the juice (47). Pectinases partially hydrolyze the pectins, which causes the particles to aggregate and settle out of solution, increasing the juice yield. To increase efficiency of the process, immobilization of pectinases has been investigated. Specifically,

Sarioglu et al. (82) immobilized a commercially available Pectinex Ultra SP-L, from *Aspergillus aculeatus* produced by Novo Nordisk Ferment in Switzerland, onto an anion-exchange resin particle by electrostatic adsorption. The kinetic constants were found to be V_{\max} 0.0091% (wt/vol)/s and K_m 2.172% (wt/vol) compared with the free enzyme V_{\max} 0.0046% (wt/vol)/s and K_m 1.137% (wt/vol).

In the production of cotton, one of the most energy- and water-consuming steps is the scouring step: the removal of various remaining cell wall components on the cellulose fibers before dyeing (49). Scouring gives fabric a high and even wetting ability, so that it can be bleached and dyed successfully. The first application of enzymes to this process was by Tzanov et al. (95), who developed a process to treat the fabric with an alkaline bacterial pectinase (Bioprep 3,000L from Novo Nordisk), which reduced the overall cellulose structure with only a 27% decrease in weight compared with chemical scouring. The positive environmental impact of the new process was recognized by the U.S. Presidential Green Chemistry Challenge Award in 2001 (49).

33.4.3. Xylanases

Hemicellulose makes up 20 to 30% of plant matter, and xylans are the major component. This polysaccharide consists of a backbone chain of xylopyranose units that are linked by 1,4- β -D-glycosidic bonds that can be hydrolyzed by xylanases. The ability to degrade the xylans in flour makes the application of xylanases in the food industry desirable to increase the quality of bread and pastry dough (9, 53). Compared with white flour, wheat flour has a higher content of soluble arabinoxylan, which increases viscosity of the dough (16). Degradation of the arabinoxylan by xylanases decreases the dough viscosity, thus increasing volume and also creating finer, more uniform crumbs (9, 79). The most common xylanase applied in the baking industry originated from *A. niger*, but Jiang et al. (43) investigated the potential of the xylanase from the extremophile *Thermomyces lanuginosus*. The enzyme remained active up to 75°C. This increase in activity of the enzyme increased specific volume of the bread by 20% (43).

Xylanases are also used in the pulp and paper industry to degrade and weaken wood fibers before processing. A white and bright product is considered high quality; therefore, the pulp is bleached to produce the desired result. The degradation of the lignin and wood fibers makes the pulp more susceptible to bleaching and is called "bleach boosting" (88). This treatment significantly decreases the amount of bleaching material required and limits the emissions of absorbable organic halides (24). The efficiency of xylanases originating from different organisms has been investigated, and Khandeparkar and Bhosle (48) determined that xylanases isolated from *Arthrobacter* sp. were the most efficient and decreased the chlorine requirement the most compared with other organisms. Previous studies in using the xylanase from *Streptomyces thermoviolaceus* yielded only a 20% reduction in chlorine usage compared with a nonenzymatic treatment, while *Arthrobacter* sp. decreased the chlorine requirement by 28%.

33.4.4. Cellulases

Cellulases are used in both the textile and pulp and paper industries to hydrolyze cellulose, a polysaccharide of 1,4- β -D-linked glucose units. In the textile industry, the quality of cotton can be improved by an enzymatic treatment known as bio-polishing (49). The treatment removes tiny strands of fiber that protrude from the surface of yarn, giving the

fabric a smoother, glossier appearance and softer handling. In denim processing, many garments are subjected to a treatment to give them a slightly worn look, called stonewashing. Traditionally, stonewashing involves pumice stones beating the surface of the fabric, which fades the color and loosens the fabric (5). This process actually damages the garment and can break the stonewashing machine. In bio-stonewashing, cellulases loosen the indigo dye on the denim, achieving the same worn look without damaging the garment and giving the option of a variety of finishes. Miettinen-Oinonen et al. (61) compared four cellulase enzymes produced by *Melanocarpus albomyces*, *Myceliophthora thermophila*, *Chaetomium thermophilum*, and *Sporotrichum thermophilum*. They determined that cellulase originating from *M. albomyces* had the highest dye-releasing activity and also had the lowest back-staining (the released dye particles restaining the back side of the fabric or other fabrics).

In the pulp and paper industry, wood chips are physically separated into free fibers. This process can utilize a lot of electricity. Cellulases break down the cellulose in the wood fibers, softening the chips so that the processing time is shortened and electrical usage is diminished (74). Cellulases are also used in the deinking of recycled papers. Conventional deinking requires large amounts of chemicals such as NaOH, NaSO₃, and H₂O₂. The cellulases loosen the fibers of the recycled paper and thus release the ink from the fiber (4). Lee et al. (54) developed a protocol for the enzymatic deinking of laser-printed waste papers with use of cellulases and hemicellulases from *A. niger*. A maximum deinking efficiency of nearly 95% was achieved with a combination of the two enzymes. The bio-deinked recycled papers had quality similar to commercial papers (54).

33.4.5. Transglutaminases

Transglutaminases catalyze an acyl-transfer reaction of γ -carboxamide groups of peptide-bound glutamine residues, which cross-links whey, soya, beef, and poultry meat proteins (106). This can be used to modify the functional properties of the foods, as first shown by Motoki et al. (63). Products such as hamburgers, minced meat, and dumplings have improved elasticity, flavor, and texture as a result of the cross-linking. Using a liver enzyme from guinea pigs, this group developed a novel meat-binding system that was based on the protein cross-linking ability of the transglutaminase to bind fragments of meat such as fish and beef together. For industrial application of the process, microbial transglutaminase was isolated from *Streptomyces mobaraensis* (105). Herrero et al. (36) used Raman spectroscopy to show that treating meats with transglutaminases increased protein β -sheet and α -turns structure, including an increase in hardness, springiness, and cohesiveness.

33.5. CONCLUSIONS AND FUTURE PROSPECTS

Biocatalysis has emerged as a powerful tool for the production of many important industrial products including, but not limited to, enantiomerically pure building blocks for pharmaceuticals and agrochemicals, active pharmaceutical ingredients, antibiotics, and food ingredients such as sweeteners and vitamins. With the discovery of powerful enzyme manipulation tools such as directed evolution techniques and the advances in genomics, applications of biocatalysis in industrial synthesis are likely to increase rapidly. The feasibility of applying biocatalysis in the chemical, pharmaceutical, food, textile, and pulp and paper industries

depends very much on the economics of each specific process. Biocatalysis provides enormous opportunities for new development, and once fine-chemical and pharmaceutical companies have acquired more experience and the necessary expertise in such processes, these companies will become more confident in developing next-generation bioprocesses.

Biocatalytic processes are heavily focused on the sustainable production of chemicals, materials, and fuels from renewable resources. These processes do not use toxic raw materials, operate under mild reaction conditions, and produce significantly less hazardous waste. Biocatalysis can help shorten complicated syntheses from as many as 12 steps to just three or four, cuts manufacturing costs 40 to 60%, and reduces capital expenditures by more than 25%, while at the same time reducing the environmental footprint (92). All these factors often translate into a reduction of production costs and an increase in competitiveness, especially in highly regulated countries. Development of a new sustainable biocatalysis platform results in job retention and creation, as well as the conservation of fossil resources. In short, social, environmental, and economic benefits of industrial biocatalysis are a self-reinforcing cycle of sustainability; industrial biocatalysis can create new employment and economic values and simultaneously reduce the negative impact on the environment.

The application of biocatalysis in industry has yet to be exploited to its maximum potential. Public databases like BioCatalysis (accelrys.com) and the University of Minnesota Biocatalysis Database (21) list over 35,000 enzyme reactions. This, together with the expanding database of whole genomes and yet unexplored microbial diversity, represents a huge pool of enzymes that are waiting to be exploited as future industrial catalysts. As technologies for developing efficient biocatalysts, such as high-throughput screening, random and recombinatory mutagenesis, metabolic engineering, and enzyme immobilization, continue to advance, many new industrial applications of biocatalysis will soon replace traditional chemical catalysis methods. The challenge is to develop a biocatalyst with high activity, specificity, and stability in the presence of high concentrations of substrate and organic solvents, or at elevated temperatures, to make the industrial process economically viable. Process-engineering solutions such as in situ product removal using a multiphase process and a robust cofactor-recycling/replacement system will help improve productivity and reduce cost. In addition, elucidation of enzyme crystal structures in combination with computer-aided modeling will enable enzymes to be custom-tailored for industrial applications. The enzymes can be evolved to be highly active, to be thermostable, and to have altered substrate specificity. The breadth and depth of knowledge in the biocatalysis area is undoubtedly still limited compared with traditional chemical catalysis. However, in years to come, the expanding biocatalytic and biomolecular toolbox and better understanding of enzymes and cell stability in industrial environments, such as large reactors and organic solvents, will soon make it easier to develop many more efficient industrial bioprocesses.

N.U.N. and W.L.T. contributed equally to this work. We thank the National Institutes of Health (GM077596), the Biotechnology Research and Development Consortium (BRDC) (Project 2-4-121), the British Petroleum Energy Biosciences Institute, and the National Science Foundation for financial support in our biocatalysis and biosynthesis studies. Biomass-Converting Enzymes and Their Bioenergy Applications

FENG XU

34

34.1. INTRODUCTION

Sustainability of energy sources is of strategic importance for the future advancement of humanity. Among various renewable energy candidates, the ones derived from biological sources, in particular, the so-called bioenergy for transportation fuels, are attracting increasing attention (for recent reviews, see references 48 and 56). Bioethanol production from sugary/starchy biomaterials and biodiesel production from vegetable oils are now viable industries (often referred as “the first generation bioenergy”). However, because of the sheer size of our fuel usage, it is believed that lignocellulosic biomass feedstocks have to be tapped as fermentable carbohydrate sources to meet the projected demand of bioenergy.

Enzymes play key roles in the development of bioenergy. Production of the first-generation bioethanol from starch relies on amylases to transform starch to glucose. To produce the “second generation” of bioethanol from lignocellulosic biomass, the development of efficient cellulases, hemicellulases, and accessory enzymes will be indispensable.

Natural evolution has equipped many organisms with the ability to degrade and feed on biomass substances with an army of enzymes. For instance, cellulolytic aerobic fungi, in general, have extracellular and freely dissociated enzymes, while some cellulolytic anaerobic bacteria have enzymes assembled into cell-bound, supramolecular cellulosomes. Comprehensive studies on biomass-active enzymes have been carried out for many decades by classical microbiological and biochemical means, and recently have been advanced by genetic engineering, genome sequencing, and systems biology (for recent reviews, see references 33, 48, and 96).

To better understand the structure-function relationships of these enzymes, many different yet corroborating and complementing (to a certain extent) classifications have been proposed based on the following.

1. IUBMB Enzyme Nomenclature and Classification (<http://www.chem.qmul.ac.uk/iubmb/enzyme/>), according to the enzymatic reactions in the EC 3.2.1 glycosidase, EC 4.2.2 lyase, and EC 3.1.1 esterase classes. Because many enzymes can catalyze different types of reactions, the EC-based classification is not always definitive.
2. CAZY database (<http://www.cazy.org/>), according to the sequence homology and three-dimensional structure in glycoside hydrolase (GH), polysaccharide lyase (PL), and carbohydrate esterase (CE) families (13). Members

of the same family have homologous three-dimensional structure and catalytic mechanism. Different families may form clans based on determinant folding features. Enzymes from different families may catalyze the same reaction (or have the same EC designation).

3. Catalytic mechanism, according to the stereochemistry of enzymatic reactions (94). For “retaining” glycoside hydrolases, the anomeric C bearing the target glycosidic bond retains the same configuration after a double-displacement hydrolysis, while for “inverting” hydrolases, the anomeric C inverts its configuration after a single nucleophilic displacement hydrolysis. Many retaining hydrolases also possess significant transglycosylation activity, because of the covalently linked transient intermediate and the anomeric compatibility of transglycosylation products with the hydrolases’ active site. Most of these hydrolases rely on two acidic amino acid residues (Glu or Asp), one as proton donor or general acid and another as nucleophile or base as the catalytic nucleophile. Two known exceptions of these canonical mechanisms are with GH4 and 109 glycosidases that use NAD⁺ cofactor in a redox mechanism (54, 107).
4. “Supertertiary”/quaternary structure, according to the modular structure or multimolecule assembly of the enzymes. Modular glycoside hydrolases may comprise one or more catalytic modules, carbohydrate-binding modules (CBMs), fibronectin 3-like modules, dockerins, immunoglobulin-like domains, or functionally unknown “X” domains, connected by linkers (48, 74, 96). Many anaerobic bacteria have biomass-active enzymes assembled into cellulosomes, in which different cellulases are anchored onto scaffoldin molecules via cohesin-dockerin interaction (1, 28).

In this chapter, the basic structure, property, and function of biomass-active enzymes are introduced, with emphasis on those most relevant to the development of cellulosic bioenergy, e.g., major cellulases and hemicellulases. Due to limited space, only the most recent reviews and selected reports are cited in this chapter. These and other published articles may be used for more detailed and authoritative referencing. Most of the cited structural and enzymological data come from CAZy (<http://www.cazy.org/>) and BRENDA (<http://www.brenda-enzymes.info/> [15]) databases, where comprehensive information on biomass-active enzymes can be found.

34.2. CELLULASES

In Nature, cellulose [a linear polysaccharide consisting of $\beta(1\rightarrow4)$ -linked D-glucopyranosyl (Glc) units] is degraded by a combination of mainly three types of cellulases (Cel): cellobiohydrolase (CBH), endo-1,4- β -D-glucanase (EG), and β -glucosidase (BG), whose catalytic modules belong to ~ 14 GH families and CBMs belong to ~ 15 CBM families (15, 35). Because of their different molecular and enzymological properties (in particular, catalytic mechanism and substrate specificity), cellulases can act synergistically on cellulosic biomass substances (for recently studied examples, see references 15, 31, 35, and 74).

34.2.1. CBHs

CBHs (cellulose 1,4- β -cellobiosidase, exo-1,4- β -D-glucanase, or Avicelase; EC 3.2.1.91, EC 3.2.1.-) are able to degrade the crystalline part of cellulose, which is recalcitrant to other types of cellulases. Different CBHs have catalytic modules belonging to the GH5, GH6, GH7, GH9, GH48, and GH74 families. CBHs may possess CBM, which is believed critical for a CBH's binding to and action on crystalline cellulose. Based on either experimental data or structural homology analysis, the stereochemistry of Cel6, Cel9, Cel48, and Cel74 CBHs is of the inverting type, while the stereochemistry of Cel5 and Cel7 CBHs is of the retaining type.

The most significant topological feature of CBH's catalytic module is the tunnel structure, which may cover the entirety (e.g., in the case of Cel7 CBH) or part of the active site (e.g., in the case of Cel48 CBH). Such a tunnel enables the enzyme to hydrolyze cellulose in a unique "processive" manner (94). The movement restriction of CBH brought by the processive dynamics, as well as the insoluble and polymeric nature of the substrate, cause the enzyme's kinetics to deviate significantly from the classical Michaelis-Menten model (44, 65, 96) and become fractal (100).

Hypocrea jecorina Cel7A CBH-I and Cel6A CBH-II are archetypical CBHs. Experimental evidence indicates that Cel7 CBHs (EC 3.2.1.-) are specific to the reducing end of the cellulose chain to initiate their processive hydrolysis. A Cel7 CBH-I may have ten subsites (denoted from -7 to $+3$ [94]) that involve intricate H-bonding and π -stacking interactions to bind and activate a bound cellulose segment, and a CBM at their C terminus. It is believed that Cel6 CBHs (EC 3.2.1.91) are specific to the nonreducing end of the cellulose chain. In general, a Cel6 CBH-II has five subsites (-2 to $+2$, $+4$) and a CBM at its N terminus. A Cel7 CBH and a Cel6 CBH can be synergistic in hydrolyzing cellulose, a phenomenon attributed to their specificities at opposing cellulose chain ends. Cel5, Cel9, Cel48, and Cel74 CBHs may also be differentiated into reducing-end or nonreducing-end specific (5, 105). Many cellulose-degrading microbes secrete more than one CBH, probably to benefit from the synergism between CBHs of different specificity. For instance, *H. jecorina* produces both Cel7A CBH-I and Cel6A CBH-II (with abundance of ~ 60 and 15% wt/wt of all secreted proteins, respectively) (34, 74).

Compared with enzymes involved in homogenous catalysis, CBHs have quite slow kinetics. With soluble substrates, apparent K_m values on the order of 1 mM and k_{cat} values on the order of 1 turnover s^{-1} are often observed for CBHs, but the kinetic parameters can vary in a wide range ($\sim 10^{-2}$ to 10^2 mM, $\sim 10^{-3}$ to 10^3 s^{-1}) depending on substrate or CBH. For insoluble substrates, only apparent K_m and k_{cat} in units such as grams of cellulose per liter and grams of cellulose per liter per milligram of enzyme per minute,

respectively, may be obtained after fitting observed kinetic data to the Michaelis-Menten model. Polymeric celluloses (e.g., microcrystalline cellulose Avicel, filter paper, bacterial cellulose, amorphous phosphoric acid-swollen cellulose [PASC]), soluble cellodextrins, and soluble β -glycosides derivatized with chromogenic or fluorogenic functional groups (e.g., *p*-nitrophenyl cellobioside, 4-methylumbelliferyl lactoside) are commonly used to assay CBH, although the soluble fluoro/chromogenic substrates in general are not active toward Cel6 CBH-II. Many CBHs are active around pH ~ 5 to 7 and under ~ 20 to 60°C , and some extremophilic CBHs can extend their activity/stability beyond the pH or temperature range.

In addition to general protein destabilizers and carboxylate-active reagents (able to modify the catalytic Glu or Asp), CBHs may be inactivated by insoluble cellulose via unproductive binding (22), adsorption onto lignin or other noncellulose substances (6, 67, 101), or inhibited by cellobiose product. At high cellobiose concentration, a Cel7 CBH-I may act as transglycosylase, elongating cellodextrin chains instead of degrading them. Such unproductive adsorption, inhibition, or transglycosylation may lead to significant loss of desired CBH activity for bioenergy applications, besides thermal unfolding due to high reaction temperature (36).

34.2.2. EGs

EGs (4- β -D-glucan 4-glucanohydrolase, or CMCCase, EC 3.2.1.4) fragment cellulose by hydrolyzing internal $\beta(1\rightarrow4)$ glycosidic bonds. Different EGs have catalytic modules belonging to the GH5 to GH9, GH12, GH44, GH45, GH48, GH51, and GH74 families. The stereochemistry of Cel8 and Cel45 EGs is of the inverting type, while that of Cel5, Cel7, Cel12, Cel44, and Cel51 EGs is of the retaining type. The catalytic modules of most EGs have a cleft/groove-shaped active site, which allows the EGs to bind and clip a cellodextrin or a cellulose segment in a somewhat random, on-off manner. However, a few Cel5, Cel9, and Cel48 EGs can act processively (as CBHs do) (16, 61, 68). Because EGs may create new reducing and nonreducing ends in cellulose for CBHs to attack, these two types of cellulases can act synergistically in cellulose degradation.

H. jecorina Cel7B EG-I, Cel5A EG-II, Cel12A EG-III, *Humicola insolens* Cel6B EG-VI, Cel45A EG-V, *Clostridium thermocellum* Cel9R, and *Clostridium cellulolyticum* Cel48F are archetypical EGs. *H. jecorina* Cel7B EG-I has four subsites and a CBM at its C terminus, and prefers internal $\beta(1\rightarrow4)$ glycosidic bonds when cellodextrins serve as substrate. *H. jecorina* Cel5A EG-II has seven subsites and a CBM at its N terminus, and prefers glycosidic bonds near the reducing end. *H. jecorina* Cel12A EG-III has six subsites but no CBM. *H. insolens* Cel45A EG-V has six subsites and a C-terminus CBM. *H. insolens* Cel6B EG-VI has six subsites but no CBM, and prefers cellobiose (over shorter cellodextrins) as well as the glycosidic bonds near the reducing end. Many cellulose-degrading microbes secrete more than one EG. For instance, *H. jecorina* produces at least five EGs: Cel7B EG-I, Cel5A EG-II (together the two EGs can have $\sim 15\%$ wt/wt abundance in secreted *H. jecorina* proteins), Cel12A EG-III, Cel45A EG-V, and CBM-less Cel5B (34). On purified, homogeneous cellulose, no significant synergism among different EGs seems to exist, except between processive and conventional EGs (96). On polymorphous/heterogeneous cellulose and complex biomass substances, however, having different EGs may be beneficial. It is postulated that Cel12 EGs may act first on

the amorphous, outer part of cellulose, and CBM-possessing EGs (particularly the processive ones) then act on the more crystalline, inner part of cellulose (74). Cel12 EG is also postulated as having expansin-like activity (108). EGs from different GHs can have different preferences for cellulose regions to bind (due to difference in CBM specificity, multiplicity, or linkage to the catalytic module), length of cellulose segment to activate, or the site of glycosidic bond to cleave (due to difference in the architecture of EG's active site). EGs from different GHs may possess significant "side activity" on noncellulose poly- or oligosaccharides. For instance, *H. jecorina* Cel7B EG-I, Cel5A EG-II, and Cel12A EG-III can hydrolyze xylan, mannan, and xyloglucan, respectively (50, 70, 83). Thus, different EGs may act in concert, with their different yet complementary or supplementary side activities, toward plant cell wall substrates in which cellulose is entangled with and shielded by hemicellulose components. Brown rots do not have CBH, but their processive EG (in general, the most abundant in their secreted proteins) may act on crystalline cellulose and team up with other EGs and enzymes to constitute a "complete" cellulolytic system (16). In addition to their polysaccharide-degrading activity, some EGs may also function in the generation of inducers for the production of other enzymes by the hosting organisms.

With soluble substrates, K_m values on the order of 1 mM and k_{cat} values on the order of 10^3 s^{-1} are often observed for EGs, but the kinetic parameters can vary in a range ($\sim 10^{-1}$ to 10^1 mM, $\sim 10^{-2}$ to 10^2 s^{-1}) depending on substrate or EG. Insoluble or polymeric celluloses (e.g., PASC, carboxymethyl cellulose [CMC]), soluble cellodextrins, and soluble derivatized β -glycosides are commonly used to assay EGs, based on either viscosity decrease, reducing-end generation, different cellodextrin distribution, or photometric change. Many EGs are active at pH ~ 4 to 8 and under ~ 20 to 60°C . Some EGs may have significant transglycosylase activity.

"CMCase" (CMC-hydrolyzing) activity is commonly applied to differentiate EG from CBH. Among their side activities, Cel5, Cel7, Cel8, Cel9, Cel12, and Cel74 EGs may prefer mannan (and related hemicelluloses such as galactomannan), xylan (and related hemicelluloses such as arabinoxylan), chitosan, chitin, β -glucan, and xyloglucan, respectively (50, 66, 70, 79, 83, 94a, 98). Such discrimination on noncellulose polysaccharides may be applied to differentiate different EGs.

34.2.3. β -D-Glucosidases

BGs (β -D-glucosidase, β -D-glucoside glucohydrolase, or cellobiase, EC 3.2.1.21) hydrolyze cellobiose or longer, soluble cellodextrins into Glc. Different BGs have catalytic modules belonging to the GH1, GH3, and GH9 families (25). Microbial BGs are, in general, not multimodular; they lack distinct CBM. Based on either experimental data or structural homology analysis, the stereochemistry of Cel1 and Cel3 BGs is of the retaining type, while the stereochemistry of Cel9 BG is of the inverting type. BGs in general have a pocket-shaped active site, which allows them to bind to the nonreducing Glc unit and clip it from cellobiose or cellodextrin. At least for Cel3 BG, only the nonreducing glucosyl is important in BG activity; steric and electronic properties of the "aglycon" part of a glycoside or oligosaccharide (occupying the +1 subsite of BG) only play a minor role (49). Because it degrades cellobiose, a known inhibitor of CBH and EG, BG is indispensable in a complete cellulase system.

H. jecorina Cel1A BG-II and *Aspergillus niger* Cel3A BG-I are archetypical extracellular BGs. Cel1 BGs often have higher tolerance toward Glc (product) inhibition, as well as broader side activity on noncellobiose di- or oligosaccharides, than Cel3 BGs. Such kinetic differences might render it advantageous to have more than one BG in a cellulase system (34).

With cellobiose or other β -glucosides, K_m values on the order of 1 mM and k_{cat} values on the order of 10^3 s^{-1} are often observed for BGs, but the kinetic parameters can vary in a range ($\sim 10^{-2}$ to 10^2 mM, $\sim 10^{-1}$ to 10^4 s^{-1}) depending on substrate or BG. Cellodextrins, β -glucosides, and enzyme-coupled assays (such as those based on glucose oxidase's action on Glc) are commonly used to assay BGs. Many BGs are active at pH ~ 4 to 7 and under ~ 20 to 60°C . BGs may be subjected to substrate inhibition from cellobiose (K_i generally on the order of 1 mM), or product inhibition from Glc (K_i generally on the order of 1 mM, but may vary from 10^{-1} to 10^2 mM, depending on BG). At high Glc concentration and low water activity, BG may act as transglycosylase, condensing Glc and other carbohydrates into dimeric or oligomeric molecules (80).

34.2.4. Cellobiose Phosphorylase

Cellobiose phosphorylase (cellobiose:phosphate β -D-glucosyltransferase, or cellodextrin phosphorylase, EC 2.4.1.20 or EC 2.4.1.49) cleaves the $\beta(1\rightarrow4)$ -bond in cellobiose (or cellodextrin) by phosphorylating a glucosyl unit while releasing a Glc. Because they are mainly intracellular and occur in anaerobic bacteria, the enzymes belonging to the GH94 family are important for in vivo bacterial cellulose utilization. Potential applications of the enzymes in enzymatic cellulose hydrolysis and H_2 production from cellulosic materials have been evaluated (15, 106).

34.2.5. Glucuronan Lyase

A few microbial glucuronan lyases have recently been characterized (19, 45). The enzyme [(1 \rightarrow 4)- β -D-glucuronan lyase, EC 4.2.2.14] cleaves $\beta(1\rightarrow4)$ -bonds in polyglucuronan (or cellouranan) by β -elimination, generating a Glc (or reducing end) and a $\Delta 4:5$ unsaturated Glc (or corresponding nonreducing end). The lyase is highly specific to polyglucuronan and has no or low activity on polygalacturonan [$\alpha(1\rightarrow4)$ backbone], hyaluronan [$\beta(1\rightarrow3, 4)$ backbone], or alginate [$\beta, \alpha(1\rightarrow4)$ backbone]. Based on sequence, glucuronan lyase belongs to the PL20 family. The in vivo function and in vitro application of the enzyme remain to be further investigated.

34.3. HEMICELLULASES

Hemicellulases hydrolyze hemicellulose, a group of complex polysaccharides consisting of different units, linkages, intramolecular architectures, or intermolecular interactions. Common hemicelluloses include β -glucan (not cellulose), xylan, xyloglucan, arabinoxylan, mannan, galactomannan, arabinan, galactan, polygalacturonan, etc., which are degraded in Nature by β -glucanase, xylanase, xyloglucanase, mannanase, arabinase, galactanase, polygalacturonase, glucuronidase, acetyl esterase, and other enzymes (82). Based on the bonds they cleave, hemicellulases may be divided into two groups: glycoside hydrolases/lyases (on glycosidic bonds) and carbohydrate esterases (on ester bonds). Based on their targets, hemicellulases may also be divided into two different groups: one acts on the backbones and the other acts on the side chains of hemicelluloses. Similar to

cellulases, many hemicellulases are modular, with catalytic modules belonging to ≥ 29 GH, 5 PL, and 9 CE families and CBMs belonging to ≥ 37 CBM families. Many GH families contain numerous cellulases and hemicellulases, indicating likely common evolution ancestry and possible overlapping functions. Most cellulolytic microbes produce an array of hemicellulases along with cellulases. Because of their different molecular and enzymological properties (in particular, catalytic mechanism and substrate specificity), hemicellulases can act synergistically among themselves or with cellulases on complex biomass substances to effectively produce fermentable sugars for bioenergy or other biorefinery applications (30, 48, 73, 74, 81).

34.3.1. Endo- β -Xylanases and β -Xylosidase

Endo- β -xylanases (endo-1,4- β -D-xylan xylanohydrolase, EC 3.2.1.8; endo-1,3- β -D-xylanase, EC 3.2.1.32) cleave backbone glycosidic bonds in xylan, a group of $\beta(1\rightarrow4)$ -linked D-xylopyranosyl polysaccharides with different O-substitutions and frequent copresence with cellulose in biomass. Different xylanases (Xyn) have catalytic modules belonging to the GH5, GH8, GH10, GH11, GH26, and GH43 families (17, 69, 72). Most known xylanases are in GH10 and GH11 families: GH11 contains solely xylanases, while GH10 contains a few other glycoside hydrolases. Xyn26 are 1,3- β -xylanases only. β -Xylosidases (EC 3.2.1.37) cleave xylobiose or longer xylooligosaccharides into xylose (Xyl). Different β -xylosidases have catalytic modules belonging to the GH3, GH30, GH39, GH43, GH52, and GH54 families.

The stereochemistry of Xyn8 and Xyn43 xylanases is of the inverting type, while that of Xyn5, Xyn10, Xyn11, and Xyn26 xylanases is of the retaining type. The catalytic modules of most endo-xylanases have a cleft-shaped active site, with four to seven subsites, which allows the enzymes to bind and clip a xylooligosaccharide or a segment of a xylan chain, in a somewhat random, on-off manner. The stereochemistry of most β -xylosidases is of the retaining type, with the exception of Xyn43 members. β -Xylosidases have a pocket-like active site with two subsites, and cleave xylobiose or xylooligosaccharides from the nonreducing end (41).

Cellulomonas fimi Xyn10A Cex, *H. jecorina* Xyn11 xylanase-I, and *H. jecorina* Xyn3 β -xylosidase are archetypical. *C. fimi* Xyn10A has a CBM2a CBM with a high affinity toward crystalline cellulose and chitin (but weak affinity toward amorphous cellulose). *H. jecorina* Xyn11 has no CBM (although many bacterial Xyn11 xylanases do have CBM). Besides molecular shape and size, Xyn10s and Xyn11s differ mainly on their substrate specificity. Compared with Xyn11s, Xyn10s in general degrade xylan into shorter oligosaccharides and have broader side activity on other polysaccharides (69, 92). Xyn10s typically act on the third or second $\beta(1\rightarrow4)$ -glycosidic bond at the “non-reducing” side of a substituted Xyl unit or a $\beta(1\rightarrow3)$ -bond, respectively (17). Xyn11s typically act only on plain/unsubstituted 1,4- β -xylan or xylooligosaccharides. Xylanases with preference on either the reducing end or nonreducing end of a xylan chain are also known (17). Some Xyn5s and Xyn43s may also act on non-xylan polysaccharides, such as β -glucan and arabinan, respectively.

Xylanases from different GHs may possess not only different specificity on xylan, but also significant side activity on non-xylan substrates. For instance, *H. jecorina* Xyn10 xylanase can hydrolyze cellulose, probably a remnant function from the enzyme's evolution ancestry shared by Cel5 EG belonging to the same GH-A clan. Thus, different

xylanases may act in concert among themselves. It is postulated that Xyn10 may further degrade the large xylooligosaccharides generated by Xyn11, thus achieving greater overall xylan degradation (69). Different xylanases may collaborate with enzymes acting on xylan side chains and cellulases to collectively attack plant cell wall substrates in which cellulose is entangled with and shielded by hemicellulose components. It has been noticed that Xyn11 and Xyn10 collaborate with feruloyl esterase better in releasing feruloyl and 5,5'-diferuloyl, respectively, from ferulated polysaccharides (26). Numerous natural fusion proteins containing xylanase and other biomass-active enzyme catalytic modules are known (17). Given the abundance of xylan in hardwood, xylanases should be an important part of enzyme systems targeting hardwood-derived biomass feedstocks. For other lignocellulosic substrates (even when only residual hemicelluloses exists after pretreatment), the benefit of including xylanase in cellulase mixtures has been observed (7, 16, 27, 30, 73, 81, 89). β -Xylosidase can keep endo-xylanase from product inhibition by degrading xylobiose or longer xylooligosaccharides (81). Many β -xylosidases have dual activity on α -L-arabinofuranoside, probably because of the configurational similarity between D-xylopyranose and L-arabinofuranose, making the enzymes useful in removing xylanase-hindering xylan side chains.

For endo-xylanase, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s $^{-1}$ are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-1}$ to 10^2 mM, $\sim 10^{-2}$ to 10^3 s $^{-1}$) depending on substrate or xylanase. Various xylan and xyloside substrates are used to assay xylanases, although some Xyn5 xylanases may have low reactivity toward short derivatized xylosides. For β -xylosidase, K_m values on the order of 10^{-1} mM and k_{cat} values on the order of 10^{-2} s $^{-1}$ are often observed, with a range ($\sim 10^{-2}$ to 10^1 mM, $\sim 10^{-3}$ to 10^2 s $^{-1}$) depending on substrate or β -xylosidase.

Many xylanases and β -xylosidases are active at pH ~ 4 to 8 and temperatures from ~ 40 to 70°C . Xylanases from (hyper)thermophiles can extend their activity/stability at much higher temperatures. These xylanases, among the most thermally active glycoside hydrolases known, may hold promise for high-temperature biomass hydrolysis.

Xylanase and β -xylosidase may be inactivated by unproductive adsorption from lignin or inhibition from substrate, product, or analogs (6, 40). They may also be strongly inhibited by plant-derived xylanase-specific proteins (e.g., *Triticum aestivum* xylanase inhibitor I and II) (8). Many retaining xylanases and β -xylosidases have significant transglycosylase activity (74). Such inhibition or transglycosylation may lead to significant xylanase activity loss in bioenergy applications (17, 69).

34.3.2. β -Glucanases

Endo- β -glucanases (non-EG) [1,3-(1,3;1,4)- β -D-glucan 3(4)-glucanohydrolase or laminarinase, EC 3.2.1.6; 1,3- β -D-glucan glucanohydrolase, EC 3.2.1.39; 1,3-1,4- β -D-glucan 4-glucanohydrolase or licheninase, EC 3.2.1.73] cleave backbone linkages in non-cellulose β -glucans [Glc polymers with $\beta(1\rightarrow3)$, $(1\rightarrow4)$, or $(1\rightarrow6)$ linkages]. Exo- β -glucanases (non-BG) (1,3- β -glucan glucohydrolase, EC 3.2.1.58; 1,6- β -glucan glucohydrolase, EC 3.2.1.75) cleave nonreducing ends of β -glucans to produce mostly Glc and sometimes gentiobiose. Different β -glucanases have catalytic modules belonging to the GH3, GH5, GH12, GH16, GH17, GH55, GH64, and GH81 families. GH16s are (1,3-1,4)- β -D-glucanases only, and GH64s β -glucanases

are specific to $\beta(1\rightarrow3)$ -D-glucan only. The stereochemistry of GH8, GH64, and GH81 β -glucanases is of the inverting type, while the stereochemistry of GH5, GH12, GH16, and GH17 β -glucanases is of the retaining type. Many microbes produce more than one β -glucanase (mostly β -1,3-glucanases), which may act in concert to degrade complex β -glucans.

For many β -glucanases, K_m values on the order of 10^{-1} mM and k_{cat} values on the order of 10^2 s $^{-1}$ are often observed for soluble substrates, with a range of $\sim 10^{-1}$ to 10^1 mM and $\sim 10^{-1}$ to 10^3 s $^{-1}$, respectively. For non-BG β -glucosidases, K_m values on the order of 1 mM and k_{cat} values on the order of 10 s $^{-1}$ are often observed, with a range of $\sim 10^{-2}$ to 10^1 mM and ~ 1 to 10 s $^{-1}$, respectively. Many β -glucanases are active at temperatures ranging from ~ 40 to 70°C and show optimal activity between pH 4 and 8.

34.3.3. Endo- β -Mannanase and β -Mannosidase

Mannans consist of $\beta(1\rightarrow4)$ -D-mannosyl or manno/glycopyranosyl polymeric backbone with variable $\beta(1\rightarrow6)$ -D-galactosyl side chains, as well as O2 and/or O3 acetylations. Endo-mannanases (1,4- β -D-mannan mannanohydrolase, EC 3.2.1.78) cleave backbone $\beta(1\rightarrow4)$ -bonds in mannan (21, 62). Different endo-mannanases (Man) have catalytic modules belonging to the GH5, GH26, and GH113 families. β -Mannosidases (β -D-mannoside mannanohydrolase, EC 3.2.1.25) cleave mannosyl units from nonreducing ends of mannan or manno oligosaccharides. Different β -mannosidases have catalytic modules belonging to the GH1, GH2, and GH5 families. Man1, Man2, Man5, Man26, and Man113 enzymes all have the retaining stereochemistry.

H. jecorina Man5A, *C. fimi* Man26A, and *Alicyclobacillus acidocaldarius* Man113A are archetypical endo-mannanases. Man5 and Man26 have approximately five to six subsites (-4 or -3 to $+2$), and often need bindings onto at least four subsites to activate a substrate. Because the CBMs in fungal mannanases in general bind to cellulose, but not to mannan, their function is postulated as mainly a locator to bring the enzymes to cellulose-bound mannan. However, many of the CBMs of bacterial mannanases are mannan specific, such as the CBM of *C. fimi* Man26A (a CBM23 CBM, linked also to an immunoglobulin-like and S-layer module specific to bacterial surface), which might directly assist in mannan binding and activating by the enzymes. Because of their retaining catalytic mechanism, some mannanases have significant transglycosylase activity. *Solanum lycopersicum* Man1, *A. niger* Man2A, and *Cellvibrio mixtus* Man5A are archetypical β -mannosidases, most of them being intracellular or membrane bound.

Many biomass-degrading microbes secrete endo-mannanase and/or β -mannosidase along with various cellulases, xylanases, and other biomass-active enzymes (34). Given the abundance of (galacto)glucomannan in softwood, mannanases could be an important part of enzyme systems targeting softwood-derived biomass feedstocks. For instance, mannanase may act together with xylanase and EG to synergistically degrade sugarcane bagasse (9). BG may further degrade endo-mannanase-produced glucomannooligosaccharide by removing nonreducing end Glc. α -Galactosidase and acetyl mannan esterase may assist endo-mannanase's hydrolysis of substituted (gluco)mannan by removing side chains (62). For enzymatic hydrolysis of complex biomass substrates, however, such side chain removal may have mixed effects, because "polished" homo-mannan may lose water solubility and stick to cellulose, thus impeding the action of cellulases (21).

For endo-mannanase, K_m values on the order of 10^{-2} mM and k_{cat} values on the order of 10^2 s $^{-1}$ are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-3}$ to 10 mM, $\sim 10^{-1}$ to 10^3 s $^{-1}$). For β -mannosidase, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s $^{-1}$ are often observed, with a range of $\sim 10^{-2}$ to 10^1 mM and $\sim 10^{-2}$ to 10^2 s $^{-1}$, respectively. Many mannanases and β -mannosidases show optimal activity between pH 3 and 8, and are active at temperatures ranging from ~ 40 to 80°C .

34.3.4. Xyloglucan Hydrolase and Xyloglucan Endo-Transglycosylase

Xyloglucan is a group of polysaccharides consisting of a 1,4- β -glucan backbone with O6 substitution of $\alpha(1\rightarrow6)$ -linked Xyl units that themselves are substituted (at O2) by either $\alpha(1\rightarrow2)$ -L-arabinofuranosyl (Ara) or $\beta(1\rightarrow2)$ -D-galactosyl (Gal) units [partially acetylated or substituted (at O2) by $\alpha(1\rightarrow2)$ -L-fucopyranosyl (Fuc)] (109). Xyloglucan hydrolases [1,4- β -D-glucan glucanohydrolase, EC 3.2.1.151; (1,6- α -D-xylo)-1,4- β -D-glucan exo-glucanohydrolase, EC 3.2.1.155; oligoxyloglucan reducing-end cellobiohydrolase, EC 3.2.1.150] cleave polymeric xyloglucan into oligoxyloglucans. Different xyloglucan hydrolases have catalytic modules belonging to the GH5, GH12, GH16, GH44, and GH74 families. Xyloglucan endo-transglycosylases (xyloglucan:xyloglucan xyloglucanotransferase, EC 2.4.1.207), found mainly in plants, transfer an oligoxyloglucan from a xyloglucan to the O4 of a nonreducing end Glc unit of another (oligo)xyloglucan, and have catalytic modules belonging to the GH12 and GH16 families. Recently, it has been proposed to group xyloglucan hydrolase and xyloglucan endo-transglycosylase into one xyloglucan transferase/hydrolase (XTH) superfamily (77; <http://labs.plantbio.cornell.edu/XTH/>). XTH may possess CBM, which seems to serve as a locator to bring XTH to specific cell wall regions, rather than an enhancer for the catalytic module's catalysis (38). The stereochemistry of XTH74 xyloglucanases is of the inverting type, while the stereochemistry of XTH5, XTH12, XTH16, and XTH44 is of the retaining type.

Panibacillus pabuli XTH5, *Bacillus licheniformis* XTH12, and *H. jecorina* XTH74A (also noted as EG-VI) are archetypical. Besides molecular shape and size, XTHs may differ on their substrate specificity. For instance, *H. jecorina* XTH74A can hydrolyze a xyloglucan at substituted Glc units, and near either end of a xyloglucan chain (20). Many XTHs may act on both xyloglucan and unsubstituted $\beta(1\rightarrow4)$ -glucan (e.g., cellulose), but their activity on the former is, in general, significantly greater than that on the latter (38), in contrast to Cel7 EG, which also acts on xyloglucan but with an activity significantly less than that on cellulose (94a).

Many biomass-degrading microbes secrete at least one XTH. For instance, both *H. jecorina* and *Phanerochaete chrysosporium* produce two XTHs. XTHs from different GH families may possess not only different specificity on xyloglucan, but also side activity on other β -glucans/polysaccharides (38). Arabinofuranosidase and esterase may enhance XTH activity by trimming off Ara-containing or acetylated side chains in xyloglucan, respectively. Given the presence of xyloglucan in plant cell wall, XTH may enhance cellulases' activity on cellulose by degrading away xyloglucan and subsequently exposing more cellulose in a biomass feedstock (3).

Various XTHs are believed to take part in the formation/expansion of plant cell wall (77). These XTHs may be active in loosening rigid lignocellulosic cell wall, by cutting and relinking load-bearing xyloglucan, to allow new growth. Different plant XTHs may have different donor and/or acceptor specificity, in terms of the size (oligo- or polymeric xyloglucan) or fine structure (e.g., Fuc substitution, arrangement of plain and Xyl-substituted backbone Glc units), as well as a different hydrolysis pattern, in terms of being internal or chain end-preferred. The xyloglucan endo-transglycosylase property may be useful in biomass conversion in which disentangling and weakening recalcitrant polysaccharides are vital for effective (hemi)cellulose hydrolysis. Thus, XTH may have a potential of becoming a cellulase enhancer for bioenergy application, although economic production of plant XTH (in fermentative microbes) remains challenging.

For XTH's hydrolase activity, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed, with a range of $\sim 10^{-1}$ to 10 mM and 10^{-2} to 10^3 s^{-1} , respectively. For xyloglucan endo-transglycosylase activity, K_m values on the order of 10^{-1} mM and k_{cat} values on the order of 10^{-3} s^{-1} are often observed, with a range of $\sim 10^{-2}$ to 10^1 mM and $\sim 10^{-4}$ to 10^{-3} s^{-1} . Many XTHs are active as hydrolases at pH 5 to 6 and ~ 40 to 70°C , and as transglycosylases at pH 5 to 6 and ~ 20 to 40°C .

34.3.5. Polygalacturonan Hydrolases and Lyases

Pectic polysaccharides are complex plant cell wall components consisting of poly- α -galacturonic acids (GalU) or polyrhamnogalacturonic acids with variable methylation/acetylation (on backbone GalU) and carbohydrate side chains (containing mainly Ara and Gal) linked to backbone rhamnosyl units. Based on catalytic mechanism, three groups of pectinolytic enzymes are involved in the degradation of pectic polysaccharides: polygalacturonases or pectinases [cleaving internal backbone $\alpha(1\rightarrow4)$ -bonds by hydrolysis], pectin/pectate lyases (cleaving internal backbone bonds by β -elimination), and pectin methyl esterase (pectin pectylhydrolase, EC 3.1.1.11; converting pectin to pectate). Polygalacturonases may be further divided into endo-polygalacturonase (EC 3.2.1.15), exo-polygalacturonidase (poly-1,4- α -D-galacturonide galacturonohydrolase, EC 3.2.1.67), and exo-polygalacturonosidase (EC 3.2.1.82). Pectin/pectate lyases cleave the glycosidic bond between glycosidic O and C4, with the help of C6-uronate, and form a $\Delta 4:5 \text{ C}=\text{C}$ bond at the nonreducing side GalU. The lyases may be further divided into endo-type pectate lyase (1,4- α -D-galacturonan lyase, EC 4.2.2.2), endo-type oligogalacturonide lyase (EC 4.2.2.6), endo-type pectin lyase (1,4-6-O-methyl- α -D-galacturonan lyase, EC 4.2.2.10), and exo-type pectate disaccharide lyase (1,4- α -D-galacturonan reducing-end-disaccharide-lyase, EC 4.2.2.9). Many pectinolytic hydrolases and lyases can act on both pectin (polymethylgalacturonic ester) and pectate (polygalacturonic acid) (39, 90). Based on sequence, polygalacturonases belong to the GH28, pectin methyl esterases belong to the CE8, and pectin/pectate lyases belong to the PL1, PL2, PL3, PL9, and PL10 families. It is known that GH28 polygalacturonases have the inverting stereochemistry.

Exo-polygalacturonases degrade their substrates processively with one dominant single product [GalU for fungal enzymes, but GalU- $\alpha(1\rightarrow4)$ -GalU for bacterial enzymes], while endo-polygalacturonases cleave internal $\alpha(1\rightarrow4)$ -bonds randomly, yielding an array of oligogalacturonan products (39, 63). Ca^{2+} is required by pectate lyase, but

not pectin lyase, although the latter may be stimulated by the cation. Fungal pectin methyl esterases are believed to act randomly along a pectin chain, but plant pectin methyl esterases may prefer to start at the ends of a pectin chain and continue in a processive manner (39, 71).

Different pectinolytic enzymes may act in concert among themselves. Endo- and exo-polygalacturonases may synergize with each other as EG and CBH do. Polygalacturonases and pectin/pectate lyases with different specificity or tolerance on poly(rhamno)galacturonan or side chains may collectively attack complex pectin or plant cell wall substrates. Pectin methyl esterase may enhance the catalysis of polygalacturonase by removing the methyl groups in pectin. α -L-Arabinofuranosidase, arabinase, galactosidase, and other enzymes may also enhance the catalysis of pectinolytic enzymes by removing the side chains from polyrhamnogalacturonan. Given the abundance of pectic polysaccharides in sugar beet and fruits, pectinolytic enzymes could be an important part of enzyme systems targeting sugar beet pulp, fruit peels, and other related biomass feedstocks.

For polygalacturonase, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-2}$ to 10^1 mM, ~ 1 to 10^3 s^{-1}). For pectin/pectate lyases, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed, with a range of $\sim 10^{-3}$ to 1 mM and $\sim 10^{-1}$ to 10^2 s^{-1} . For pectin methyl esterases, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed, with a range of $\sim 10^{-2}$ to 1 mM and ~ 10 to 10^2 s^{-1} , respectively. Many polygalacturonases, pectin/pectate lyases, and pectin methyl esterases are active at temperatures ranging from ~ 30 to 60°C , 40 to 70°C , and 30 to 70°C , as well as pH values ranging from 4 to 6, 5 to 10, and 4 to 9, respectively. Polygalacturonases and pectin methyl esterases may be susceptible to plant-derived specific protein inhibitors (71).

34.3.6. α -L-Arabinofuranosidase and Endo-1,5- α -Arabinanase

α -L-Arabinofuranosidase (α -L-arabinofuranoside arabinofuranohydrolase, EC 3.2.1.55) cleaves α -glycosidic bonds linking Ara in many hemicelluloses. Different arabinofuranosidases have catalytic modules belonging to the GH3, GH43, GH51, GH54, and GH62 families. Endo-1,5- α -arabinanase (1,5- α -L-arabinan 1,5- α -L-arabinanohydrolase, EC 3.2.1.99) cleaves internal $\alpha(1\rightarrow5)$ -glycosidic bonds in arabinan or Ara side chain of some hemicelluloses. The catalytic modules of α -arabinases belong to the GH43 family. The stereochemistry of GH43 arabinofuranosidase and arabinase is of the inverting type, while that of GH3, GH51, and GH54 arabinofuranosidases is of the retaining type.

Arabidopsis thaliana GH3, *Bacillus subtilis* GH43A, *C. thermocellum* GH51A, *Aspergillus kawachii* GH54, and *H. jecorina* GH62 arabinofuranosidases are archetypical. Many arabinofuranosidases contain CBM, whose role may be to anchor the enzymes to a particular region in a biomass substrate rather than to bind the enzymes onto an arabinan (37). Besides molecular shape and size, arabinofuranosidases may differ in their substrate specificity. Some arabinofuranosidases prefer Ara singly linked to either a Xyl's O2, O3, or O5 site in (oligo)xylan or arabinan, while others prefer Ara doubly linked to O2 and O3 sites (55, 64, 82). It is reported that GH51 arabinofuranosidases only act on short Ara-oligosaccharides, while GH54 arabinofuranosidases act on both the oligosaccharides and polymeric arabinoxylan (32).

Many arabinofuranosidases have significant xylosidase, transglycosylase, or other dual or side activities (55). Different arabinofuranosidases may act in concert among themselves when their specificities toward different Ara substitution supplement/synergize each other (85). Arabinofuranosidase and arabinase may also act together, in an exo-endo synergism, to effectively degrade arabinan or Ara side chains of other polysaccharides (103). Arabinofuranosidase's removal of Ara side chains in xylan, pectin, or other polysaccharides may enhance the activity of xylanase, pectinase, or other hemicellulases (85). Given the heavy occurrence of Ara substitution of xylan in softwood, arabinoxylan in cereal and grasses, and pectin in many plant cell walls, arabinofuranosidase could be an important part of enzyme systems targeting feedstocks derived from such biomass materials (75).

For arabinofuranosidases, K_m values on the order of 1 mM and k_{cat} values on the order of 1 s^{-1} are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-2}$ to 10 mM, $\sim 10^{-2}$ to 10^2 s^{-1}). For arabinase, K_m values on the order of 1 mM and k_{cat} values on the order of 10 s^{-1} are often observed, with a range of $\sim 10^{-1}$ to 10 mM and $\sim 10^{-2}$ to 10^2 s^{-1} . Many arabinofuranosidases are active at temperatures ranging from ~ 30 to 80°C , and some arabinofuranosidases from extremophiles can extend their activity/stability at higher temperatures. Arabinofuranosidases, in general, show optimal activity between pH 3 and 7. Endo-arabinases are active at temperatures ranging from ~ 50 to 70°C , and pH values ranging from 4 to 6.

34.3.7. α -Galactosidase and Endo-Galactanase

α -Galactosidase (α -D-galactoside galactohydrolase, EC 3.2.1.22) cleaves α -glycosidic bonds linking Gal in many hemicelluloses. Different α -galactosidases have catalytic modules belonging to the GH4, GH27, GH36, GH57, and GH110 families. Endo-galactanase (arabinogalactan 4- β -D-galactanohydrolase, EC 3.2.1.89) cleaves internal $\beta(1\rightarrow4)$ -bonds in galactan or Gal side chains of some hemicelluloses. All endo-galactanases belong to the GH53 family. The stereochemistry of GH110 α -galactosidases is of the inverting type, while that of GH4, GH27, GH36, and GH57 α -galactosidases, as well as GH53 endo-galactanases, is of the retaining type. *B. subtilis* GH4, *H. jecorina* GH27, *Thermotoga maritima* GH36, *Pyrococcus furiosus* GH57, and *Bacteroides fragilis* GH110A α -galactosidases, as well as *H. insolens* GH53 endo-galactanase, are archetypical. GH4 α -galactosidases along with other GH4 enzymes have the only mechanism exception in all known glycoside hydrolases: they use an NAD^+ cofactor in a redox mechanism to hydrolyze their substrates (107).

Comparative study on microbial α -galactosidase and endo-galactanase remains limited, in contrast to other biomass-active enzymes. Given the heavy occurrence of Gal $\alpha(1\rightarrow6)$ substitution and/or Gal side chain in galactomannan, pectin, and other hemicelluloses, these enzymes could be a useful part of enzyme systems targeting feedstocks rich in such hemicelluloses.

For α -galactosidases, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-1}$ to 10 mM, $\sim 10^{-2}$ to 10^4 s^{-1}). For endo-galactanase, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed, with a range of ~ 10 to 10^3 s^{-1} . Many α -galactosidases are active at temperatures ranging from ~ 30 to 70°C , and some from extremophiles can extend their activity/stability at higher temperatures. α -Galactosidases, in general, show optimal

activity between pH 3 and 7. Endo-galactanases are active at temperatures ranging from ~ 40 to 60°C and pH values ranging from 4 to 8.

34.3.8. α -Glucuronidase

α -Glucuronidases [α -D-glucosiduronate glucuronohydrolase, EC 3.2.1.139; xylan α -D-1,2-(4-O-methyl)glucuronohydrolase, EC 3.2.1.131] cleave $\alpha(1\rightarrow2)$ -bonds linking (methyl)GlcU units in xylan or other hemicelluloses. Almost all α -glucuronidases belong to the exclusive GH67 family (GH4 contains two *T. maritima* α -glucuronidases) with an inverting stereochemistry.

Cellvibrio japonicus GH67A and *Aspergillus nidulans* GH67A are archetypical. Different α -glucuronidases may have different specificity. For instance, some xylan α -glucuronidases prefer glucuroylated xylooligosaccharides, while others prefer polymeric glucuronoxylan (69). α -Glucuronidase may assist xylanase action on complex xyans by removing GlcU side chains.

For α -glucuronidases, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed, with a range of $\sim 10^{-1}$ to 10 mM and $\sim 10^{-2}$ to 10^2 s^{-1} , respectively. Many α -glucuronidases are active at temperatures ranging from ~ 40 to 80°C and pH values ranging from 3 to 7.

34.3.9. Acetyl Xylan Esterase, Feruloyl Esterase, and Glucuronoyl Esterase

Acetyl xylan esterase (AXE, EC 3.1.1.72) and feruloyl esterase (FAE, 4-hydroxy-3-methoxycinnamoyl-sugar hydrolase or ferulic acid esterase, EC 3.1.1.73) hydrolyze the acetyl and hydroxycinnamoyl ester bonds, respectively, found in xylan or other hemicelluloses. Acetylation occurs in many hemicelluloses' backbone glycosyl units (at the O2 or O3 site), and hydroxycinnamoyl (e.g., feruloyl) esterification occurs in α -L-Ara (O2 or O5 site), β -D-Gal (O6 site), or α -D-Xyl side chains of arabinan/arabinoxylan, rhamnogalacturonan, or xyloglucan. The esterifications are believed to serve the purpose of linking hemicellulose to lignin. Glucuronoyl esterase (GE, EC 3.1.1.-) hydrolyzes the O6 methyl in methyl-esterified GlcU $\alpha(1\rightarrow2)$ -linked to some backbone Xyl in glucuronoarabinoxylan. Compared with AXE, sequence information on FAE and GE is rather limited (53). The catalytic modules of all FAEs are classified in the CE1 family (although seven subfamilies of FAE may be constructed [4]), all GEs are in the CE15, while AXEs are in the CE1, CE2, CE3, CE4, CE5, CE6, CE7, and CE12 families. CE2, CE3, and CE6 contain only AXE.

Being esterases, many AXEs and FAEs are believed to possess the canonical Ser-His-Asp catalytic triad as well as the "oxy anion hole" for their catalysis, similar to other esterases, lipases, or serine proteases. Some AXEs and FAEs may also use metal ions (e.g., Zn^{2+}) for their activity. Many FAEs are modular and contain CBM. Based on specificity, four types of FAE have been proposed. Type A FAEs (e.g., *A. niger* FAE-A) prefer to act on esters of methoxylated cinnamoyl; feruloyl α -Ara ester (at O5, but not O2; site in Ara) in xylan; feruloyl β -Gal ester in pectin; and 5,5'-diferuloyl esters. In contrast, type B FAEs (e.g., *A. niger* FAE-B) prefer to act on esters of hydroxylated cinnamoyl, feruloyl α -Ara ester (at both O2 and O5 sites) in both xylan and pectin, but not diferuloyl esters. Type C (e.g., *Sporotrichum thermophile* FAE-C) and type D (e.g., *Piromyces equi* FAE) FAEs can act on esters of both methoxylated and hydroxylated cinnamoyls, but only the latter type FAEs can act on diferuloyl esters (4, 91, 97). Although few FAEs have been thoroughly characterized, *Schizophyllum commune* PE

does not seem to be a serine type or metalloesterase (87). Based on cloned sequence, a few GEs have CBM (23).

Different AXEs, FAEs, and GEs may complement/supplement each other in attacking heterogeneously acetylated, feruloylated, or methyl esterified substrates. For FAEs, FAE-B would suit the need to hydrolyze dicots arabinans in which feruloyls esterify the O2 site of α -L-Ara units, and FAE-A or FAE-D would suit the need to hydrolyze 5,5'-diferuloyl esters. AXE or FAE can assist hemicellulases and/or cellulase, by deacetylating or lignin-delinking hemicelluloses in hydrolyzing complex plant cell wall substrates (30, 89). Other enzymes (including arabinase and α -L-arabinofuranosidase) can also assist AXE or FAE by generating shorter, less hindered oligomeric substrates for AXE or FAE (97). To hydrolyze feruloyl or diferuloyl esters in ferulated biomass feedstocks, FAE prefers collaboration from Xyn11 or Xyn10 xylanase, respectively (26). GE seems to have specificity different from those of AXE or FAE (87), and may assist α -glucuronidase by converting GlcU ester to GlcU. Given the heavy occurrence of acetylation of hardwood xylan and feruloyl esterification of arabinoxylan, AXE and FAE could be an important part, respectively, of enzyme systems targeting hardwood- and grass-derived biomass feedstocks.

For AXE, K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed for soluble substrates, but the kinetic parameters can vary in a range ($\sim 10^{-1}$ to 1 mM, ~ 10 to 10^2 s^{-1}). For FAE, K_m values on the order of 0.1 mM and k_{cat} values on the order of 10^3 s^{-1} are often observed, with a range of $\sim 10^{-2}$ to 10 mM and $\sim 10^{-1}$ to 10^4 s^{-1} , respectively. Kinetic data on GE are limited, but *S. commune* PE has a K_m of 0.3 mM and a k_{cat} of 3 s^{-1} on soluble, surrogate substrates (87). Many AXEs and FAEs are active at temperatures ranging from ~ 40 to 70°C , and pH values from ~ 4 to 8.

34.4. ACCESSORY ENZYMES, PROTEINS, AND OTHER SUBSTANCES

In Nature, biomass-active organisms often produce other types of enzymes or even noncatalytic proteins, often called "accessory enzymes or proteins," that may assist polysaccharide-degrading enzymes. These enzymes or proteins may exert their effects by degrading lignin, disrupting H-bonds in cellulose, preventing "nonproductive" enzyme adsorption by lignin, interacting with biomass-active enzymes, or functioning in mechanisms yet to be understood. These proteins are of interest, not only for the elucidation of natural biomass conversion processes, but also for the development of enzymes for bioenergy.

34.4.1. Expansin and Swollenin

Believed responsible for pH-dependent *in vivo* plant wall loosening, expansin is a group of plant proteins able to loosen, but not weaken, plant cell walls (18). Being apparently noncatalytic, expansin may disrupt noncovalent bonds among cell wall polysaccharides, leading to wall relaxation. Expansin has an N-terminal domain with a distant sequence homology to Cel45 EG, and a C-terminal domain homologous to grass pollen allergen. Among the four subfamilies of expansin, only the α -expansin and β -expansin subfamilies are known able to extend cell wall. While the diversity of natural plant expansins continues to be probed, microbial genes homologous to plant expansins have recently been found, and their recombinant protein products have plant cell wall-loosening activity (43). This opens a new venue for finding and characterizing new expansins.

Besides independent expansins, expansin-like modules are found in some microbial proteins, in particular, fungal swollenin. Swollenin is an extracellular protein known to be produced by several cellulolytic fungi, consisting of an expansin-like domain linked to a CBM and/or other modules often found in cellulases. It is reported that swollenin is able to disperse cellulosic cotton fiber, weaken filter paper, or disrupt *Valonia* cell walls, without releasing detectable reducing sugars (degradation products). No significant cellulase activity has been observed for swollenin, indicating a noncatalytic nature of the protein (104). Recently, an expansin-like module has also been found in a putative plant EG, suggesting possible interaction with EG activity (11).

The unique plant cell wall-loosening effect of expansin and swollenin makes the proteins interesting as potential contributors to the enzyme systems for bioenergy application. Indeed, a few studies showed the benefit of adding expansin or swollenin to cellulases for improved lignocellulose hydrolysis, an effect ascribed to the proteins' putative cellulose-disrupting action (18, 43). However, the generality and applicability of such enhancement from expansin or swollenin on biomass-active enzymes remain to be further investigated.

34.4.2. CBM

For modular biomass-active enzymes, CBM is the second most important module after the catalytic module. The amazing specificity, versatility, and efficiency of CBM can be demonstrated by the frequent occurrence in different enzymes of a same or highly homologous CBM linked to different catalytic modules, as well as different CBMs linked to a same or homologous catalytic module. CBM has a large natural diversity, with variable sequence, composition, size, or folding, leading to diverse affinities toward polysaccharides. Based on sequence homology, CBMs are classified into ~ 53 families (mostly fungal CBMs in CBM1). Based on their interaction with carbohydrate, CBMs can be divided into three general groups. The first group (exemplified by CBM1, CBM2, and CBM3) has planar surfaces with exposed aromatic residues (e.g., Phe, Tyr) suited for the binding of bundled polysaccharide chains (e.g., crystalline cellulose microfibrils), mainly via π -stacking between the aromatic residues and furan/pyranosyl units. The second type (exemplified by CBM4 and CBM6) has clefts with hidden aromatic residues suited for the binding of individual polysaccharide chains or oligosaccharides, similar to many glycoside hydrolases' catalytic modules. The third type (exemplified by CBM42) has pockets suited for the binding of small saccharides, similar to lectins. Many CBMs need Ca^{2+} for folding or carbohydrate binding. Different CBMs have different specificities. For instance, CBM1 and CBM49 prefer crystalline cellulose (but not chitin); CBM2 and CBM37 bind to cellulose, xylan, or chitin; CBM2–CBM5, CBM8–CBM10, CBM16, CBM17, CBM28, CBM30, CBM44, and CBM46 bind to amorphous cellulose; CBM4, CBM6, CBM11, CBM28, CBM39, CBM43, and CBM52 bind to β -glucan; CBM2, CBM6, CBM13, CBM15, CBM22, CBM31, and CBM35–CBM37 bind to xylan; CBM44 binds to xyloglucan; CBM32 binds to pectin; CBM16, CBM23, CBM27, and CBM29 bind to (gluco)mannan; CBM20, CBM21, CBM25, CBM26, CBM34, CBM41, CBM45, and CBM53 bind to starch; CBM41 binds to pullulan; CBM24 binds to α -glucan (mutan); CBM38 binds to inulin (a fructan); CBM2, CBM12, CBM14, CBM18, CBM33, CBM37, and CBM50 bind to chitin; CBM13 binds to Man; CBM33 and CBM51 bind to Gal; CBM42 binds to Ara; and CBM47

binds to Fuc. Most native CBMs are part of various biomass-active enzymes, but some exist as either independent binding proteins or as part of apparently noncatalytic proteins (32, 35, 84).

Two key native roles are postulated for CBM: anchoring enzymes to targeted carbohydrate substrates (and bringing catalytic modules to close proximity of substrates), and/or directing enzymes to specific regions in complex biomass substances (10). In addition, a xylan-specific CBM22 can stabilize a xylanase catalytic module against thermal inactivation (88). A few studies show that free CBM or noncatalytic CBM-containing proteins may even “directly” assist in the catalysis of a glycoside hydrolase (e.g., cellulase), under laboratory conditions, by physically modifying a polysaccharide substrate (e.g., disrupting crystalline cellulose microfibrils) so it becomes more reactive toward the enzyme (74). However, more comparative and systematic studies are needed to further validate and explore this intriguing CBM effect (96).

34.4.3. GH61, Cip, and HbpA

Among *H. jecorina*-secreted proteins, EG-IV is the product of one of three GH61 genes of the organism. Weak EG-like activity from wild-type and recombinant GH61s is reported in some studies, but not others (42, 46). All known GH61s are from cellulolytic fungi with one exception (a single GH61 gene in *Cryptococcus neoformans*), and some of them have CBM. *H. jecorina* GH61B has a fold and metal ion site similar to that of a chitin-binding protein (42). Although GH61 may be noncatalytic on many typical glycoside hydrolase substrates, a recent study showed for the first time that it can enhance the action of cellulases on lignocellulose (12).

H. jecorina secretes a Cip1 protein, consisting of a CBM and a “core” homologous to a putative *Streptomyces coelicolor* hydrolase, which has recently been reported to enhance cellulase activity either alone or together with GH61 and swollenin (B. R. Scott, C. Hill, J. Tomashek, and C. Liu, U.S. patent application 0,061,484). *H. jecorina* also secretes another CBM-bearing protein, Cip2, whose core is identified as a glucuronoyl esterase (53).

C. cellulovorans produces a noncatalytic cellulosomal protein, HbpA, which has a surface layer module and a cohesin. The protein may interact with two dockerin-bearing EGs, bind them to cell surface and to polysaccharides, and stimulate the EGs' hydrolysis of insoluble cellulosic substances (60).

34.4.4. Oxidoreductase

Many cellulolytic microbes (in particular, white and brown rots) secrete oxidoreductases, believed to be important for the organisms' degradation of lignaceous biomass. Lignin is a group of highly heterogeneous, branched, and recalcitrant aromatic polymers that cross-link to, entangle with, and shield hemicellulose or cellulose. Degradation of lignin is crucial for effective enzymatic hydrolysis of many biomass feedstocks, in terms of increased cellulose accessibility as well as decreased lignin inhibition for cellulase/hemicellulase. Natural microbial degradation of lignin involves phenol oxidase (laccase), peroxidase, or H₂O₂-generating carbohydrate/alcohol oxidoreductase, which attack lignin via high-valence oxidative species (52, 59). Laccase (EC 1.10.3.2), lignin peroxidase (EC 1.11.1.14), Mn peroxidase (EC 1.11.1.13), versatile peroxidase (EC 1.11.1.16), cellobiose dehydrogenase (EC 1.1.99.18), and various oxidases (e.g., aryl-alcohol oxidase, EC 1.1.3.7; glyoxal oxidase, EC 1.1.3.-) are of particular

interest as industrial delignifying enzymes and potential contributors to enzymatic systems for bioenergy. Comprehensive structural information on these oxidoreductases can be found in the Fungal Oxidative Lignin Enzymes (FOLY) database (52; <http://foly.esil.univ-mrs.fr/>).

Almost all of the known delignifying enzymes invoke highly reactive species to oxidatively degrade lignin. However, the oxidants may also oxidatively modify cellulose or hemicelluloses, leading to decreased enzyme digestibility (2; F. Xu, H. Ding, A. Tejirian, and J. Quinlan, presented at the 30th Symposium on Biotechnology for Fuels and Chemicals, 2008). Applying such enzymes may facilitate enzymatic biomass hydrolysis under certain conditions (47) but not under others (89); hence, more research is needed to evaluate both the positive and negative impacts from the oxidoreductases.

34.5. AMYLASES

Amylases are enzymes that hydrolyze starch comprising mainly linear amylose [$\alpha(1\rightarrow4)$ -linked D-Glc polymer] and branched amylopectin [$\alpha(1\rightarrow4, 1\rightarrow6)$ -linked D-Glc polymer]. In Nature, starch is degraded mainly by a combination of two types of hydrolases, endo-type (e.g., α -amylase) and exo-type (e.g., glucoamylase), with approximately 30 enzymatic specificities (58). In general, amylases are modular enzymes, with catalytic modules and CBMs belonging to eight GH and CBM families, respectively. Starch-binding CBMs are believed to enable amylase activity on raw starch granules, by increasing local amylase concentration on insoluble starch or even by disrupting surface starch structure (76). Because of their different molecular and enzymological properties (in particular, catalytic mechanism and substrate specificity), amylases can act synergistically on starchy substances. Industrial-scale starch hydrolysis (for bioethanol production) generally applies first α -amylase to fragment raw starch into soluble starch or dextrans (“liquefaction”), then glucoamylase and other amylolytic enzymes (e.g., α -amylase, isoamylase) to hydrolyze dextrans into Glc (“saccharification”). Amylolytic enzymes acting on $\alpha(1\rightarrow6)$ -bonds or branched segments in starch can assist the hydrolysis of the $\alpha(1\rightarrow4)$ -bond-specific amylases, leading to more effective starch conversion.

34.5.1. α -Amylases

α -Amylase (1,4- α -D-glucan glucanohydrolase, EC 3.2.1.1) is an endo-amylolytic enzyme that cleaves internal $\alpha(1\rightarrow4)$ -bonds in starch. The catalytic modules of the majority of α -amylases belong to the GH13 family, while those of some prokaryotic α -amylases belong to the GH57 family. The stereochemistry of α -amylases is of the retaining type. A minority (~10%) of α -amylases use one or more starch-binding CBMs (belonging to the CBM20, CBM21, CBM25, CBM26, CBM34, and CBM45 family, commonly linked to the C terminus of catalytic modules), prerequisite for amylase activity on raw starch (57, 58, 76). *Aspergillus oryzae* TAKA α -amylase and barley Amy1 are archetypical Amy13 α -amylases. Many α -amylases are Ca²⁺ dependent (for both activity and stability).

With soluble substrates, K_m values on the order of 1 mM and k_{cat} values on the order of 10² s⁻¹ are often observed for α -amylases, but the kinetic parameters can vary in a range (~10⁻² to 10 mM, ~10⁻¹ to 10³ s⁻¹). Insoluble (raw) starch granule, soluble amylose or maltodextrins, and soluble α -glucosides are commonly used to assay α -amylase, based on changes in viscosity, reducing sugar, dextrin distribution,

photometry, or other physicochemical properties. Many α -amylases show optimal activity around pH 3 to 10, and are active at temperatures ranging from ~ 30 to 80°C (hyperthermophilic α -amylases can extend their activity/stability above 100°C). In general, α -amylases may be inhibited by metal chelators such as EDTA, and some α -amylases may be inhibited by proteinaceous inhibitors, such as barley amylase/subtilisin inhibitor. Lacking a CBM may decrease the thermal stability of some α -amylases.

Although producing bioethanol from starch is a viable industry at present, continued optimizations, including that on enzymatic starch hydrolysis, are still of interest. For instance, better liquefying α -amylases are sought in terms of higher thermal activity and stability (which may be achieved with hyperthermophilic amylases), higher raw starch-binding and activity (which may be achieved with single or tandem CBM grafting), or lower dependence on Ca^{2+} concentration.

34.5.2. β -Amylase

β -Amylase (1,4- α -D-glucan maltohydrolase, EC 3.2.1.2) is an exo-amyolytic enzyme that cleaves the second $\alpha(1\rightarrow4)$ -bond at the nonreducing end of the amylose chain to produce maltose. β -Amylases have catalytic modules belonging to the GH14 family, and act under the inverting stereochemistry. Some bacterial β -amylases have starch-binding CBM (belonging to the CBM20 and CBM25 families). *Bacillus cereus* and soybean β -amylases are archetypical. With soluble substrates, K_m values on the order of 1 mM and k_{cat} values on the order of 10^3 s^{-1} are often observed for β -amylases, but the kinetic parameters can vary ($\sim 10^{-2}$ to 10 mM, $\sim 10^{-1}$ to 10^4 s^{-1}). Many β -amylases are active at temperatures ranging from ~ 30 to 80°C and pH values ranging from 4 to 8.

34.5.3. Glucoamylase and α -Glucosidase

Glucoamylase (1,4- α -D-glucan glucohydrolase or amyloglucosidase, EC 3.2.1.3) is an exo-amyolytic enzyme that cleaves Glc from the nonreducing end of an α -glucan chain. The enzyme's catalytic module belongs to the GH15 family, and the enzyme acts under the inverting stereochemistry. Some fungal glucoamylases have starch-binding CBM (belonging to the CBM20 and CBM21 families). *Aspergillus awamori* glucoamylase is archetypical.

α -Glucosidase (α -D-glucoside glucohydrolase or maltase, EC 3.2.1.20) is another exo-amyolytic enzyme that cleaves Glc from the nonreducing end of α -glucooligosaccharides. α -Glucosidases have catalytic modules belonging to the GH4, GH13, GH31, GH63, and GH97 families. GH63 and part of GH97 α -glucosidases have the inverting stereochemistry, while GH4, GH13, GH31, and the other part of GH97 α -glucosidases have the retaining stereochemistry. Unlike other α -glucosidases, GH4 α -glucosidases are expected to use NAD^+ cofactor in a redox mechanism (107). Some glucoamylases have starch-binding CBM (belonging to the CBM20 and CBM21 families). *A. awamori* glucoamylase is archetypical.

Although both glucoamylase and α -glucosidase are exo-amylases, there are differences between the two types of enzymes (93). In general, glucoamylases prefer starch (with relatively low k_{cat} and high K_m on maltose, but high k_{cat} and low K_m on maltotetraose, longer maltodextrins, or starch), while α -glucosidases prefer maltodextrins (with approximately the same k_{cat} on maltotetraose and longer maltodextrins, but higher K_m on longer maltodextrins), although a few α -glucosidases may act on raw starch granules.

K_m values on the order of 10 mM and k_{cat} values on the order of 10^2 s^{-1} are common for glucoamylases and α -glucosidases, although the kinetic parameters can vary ($\sim 10^{-3}$ to 10^2 mM , $\sim 10^{-1}$ to 10^3 s^{-1}). Many glucoamylases and α -glucosidases are active at pH values ranging from 3 to 8 under temperatures ranging from ~ 20 to 80°C .

34.5.4. Pullulanase and Isoamylase

Pullulanase (pullulan α -1,6-glucohydrolase, EC 3.2.1.41) is a "debranching" amyolytic enzyme that cleaves $\alpha(1\rightarrow6)$ -bonds in amylopectin, glycogen, pullulan ($\alpha(1\rightarrow6)$ -linked maltotriosyl polymer), or branched dextrans. The catalytic modules of pullulanases belong to the GH13, GH49, and GH57 families. The stereochemistry of GH13 and GH57 pullulanases is retaining, while that of GH49 pullulanases is inverting. Some pullulanases have CBM (belonging to the CBM20 and CBM41 families).

Isoamylase (glycogen α -1,6-glucohydrolase, EC 3.2.1.68) is another debranching amyolytic enzyme that cleaves $\alpha(1\rightarrow6)$ -bonds in amylopectin or glycogen. The catalytic modules of isoamylases belong to the GH13 family, with a retaining stereochemistry.

Although both pullulanase and isoamylase cleave $\alpha(1\rightarrow6)$ -bonds, there are differences between the two types of enzymes. Isoamylases act on amylopectin (starch) and glycogen, but not pullulan, while pullulanases act on all three α -glucans. For amylopectin and glycogen, isoamylases can cleave both inner and outer $\alpha(1\rightarrow6)$ -bonds, but pullulanases prefer those near the ends of α -glucan chains.

K_m values on the order of 1 mM and k_{cat} values on the order of 10^2 s^{-1} are often observed for pullulanases, but the kinetic parameters can vary in a range ($\sim 10^{-2}$ to 1 mM, $\sim 10^2$ to 10^3 s^{-1}). Many pullulanases are active at temperatures ranging from ~ 40 to 90°C (but hyperthermophilic pullulanases can retain activity above 100°C), and pH values ranging from ~ 5 to 9. K_m values on the order of 10^{-4} mM and k_{cat} values on the order of 10^2 s^{-1} are often observed for isoamylases, with a range of $\sim 10^{-4}$ to 10^{-2} mM and ~ 1 to 10^2 s^{-1} , respectively. Many isoamylases are active at temperatures ranging from ~ 30 to 60°C , and pHs ranging from ~ 3 to 9.

Pullulanase and isoamylase may, through their specificity on $\alpha(1\rightarrow6)$ -bonds, act synergistically with $\alpha(1\rightarrow4)$ -bond-specific amylases in hydrolyzing starch, making them important components of efficient enzymatic starch hydrolysis systems. At high starch consistency, the transglycosylase side activity of pullulanase and isoamylase may become significant enough to negatively impact the starch-to-Glc hydrolysis.

34.5.5. α -Glucan Lyase

1,4- α -Glucan lyase (1,4- α -D-glucan exo-4-lyase [1,5-anhydro-D-fructose-forming], EC 4.2.2.13) cleaves internal $\alpha(1\rightarrow4)$ -bonds in linear α -glucan by β -elimination. Such lyases are classified to the GH31 family. The glucan lyase is specific to $\alpha(1\rightarrow4)$ -glycosidic bonds, acts on the nonreducing end of an α -glucan chain, prefers maltodextrins or α -glucan over simple α -glucosides, and has high affinity to starch despite lacking a distinct CBM (51).

For α -glucan lyase, K_m values on the order of 1 mM and k_{cat} values on the order of 10 s^{-1} are often observed for soluble substrates, but the kinetic parameters can vary ($\sim 10^{-1}$ to 10 mM, ~ 1 to 10^2 s^{-1}). Many α -glucan lyases are active in the temperature range of ~ 30 to 50°C and pH range of 3 to 7.

Compared with polygalacturonan lyases, α -glucan lyase has a different mechanism and produces a different product. Polygalacturonan lyase cleaves the bond between glycosidic O and C4, and the β -elimination results in a Δ 4:5-unsaturated GalU moiety. α -Glucan lyase cleaves the bond between anomeric C1 and glycosidic O, and the β -elimination results in a Δ 1:2 unsaturated Glc moiety, which rearranges into a 1,5-anhydro-D-Fru (51).

34.6. ONGOING DEVELOPMENTS AND FUTURE PROSPECTS OF BIOENERGY ENZYMES

Increasingly intensive research is being conducted to understand natural conversion of energy-storing polysaccharides into fermentable carbohydrates, and to discover and improve enzymes for industrial conversion of such polysaccharides from various biomass feedstocks (24, 56, 99). Current strategies include engineering known enzymes (for better specificity, activity, or stability), searching for carbohydrate-active enzymes that can work at elevated temperature (to benefit from potential thermal acceleration on biomass hydrolysis), and exploring synergistic enzyme mixtures (with lowered overall dosage).

34.6.1. Protein Engineering of Biomass-Active Enzymes

Among the bioenergy enzymes actively under study, cellulases have attracted, and will continue to attract, the most attention because of the significance of converting cellulose to Glc in the development of cellulosic biofuels. The increase in solved three-dimensional cellulase structures and decoded cellulase genes has propelled rapid progress in site-directed mutagenesis, directed evolution, module or domain grafting, and other genetic/protein engineering of cellulases. Many variants of CBH, EG, or BG have been constructed and characterized for improved kinetic or thermal properties. Hemicellulases with improved activities and CBMs with improved or altered specificity have also been studied by various protein engineering methods (29).

Of many improvements on cellulases, enhanced thermal activity and stability are particularly desirable. Two approaches are currently being taken: engineering known but mesophilic cellulases, or finding new thermophilic wild-type cellulases. New cellulases and hemicellulases with enhanced specificity, shifted pH optimum, or increased inhibition resilience are of interest as well.

Constructing designer carbohydrate-active enzymes with selected catalytic modules, CBMs, dockerins, or other modules may result in novel and/or desired functionalities. Hybrid cellulases may have additional copies of a native module or nonnative modules, so as to multiply a native or possess a nonnative but beneficial functionality. Some fusion proteins bring a cellulase at close vicinity with its collaborative partner enzyme (e.g., CBH-EG fusion, cellulase-feruloyl esterase) or accessory protein (e.g., cellulase-expansin, feruloyl esterase-swollenin, cellulase-protease inhibitor fusions), potentially beneficial for not only hydrolysis but also control of enzyme stoichiometry. Some chimeras may have a dockerin linked to a native cellulase or other enzymes to allow their incorporation, along with synergistic partner enzymes, into a tailor-made cellulosome (14). CBM may be engineered for nonnative specificity (29). Optimal combination of the selected modules/enzymes may be achieved by careful selection of linkers (rigidity and length), dockerin-cohesion pairs, or scaffoldins (hosting capacity, cell binding, and substrate

binding), although the art is far from perfection. Biomass-active enzymes may even be planted on a surface of selected microbes, via interactions such as that from bacterial S-layer proteins, to facilitate combined reactions or recovery.

34.6.2. Synergistic and Novel Multienzyme Systems

It is believed that a minimal complete cellulase mixture needs four interdependent and/or complementary enzymes: one CBH-I, one CBH-II, one EG, and one BG. In general, cellulolytic organisms have far more than four cellulase genes, and produce more than four cellulases. Multiple enzymes often exist for one basic type of cellulase action (e.g., EG catalysis) in natural cellulase mixtures. Because the cellulase compositions produced by laboratory-grown microbes may well not be optimal with regard to industry-relevant biomass substrates and hydrolysis conditions, they often need to be supplemented for one or more components (99), or complemented with other enzymes that may assist the cellulases and/or convert noncellulose parts of the feedstocks (3, 27, 30, 73, 78, 81, 89). Similar to the case of cellulases, complete hemicellulase mixtures for hydrolyzing hemicelluloses, as well as needs for supplementing/complementing them for improved hydrolysis, also exist (86). Seeking the best stoichiometry and synergism among different cellulases, hemicellulases, other enzymes, or accessory proteins is vital for the development of bioenergy enzymes.

New structural and enzymological studies are expanding or even challenging our current beliefs. For instance, there might be a third type of natural cellulose degradation relying on nonprocessive, noncellulosomal cellulases to fragment cellulose, cellular import of cellodextrins, and intracellular cellodextrin degradation, a process fundamentally different from the two conventional degradations relying on mixtures of dissociated CBH, EG, and BG or on cellulosomes (96). We are in an early stage in the investigation of noncatalytic proteins, coproduced along with biomass-active enzymes by many cellulolytic microbes, about their *in vivo* function and potential accessory role in enzyme systems for bioenergy (24). The cellulolytic machinery of brown rots is also of interest, because, in addition to hydrolases and hydrolysis, the organisms apparently use oxidoreductases and redox or radical chemistry (59, 95), which might complement bioenergy enzymes produced by cellulolytic organisms.

Robert L. Starnes, Paul Harris, and Claus C. Fuglsang from Novozymes provided critical suggestions.

The Use of Enzymes for Nonaqueous Organic Transformations

ELTON P. HUDSON, MICHAEL J. LISZKA, AND DOUGLAS S. CLARK

35

The use of enzymes in organic synthesis is becoming an increasingly attractive alternative to traditional chemical routes (39). This chapter focuses on synthetic applications of enzymes in monophasic organic solvents and is intended to illustrate many types of transformations that can be catalyzed by enzymes in organic solvents. Methods to prepare the biocatalyst for optimal activity or stability are also presented, noting that enzymes in organic solvents are the subject of recent monographs and reviews (16, 30). The following section surveys techniques used to prepare and activate enzymes for use in organic solvents.

35.1. PREPARATION OF ENZYMES FOR NONAQUEOUS BIOCATALYSIS

Nonaqueous enzyme systems can be divided into two classes: homogeneous systems in which enzymes are modified to be soluble, and heterogeneous systems in which the catalyst is in an insoluble form. The bulk of the reaction mixture can be a liquid, gas, or supercritical fluid. Heuristics for choosing an appropriate preparation have been developed based on the combination of enzyme and solvent (12, 66). Several types of enzyme preparations are illustrated in Fig. 1.

Although many enzymes remain active in a variety of low-water organic systems, when used as unmodified and insoluble powders (commonly referred to as “as received”) they usually exhibit activities that are orders of magnitude lower than in aqueous solutions. The low activity in organic solvents has been attributed to a number of factors, including a decrease in the enzyme’s active-site polarity, a loss of conformational mobility, and structural changes during freeze-drying of the biocatalyst. Fortunately, there are well-documented methods to activate enzymes relative to their as-received form and frequently these methodologies are simple to implement. However, in some cases the activation technique can alter an enzyme’s reactive properties. A notable example of this comes from Altreuter et al. (5), who found that two preparations of subtilisin, lyophilized with nonbuffer salts and solubilized with a surfactant, exhibited different regioselectivities toward reactive hydroxyl groups of the chemotherapeutic doxorubicin (Fig. 2). This unexpected regioselectivity was recently exploited in generating a library of new doxorubicin analogs (26).

35.1.1. Heterogeneous Preparations

Enzymes are routinely obtained commercially as purified powders or immobilized on an inert support. Solid catalyst preparations have the advantage of easy recoverability for reuse and are often more stable than their soluble counterparts. In the case of enzyme powders, a contributing factor to the low reaction rates observed in organic solvents can be that the powder has been formulated from an aqueous solution at a pH different than the enzyme’s optimal pH. Therefore, a typical first step in using enzyme powders is resuspension and freeze-drying (lyophilization) from an aqueous buffer at the optimal pH (144). Further adjustment of the reaction rate can be made through water control, or by doping in small amounts of typically denaturing organic solvents (4). Diffusional limitations may also be an important consideration, although, in at least one case, they were ruled out as a factor affecting overall reaction rates (8). However, the adjustments due to water and pH are often overshadowed by the activation afforded by many of the preparation methods described below.

35.1.1.1. Immobilization

A common form of biocatalyst for use in organic solvents is immobilized on a solid support, either through covalent attachment or adsorption. Most often the enzyme is attached to the support in aqueous solution, and a wealth of literature exists on attachment chemistries and adsorption conditions (for an early but thorough review, see reference 69). Common supports to which enzymes can be covalently attached (usually through amino groups) include activated resins, coated glass, or zeolites. In some cases covalent attachment of enzymes to solid supports can increase both the thermal and solvent stability, and immobilized enzymes often have longer half-lives than their suspended counterparts (17, 19). For example, cutinase immobilized onto an NaY (Faujasite) zeolite showed very little loss in activity after incubation in isooctane for 45 days (42). Among many other examples, subtilisin and thermolysin exhibited increased thermal and solvent stability over aqueous and commercially available immobilized forms when covalently attached to an acrylic support through a polyethylene linker (141).

Popular supports for noncovalent immobilization in organic solvents include porous glass beads and fumed silica, which can be impregnated through saturation with an aqueous enzyme solution and subsequent washings to

FIGURE 1 Enzyme preparations used in organic solvents. (A) Lyophilized powder. (B) Immobilized enzymes (left to right): single-point covalent attachment, multipoint covalent attachment, and physisorption. (C) Directly solubilized as a cluster via a surfactant. (D) Colyophilized powder containing an excipient. (E) Covalently modified with PEG. (F) Reverse micelle encapsulation with retained water. (G) Surfactant-paired, extracted single-enzyme molecules.

remove nonadsorbed enzyme. Other commercially available resins can serve as ion exchangers for enzymes, in which adsorption is due to strong ionic interactions. Upon enzyme deactivation, these catalysts can be cleansed with solutions of high ionic strength and regenerated. When choosing an immobilization support, it is important to note that the ionization state of both the enzyme *and* the support contribute to the activity of the catalyst (145). In addition, the scale of the material's morphology relative to the enzyme's size may also influence activity. For example, Takahashi et al. (125) investigated the effect of pore size on the activity of horseradish peroxidase adsorbed onto mesoporous silica and found that the highest activity was achieved in materials with a pore size slightly larger than the enzyme diameter. Other nanoscale materials, such as single-walled carbon nanotubes or nanoparticles, have been shown to impart increased thermal and solvent stability (7, 60).

FIGURE 2 Doxorubicin derivatives generated with solubilized and salt-activated lipase and subtilisin preparations. All preparations could acylate the 14-O hydroxyl of doxorubicin (black arrow) in toluene, but only salt-activated subtilisin Carlsberg could modify the amino and hydroxyl groups indicated by the white arrows (5).

35.1.1.2. Lyophilization with Excipients

Colyophilisates for use with enzymes in organic solvents can be categorized according to three primary acting mechanisms: activating salts, molecular imprinting agents/molds, and lyoprotectants. Each of these groups affects the activity and structure of the enzyme in different ways, and the entangled effects can be difficult to separate.

Salt activation has yielded some of the largest improvements in enzyme activity in organic solvents, up to a 35,000-fold increase (78). Serdakowski and Dordick (115) recently reviewed colyophilized enzyme preparations, with a focus on salt activation. The current hypothesis is that chaotropic and kosmotropic ions order water differently around the enzyme. Both the activity of salt-lyophilized enzymes and the amount of bound water were reported to increase with the kosmotropicity of the salt (110). Deuterium nuclear magnetic resonance studies on the dynamics of water in salt-activated formulations revealed that activity also increases as the mobility of the bound water increases (38).

Recognizing that enzymes are more static in organic solvents, colyophilizing enzymes with ligands or transition state analogs can activate them by "freezing" the enzyme into an active conformation (70). Such imprinted catalysts are created by adding a small amount of ligand to an aqueous enzyme solution, freeze-drying, and washing the resulting powder with an anhydrous solvent to remove the bound ligand (111). Molecular imprinting has more recently found use in nonbiological catalysts, where functional groups are incorporated into a polymer and the system is cured/cross-linked with a ligand present (76).

Other molecules, such as crown ethers (132), sugars, and polymers, are collectively referred to as lyoprotectants (28). Associated with the work by Hofmeister on salt stabilization, these molecules are believed to prevent the enzyme from deactivating during the freeze-drying process by increasing the free energy of transfer of hydrophobic residues.

35.1.1.3. Cross-Linked Enzyme Crystals/Aggregates (CLECs/CLEAs)

Cross-linking of enzymes was originally used for diffraction measurements because cross-linked crystals were found to have similar cell dimensions but improved mechanical stability compared with non-cross-linked protein crystals (104). After an enzyme is crystallized, the crystal is treated with a difunctional cross-linking agent, typically gluteraldehyde. Cross-linked enzyme crystals, or CLECS, have since gained favor as biocatalysts for nonaqueous reactions. Cross-linked subtilisin was shown to be more stable against inactivation in organic solvents; in octane and acetonitrile the half-life of subtilisin was extended 40- and 90-fold, respectively, relative to suspended powders.

Whereas cross-linked crystals exhibit increased stability, their preparation is time-consuming and requires highly pure enzymes. To remedy this, Sheldon et al. (117) developed a procedure where enzymes are instead precipitated first from solution and then cross-linked. Any common precipitant, such as sulfate salts or polymers, may be used providing the enzyme retains an active conformation prior to cross-linking.

35.1.2. Homogeneous Preparations

35.1.2.1. Covalent Modification

Solubilizing enzymes can increase their specific activity over suspended powders (136), but reduces the possibility of recovery and reuse. To this end, a wide array of molecules can be coupled to the surface groups displayed on a protein. Amines, carboxylic acids, and thiols are the most readily available for modification, with amines being the most utilized. Amphiphiles or polyelectrolytes can be attached to provide a variety of functionality, including increased solubility, selective partitioning, or ionic adsorption for immobilization.

Inada et al. (58) introduced a method of creating highly soluble enzymes by polyethylene glycol (PEG) modification, and covalent attachment of PEG has become a common method for solubilizing enzymes in organic solvents. PEG is first functionalized for specific chemistry or multiple attachments, and then coupled to an exposed protein residue. An extensive review of the possible attachment chemistries is provided by Veronese (133). Most reactions can be performed under mild aqueous conditions, and the modified enzyme is purified by repeated dialysis. Purified PEGylated proteins are then lyophilized and dissolved in the solvent of choice. The degree of modification can be adjusted by changing the length of the polymer or the molar ratio of protein to activated PEG. Lipase and chymotrypsin have both shown improvement in activity in a range of solvents because of PEG modification (18, 58). Castillo et al. (20) studied the effect of PEG-modified subtilisin in dioxane, and found that, as the amount of PEG attached to the enzyme increased, both the dynamics (measured by H/D exchange) and the activity increased. When the number of modifiable functional groups is either too high or too low, mutagenesis can be used to remove or add suitable residues.

35.1.2.2. Noncovalent Modification

Surfactants can be used to extract enzymes into organic solvents with highly varying amounts of water and thus highly varying properties. Reverse micelles can segregate a near-native enzyme from the solvent and contain "pools" of water with bulk-like properties. At the other extreme, reverse micelles can be dehydrated to the point of including only

structured or enzyme-bound water molecules. At very low surfactant concentrations, the enzyme is directly exposed to the solvent and even less water may be present.

Reverse micelles can form stable microemulsions containing water in millimolar or lower concentrations. A reverse-micelle system is prepared by liquid-liquid extraction of an aqueous enzyme solution with an organic phase containing surfactant. This can typically be accomplished by vigorously mixing the two phases together. In these systems, the amount of water included with the enzyme in the organic phase can be modified by direct addition of water or through techniques discussed in the next section.

The use of surfactants at amounts below the critical micelle concentration solubilizes enzymes without forming reverse micelles. By modulating the surfactant and solvent properties, nearly all of the enzyme in the aqueous phase can be extracted to the organic phase. Paradkar et al. (97) used low concentrations of dioctyl sodium sulfosuccinate (AOT) (2 mM) to extract 93% of aqueous chymotrypsin into isoctane. Hobbs et al. (52) paired a fluorinated surfactant with a fluorinated solvent to extract greater than 99% of aqueous cytochrome *c* into the organic phase. Lipase PS (Amano Pharm. Ltd.) paired with a nonionic surfactant provided the greatest activation versus either cationic or anionic surfactants (95).

So-called "direct solubilization" of enzyme suspensions was shown to yield highly active, soluble aggregates. In this system, the enzyme powder was added directly to a solvent containing a small amount of surfactant and water. Directly solubilized subtilisin was ca. 70 times more active in tetrahydrofuran (THF) than either the extracted or suspended enzyme system. A similar trend was found for isoctane with a 25-fold increase over the extracted enzyme (3).

35.1.3. Other Considerations

35.1.3.1. Water Control

One of the simplest methods for manipulating reaction rates of enzymes in organic solvents is to control the amount of water present in the system. Water content can be controlled through established techniques of using salt hydrates or saturated salt solutions (72, 142). The water content of a nonpolar organic solvent can be adjusted by mixing the solvent with a salt hydrate. The other components of the system, as well as polar organic solvents, can be equilibrated to a desired water content by exposing them indirectly to a saturated salt solution. In situ control can be achieved by including salt hydrates directly in the reaction mixture to act as a source or sink of water. Care is required when selecting which salt pair to use, because both the cation and anion have been shown to affect the reaction independently (142).

35.1.3.2. pH

Early studies revealed that the pH of the aqueous solution during extraction or lyophilization can have a dramatic effect on the enzyme activity in the organic phase. This "pH memory" usually leads to the same bell-shaped dependence of the activity on transfer pH in the organic phase as in the aqueous phase. An interesting exception to this trend was reported for liver alcohol dehydrogenase, where the pH optimum in heptane was 2.0, far from the aqueous optimum of 7.5 (47). Buffer salts can be used as solid-state pH buffers for control of protonation states of the enzyme in organic solvents, similar to in aqueous solutions. Partridge et al. (98) showed that zwitterionic salts can be used to actively control

the protonation state of the protein, and to remove acidic or basic by-products that can inhibit the reaction. Zwitterionic salts were preferred because they have a lower tendency to dissolve (by remaining charged), and they are able to act as both an acid and a base.

35.1.3.3. Solvent Effects

Thermal stability, catalytic activity, and selectivity in many organic-phase enzyme systems are strongly affected by the solvent, and the literature on solvent effects is large and expanding (54, 115). Numerous recent experimental and

molecular simulation studies demonstrate negative solvent effects on enzyme properties thought to be critical to catalysis: loss of protein secondary structure (18, 45, 140), a decrease in active-site polarity (116), and reduced protein dynamics (37, 53, 84). The confluence of these effects can cause enzyme half-life (136), enantioselectivity (40), and catalytic activity (114) to vary by orders of magnitude between solvents.

Many studies have attempted to relate selectivity and catalytic activity to simple solvent properties such as hydrophobicity, polarizability, and size (see references 9

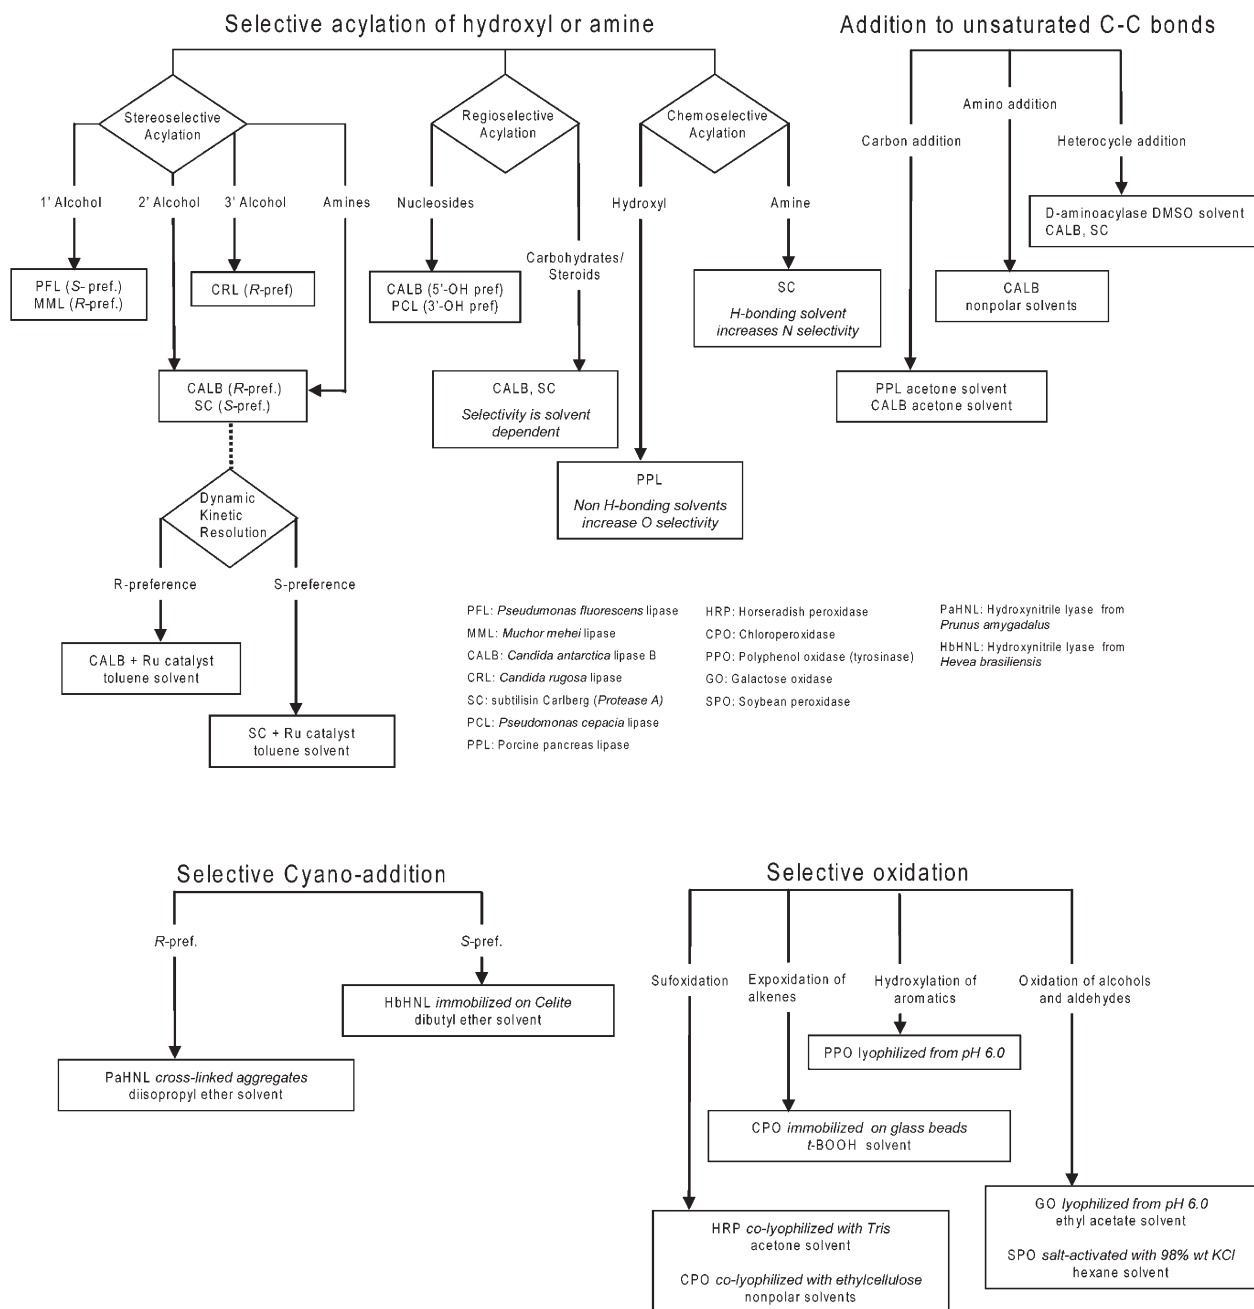

FIGURE 3 Recommended enzymes for catalyzing various reactions in organic solvents. The recommended systems are those shown to give the best performance for a certain reaction (high enzyme stability, reactivity, and selectivity) based on the literature cited in this chapter.

and 14 for recent reviews). Some heuristics are available, which are demonstrated mostly with proteases and lipases. In general, these enzymes are more thermally stable, enantioselective, and catalytically active in nonpolar solvents such as hexane than in polar solvents such as THF or acetone (73). The low dielectric environment provided by nonpolar solvents restricts enzyme conformational dynamics, preventing unfolding (143) and locking the active site into a specific conformation (106). Several recent reports present inverse correlations between protein flexibility and stability (96, 109) as well as flexibility and enantioselectivity (20). In polar solvents, enzyme-bound water molecules are stripped from the protein surface (43), and the resulting solvent-protein interactions alter enzyme structure (53, 136), reducing stability and catalytic activity relative to nonpolar solvents. As mentioned previously, the addition of water can alleviate these effects (2, 114), and can drastically increase enzyme activity, in particular, in polar solvents (101). The previously mentioned activation techniques, such as covalent modification or salt activation, can increase enzyme activity and allow the choice of solvent to be dictated more by substrate solubility than enzyme behavior.

35.2. SYNTHETIC APPLICATIONS OF ENZYMES IN NONAQUEOUS SOLVENTS

This section summarizes many applications of enzymes in organic solvents, with focus placed on three classes of enzymes that have found a wide measure of use in organic solvents: hydrolases (EC 3), lyases (EC 4), and oxidoreductases (EC 1). Seminal examples illustrate the types of transformations that enzymes can catalyze in organic solvents, and when an enzyme may be preferred over a traditional chemical method. Often the particular desired reaction is identified and several possible enzymes are tested for the proper reactivity (see Fig. 3). After finding an enzyme that catalyzes the desired reaction, its reactivity can be increased (or diversified) using the preparation techniques discussed in section 35.1.

35.2.1. Hydrolases

Hydrolase enzymes (EC 3) comprise the predominant biocatalysts for transformations reported in organic solvents, and two groups, lipases and proteases, enjoy widespread use. Hydrolases have traditionally been used to catalyze selective acylations of alcohols and amines using a variety of acyl donors and solvents. Their selectivities have been exploited in kinetic resolution of racemic mixtures (15), combinatorial lead optimization (90), and organic-phase peptide synthesis (80). It has been shown that wild-type proteases and lipases retain their ping-pong mechanisms in organic solvents, and in some cases individual rate constants have been determined (21, 55, 62).

Many hydrolases are available commercially as freeze-dried powders or as specialized preparations, such as immobilized on acrylic resin (Novozyme 435), polypropylene (Accurel), glass beads, or cellulose; or as CLEAs or CLECs. These preparations can be very robust, exhibiting half-lives up to hundreds of hours in a range of organic solvents, even when used as received. The most common lipases used in organic solvents are from *Candida antarctica* (CALB), porcine pancreas (PPL), *Pseudomonas* spp. (PCL and PFL), and *Mucor* spp. (MML and MJL). Commonly used proteases in organic solvents are subtilisins from *Bacillus* spp. (subtilisin Carlsberg and subtilisin BPN'), penicillin

FIGURE 4 A simple scheme for the hydrolase-catalyzed resolution of an alcohol. Vinyl acetate is a common acyl donor in alcohol resolutions. Upon enzyme acylation by vinyl acetate, vinyl alcohol is released, which rapidly tautomerizes to the nonnucleophilic acetaldehyde. The acyl-enzyme intermediate is then attacked preferentially by the (R)- or (S)-alcohol enantiomer.

amidase from *Escherichia coli*, and α -chymotrypsin from bovine pancreas. Appreciable conversions are often achieved for model reactions in a few hours by use of biocatalyst concentrations of 5 to 10 mg/ml, although this heuristic will depend on the specific activity of the enzyme preparation and the solvent used.

35.2.1.1. Enantioselective Resolution of Racemic Alcohols and Amines

In kinetic resolutions the hydrolase enzyme reacts preferentially with one enantiomer, (R)- or (S)-, of a racemic substrate mixture. Figure 4 shows a typical reaction scheme. The enzyme is first acylated by an acyl donor (vinyl acetate is common because of its nonnucleophilic product, acetaldehyde [134]). The acyl-enzyme complex is then attacked preferentially by the (R)- or (S)-alcohol or amine enantiomer. The acylated product can be separated from the solution via chromatography or extraction, enabling resolution of polyfunctionalized alcohols or amines on large scales. For example, Feng and coworkers recently demonstrated the large-scale CALB-catalyzed resolution of several racemic alkyl alcohols with vinyl acetate and succinic anhydride, producing 2.0 g of (S)-2-pentanol at 99% enantiomeric excess (ee %) (135).

An enzyme's enantioselectivity, E , is commonly expressed as the ratio of k_{cat}/K_m for one enantiomer over the other (equation 1). Enantioselectivity is related to the product's enantiomeric excess ee and substrate conversion c (equations 2 and 3), where R and S are the concentrations of (R)- and (S)-forms of the product at a given substrate conversion c . For example, if $E = 60$, the $ee_{product} = 98\%$ at 30% substrate conversion. Enantioselectivities for hydrolases in organic solvent range from $E = 1$ for a nonselective process to $E = 400$, but typically fall in the range of 30 to 200. For one-step resolutions, $E = 100$ is a typical benchmark.

$$E = \frac{\left(\frac{k_{cat}}{K_m}\right)_R}{\left(\frac{k_{cat}}{K_m}\right)_S} \quad (1)$$

$$ee_R (\%) = \left(\frac{R - S}{R + S}\right) * 100 \quad (2)$$

$$E = \frac{\ln [1 - c(1 + ee_{product})]}{\ln [1 - c(1 - ee_{product})]} \quad (3)$$

FIGURE 5 These *rac*-alcohols were resolved enantioselectively [(*R*)-preference] by acylation with vinyl acetate in diisopropyl ether by three lipases. *E* values are for CALB. Adapted from reference 135.

35.2.1.1.1. Alcohols

Hydrolases display the greatest enantioselectivity for secondary alcohols (often $E > 100$). Resolutions of primary alcohols typically exhibit lower *E* values (often $E < 10$). Resolution of tertiary alcohols is rare. Figure 5 presents a sampling of secondary alcohols that can be resolved with high selectivity (135). In general, increasing the chain length of the acyl donor (Fig. 6) and addition of bulky substituents to the acyl acceptor (Fig. 7) (88) can increase lipase enantioselectivities by exacerbating discriminatory steric constraints.

Molecular modeling studies of enzyme-substrate interactions have been used to rationalize observed enantioselectivities for certain racemic substrates (61, 77, 102), as well as regioselectivities for acylations of sugars (105) and nucleosides (74). Molecular modeling can help predict which enzyme will display the highest *E* for a given transformation and can also provide guidance into the rational design of enzymes with new reactivities. In one striking example, CALB was rationally redesigned to exhibit inverted enantioselectivity in a variety of organic solvents (81).

For resolution of secondary alcohols it is known that most lipases react preferentially with the (*R*)-enantiomer [(*R*)-preference] (64), while proteases such as subtilisin BPN' and Carlsberg exhibit (*S*)-preference (10) (Fig. 8). This trend is not applicable to the resolution of primary alcohols (126); for example, the lipase PCL shows opposite preference (*S*-) when acting on primary alcohols (128).

FIGURE 7 To facilitate resolution of *rac*-cyclo-hexenol, the bulky benzylthiol was added. After resolution by CALB in diisopropyl ether (di-IPE), the benzylthiol was removed. Adapted from reference 88.

FIGURE 6 Increasing the chain length of acyl donor increased *E* from 33 to 65 in the subtilisin Carlsberg-catalyzed acylation of 1-phenyl ethanol in THF. Adapted from reference 10.

Enantioselectivities of hydrolases toward primary alcohols are typically lower than those observed for secondary alcohols. This is particularly true for simple methyl alkanols, where enantioselectivities were low ($2 < E < 10$) for the lipases PFL and PCL in chloroform (93). PFL- and PCL-catalyzed resolution of primary alcohols with larger substituents such as phenyl rings exhibited enantioselectivities that are an order of magnitude higher ($E > 100$) (94).

There are presently very few examples of hydrolase-catalyzed resolutions of tertiary alcohols. The inability of lipases to accept tertiary alcohols is due to steric exclusion of the substrate from the enzyme's active site. In a recent study, 25 commercial lipases were screened for the ability to hydrolyze several acylated *tert*-alcohols. Only *Candida rugosa* lipase (CRL) and *C. antarctica* lipase A (CALA) were reactive toward the substrates (51). A unique flexible loop in the active site of CRL (the crystal structure of CALA has not been solved) allows the enzyme to accommodate bulkier substrates. Recent work has shown that binding-site mutations can enable esterases and proteases to accept tertiary alcohols, but these studies have been limited to aqueous/organic mixtures (50).

It is also noteworthy that hydrolases can resolve racemic substrates with stereocenters far from the reactive OH moiety, although with less fidelity (93). It may therefore be necessary to use multiple enzymes to obtain satisfactory enantiomeric excess. Figure 9 shows a primary alcohol with a stereocenter three carbon atoms removed from the hydroxyl group. This substrate was resolved with two lipases in multiple steps, yielding high enantiomeric excess ($ee > 98\%$) (113). When each lipase was used individually, ee_{product} was less than 60%.

35.2.1.1.2. Amines

Hydrolases have been used to resolve alkyl and aryl amines in a manner similar to that of alcohols, and these reactions have been reviewed recently (131). The preferential enantioselectivity of lipases and proteases follows the same

FIGURE 8 Due to different active-site geometries, lipases and proteases show opposite enantioselectivity in the resolution of *rac*-secondary alcohols if the substituents differ in size (64).

trend as with secondary alcohols [most lipases show (*R*)-preference and most proteases show (*S*)-preference]. As observed with alcohols, increasing the size of the substituent can substantially increase *E* (Fig. 10). Amines are more susceptible to noncatalyzed (and nonselective) acylation than alcohols, and this spontaneous reaction occurs faster in nonpolar solvents. Therefore, special care should be taken in choosing the appropriate reaction solvent.

Several commercial hydrolases have been shown to catalyze the formation of peptide bonds in organic solvents as immobilized (86) or soluble (6) biocatalysts. These have been used for small oligomer synthesis and segment condensation. A variety of activating moieties on the acyl donor in the peptide synthesis reaction broaden enzyme specificity and improve coupling yields for amino acids that are typically poor substrates for a given enzyme (85, 87). Enzyme-catalyzed peptide synthesis has been reviewed recently (80).

35.2.1.1.3. Dynamic Kinetic Resolution

In an enantiospecific resolution of a racemic substrate, only one enantiomer will react, limiting the maximum percentage yield to 50%. Dynamic kinetic resolution can be used to overcome this theoretical limitation. As one substrate enantiomer is selectively modified by the enzyme, it is replenished by the chemically catalyzed (metal catalysts are typically used) racemization of the other substrate enantiomer (Fig. 11). This “one-pot” technique has been optimized through a thorough tuning of conditions, enzymes, and racemization catalysts (33, 82, 100). Toluene affords high racemization rates for ruthenium and palladium catalysts, and high selectivities for

FIGURE 9 Multistep lipase-catalyzed resolution of a primary alcohol with distant stereocenter. di-IPE, diisopropyl ether. Adapted from reference 113.

immobilized lipases such as CALB. Dynamic kinetic resolution has been reviewed recently (41).

35.2.1.2. Regio- and Chemoselectivity of Hydrolases

The ability of hydrolases to modify a particular functional group in the presence of more reactive functional groups has been exploited in a variety of transformations on many classes of compounds. This section provides illustrative examples of such selective reactivities for lipases and proteases in neat organic solvents. Similar to the kinetic resolutions described above, most of these reactions involve acyl acceptors that are large and traditionally difficult to modify in a regioselective or chemoselective fashion. By comparison, the acyl donors are usually smaller and are thus able to coexist with the larger acyl acceptor in the enzyme's active site.

The regioselectivity of lipases and proteases in organic solvents is elegantly demonstrated in the acylation patterns of dihydroxy steroids: lipases show preference for A-ring acylations, while proteases such as subtilisin BPN' show preference for D-ring acylations (27, 108) (Fig. 12A). After acylation of one hydroxyl, the others can be oxidized chemically; subsequent alkaline deacylation thus provides a route to regioselective oxidation of the steroid without an oxidase enzyme. Regioselective acylation and deacylation of steroids have been used recently in the synthesis of several pharmacologically relevant steroid metabolites (119).

Distinct regioselectivity patterns are also observed in hydrolase-catalyzed acylations of a variety of carbohydrates, including polysaccharides (99), carboxymethyl cellulose

FIGURE 10 Enantioselectivities of suspended CALB and suspended subtilisin Carlsberg against various acyl acceptors in organic solvents. CALB reaction was in neat ethyl acetate, which was also the acyl donor (57). Subtilisin reactions were in 3-methyl-3-pentanol, with trifluoroethyl butyrate as the acyl donor (67).

FIGURE 11 A dynamic kinetic resolution scheme. The lipase CALB and ruthenium and palladium catalysts are compatible with resolutions in organic solvents, affording fast racemization and 98% product yield (23).

FIGURE 13 Loss of chemoselectivity by PCL when the solvent is changed. The enzyme was 20-fold more selective at hydroxyl acylation in dichloroethane than in *t*-butanol (127).

(139), and *N*-acetylhexosamines (120). Hydrolases have been used in the organic synthesis of carbohydrate-peptide conjugates (121) and novel vitamin D and deoxynucleoside derivatives (44).

As with regio- and enantioselectivity, chemoselectivity of hydrolases in organic solvents (e.g., preferred acylation of $-OH$ or $-NH_2$) can be adjusted by solvent selection. In certain cases the solvent can increase the effective nucleophilicity of the OH and NH_2 groups by disrupting intramolecular hydrogen bonding (32). In contrast, hydrogen-bonding solvents can preferentially hydrogen bond with a substrate OH group, rendering it less nucleophilic and shifting chemoselectivity toward an NH_2 group (Fig. 13).

The ability to use “medium engineering” to bias reactions toward a desired product is a hallmark of nonaqueous biocatalysis. When multiple reaction products are formed,

it is possible to change the product distribution by performing the reaction in a solvent more amenable to the formation of one product over the other. For example, Castillo and coworkers recently demonstrated the ability to adjust the equilibrium distribution of CALB-catalyzed products by changing the polarity of the solvent (103). Nonpolar solvents such as hexane gave low yields of the aminolysis product, due to its limited solubility, and therefore allowed for the accumulation of the more slowly formed Michael addition product (Fig. 14).

These examples of unexpected selectivity raise the possibility of discovering new bioactive compounds by screening various solvents and enzymes against natural products. For example, PPL was used in *tert*-amyl alcohol to selectively diversify hydroxyls on the carboxylic acid and amine components of the four-component Ugi reaction, resulting in a new nine-member

2M2B	41.0	20:80

FIGURE 14 Medium engineering to favor CALB-catalyzed Michael addition (3) over aminolysis (4) in various anhydrous organic solvents. Adapted from reference 103.

Ugi library (79). In addition, new analogs of the flavonoid morin were generated by regioselective modification with several lipases in THF (29, 92) (Fig. 12B), and over 50 commercial hydrolases were screened as biocatalysts en route to generating over 160 analogs of the antioxidant berginin (90) (Fig. 12D). A similar screening strategy was used in preparing taxol derivatives, whereby the zinc protease thermolysin and lipase were key enzymes involved in generating taxol derivatives that were up to 1,000 times more soluble in water (65).

35.2.1.3. Other Hydrolase Reactions

The most common reactions for hydrolases in organic solvents are the alcoholysis and aminolysis reactions described above; however, other reactions have been reported, including Michael additions (PPL and subtilisin Carlsberg [13]), Markovnikov additions (D- and L-amino acylases [137]), and aldol additions (PPL [75]). Two examples are shown in Fig. 15. The very low rates of these promiscuous reactions (it is not uncommon to let the reaction run for several days) have provided impetus for protein engineering of hydrolases

FIGURE 15 The Markovnikov addition of imidazoles to vinyl esters in dimethyl sulfoxide by several acylases (137) (top), and the asymmetric aldol addition of ketones and aldehydes catalyzed by PPL in acetone (75) (bottom). di-IPE, diisopropyl ether.

with higher activities for new reactions. Several studies (see reference 56 for a recent review) have used a mutated variant of CALB, in which the catalytic serine is changed to alanine. The mutant's catalytic dyad can activate a number of different nucleophiles, allowing for reactions that cannot be catalyzed with the wild-type enzyme, such as H_2O_2 epoxidations of unsaturated aldehydes (123), carbon-carbon bond formation via Michael addition of unsaturated carbonyl compounds to diketones (124), and aldol addition of aldehydes (11).

35.2.2. Hydroxynitrile Lyases

From the lyase class of enzymes (EC 4), hydroxynitrile lyases (HNLs) have been used for synthetic applications in organic solvents. Under the proper conditions HNLs can be used to asymmetrically add HCN to aldehydes (Fig. 16) and show high selectivities ($E > 100$) for a range of branched and polycyclic substrates (118). Common (*R*)-selective HNLs are from *Prunus amygdalus* (PaHNL) and *Linum usitatissimum* (LuHNL); common (*S*)-selective HNLs are from *Hevea brasiliensis* (HbHNL), *Manihot esculenta* (MeHNL), and *Sorghum bicolor* (SbHNL). The (*S*)-HNLs typically exhibit lower reaction rates (36). Chiral cyanohydrins produced by HNLs in organic solvents have been used as building blocks in the synthesis of various of bioactive compounds, such as epinephrine derivatives (34).

The use of HNLs in organic/aqueous biphasic systems has been reviewed recently (see chapter 9 in reference 16). Monophasic solvent systems are used to improve enzyme stability and to suppress the uncatalyzed, nonselective addition of HCN. The consensus view of the literature is that the best solvents for monophasic reactions are diisopropyl ether and ethyl acetate. These solvents afford very high enantioselectivities ($E = 200$) and afford exceptional stability (half-lives of hundreds of hours have been reported [24]) for crude preparations such as defatted almond meal and HNLs immobilized on solid supports such as Celite and Avicel. However, monophasic solvents can reduce enzyme reaction rates by orders of magnitude relative to aqueous/organic biphasic systems (36).

Several studies aimed at optimizing activity and enantioselectivity of monophasic HNL systems have demonstrated that addition of small amounts of water (0.1 to 1% vol) to an immobilized or crude enzyme system dramatically increases enzyme activity and enantioselectivity (22, 48). For example, Adlercreutz and coworkers (25) measured the effect of adding water on HCN addition to 3-phenylpropionaldehyde catalyzed by HbHNL adsorbed on Celite in dibutylether, and found that 1% vol/vol added water increased the initial rate 30-fold and the product ee_p from 15% to 85%. Higher water contents reduced reaction rates but had no effect on ee_p .

As an alternative to solid-supported enzymes, HNLs can be used as CLEAs (glutaraldehyde and dextran polyaldehyde are common cross-linkers), whereby the enzyme retains enough water to show high activity in monophasic organic

FIGURE 16 Asymmetric hydrocyanic addition of prochiral benzaldehyde is a popular model reaction for HNLs.

FIGURE 17 A one-pot synthesis involving Celite-HbHNL and CALB in water-saturated toluene. The water present was used by CALB to generate acetic acid, which deactivated the HbHNL. Adapted from reference 49.

solvents. For example, Sheldon and coworkers (130) demonstrated that the CLEA of PaHNL produced high conversions (>95%) and enantiomeric excesses (>95%) with several functionalized aldehydes in diisopropyl ether, and the catalyst could be recycled up to 10 times without loss of activity.

HNLs have also been used in several attractive “one-pot” schemes that combine selective cyanoadditions with further reactions, using either separately suspended enzymes or coenzyme CLEAs (83). While their synthetic utility is apparent, these schemes illustrate the potential incompatibility of HNLs with other enzymes. An attempt to couple HbHNL cyanoaddition with selective acylation by CALB was thwarted by the undesired hydrolysis of vinyl acetate catalyzed by CALB. The released acid deactivated the Celite-immobilized HbHNL (Fig. 17) (49).

Although HNLs provide a direct way for selective cyanoaddition, it is possible to arrive at the same product by use of a different enzyme system. An illustrative example is the production of α -cyano-3-phenoxybenzyl alcohol, a chiral building block for the insecticide pyrethrin (Fig. 18). In one synthesis route, (*S*)-selective SbHNL was used for

FIGURE 18 Alternative reaction paths to optically active α -cyano-3-phenoxybenzyl alcohol, a building block in pyrethrin insecticides. In the top path, an (*S*)-selective HNL is used for direct cyanoaddition (35). In the bottom path, nonselective cyanoaddition is coupled with enantioselective lipase acylation in a dynamic kinetic resolution (59). di-IPE, diisopropyl ether.

direct cyanoaddition at $ee_p = 90\%$ and a 90% product yield (35). An alternative route was nonselective, chemically catalyzed cyanoaddition, followed by selective acylation using a lipase, followed by nonselective hydrolysis. In this one-pot scheme, the basic conditions for cyanoaddition also racemize the cyanohydrin in a dynamic kinetic resolution (59). This approach gave $ee_p = 90\%$ at 85% product yield.

35.2.3. Oxidoreductases

Examples of enzymes from this class (EC 1) that have been used in monophasic organic solvents include oxidoreductases that use peroxide (horseradish peroxidase [112]; soybean peroxidase [116]; and chloroperoxidase [129]), molecular oxygen (phenol oxidase [63], galactose oxidase [71], and xanthine oxidase [89]), and nicotinamide cofactors (alcohol dehydrogenase, ADH). Dehydrated whole cells of *Rhodococcus ruber* have also been used, catalyzing the oxidation of *sec*-alcohols in anhydrous hexane at 5% the rate in aqueous buffer (122).

In an early, seminal report demonstrating the potential of oxidoreductases in organic solvents, Klibanov and coworkers (63) used polyphenol oxidase immobilized on glass beads to regioselectively oxidize phenols to quinones (Fig. 19). These reactions were difficult in aqueous media because of rapid inactivation of the enzyme and the

FIGURE 19 Polyphenol oxidase conversion of benzalcohols to diquinones in chloroform. This reaction was difficult in aqueous buffer because both the enzyme and quinone were unstable (63). In a subsequent study, the enzyme-generated quinone was subjected to various olefins to prepare bicyclooctenones (91).

FIGURE 20 Horse liver alcohol dehydrogenase catalyzes the selective reduction of a racemic aldehyde with the consumption of NADH in isopropyl ether. The enzyme and NADH cofactor were coimmobilized on a glass support. The NADH was regenerated by the same enzyme in the oxidation of ethanol to acetaldehyde (46).

tendency of the quinones to polymerize. The reactions also benefitted from the high solubility of O_2 in chloroform. Polyphenol oxidase-generated quinones have been used in one-pot cycloadditions with various olefins to yield useful bicyclooctenones (91).

Horseradish peroxidase and chloroperoxidase have also been used for enantioselective sulfoxidations in organic solvents, where they exhibit increased enantioselectivity relative to the aqueous enzyme preparations (see reference 68 for a recent review). For example, the enantioselectivity of a horseradish peroxidase suspension toward the oxidation of thioanisole with *t*-butyl hydroperoxide was $E = 8.0$ in isopropyl alcohol and 1.8 in aqueous buffer (138).

Cofactor-requiring oxidoreductases such as the $NAD^+/NADH$ -requiring ADH must be colyophilized or coprecipitated with the cofactor from an aqueous buffer to ensure enzyme-cofactor contact in organic solvent. Coimmobilization of horse liver ADH with NAD^+ on controlled-pore glass (47), coimmobilization on Sepharose (31), and colyophilization from an aqueous mixture (89) have all been used. Coimmobilized preparations required the addition of small amounts of water (0.1 to 1% vol/vol) for catalytic activity in polar solvents such as acetone and acetonitrile to ensure the proper conformation of the ADH active site (46, 47). However, even with added water, the ADH reactions were very slow, requiring several days for appreciable conversion.

Cofactor regeneration in the ADH $NAD^+/NADH$ system is most easily realized with the "second substrate" approach, in which the same enzyme catalyzes the depletion and regeneration of the cofactor in a cycle with a second substrate (Fig. 20). It has also been demonstrated that coimmobilization of a second enzyme (such as diaphorase) can accept the NADH generated by ADH and convert it to NAD^+ (31). There are many ways to regenerate depleted cofactors in aqueous or organic-aqueous mixtures, typically involving a second enzyme and substrate (see reference 1 for a thorough review).

35.3. CONCLUSION

Enzymes are not only active in organic solvents, they often display high regio-, chemo-, and enantioselectivities, making them particularly suited for the selective modification of complex molecules. Enzymatic reactions are thus often attractive alternatives to complex and inefficient chemical synthesis schemes for the preparation of pharmaceutical intermediates and derivatives. While the hydrolase enzymes are most widely used, enzymes from the lyase and oxidoreductase classes are also prominent, and other enzyme classes will no

doubt receive greater attention in the future. Novel enzyme preparation methods and system conditions, along with multi-enzyme processes and the ability to engineer enzymes with improved properties for synthesis, will lead to new synthetic routes and ensure an expanding role of organic-phase biocatalysis in the synthetic chemist's repertoire.

Enzyme Promiscuity and Evolution of New Protein Functions

BERT VAN LOO AND FLORIAN HOLLFELDER

36

36.1. INTRODUCTION

Promiscuous enzymes can perform additional functions besides their “native” activities, challenging the textbook adage “one enzyme, one activity.” Changing the function of enzymes or even creating entirely new catalysts *de novo* by design has proven difficult (43), despite some exciting recent advances (52, 96). Likewise, directed evolution of an enzyme toward an entirely new function has to overcome the—often large—thermodynamic barriers of the target reaction, until a catalytic effect can be visibly detected. Jensen (51) and later O’Brien and Herschlag (85) recognized that promiscuous activities can provide a solution to this dilemma: catalytic promiscuity equips a protein with a second head-start activity that can be adapted and enhanced when the gene is duplicated without compromising the original activity (2, 48, 61, 85). Typical k_{cat}/K_m values for specialized functions that are considered highly evolved range up to 10^6 to $10^7 \text{ M}^{-1}\text{s}^{-1}$ (123). However, substantially lower activities could already be sufficient to support a metabolic function. In natural evolution the level of promiscuous activity needed for the new function to provide a selective advantage was estimated to be as low as $0.3 \text{ M}^{-1} \text{ s}^{-1}$ for k_{cat}/K_m , provided the enzyme was expressed at high levels (90). This figure suggests that even rates that one would consider small compared with those of “mature” enzymes can matter in evolution. Likewise, the lower limit for a promiscuous activity assigned in a laboratory experiment will depend on the sensitivity of the assay system, a feature that must be kept in mind for any *in vitro* evolution studies: if activities fall below the experimental threshold, they cannot be selected for.

In an effort to discover evolutionary starting points, there has been an increase in systematic analysis of enzyme promiscuity in recent years combining not only newly discovered enzymes, but also numerous historic examples from earlier studies in which the phenomenon of promiscuity was not explicitly discussed as such. This chapter introduces the various categories of promiscuity and their possible role in enzyme evolution. We also review some of the well-known examples of enzymes for which the promiscuous function is industrially relevant, leading to conversions of nonnatural compounds. In some cases these promiscuous activities have been improved by site-directed and/or random mutagenesis methods, suggesting that the study of catalytic promiscuity may help identification of new functions by directed evolution. Thus, enzyme promiscuity is becoming

an increasingly important phenomenon in the field of biocatalysis, both directly and indirectly: directly, because many desirable conversions are “unnatural,” so expansion of the existing functions of protein catalysts is necessary to convert these “promiscuous” substrates; indirectly, through the observation that promiscuous enzymes may be particularly evolvable, opening a wide range of possibilities for engineering these potentially valuable side activities.

36.2. ENZYME PROMISCUITY: DEFINITION AND OVERVIEW

Promiscuity is the ability of an enzyme to catalyze a reaction other than its native one, i.e., active site residues can recognize and turn over alternative substrates. Promiscuity can be divided conceptually into several classes, based on the similarities and/or differences between the two or more substrates that are accepted by one enzyme, as illustrated in Fig. 1. The examples mentioned are discussed in more detail in subsequent paragraphs.

1. *Substrate promiscuity* (Fig. 1A)—sometimes described as “substrate ambiguity” or simply referred to as “substrate range”—is the ability to perform the same chemical reaction on different substrates. For instance, many hydrolases, such as esterases (53) and epoxide hydrolases (3, 101, 116), accept a wide range of substrates with different substituents, but always tackle the same chemical functionality. This type of promiscuity, e.g., in esterases and lipases, is used successfully in fine-chemical synthesis (53). It is often difficult to derive molecular recognition rules from the accidental discovery of this phenomenon because most studies exploring the substrate range of enzymes have been driven by application to industrially relevant compounds. The recent systematic analysis of a comprehensive set of more than 30 promiscuous substrates in a biosynthetic enzyme (TycA, an adenylation domain involved in nonribosomal peptide synthesis) suggests that profiling the active-site properties that determine enzyme-substrate recognition is possible based on an extensive survey of alternative substrates (117).
2. In *product promiscuity*, one substrate is converted into various products (Fig. 1B) by use of similar or identical chemistry. Fascinating examples of this principle are the various sesquiterpene cyclases. This class of enzyme uses the same farnesyl diphosphate substrate that can be

FIGURE 1 Different types of enzyme promiscuity. Promiscuous molecular recognition can take place at different stages of a reaction cycle. (A) In substrate promiscuity, the enzyme is able to recognize substrates with different structural features, but the chemical transformation performed is identical despite different substituents. (B) In product promiscuity, one substrate can be converted to many alternative products. The molecular recognition of the intermediate is conserved, but the folding of the intermediate or rearrangements of the reactive centers on the intermediate, e.g., by steric complementarity of the active-site template, lead to a variety of products onward from this reactive intermediate. (C) To achieve catalytic promiscuity, the tightest interactions—those in the transition state—have to be tolerant enough to recognize different reaction centers and bond-making and -breaking processes around them.

converted into various cyclic products, depending on carbocation rearrangements that take place in the active site (100). Here, the active site provides a template for “folding” a reactive intermediate into a conformation that leads to a transition state resembling the product

structure. Depending on the shape of the active site, rerouting of a common reactive intermediate leads to various “promiscuous” alternative products.

3. *Catalytic promiscuity* is the ability of one enzyme to catalyze chemically different conversions (Fig. 1C).

This may be the same class of reaction (e.g., hydrolysis), but the bonds made and broken or the transition states differ between native and promiscuous functions. A prominent example for a structural superfamily of hydrolases catalyzing a range of chemistries is the ability of phosphatases to hydrolyze sulfate ester bonds and vice versa (4, 55, 66, 84, 86, 87, 115a, 124). Alternatively, the promiscuous function facilitates a different class of reaction altogether, using at least part of the same catalytic machinery, as is the case for the carbon-carbon and carbon-oxygen bond-forming reactions that are catalyzed by *Candida antarctica* lipase B (CALB), which normally hydrolyzes carboxylic ester bonds (10, 12, 13, 104, 105).

The following review discusses examples for each of these types of promiscuity with special attention for enzymes of relevance for applied biocatalysis. Several other reviews are available that cover the growing body of evidence in this area and discuss its implication for a variety of research fields (8, 21, 38, 49, 54, 55, 61, 83, 85).

36.2.1. Hydrolase Promiscuity: CALB

CALB is a well-known lipase used for the stereoselective production of a range of enantiopure esters and alcohols (36, 118), using the same chemistry as for its native lipolytic activity. CALB is a typical representative of the α/β -hydrolase fold family of enzymes comprising not only a number of other esterases, but also haloalkane dehalogenases and epoxide hydrolases (46, 88). As for most of its family members the CALB active site contains the Asp-His-Ser catalytic triad characteristic of the serine hydrolases

of this family, and also an oxyanion hole that activates the carbonyl functionality of the substrate. The Asp-His pair activates the serine residue for nucleophilic attack on the carbonyl function of the ester substrate (Fig. 2). The oxyanion hole stabilizes the negative charge that develops on the carbonyl oxygen during the transition state. The acyl-enzyme intermediate that is formed is subsequently hydrolyzed by a water molecule that is activated by the Asp-His pair. During this second step, negative charge again develops on the carbonyl oxygen. The water molecule can be replaced by another nucleophile, resulting in transesterification instead of hydrolysis. The abundance of reactive features in this active site seems to be sufficient to activate both an electrophile and a nucleophile in close proximity to a substrate molecule.

It is therefore perhaps not surprising that both the general base (Asp-His pair) and the oxyanion hole play an important role in a number of synthetic reactions that are catalyzed by CALB, making it also catalytically promiscuous. The oxyanion hole appears to be an intrinsically promiscuous feature that can be used by other reactions that also involve charge accumulation on carbonyl oxygens: CALB can also catalyze aldol condensations (10), Michael additions (13, 105), and epoxidations (104) (Fig. 3B to D). A molecular modeling study suggests that CALB can also catalyze Baeyer-Villiger reactions (12) (Fig. 3E), but no experimental data are available to support this claim. For the Michael additions and the epoxidation reactions the carbonyl group of the electrophilic partner in the bimolecular reaction is recognized and activated by the oxyanion hole. The activation occurs through polarization of the carbonyl group and subsequent stabilization of the developing

FIGURE 2 Mechanism of the native esterolytic activity of CALB. Upon substrate binding, the carbonyl functionality becomes positioned and polarized by the oxyanion hole (step a). The activated Asp-His pair activates the serine nucleophile, which performs a nucleophilic attack on the carbonyl carbon (b), ultimately resulting in the release of an alcohol and binding of a water molecule (c). The Asp-His pair now activates a water molecule for nucleophilic attack on the carbonyl carbon by general base catalysis, and the oxyanion hole performs the same role as it did for the first step, resulting in hydrolysis of the acyl-enzyme complex and release of the carboxylic acid (d).

FIGURE 3 Catalytic promiscuity of CALB. The oxyanion hole is a key catalytic feature, polarizing the carbonyl bond of the electrophile in each reaction and offsetting the development of negative charge at oxygen. The reactions catalyzed by CALB are: (A) native carboxylic ester hydrolysis (112); (B) aldol condensation (10); (C) Michael-type addition (13, 105); (D) epoxidation (104); and (E) the predicted Baeyer-Villiger reaction (12). For the promiscuous functions, the catalytic nucleophile does not take part in catalysis. The other parts of the active-site residues play a similar role, and the serine has been replaced by an external nucleophile that is activated by the Asp-His pair, which acts as a general base.

negative charge on this oxygen center, as in its native hydrolytic reaction. The Asp-His pair of the catalytic triad acts as a general base to activate the nucleophile in these promiscuous reactions, again mirroring the mechanism of its native activity. For the aldol condensation, the oxyanion hole and Asp-His pair stabilize an enolate ion. During the formation of the enolate intermediate the histidine picks up a proton. This protonated histidine acts as a general acid in the second step of the reaction, in which the enolate ion reacts with a second carbonyl functionality (10).

The originally catalytic serine nucleophile is not required for all these promiscuous reactions. The mutant CALB Ser105Ala, in which this serine is removed by site-directed mutagenesis, shows improved activity for all promiscuous reactions (10, 13, 104, 105), whereas the native esterolytic activity is severely impaired. This mutant and the wild type seem fairly indiscriminate with respect to the promiscuous substrates: as long as a carbonyl functionality is present in the electrophile, many reactions are possible. Unlike for the native lipase activity, the promiscuous reactions do not involve a covalent intermediate, circumventing the possible formation of a suicide complex between enzyme and substrate.

36.2.2. Promiscuity in Secondary Metabolism: Combinatorial Biosynthesis

Nonribosomal peptide synthetases (NRPSs) and polyketide synthetases are large multimodular enzymes that are involved in the synthesis of natural products. Many of these natural products have unique bioactivity and are thus of great interest to the pharmaceutical industry. NRPSs and polyketide synthetases act as “molecular assembly lines” in which each module of the multienzyme complex incorporates a different building block into the correspondingly modular natural product (11, 62, 122). A temptingly logical approach to produce a variety of altered natural products would be to “mix and match” modules from other enzyme

assembly lines, although transplantation of modules often yields chimeric proteins with impaired activity (82, 97, 98), probably because of the lack of crucial interdomain contacts in the multienzyme complexes (35, 40, 59, 108). Substrate promiscuity of individual modules would greatly facilitate the production of alternative natural products, allowing the incorporation of alternative building blocks while minimizing potentially disruptive module insertion.

One of the most striking examples of the exploitation of substrate promiscuity in such enzymes is the biosynthesis of avermectins, a series of anthelmintic compounds produced by *Streptomyces avermitilis* (Fig. 4). A mutant *S. avermitilis* strain that lacks branched-chain 2-oxo acid dehydrogenase activity is unable to produce avermectin. Production of avermectin can be restored by feeding the appropriate fatty acid to the culture medium (39). Feeding alternative fatty acids to this mutant strain results in avermectin analogs for more than 40 acids that are incorporated (resulting in variation at position R₂ as indicated in Fig. 4), making the loading module for the fatty acid one of the most promiscuous enzymes described. These data also suggest that downstream modules are similarly tolerant: not only the loading module, but also the downstream extension and termination modules must process the alternative intermediates to be able to generate the avermectin framework (28), suggesting that “local” specificity (near the reaction center) is maintained, while “remote” specificity (away from the reaction center) is relaxed. Fusing the avermectin-loading module to the erythromycin elongation and termination modules (comprising some 30 active sites) also resulted in functional antibiotic products, showing that the erythromycin-producing modules are likewise highly tolerant (76). If one carboxylic acid substrate can be fed exclusively—i.e., it is the only available module to be incorporated and thus does not compete against the more efficient incorporation of native substrate—this promiscuity can bring about new natural products and is highly useful. The same pathway-directed evolution

FIGURE 4 Substrate promiscuity allows the combinatorial biosynthesis of avermectin analogs. The R_2 group in the avermectin structure originates from either 2-methylbutyryl-coenzyme A or isobutyryl-coenzyme A, which are generated from *L*-leucine and *L*-valine, respectively. In *S. avermitilis* ATCC 53569, a branched-chain α -keto acid dehydrogenase that is essential for the *in vivo* production of the branched-chain fatty acids is absent (27, 39), rendering this strain unable to produce avermectins. Feeding up 40 different fatty acid compounds (with a variety of substitutions in R_2) to this mutant strain restores the biosynthetic machinery, resulting, in each case, in a different avermectin analog (28). For instance, in doramectin biosynthesis, cyclohexane carboxylic acid is incorporated (102), replacing either methylbutyric acid or isobutyric acid in the wild-type strain (39).

has been used (102, 103) to shift the product ratio in favor of the desired analog doramectin (28, 39), which incorporates a promiscuous substrate, cyclohexane carboxylic acid, to replace the native butyric acid (28, 39). No kinetic data on these transformations are available, so the extent of promiscuity is only qualitatively, not quantitatively characterized.

There are a number of indications that, in principle, NRPS enzymes can also be promiscuous. For example, the composition of peptide antibiotics depends on the amino acid-feeding regime during their production (37, 67, 78). However, in this case, a kinetic analysis is available to inform on the quantitative aspects of the specificity of catalysis, rather than the largely qualitative detection of product. A recent systematic study showed that TycA, the first module

in tyrocidine biosynthesis, can accept 29 different amino acids besides the native phenylalanine substrate (117). This large number of substrates was systematically characterized by their relative catalytic efficiencies (measured by k_{cat}/K_m) highlighting the factors involved in substrate recognition. Although, in principle, many substrates are accepted, the efficiency varies greatly: k_{cat}/K_m values range over 6 orders of magnitude. The hydrophobicity of the substrates (measured by the log P for the substrate side chain) showed a linear correlation, suggesting that matching the hydrophobicity of substrate and active site is a key requirement of achieving promiscuity. In addition, there are other layers of substrate recognition control, namely, size exclusion, that make this enzyme by direct comparison with aminoacyl-tRNA synthetases similarly specific. Aminoacyl-tRNA synthetases catalyze the same chemical reaction, but are involved in safeguarding the fidelity of protein production during translation. The observation of similar discrimination—and, in fact, similar promiscuity—in both enzymes may suggest the generality of these observations. By extension, one may assume that promiscuity is a feature even of enzymes under evolutionary pressure to be specific to some extent and thus a general property of active sites, which could be quantified if substrate collections (and enough time for such painstaking, repetitive experiments) were available. The low activities for the promiscuous reactions in TycA and the observed discrimination suggest that not every module in combinatorial biosynthesis is tolerant. Downstream domains (e.g., those responsible for condensation [5, 29] of amino acid building blocks and processing by cyclization [64, 111]) have also been shown to possess some specificity. Collectively, these results suggest that enzymes involved in secondary metabolism can be nonspecific (as has been suggested [30, 31]), but that the actual promiscuity should be tested on a case-by-case basis.

36.2.3. Tolerance for the Catalytic Nucleophile: Halohydrin Lyases/Haloalcohol Dehalogenases

Halohydrin lyases or haloalcohol dehalogenases are enzymes that catalyze the dehalogenation of vicinal haloalcohols by intramolecular attack of the hydroxyl group that displaces the halide, resulting in an epoxide, a halide ion, and a proton. They are found in various bacteria that are able to use halogenated hydrocarbons as a sole source of carbon and energy (14, 94, 113, 114). In these organisms they are part of the degradation pathways of halo propanols and 1,2-dibromoethane in concert with an epoxide hydrolase (Fig. 5A) and haloalkane dehalogenase (Fig. 5B), respectively (94, 113).

FIGURE 5 Biodegradation routes for halogenated hydrocarbons involving haloalcohol dehalogenases. (A) Degradation of 1,3-dichloro-2-propanol to glycerol in *A. radiobacter* AD1, catalyzed by a haloalcohol dehalogenase (HheC) and an epoxide hydrolase (EchA) (113). (B) Degradation of 1,2-dibromoethane to ethylene oxide in *Mycobacterium* sp. GP1, catalyzed by a haloalkane dehalogenase (DhaAf) and a haloalcohol dehalogenase (HheB) (94).

FIGURE 6 Mechanism of haloalcohol dehalogenases and their likely precursors, the short-chain dehydrogenases/reductases (SDRs). (A) Proposed mechanism of *A. radiobacter* AD1 haloalcohol dehalogenase (HheC)-catalyzed ring closure of a vicinal haloalcohol. The Tyr145/Arg149 pair acts as a general base to abstract a proton from the hydroxyl group, resulting in an intramolecular nucleophilic displacement of the halide, aided by leaving group stabilization by the halide binding site (25). (B) Proposed mechanism of SDR enzymes, in which the proton abstraction from the hydroxyl group is followed by hydrogen abstraction by the NAD⁺, resulting in the corresponding ketone.

Sequence similarity searches and sequence alignments show that haloalcohol dehalogenases are related to proteins from the short-chain dehydrogenase/reductase (SDR) family of enzymes (115). These NAD(P)H-dependent oxidoreductases catalyze a wide variety of oxidation and reduction reactions. The X-ray structures of two haloalcohol dehalogenases strengthened the conclusion that these dehalogenases are related to SDR proteins (24, 25), and showed that the proposed divergence of the haloalcohol dehalogenases from the SDR precursors occurred twice: one divergence resulted in the A- and C-type haloalcohol dehalogenases, the other in the B type (25). The main difference between SDR proteins and the halohydrin lyases is the absence of a nicotinamide cofactor in the latter. In SDR proteins this cofactor accepts/donates a hydride from/to the alcohol/ketone substrate. In haloalcohol dehalogenases the location at which the sugar phosphate part of the cofactor would bind in SDR proteins is filled up with amino acids, and the space where the nicotinamide ring would bind is now the halide binding site (Fig. 6) (25).

As with the SDR proteins, the reactions that these haloalcohol dehalogenases catalyze are reversible. For vicinal haloalcohols, the equilibrium lies toward the side of the epoxide and the free halide. These enzymes are promiscuous with regard to the nucleophiles they can accept in the ring-opening reaction. This ability was first acknowledged in the early 1990s, when haloalcohol dehalogenases from *Corynebacterium* sp. strain N-1074 were used for the enantioselective ring opening of epoxides with cyanide as the nucleophile (80, 81). More extensive research, especially with the haloalcohol dehalogenase from *Agrobacterium radiobacter* AD1 (HheC), showed that up to nine different nucleophiles are accepted by the enzyme (Fig. 7), depending on which epoxide substrate is used (41, 42, 68, 70–74). For the three different halides (Cl⁻, Br⁻, and I⁻) the equilibrium of the reaction is on the side of the epoxide, as mentioned above, but for all other accepted nucleophiles the equilibrium is shifted toward the vicinal alcohol (42).

The molecular basis for this remarkable promiscuity was suggested to be possible when alternative nucleophiles were known halide mimics (25). A systematic screening of possible nucleophiles for the HheC-catalyzed ring opening of 1,2-epoxybutane showed a preference of the enzyme for relatively small anionic linear nucleophiles (42). Nonanionic nucleophiles, such as primary alcohols and amines, were not accepted and neither were more bulky nonlinear ions such as phosphates, sulfates, and organic carboxylates. To be accepted in the halide binding site a molecule must be small and negatively charged and have “linear” geometry (42), although the binding of several of the accepted nucleophiles may be in a different location from the halide binding site (42, 68). Fluoride ion, the least polarizable halide nucleophile, was not accepted, in line with the extreme recalcitrance of fluorinated hydrocarbons compared with their chlorinated and brominated counterparts. The promiscuous cyanolysis activity appears to be present in most of the haloalcohol dehalogenases that have been characterized so far (71, 80, 81). A systematic understanding of nucleophile acceptance in the different classes of haloalcohol dehalogenases (A, B, and C types) is lacking, and it is not known whether the A and B types can use nucleophiles that are not accepted by HheC.

FIGURE 7 Nucleophile promiscuity for the halohydrin dehalogenase-catalyzed epoxide ring opening. The position of the equilibrium is dependent on the nucleophile.

FIGURE 8 Schematic representation of (A) (*R*)- and (B) (*S*)-pNSO in the active site of haloalcohol dehalogenase from *A. radiobacter* AD1 (HheC) (26). The proposed difference in binding modes is based on X-ray structures of HheC in complex with (*R*)- and (*S*)-pNSO, respectively. Both structures were refined with *p*-nitrophenylcyclopropane as the substrate to obtain an unbiased view of the interactions of the Ser132/Tyr145 pair with the epoxide ring. These data show that the refinement data for both structures can be completely superimposed, apart from the epoxide ring, in which the (*R*)-enantiomer comes close enough to the Ser/Tyr pair to form a productive hydrogen bond. The calculated difference in Gibbs binding energy for both structures is also in agreement with the loss of one hydrogen bond.

In contrast to the very promiscuous behavior with respect to the nucleophile in the ring-opening reaction, HheC is often selective with respect to substrate stereochemistry, since the enantioselectivity as represented by the *E* value is often high ($E > 100$) (41, 68–71, 73, 74). The basis for this behavior can be explained based on X-ray structures of HheC in complex with both (*R*)- and (*S*)-*para*-nitrostyrene oxide (pNSO) (Fig. 8), in which the substituent on the epoxide ring guides substrate binding. This means that binding of one of the enantiomers results in an unproductive enzyme-substrate complex since the carbon atom that would normally be susceptible to nucleophilic ring opening is too far away from a water molecule sitting where the nucleophile would normally bind (26). The stereoselectivities toward epoxides with smaller substituents are lower, probably because of higher degrees of freedom with respect to binding

of the side chain, resulting in productive binding modes for both enantiomers. The structure of the A-type haloalcohol dehalogenase from *Arthrobacter* sp. (HheA) (24) revealed a more spacious active site, which was consistent with its lower stereoselectivity compared with HheC (71, 115).

Many of the promiscuous reactions catalyzed by Hhes result in the stereoselective production of a number of interesting compounds. In one particular example, the native and one of the promiscuous activities of HheC W249F, a mutant with improved stereoselectivity (107), were exploited for the one-pot conversion of a racemic haloalcohol to the corresponding (*S*)-cyano alcohol, leaving the (*R*)-haloalcohol largely unreacted (72) (Fig. 9). The first step of the synthesis involved the native activity (haloalcohol ring closure); the second step was one of the promiscuous activities (cyanolysis of an epoxide). Both reactions were enantioselective, and the one-pot approach amplified this phenomenon.

36.2.4. Promiscuity in Cofactor-Dependent Enzymes: Baeyer-Villiger Monooxygenases

The Baeyer-Villiger reaction is the conversion of a ketone into a carboxylic ester using peracid as the oxidative reagent, and it is a reaction of industrial relevance. Baeyer-Villiger monooxygenases (BVMOs) are flavin-dependent monooxygenases that use molecular oxygen as the oxidant. All BVMOs that have been characterized thus far use NADPH to reduce the flavin cofactor during the catalytic cycle (33, 34, 57). The reducing equivalents (H^- and H^+) are ultimately accepted by the remaining oxygen atom to form H_2O (Fig. 10). The first BVMO that was extensively characterized, and for which the gene was cloned, was cyclohexanone monooxygenase from *Acinetobacter* NCIB 9871 (16). Since then various other BVMOs have been cloned and overexpressed (34, 50, 58, 65, 79), and an X-ray structure was solved for phenyl acetone monooxygenase (PAMO), providing insight into the mechanism of BVMOs (75). Based on early work by Walsh and Chen on cyclohexanone monooxygenase (119) and, more recently, by Fraaije and coworkers on structural and kinetic studies with PAMO (75, 109), a mechanism was proposed for the native reaction of BVMOs (Fig. 10). The central feature of these enzymes is the highly reactive peroxyflavin intermediate, which is responsible for catalysis. A strictly conserved arginine was originally thought to be mainly responsible for stabilization of the peroxyflavin intermediate (75), but spectroscopic and kinetic data for an alanine mutant at this conserved position showed that the peroxyflavin intermediate could still be formed and, in fact, had a lower decomposition rate than in the wild type (109).

BVMOs are promiscuous enzymes and have been shown to catalyze epoxidations (17), boron oxidations (9, 22, 23), sulfoxidations (15, 18, 19, 22, 23), seleno oxidations (119),

FIGURE 9 One-pot synthesis of (*S*)-4-cyano-3-hydroxybutanoate methyl ester from racemic 4-chloro-3-hydroxybutanoate methyl ester using a mutant haloalcohol dehalogenase (HheC W249F [107]). This method makes use of both the native activity (step a) and one of the promiscuous activities (step b) of HheC (72).

FIGURE 10 Catalytic promiscuity of BVMOs. (A) Proposed reaction cycle for each of the different conversions (57, 109). The reaction cycle starts with reduction of the oxidized flavin (I) by NADPH, resulting in reduced flavin (II) and NADP^+ , which is released from the enzyme only at the end of the catalytic cycle. The reduced flavin subsequently reacts with molecular oxygen to form the peroxyflavin intermediate (IIIa), which has been suggested to exist also in the protonated state (IIIb). This highly reactive intermediate is stabilized by various interactions with residues in the active site and can react with a variety of different substrates, both electron-rich and electron-deficient substrates (B) (119). The resulting hydroxyflavin (IV) subsequently decomposes into oxidized flavin (I) by eliminating water. Finally, NADP^+ is released from the enzyme, allowing the enzyme to start another catalytic cycle.

and amine oxidations (20, 23, 89), besides their native Baeyer-Villiger reaction (Fig. 10). The sulfoxidation activity of a BVMO in *Mycobacterium tuberculosis* (EtaA) (33) is responsible for the activation of thioamide drugs. Mutant strains in which the activity was impaired were therefore resistant to the treatment with these second-line antitubercular drugs. The very promiscuous behavior of these enzymes most likely stems from the intrinsic reactivity of the peroxyflavin intermediate. In solution this intermediate would rapidly decompose, producing hydrogen peroxide. When this is the case for a BVMO it, in principle, should act as an NADPH oxidase.

The enzyme active site provides stabilization of the peroxyflavin and introduces some form of selectivity, since the various BVMOs do differ with respect to the kind of R-groups they can accept (6, 15, 18–20, 22, 23, 34, 57, 77, 119). The detailed mechanisms for the alternative conversions are largely unknown, but some suggestions have been made. The boron oxidations are thought to involve the deprotonated peroxyflavin, as is the case for the native conversion, whereas the heteroatom oxidations (Fig. 10B, reactions 4 to 6) are thought to require the more electrophilic protonated peroxyflavin (57). The pathway for BVMO-catalyzed epoxidation was originally suggested to proceed via the electrophilic peroxyflavin (119), but experimental data obtained by Colonna and coworkers (17) suggest that the nucleophilic peroxyflavin is responsible for this reaction.

The catalytic prowess for each of the different oxidations differs little between the different chemistries. Catalytic efficiency seems at least equally or even more dependent on the carbon skeletons that surround the ketone, sulfide, or amino functionality. An example in support of this idea is the observation that PAMO oxidizes α -methylacetone

(Baeyer-Villiger reaction) and methyl 4-tolylsulfide (sulf-oxidation) with equal efficiency ($k_{\text{cat}}/K_m = 2.4 \times 10^3$), yet phenylacetone is oxidized with far greater efficiency ($k_{\text{cat}}/K_m = 32 \times 10^3$) (34). The reaction pathways for both these reaction types are at least partly similar, since removal of the essential arginine in PAMO abolished both activities (109). In addition, these enzymes are also highly stereoselective for some conversions (22), despite their mechanistic tolerance.

36.3. CROSSWISE CATALYTIC PROMISCUITY IN THE ALKALINE PHOSPHATASE SUPERFAMILY: EFFICIENT PROMISCUOUS HYDROLASES

Perhaps the most systematically studied group of promiscuous enzymes is a group of hydrolytic enzymes related to the familiar textbook enzyme alkaline phosphatase (AP; Fig. 11A). Assignment to the AP superfamily is based on structural homology (despite low sequence homology) and complemented by mechanistic parallels: the active-site residues diverge considerably, but the character of the active-site residues is conserved. Like most metallohydrolases, the proteins in this superfamily benefit from the availability of a nucleophile activated (i.e., deprotonated) by general base catalysis and metal coordination, and from offsetting negative-charge development on the leaving group of phosphoryl/sulfuryl oxygens by Lewis acid catalysis. Figure 11 shows how this general pattern is adapted in individual superfamily members. Remarkably, in the context of this review, the superfamily is also defined by extraordinarily efficient crosswise promiscuity; i.e., the native activity of one family member corresponds to the promiscuous activity of another.

FIGURE 11 Mechanisms of the various hydrolases that belong to the alkaline phosphatase superfamily. (A) *Escherichia coli* AP (99). (B) *Xanthomonas axonopodis* NPP (124). (C) *P. aeruginosa* arylsulfatase (7). (D) Mechanism proposed for the PMH from *Rhizobium leguminosarum* (RIPMH), based on X-ray structural data and the kinetic data of various active-site mutants (56). The active-site residues of PMH from *Burkholderia caryophylli* (BcPMH) superimpose ideally on RIPMH (86% amino acid identity), suggesting that BcPMH uses the same mechanism (115a).

O'Brien and Herschlag pioneered the functional exploration of promiscuity in this superfamily and detected additional promiscuous activities in AP, namely, sulfate monoesterase (84), phosphate diesterase, and phosphonate monoesterase (86) activities in addition to AP's original phosphate monoesterase activity. Promiscuous catalysis occurred with substantial rate accelerations characterized by second-order rate enhancements $[(k_{cat}/K_m)/k_2]$ ranging up to 10^{11} (Table 1). A structurally homologous family member, the arylsulfatase from *Pseudomonas aeruginosa* (PAS), exhibits promiscuity mirroring the repertoire of AP. PAS accelerates the hydrolysis of phosphate monoesters by 10^{13} (87) and phosphate diesters by factors between 10^{15} and 10^{18} , depending on the structure of the diester substrate (4).

A further member of the AP superfamily, a phosphonate monoester hydrolase (PMH), shows activity toward the originally assigned cognate substrate phosphonate monoester as well as phosphate mono- and diesters, sulfates, and sulfonates with accelerations ranging from 10^{10} to as high as 10^{18} (Table 1) (115a). PMH thus sums up all activities of other family members, but branches out into new activities, too.

Despite the common net hydrolysis reaction in the AP superfamily, this collection encompasses a range of diverse substrates: their charges range between 0 and -2 , the reactions involve transition states of a different nature

(in terms of bond making and breaking) (44, 45, 63), they attack at two different reaction centers (P and S), and they exhibit diverse intrinsic reactivities (with half-lives between 20 and 85,000 years under near-neutral conditions). It is remarkable that one catalytic machine can solve the diverging molecular recognition challenges that are involved in turnover for this set of substrates—with extraordinary rate accelerations.

The data in Table 1 challenge the notion that high rate accelerations can only be observed for specialized enzymes, since PMH is an excellent phosphodiesterase, yet highly promiscuous, and may be adapted further by evolution. One may speculate that the enzymes of this superfamily are derived from a common ancestor that was even less specific, catalyzing all the reactions that are now the extant activities of the enzyme family: this would be the ideal starting point for differentiation of hydrolases by directed evolution.

Promiscuity has been observed in other superfamilies: Glasner et al. (38) used assignment to a superfamily as a clue to identify uncharacterized family members in the enolase family. In a recent review by Poelarends and coworkers (95), the evolutionary relationship between the various members of the tautomerase superfamily, each of which carries an N-terminal proline as part of its active site, was extensively discussed. This proline can act either as a general base or as a general acid. Although there is

limited evidence of crosswise catalytic promiscuity in this enzyme family with respect to the native substrates (91, 120), a number of family members show hydratase activity (92, 93, 121), unifying these enzymes mechanistically. Furthermore, for this family, the observed promiscuous behavior provided insight into the mechanism of one of the family members (91).

36.4. IMPROVEMENT OF PROMISCUOUS FUNCTIONS BY MUTAGENESIS

Some of the promiscuous functions mentioned above have been improved, either by random methods (32) or by structure-inspired, site-directed mutagenesis (12, 13, 104, 105, 110).

The production of an enantiopure cyano alcohol from the corresponding haloalcohol by HheC, similar to the one depicted in Fig. 9, was improved 4,000-fold (volumetric productivity) by use of protein sequence activity relationships (ProSAR). For this approach diversity was generated by use of various methods such as site-saturation mutagenesis and error-prone PCR, and activity data were obtained for a limited number of variants. This multivariate optimization strategy links the activity of a number of enzyme variants in each round to the mutations they carry, inferring the effect of the contribution of each single mutation. Thereby, detrimental mutations or “genetic hitchhikers” could be sifted out. At the start of each round, new diversity was introduced by mutagenic techniques to maintain diversity. On average, each round resulted in 1.5- to 3-fold improvement of the parent (the best variant from the previous round), which after 18 rounds resulted in 4,000-fold improvement of the activity under production conditions (32). Since the selection includes both the ring closure of a haloalcohol and the ring opening of an epoxide by cyanide, both the native and the promiscuous activity were maintained at a high level in the same catalyst.

The improvement of several of the promiscuous reactions of CALB was obtained by removing the catalytic nucleophile, naturally resulting in decreased performance for the native activity (10, 13, 104, 105). Removal of Ser105

resulted in 2- to 10-fold-increased turnover for all the promiscuous functions compared with wild type. The more spacious active site was apparently more tolerant than wild type for the alternative nucleophiles.

More systematic studies into the role of promiscuous functions for the evolution of new functions were performed with carbonic anhydrase II (which also has weak esterase activity), phosphotriesterase (esterase/lactonase), and PON1 lactonase (phosphotriesterase/esterase) (2). These studies showed that mutations that confer improved promiscuous activities do not necessarily decrease the native activity. This means that a promiscuous function can evolve in an enzyme without compromising its native one, potentially allowing evolution prior to a duplication event. Analysis of the positions of these mutations in the three enzymes under investigation in this study and of a number of literature examples on directed evolution of promiscuous features showed that many of these mutations accumulated in loops and that the active-site residues and residues important for stability were generally unmodified (2).

36.5. CONCLUSIONS

The increasing number of bona fide promiscuous enzymes suggests that their active sites deserve this name in a more general sense than usually applied: apparently the high concentration of functional groups brings about additional activities. New high-throughput screening systems (1, 47, 60, 106) that can characterize multiple activities for entire libraries will no doubt play a role in comprehensively assessing how far this observation can be generalized. The systematic analysis of this phenomenon—either in metagenomic libraries or during cycles of directed evolution—will inform a future strategy for identification and alteration of promiscuous functions.

The question then arising is where promiscuity should be suspected and what the best choice of a starting template for enhancing an existing promiscuous activity by directed evolution is. At the moment, the ultimate answer is not available, but some preliminary rules and requirements can

be drawn up to guide the experimentalist to new promiscuous activities, as follows.

1. *The shape of the active site.* At a minimum, alternative substrates have to fit in the active site, to be within reach of the catalytic functionality, so a large, accessible binding pocket is a key requirement for substrate acceptance. For promiscuous hydrolases such as PMH, AP, or PAS, this criterion is sufficient. In addition, conformational flexibility of an active site may promote acceptance of alternative substrates by “induced fit,” e.g., based on relatively nonspecific hydrophobic interactions (117).

For the product-promiscuous enzymes (such as the cationic cyclization reactions carried out by γ -humulene synthase [100]), the rules are somewhat reversed. Here, the shape of the active site is used to favor specificity, and strategically placing them provides access to alternative products.

2. *Reactive active-site groups.* This need for high reactivity is most clearly illustrated by the promiscuous examples that carry reactive cofactors, such as metal ions (in PMH, PAS, and AP [7, 56, 99, 115a]) or flavin (BVMOs [34, 50, 58, 65, 79]), which are not covalently bound to the enzyme. Promiscuous behavior of some of the adjacent amino acid side chains and cofactors can result in promiscuous functions, mainly because of different protonation states, which, depending on the pK_a of any particular group, can exist side by side. For instance, the catalysis carried out by BVMOs is highly dependent on the protonation state of the peroxyflavin intermediate, which makes it react either as a nucleophile (deprotonated) or electrophile (protonated), or, the case of CALB, where His224 can act as a general base and acid in the same reaction (aldol condensation) (10).

3. *Native and promiscuous reactions share some key features.* Stabilization of negative charges that accumulate as the transition state is approached at considerable energetic cost will benefit a range of mechanisms. Groups that could provide such stabilization are, e.g., the oxyanion hole (as in CALB [10, 13, 104, 105]) or metal ions (as in AP, PAS, nucleotide pyrophosphatase/phosphodiesterase [NPP], or PMH [7, 56, 99, 115a, 124]) acting as general acid catalysts and/or electrostatic catalysts. In all reactions catalyzed by these enzymes the buildup of negative charge is part of the mechanism. Similar arguments can be made for the accumulation of positive charges. The positioning of stabilizing groups is important, but—at the cost of efficiency—does not have to match alternative transition states too precisely.

Fortunately, the observation of degrees of freedom extends to the molecular recognition of transition-state structures for native and promiscuous reactions as defined by the extent of bond making and breaking. For example, both AP and PAS achieve higher rate accelerations for phosphate diester hydrolysis (with an associative transition state) than for their respective promiscuous sulfate or phosphate monoesterase reactions (with a dissociative transition state resembling the transition state of their native reactions) (4, 84, 86, 87) (Table 1). So the nature of the transition state appears to be relatively unimportant, and even for efficient multiple promiscuous catalysis. The same groups must be able to stabilize transition states with different bond-breaking and -making characteristics (115a). The implication is that a reaction mechanism will not easily change its nature and—rather than fitting into the corset of the

native reaction—the most favorable interactions with the given active-site functionality will be sought.

4. *Avoiding dead-end complexes.* Covalent intermediates are commonplace in highly evolved enzymes taking advantage of nucleophilic catalysis. This catalytic strategy carries the danger of a dead-end covalent adduct (similar to a suicide substrate), leading to only one turnover and rendering the catalyst a stoichiometric reagent only. Many of the examples of catalytic promiscuity discussed in this review do not involve covalent catalysis, and in the very promiscuous PMH and AS, resolution of the covalent intermediate is unified for all conversions (4, 54, 87, 115a).

For the moment, these emerging rules are consistent with the available body of evidence, but they will have to be revised or refined in response to the discovery of more promiscuous activities. Since biocatalytic application intrinsically involves “nonnatural” conversions, there is a strong commercial driving force behind this effort. Fortunately, even promiscuous enzymes are still chiral reagents, giving access to regio- and stereoselective catalysis (22, 41, 68–71, 73, 74). Thus, enzyme promiscuity remains a useful vehicle for the identification of catalysts for a wider range of green, high-quality, and hopefully efficient biotransformations.

37.1. INTRODUCTION

As efficient biocatalysts, enzymes are used widely in the food, pharmaceutical, and chemical industries. In addition to these traditional applications, many enzymes, and in particular those with human origins, are increasingly being used as therapeutic agents to treat a wide range of genetic diseases including lysosomal storage disorders (90). Because of their widespread use, methods for producing enzymes have been developed for a variety of biological systems including bacteria, yeasts, fungi, mammalian cells, insect cells, human or animal tissues, and plants. Despite the availability of these diverse expression systems, industrial enzymes traditionally have been produced commercially by use of overproducing strains of microorganisms from which they are naturally secreted. These overproducing strains are usually generated from the wild-type strains over years of genetic selection/screening. For example, the nitrile-converting strain *Rhodococcus rhodochrous* J1, which is used for production of acrylamide from nitrile at a scale of 4,000 tons/year, is a third-generation biocatalyst developed 6 years after the first large-scale production process using *Rhodococcus* sp. N774 was initialized (60). Depending on the intended application, some industrial enzymes are isolated and purified before being formulated, such as subtilisin, a common protease used in detergents (1). Others are used in the form of whole-cell catalysts, such as nitrile hydratase, the enzyme produced by *R. rhodochrous* for acrylamide production. In contrast, therapeutic proteins are all purified and formulated with procedures approved by the FDA. In addition, once a production method for a therapeutic enzyme has been established, further improvement of the method is generally undesirable because obtaining FDA approval, a prolonged and costly process, is necessary to use the altered method (58).

With the development of recombinant DNA technology, industrial enzymes are increasingly being produced in heterologous hosts, particularly in the bacterium *Escherichia coli* and the yeasts *Saccharomyces cerevisiae* and *Pichia pastoris*. These microbial strains are chosen largely because of their well-understood genetics, established genetic manipulation methods, and the availability of large numbers of expression vectors and strains. Therapeutic enzymes are produced almost exclusively in recombinant forms, resulting in a recombinant therapeutic protein market that has increased steadily during the past few decades (110).

Although mammalian cells are predominately used for the production of recombinant human enzymes, this review will focus on the use of *E. coli* as an alternative host for the production of recombinant enzymes (93).

Developing a cost-effective recombinant protein production method requires the integration of genetic engineering with fermentation process design. At the genetic level, regulatory methods not only have to be selected to control protein expression levels (68), but additional elements that affect protein folding, stability, and transport might also need to be considered to achieve high production levels or to simplify downstream processing (64). The selection of the host strain is critical during this process, because the genetic background and phenotypes of the host can greatly affect gene expression, protein stabilization, and protein secretion. In designing the fermentation process, the preferred method is the use of high-cell-density fermentations in stirred-tank reactors. To this end, novel autoinducing gene regulatory methods that are able to function in fed-batch fermentation processes may represent a strategy superior to conventional inducible gene expression methods. We will discuss these aspects of recombinant protein production in the following sections.

37.2. OVERVIEW OF GENE EXPRESSION REGULATION

Once a protein of interest is identified, the first steps in developing a production method include selection of the host cells to be used for expression, selection of a method for gene expression regulation, and selection of a method for protein targeting (50). Although constitutive gene expression has traditionally been used for the industrial production of recombinant proteins because of its simplicity, inducible gene regulatory systems are desired for high-level recombinant protein production (Table 1). High-level recombinant protein production commonly redirects metabolic flux from cellular growth to the overproduction of the desired proteins, and the resulting increased metabolic burden can hamper host cell growth, resulting in an overall low level of recombinant protein production. In comparison, inducible gene regulation allows for activation of gene expression at a desired cell density or cell growth phase, at which point the large number of cells in the culture can achieve a high level of recombinant protein production despite the presence of

TABLE 1 Some recent examples of producing recombinant proteins in *E. coli*

Product	Host strain	Reactor	Productivity	Reference
Human interferon- α 2	DH5 α	2 liters, fed-batch	5.2 g/liter	101
Human interferon- γ	BL21(DE3)	2 liters, fed-batch	42.5 g/liter	4
Human tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)	C600	3.7 liters, fed-batch	4.51 g/liter	62
Aminolevulinate synthase	MG1655	2.5 liters, batch	5.2 g/liter	112
Alkaline phosphatase	HB101	6.6 liters, fed-batch	5.2 g/liter	16
Tilapia insulin-like growth factor-2	BL21(DE3)	5 liters, fed-batch	9.69 g/liter	47
Fructose 1,6-bisphosphate aldolase	BL21(DE3)	1.5 liters, batch	1.5 g (70 U/mg)	57
Glycine oxidase	Rosetta(DE3)	5 liters, fed-batch	1,154 U/liter	66

metabolic burden. This delay is particularly important for the large-scale production of toxic recombinant proteins that are able to inhibit cell growth even at low cellular concentrations (88). In addition to the timing of gene expression, inducible gene regulation allows for the fine-tuning of expression levels, which is frequently necessary for efficient protein secretion, correct protein folding, and the formation of disulfide bonds (5, 69). In these cases, optimizing rather than maximizing gene expression levels is desired.

The choice of an expression host strain for recombinant protein production is determined by the expected expression levels, origins of the proteins of interest, presence of post-translational modifications, and methods of gene expression regulation. While most recombinant proteins are expressed in their biologically active forms in industrial production processes, some recombinant proteins, and biopharmaceuticals produced in *E. coli*, in particular, are expressed as inclusion bodies with the biological activities being recovered only after isolation and refolding (70, 93). Isolation and purification of recombinant proteins can be significantly simplified if the proteins can be secreted into culture media or periplasm, because the recovery of cytoplasmic proteins requires disruption of the cell wall to release all cellular components, which complicates downstream purification. For proteins with disulfide bonds, periplasmic expression in *E. coli* is necessary to obtain their active forms. Despite the presence of various protein secretion pathways and the ability to obtain high levels of secretory protein production (18, 52), *E. coli* is not considered the preferred host organism for extracellular protein secretion.

37.3. HOST CELL SELECTION

The gram-negative bacterium *E. coli* is the most widely used prokaryotic organism for recombinant protein production. This is largely due to its long history and ubiquitous use in the laboratory as a model organism for bacteriology and molecular biology research. Extensive characterizations have also generated rich information about its physiology and genetics (72). This information has been used to generate a comprehensive genetic knockout library of *E. coli* mutants that can be readily obtained from culture collections (3), and has led to the creation of efficient genetic manipulation methods, such as DNA transformation and plasmid purification, that are exclusive to *E. coli*. In addition, *E. coli* can be cultivated in a wide variety of defined and rich media with a minimum achievable doubling time of 20 to 30 min, which is substantially faster than other model organisms. During the past several decades, efficient high-cell-density fermentation methods for *E. coli* have been established,

and cell densities as high as 200 g/liter (dry weight) can be achieved (96). Its potential to produce high-level recombinant proteins has been demonstrated by accumulating recombinant proteins in the periplasm at concentrations of approximately 8.5 g/liter, constituting 30% of the total intracellular proteins (52).

The most common *E. coli* strains used for recombinant protein expression are commercially available derivatives of the *E. coli* K-12 and BL strains (Table 2). These strains are engineered to enhance recombinant protein production by eliminating the host proteases encoded by the *lon* and *ompT* genes, which tend to attach to inclusion bodies separated by centrifugation to cause degradation during protein recovery. To minimize the frequency of rearrangements of genes in plasmids with multiple copy numbers, most *E. coli* expression strains are also mutated to be deficient in homologous recombination. In addition to these common mutations, a number of special strains are also available to allow for the enhanced production of proteins that are difficult to produce. These include special strains that are engineered to enable the expression of proteins with rare codons, and others that are engineered to more efficiently express toxic proteins, such as the ABLE C and ABLE K strains, which reduce the copy number of ColE1-derived plasmids to maintain a low basal expression level (12). In addition to these considerations, another important factor in the selection of an *E. coli* strain for recombinant protein production is the type of inducible gene expression system that is to be used. For example, many inducible gene expression systems, including those with the T7, *lacUV5*, and *tac* promoters, require the expression of the LacI repressor in the host strain for the repression of gene expression in the absence of chemical inducers. If the T7 gene expression system is used, expression of the T7 RNA polymerase in the host strain is also necessary to activate gene expression (26). Alternatively, it is not uncommon for repressor proteins to be produced independent of the host strain in *trans*. This is especially true for production from high-copy-number plasmids, because the higher production levels in *trans* ensure that significant amounts of the repressor are produced to completely repress gene expression. This approach is exemplified by the commercially available P_{BAD}-inducible gene expression system (36).

Despite the availability of an array of engineered *E. coli* strains for recombinant protein production, the engineering of an *E. coli* host strain is frequently necessary to achieve high-level recombinant protein production for a specific application. One example is the engineering of strains for the periplasmic production of recombinant

TABLE 2 Genotypes and key features of common *E. coli* strains^a

Strain	Genotype	Key features
ABLE C	<i>E. coli</i> C, <i>lac</i> (<i>LacZ</i> ^ω), <i>mcrA</i> , <i>mcrCB</i> , <i>mcrF</i> , <i>mrr</i> , <i>hsdR</i> (<i>r_K</i> -, <i>m_K</i> -), F' [<i>proAB</i> , <i>lacI</i> ^q , <i>lacZ</i> Δ <i>M15</i> :: <i>Tn10</i>] (<i>Kan</i> ^r , <i>Tet</i> ^r)	Reduced plasmid copy number; tetracycline resistance
BL21	<i>E. coli</i> B, F ⁻ , <i>ompT</i> , <i>hsdS_B</i> (<i>r_B</i> -, <i>m_B</i> -), <i>dcm</i> , <i>gal</i>	Protease deficient; Eco restriction and methylation deficient; galactose metabolism deficient
BL21(DE3)	BL21, λ(DE3)	Lysogene of DE3 containing T7 RNA polymerase regulated by a <i>lacUV5</i> promoter
BL21(DE3)pLysS	BL21(DE3), pLysS, <i>Cam</i> ^r	Expresses T7 lysozyme for inhibition of T7 RNA polymerase; chloramphenicol resistance
Tuner ^b	BL21, <i>lacY</i>	Decreased protein expression heterogeneity caused by removal of lactose permease
Origami B ^b	Tuner, <i>ahpC</i> , <i>gor522</i> :: <i>Tn10</i> , <i>trxB</i> (<i>Kan</i> ^r , <i>Tet</i> ^r)	Facilitates cytoplasmic disulfide bond formation; lactose permease deficient; kanamycin and tetracycline resistance
Origami 2 ^b	<i>E. coli</i> K-12, Δ(<i>ara-leu</i>)7697, Δ <i>lacX74</i> , Δ <i>phoA</i> , PvuII, <i>phoR</i> , <i>araD139</i> , <i>ahpC</i> , <i>galE</i> , <i>galK</i> , <i>rpsL</i> , F'[<i>lac</i> ⁺ , <i>lacI</i> ^q , <i>pro</i>], <i>gor522</i> :: <i>Tn10</i> <i>trxB</i> (<i>Str</i> ^r , <i>Tet</i> ^r)	Enhanced cytoplasmic disulfide bond formation; tetracycline and streptomycin resistance
Rosetta ^b	BL21, pRARE (<i>Cam</i> ^r)	Enhances expression of genes with rare codons; chloramphenicol resistance
BLR ^b	BL21, Δ(<i>srl-recA</i>)306:: <i>Tn10</i> (<i>Tet</i> ^r)	Improved plasmid monomer yields; tetracycline resistance
HMS174 ^b	<i>E. coli</i> K-12, F ⁻ , <i>recA1</i> , <i>hsdR</i> (<i>r_{K12}</i> -, <i>m_{K12}</i> +) (<i>Rif</i> ^r)	Improved plasmid monomer yields; rifampin resistance

^aData are gathered from literature and suppliers' product catalogs. Strains are available from common commercial resources, such as Invitrogen, Novagene/EMD Biosciences, and Stratagene/Agilent Technologies.

^bAlso available with DE3 or (DE3)pLysS.

proteins, which is considered superior to cytoplasmic production and is necessary for the active expression of target proteins containing disulfide bonds (18, 34). In one such study, the periplasmic production of insulin-like growth factor-I in *E. coli* was doubled by coexpression of DsbA or DsbC, two proteins involved in disulfide bond formation (52). The overexpression of membrane proteins in *E. coli* is also notoriously challenging (25). To incorporate a membrane protein into the membrane to form a functional protein, periplasmic domains of the membrane protein are first translocated across the inner membrane via the Sec secretory pathways and then targeted into the inner membrane primarily via the signal recognition particle (SRP) targeting pathway (22, 40, 61). However, membrane proteins frequently form inclusion bodies during cytoplasmic overexpression, presumably because of fast protein expression and slow protein translocation. This problem has been addressed by Wagner et al. (109), who reported the engineering of *E. coli* strains C41(DE3) and C43(DE3), two derivatives of BL21(DE3), for fine-tuning of the expression levels of membrane proteins. These strains use the expression of T7 lysozyme to inhibit the activity of T7 RNA polymerase, allowing for the expression levels of membrane proteins to be optimized to yield maximum amounts of active protein.

37.4. VECTOR DESIGN

Genes encoding proteins of interest can either be inserted into plasmids or into the *E. coli* chromosomal DNA for gene expression. Integration into the chromosomal DNA has many advantages including enhanced expression stability, easy strain maintenance, and antibiotic-free cultivation. Despite these advantages, the use of chromosomal

integration is limited by the difficulty in achieving a high level of expression because of low gene copy numbers. This problem can be slightly alleviated by introducing multiple copies of the gene into the chromosome (78).

As an alternative to chromosomal insertion, the use of plasmids to harbor genes of interest has proven to be effective for high-level gene expression. Most native plasmids are circular DNA, which can replicate autonomously, and vary from a few to more than 1,000 kilobase pairs in size. Most natural plasmids harbor genes encoding proteins that contribute diverse functions to the host cells, such as antibiotic resistance, conjugation, virulence, and degradation of toxic substances. Plasmids are present in their host cells at a specific number of copies, ranging from one to more than one hundred. During cell division, high-copy-number plasmids are partitioned into daughter cells in a near-random fashion, while low-copy-number plasmids may be distributed via active partition systems to ensure faithful inheritance (9). Wild-type plasmids also take advantage of the bacterial site-specific recombination mechanism to overcome homologous recombination and maintain plasmid monomers (13, 104). Some plasmids contain a toxin-antitoxin system to ensure at least one copy of the plasmid is present in each surviving daughter cell (10, 35). This is best illustrated by the CcdAB toxin-antitoxin system encoded in the *E. coli* F plasmid (19). CcdB is a toxin that specifically targets gyrase to inhibit DNA replication. The CcdA antitoxin binds CcdB to prevent gyrase inhibition, and allows DNA replication to resume. Because CcdA is prone to degradation by the Lon protease, constitutive production of CcdA is necessary to neutralize the CcdB toxicity. If a daughter cell does not acquire an F plasmid during cell division, production of CcdA and CcdB discontinues; however, CcdA inherited from the parental cell is more rapidly degraded

than CcdB, resulting in cell death due to blocked DNA replication by CcdB. Based on this principle, a strategy has been devised to engineer *E. coli* for antibiotic-free cell cultivation in a minimal medium by use of plasmids containing a toxin-antitoxin system (21).

Most plasmids used for recombinant protein production in *E. coli* consist of an origin of replication, a promoter, a set of multicloning sites, transcription and translation terminators, and a selection marker (Table 3) (68). The origin of replication determines the copy number of a plasmid, and also plays a critical role in determining the compatibility of the plasmid with other plasmids. Various promoters are available that use a diverse array of inducing agents or methods with the expression levels of recombinant proteins largely determined by promoter strength. Many commercial plasmids also contain N- and C-terminal tags to form fusion proteins that facilitate recombinant protein detection and purification. Common tags include the *myc* tag for protein detection and the *his* tag for protein purification (30, 43, 44). These tags, however, are rarely used in large-scale recombinant protein production. Many different methods have been used to enhance gene expression in a plasmid-based system including using high-copy-number plasmids (38, 99) and strong promoters (51), as well as engineering translation efficiency (11, 80). However, enhanced gene expression inevitably increases the metabolic burden on the host cells, resulting in slower growth rates that ultimately lower production yields (68). As a result, there is no general rule for choosing a “perfect” plasmid to maximize recombinant protein expression, and “trial and error” is still applied to identify a balance between protein production levels and metabolic burden on the host cells.

TABLE 3 Genetic elements that determine gene expression in a typical *E. coli* plasmid

Element	Function
Repressor	Represses or activates gene expression in <i>trans</i> ; enables inducible gene expression
Promoter	Activates gene expression by recruiting RNA polymerase and transcription factors; fine-tuning of gene expression levels using inducing agents; binary or graded gene expression control
mRNA secondary structure	Fine-tuning of translation efficiency
RBS	Recruits ribosomes; fine-tuning of translation efficiency
Stop codon	Terminates gene translation
Transcription terminator	Terminates transcription; enhances mRNA stability
Antibiotic resistance gene	Confers antibiotic resistance; determines compatibility with other antibiotic-resistance plasmids
Origin of replication	Initiates plasmid DNA replication; determines copy number and incompatibility with other plasmids

37.4.1. Origin of Replication

The copy number of a plasmid is largely determined by the origin of replication. A strong origin of replication is generally preferred for the expression of recombinant proteins so as to achieve high production levels. Commonly used origins of replication include the high-copy-number pUC replicon, which can maintain a couple of hundred copies per cell (113), the ColE1 replicon, which has a medium copy number with 15 to 60 copies (39, 65), and the p15A replicon, with a copy number of 10 to 12 (42). Some origins of replication, such as pSC101, generate an even smaller number of copies per cell, and may be useful for the production of toxic proteins (79).

Origins of replication also determine plasmid incompatibility, which has been used to classify plasmids into incompatibility groups (20, 23, 106). When multiple incompatible plasmids are present in the same host strain simultaneously, not all plasmids will be inherited into the daughter cells because of the absence of selection pressure, a process referred to as plasmid segregation (27). Although many biological processes are involved in determining plasmid incompatibility, stochasticity during cell division is believed to be a significant factor that results in the loss of plasmids with the same origins of replication during the random partitioning process (9, 76). To avoid the plasmid loss, the use of plasmids in different incompatibility groups is preferred when two plasmids are necessary for recombinant protein production, because this eliminates the need to use two antibiotics simultaneously to maintain the plasmids. However, the use of antibiotics to maintain compatible plasmids is necessary, though undesired for increased cost, to prevent the loss of both plasmids during cell division, which generates plasmid-free cells whose faster growth rates may result in the domination of the culture.

37.4.2. Transcriptional Regulation

Promoters and transcription terminators are the primary genetic elements for transcriptional regulation. The essential components of a typical *E. coli* promoter are shown in Table 3. The *E. coli* RNA polymerase specifically recognizes two DNA sequences located 35 bases (−35 site) and 10 bases (−10 site) upstream of the transcription start site; the latter is also known as TATA boxes. These sites have conserved sequences, with the −35 site having a consensus sequence of TTGACA and the −10 site having a consensus sequence of TATAAT (37). Base changes in these regions or length changes to the spacer can significantly reduce gene expression levels. In addition, strong promoters have an additional AT-rich sequence (known as UP element) upstream of the −35 position (86). Finally, many bacterial promoters also contain an operator that interacts with a cognate transcription factor. In the presence of this transcription factor, gene expression from the promoter can be activated or repressed depending on the nature of the transcription factor as well as the presence of an inducing agent. This mode of gene regulation is commonly referred to as inducible gene expression, and is frequently the most important property of a promoter used for recombinant protein production.

Because the number of gene transcripts is the strongest determinant of high-level protein production, transcriptional regulation is the most important consideration when developing protein production methods. In *E. coli*, the rate of transcription from a promoter depends on the strength of the interaction between the promoter and RNA polymerase, with strong promoters having strong interactions. As a result, strong promoters are preferred in recombinant

protein production, although using a strong promoter does not always warrant a higher expression level (discussed in the following sections). The basal expression level of a promoter is also an important consideration, in particular, for toxic protein production, because high basal expression levels of toxic proteins can significantly inhibit cell growth, resulting in an overall low production level. Common strategies for reducing the basal expression level of a promoter include the insertion of a DNA sequence into the native promoter that is recognized by a repressor protein, such as the *lac* operator, to which the LacI repressor protein specifically binds (8). This strategy is used in a number of commercial plasmids to ensure low basal expression levels from their regulated promoters, including the strong T7 and P_{BAD} promoters (see the following sections). In addition, this strategy was demonstrated in recent work to reduce the basal expression level of the P_{luxI} promoter (92). After insertion of the *lacI* recognition sequence upstream of the transcriptional start site, the basal expression level of the P_{luxI} promoter was reduced by more than fourfold.

Transcription terminators are also an important determinant of the strength of protein production, because they seem to affect mRNA stability (74, 77). It has been well demonstrated that differential mRNA stability can influence relative gene expression levels (46, 67, 73). As a result, enhancing mRNA stability in a transcriptional regulatory system can be used to further increase gene expression levels. This can be achieved by inserting repeat sequences downstream of the coding sequence to form stable RNA structures or stem loops, which can slow mRNA degradation by preventing the 3'→5' exonuclease activity of RNase II and polynucleotide phosphorylase (41). Bacterial transcription terminators are composed of repeat sequences (46). As a result, transcription terminators can be used to prevent continued transcription and to increase mRNA stability and enhance gene expression (111). Because of their importance, most commercial plasmids contain two tandem transcription terminators downstream of the encoding gene, such as the T1 and T2 terminators.

37.4.3. Translational Regulation

Translation is initialized by the binding of a ribosome to a ribosome binding site (RBS) located downstream of the transcription initiation site. An RBS contains a Shine-Dalgarno (SD) sequence that is complementary to nucleotides at the 3' end of the 16S rRNA, a spacer sequence to the translation start codon, a start codon, and a sequence downstream of the start codon. The actual SD sequence in an RBS varies, but all contain a purine-rich sequence positioned 5 to 12 nucleotides upstream of the start codon (49). It has been demonstrated that the sequence UAAGGAGG is more efficient than AAGGA, and that the length and sequence of the spacer region can also have a significant influence on the translational efficiency (85). Despite extensive exploration of the influence of the SD and the spacer sequences on translational efficiency, the re-engineering of these sequences in a commercial plasmid is rare. Studies have also examined the influence of the start codon and the sequences immediately downstream of the start codon on translation efficiency, and it was found that AUG is the most efficient start codon for translation initiation in *E. coli* (83, 85). It should be noted that the use of the AUG start codon may introduce a nonnative methionine residue as the first amino acid in the protein sequence. If such an addition is undesired, periplasmic production of the protein can be used to completely eliminate this residue during the

proteolytic removal of the leader sequence. Finally, efficient translation also depends on the presence of a stop codon, with the sequence UAA being preferred in *E. coli* and the most efficient termination sequence being UAAU (82).

The secondary structure of the transcribed mRNA is also an important factor in the efficiency of translation, and the engineering of mRNA secondary structures and 5'-untranslated regions (5'-UTR) can be used to alter expression levels. The local secondary structures of mRNA in the RBS are known to have a profound impact on the translation efficiency, and up to a 100-fold increase in expression level has been observed for engineered systems (94). Such a significant change is believed to be caused by competition between the formation of secondary structure and the binding of the ribosome (24). Based on this principle, expression of a porcine P450 enzyme in *E. coli* was enhanced by approximately 100-fold by engineering the secondary structure of the RBS (56). Despite the potential for marked improvements in recombinant protein production, engineering mRNA secondary structures is more commonly used for fine-tuning gene expression levels rather than maximizing protein production. This has been demonstrated nicely by Keasling and coworkers (98, 100), who varied the relative expression levels of two genes expressed in an operon by inserting different DNA sequences that encoded for mRNA secondary structures or RNase sites between the two genes. This strategy was subsequently applied to modulate the expression levels of multiple genes in a synthetic pathway (81). In another study, Isaacs et al. inserted a small DNA sequence between a promoter and an RBS to repress gene expression in *cis* through formation of mRNA secondary structure that blocked ribosome binding. The repression can be completely alleviated by use of a second DNA sequence provided in *trans* which can form a more stable mRNA secondary structure with the introduced DNA fragment to release the RBS and activate gene expression (48), providing a novel method for positive and negative regulation of gene expression.

37.4.4. Protein Secretion

Secretion of recombinant proteins in *E. coli* can refer to delivery of the proteins to the periplasmic space, or the export of proteins across the outer membrane to the culture media. The secretion of proteins across the outer membrane of *E. coli* has been reported occasionally. However, *E. coli* is not the preferred organism for protein export because it has not been evolved to produce large quantities of exported proteins. Protein secretion to the periplasm, in contrast, has been used extensively to produce functional proteins, obtain authentic protein sequences, increase yields, and facilitate protein purification (18, 34). Five types of secretory pathways have been identified in gram-negative bacteria, with the type I and II secretory mechanisms being the most commonly used for recombinant protein secretion (69). Type I secretion transports proteins without formation of a periplasmic intermediate and is capable of exporting target proteins to the culture media (95). In contrast, all type II secretory pathways, including the SecB-dependent secretion pathway (28), the SRP pathway (61), and the twin-arginine translocation (TAT) secretion pathway (6, 7), transport target proteins via a two-step process. The advantages and disadvantages of each secretion pathway are summarized in Table 4. Regardless of the actual secretion mechanisms, an N-terminal peptide sequence, also referred to as a leader sequence, is necessary for targeted proteins to be recognized for secretion (49). It should be noted that the effectiveness

TABLE 4 Secretory systems used in *E. coli* for recombinant protein production

Type	Advantages	Disadvantages
Type I secretion pathway	Single-step secretion; capable of extracellular export	The leader sequence is not removed after secretion; low transport efficiency
SecB-dependent pathway	Used extensively for recombinant protein secretion; rich biochemical and biophysical information; various strategies for improving secretion efficiency	Unable to secrete folded proteins; low transport efficiency for some proteins
PRP	Transport efficiency can be altered by changing the leader sequence	Less commonly used for recombinant protein production
TAT	Capable of secreting folded proteins as a mechanism for protein-folding quality control	Relatively new system; low efficiency; slow transport rates; high energy cost

of a leader sequence for protein secretion is highly protein sequence dependent, and is substantially influenced by the genotype of the host strain (14). Finally, it is known that the fine-tuning of gene expression rates is necessary to obtain increased secretion efficiency, because highly expressed proteins tend to overwhelm the secretion machinery, resulting in the formation of inclusion bodies. Because of this effect, secretion efficiency can be enhanced by coexpression of chaperones to facilitate protein folding and disulfide bond formation in the periplasm (52).

37.5. INDUCIBLE GENE EXPRESSION SYSTEMS

Inducible gene expression systems are commonly used in recombinant protein production. The desired properties for such a system include tight regulation (low basal expression levels), inducibility (activation of gene expression in the presence of inducing agents), low cost of inducer, and large dynamic ranges (fine-tuning of expression levels through a broad range). For therapeutic proteins, any inducing agents also need to be approved for use by the FDA. If the proteins of interest are toxic to *E. coli* hosts, extremely low basal expression levels are critical. Although many inducible gene expression systems have been developed, there are a handful of systems that are predominantly used for recombinant protein production.

The *lac* system is derived from the *E. coli lac* operon and contains a *lac* promoter that is repressed by the binding of the LacI repressor protein to the *lac* operator. LacI can form a complex with lactose or synthetic analogs of lactose that prevents the repressor from interacting with the *lac* operator, resulting in activation of the *lac* promoter. Even though lactose can efficiently activate the *lac* promoter, it is also decomposed by β -galactosidase, an enzyme regulated by the native *lac* operon. As a result, synthetic (gratuitous) inducers, such as isopropyl- β -D-thiogalactoside (IPTG), that are not degraded by β -galactosidase are more commonly used to activate the *lac* promoter. IPTG has the additional advantage in that it can freely diffuse across the cell wall, while LacY (lactose permease) is required to transport lactose into cells (55). Since LacY is regulated by the *lac* promoter of the *E. coli* chromosome, it forms a positive-feedback loop to transport more lactose into the cell upon activation, resulting in heterogeneity of gene expression in a cell population. It should be noted that activation of the *lac* promoter is also subject to catabolite repression, because activation of the promoter requires the efficient formation

of cyclic AMP (cAMP)-cAMP receptor protein complexes. Low concentrations of cAMP are generated in the presence of glucose in the culture medium, and therefore, catabolite repression of the *lac* promoter excludes the use of the *lac* promoter in cells growing in rich media. A variant of the *lac* promoter, *lacUV5*, is a stronger promoter with activation that is less affected by catabolite repression and is more commonly used in production of recombinant proteins. A mutant repressor protein, LacI^q, with improved expression levels is also commonly used as the increased level of LacI reduces basal gene expression.

The T7 gene expression system has become an increasingly popular tool for recombinant protein production (103). The T7 promoter is activated exclusively by the bacteriophage T7 RNA polymerase and cannot be activated by the *E. coli* RNA polymerase because of the lack of -35 and -10 sequences in the promoter. A significant advantage in using the T7 expression system is the highly efficient transcriptional initiation of the T7 RNA polymerase that allows for high-level recombinant protein production. A variety of *E. coli* host strains is commercially available for use with the T7 gene expression system, where the T7 RNA polymerase is encoded on an F plasmid [such as BL21(DE3)] regulated by an engineered *lac* promoter. The basal expression level of the T7 promoter can also be lowered by using a hybrid promoter incorporating the *lac* operator (26), making it possible to express highly toxic proteins in *E. coli* (88). Because of the presence of the *lac* regulatory components, host strains used for T7 expression generally harbor the mutations used by the *lac* gene expression system for increased repression and reduced expression heterogeneity. Further reductions in basal expression levels can be achieved by expressing the inhibitor of the T7 RNA polymerase, T7 lysozyme (strains with pLysS or pLysE plasmid). Additional strains, such as the Tuner strains, can be used for the fine-tuning of gene expression (Table 2).

The pBAD expression system has been used widely for recombinant protein production because it offers tight regulation and high tunability (36, 75). The system is based on the P_{BAD} promoter, which controls the *E. coli* arabinose operon and is regulated by AraC. In contrast to the LacI repressor, which functions as a negative regulator, AraC acts as a both positive and negative regulator. In the absence of arabinose, AraC binds to one set of sites in the P_{BAD} promoter and inhibits gene expression; in the presence of arabinose, AraC binds to a different set of sites in the promoter to activate gene expression. Because AraC is required for both repression and activation of gene expression, it is

preferentially provided in *trans* so as to achieve the high levels of cellular AraC that are necessary to regulate the promoter harbored in high-copy-number plasmids. Analogous to the *lac* promoter, heterogeneous expression has also been observed upon induction by arabinose due to the autocatalytic transport of arabinose by the gene products of *araA* and *araFGH*, which are regulated by the *E. coli* P_{BAD} promoter (97). Engineered strains have been developed to allow homogeneous gene expression in the presence of subsaturating concentrations of arabinose, primarily containing mutations of *araA*, *araGFH*, *araBCD* (genes encoding proteins for arabinose degradation), and *lacY* (71). A hybrid P_{BAD} promoter incorporating a *lac* operator has also been engineered, and the resulting hybrid promoter allows tunable gene expression with a dynamic range of up to 1,800-fold by use of a combination of IPTG and arabinose (63).

Inducible gene expression allows production of high levels of recombinant proteins; however, the introduction of inducing agents is undesired in large-scale fermentations, because this requires interruption of the fermentation process and the use of special devices to introduce the chemical inducers. These additional operations increase the cost of manufacturing recombinant proteins, and more importantly, may introduce contaminants that compromise the quality of the whole culture batch. While the use of temperature-sensitive gene expression systems may eliminate the risk of introducing contamination, changing the temperature of a large fermentation vessel is inefficient, and is generally avoided for the production of therapeutic proteins. A more practical alternative is the use of auto-inducible gene expression systems. One example of an autoinducible strategy is the use of autoinducing media (102). Such media are composed of a specific amount of glucose in addition to other carbon sources and nutrition. In the presence of glucose, catabolite repression inhibits gene expression from promoters regulated by a *lac* operator. Upon the complete consumption of glucose, the promoters are activated, causing gene expression. By adjusting the starting concentrations of glucose, the induction time can be fine-tuned to optimize recombinant protein production (45). Another strategy to implement autoinduction is based on the bacterial quorum-sensing mechanism (33). Quorum-sensing systems produce an autoinducer that is recognized by its cognate transcription factor to activate gene expression once concentrations of the autoinducer exceed a threshold level. Because autoinducer concentrations largely depend on local population concentrations, quorum sensing enables cell-density-dependent gene expression. In the LuxI-LuxR quorum-sensing system, LuxI catalyzes the synthesis of the autoinducer, *N*-3-oxo-hexanoyl homoserine lactone (OHHL). At concentrations higher than the threshold level, OHHL interacts with the LuxR transcriptional activator, and the LuxR-OHHL complex activates gene expression from the P_{luxI} promoter. Because a quorum-sensing system is self-sufficient, its activation is completely autonomous. An attempt to use the LuxI-LuxR system for recombinant gene production has been reported (107). Because a wild-type quorum-sensing system is activated at a defined cell density, tunable quorum-sensing systems are desired for recombinant protein production so the induction timing can be optimized for each target protein. A method for creating these tunable systems by use of protein engineering has been proposed (89), and mutant quorum-sensing components have been generated by use of directed evolution (53, 54, 91). By use of LuxI and LuxR mutants, a series of engineered LuxI-LuxR systems can be generated for the activation of gene expression at a wide

range of unique cell densities. Compared with the use of autoinducing media, quorum sensing can be used in a broad range of culture media, including those designed for high-cell-density fermentations.

37.6. HIGH-CELL-DENSITY FERMENTATION

High-cell-density fermentations of *E. coli* are used to obtain high volumetric productivities of recombinant proteins (17). During the past few decades, various medium compositions and operating conditions have been established to cultivate *E. coli* to densities as high as 200 g/liter (dry cell weight), making it possible to produce recombinant proteins at concentrations above 10 g/liter (59). It should be noted that all nutrients and trace ions become toxic to cells at high concentrations and should be avoided in high-cell-density fermentations. For example, glucose becomes inhibitory if its concentration exceeds 50 g/liter, and the inhibitory concentrations of ammonia and iron are 3 g/liter and 1.15 g/liter, respectively (84). Oxygen levels also commonly exert significant constraints on achievable cell densities, and efficient aeration conditions and the use of pure oxygen are necessary. It has been established that 1.96 g of oxygen is required to grow *E. coli* to 1 g of dry cell weight (84). Cell growth is also significantly inhibited by acetate accumulation at concentrations of 2 g/liter or higher, and control of acetate secretion by *E. coli* is necessary for high-cell-density fermentations (29). Limiting essential nutrient levels, and therefore cell growth rates, is an effective strategy to reduce acetate production. However, because this approach reduces cell growth rates, it is not desired if other options are available.

High-cell-density fermentations are performed in fermentors or stirred-tank reactors, and fed-batch (semibatch) fermentation is more common than batch operation (84). In a fed-batch operation, the culture medium can be simply introduced into a fermentor at a predefined mass flow rate, which can be constant, stepwise (gradual or linear), or exponential. Constant rate feeding is technically simple, but the specific cellular growth rate changes over time. Stepwise feeding enables increased cell growth at the late growth phase and extends the exponential growth phase, which favors recombinant protein production. Exponential rate feeding has a significant advantage in that a constant specific growth rate can be maintained, and methods exist to calculate the exponential feeding rates that are necessary for a specific growth rate (15). By choosing specific growth rates below the threshold level for acetate accumulation (1.5 to 2 g/liter), cell growth inhibition by acetate can be minimized. A specific growth rate can also be maintained if the feeding rate is coupled to feedback-control systems that regulate cell growth conditions (2).

37.7. CONCLUSION

Despite extensive developments in the engineering of *E. coli* strains and the construction of vectors for recombinant protein production, it still remains a challenge to produce any protein of interest profitably at an industrial scale. In particular, the isolation of expressed proteins remains an inefficient process involving multiple steps. On the production side, achieving a balance between protein production levels and the metabolic burden on the cell is a time-consuming process. However, sophisticated biomolecular engineering methods have been developed over the past few decades to address similar issues in metabolic engineering, and they could be used to circumvent some of the challenges present

in the high-level production of recombinant proteins in *E. coli*. For example, Farmer and Liao (31) designed a genetic feedback-control circuit to adjust expression levels according to carbon availability. This strategy autonomously responded to the metabolic burden caused by overexpression of recombinant proteins, and resulted in increased production titers. The arresting of *E. coli* cells at the quiescent state, allowing for cells to divert resources typically used for biomass synthesis to recombinant protein production, has also been demonstrated, effectively uncoupling protein overexpression and cellular growth (87). Other approaches have looked at simplifying the purification of produced proteins, typically by engineering of the protein secretory pathways for enhanced secretion efficiency (105). A more novel approach was pursued by Suzuki et al., who developed a method for the degradation of all cellular proteins except the protein of interest by engineering mRNA degradation, a strategy that may significantly facilitate protein purification (105). Finally, a minimal cell harboring exclusively essential genes has been constructed (32, 108). Although such a cell may exhibit undesired vulnerability, it may allow as many resources as possible to be used for recombinant protein production when cultivated in well-controlled environments. While many of these strategies have not been tested extensively enough to determine their actual benefits, they show how our current ability to engineer and program cellular systems has created new methods to enhance the production of recombinant proteins, and show the promise of ever more sophisticated methods.

Bioprocess Development

LUTZ HILTERHAUS AND ANDREAS LIESE

38

38.1. BACKGROUND

Within bioprocesses, organic compounds are converted by either isolated enzymes or whole-cell biocatalysts. Thus, the enzyme is the elementary operational component in a bioprocess, while the spectrum of bioprocesses ranges from reactions with single purified enzymes to complex cellular systems. Biotransformations can be differentiated into enzymatic and metabolic bioconversions. Enzymatic biotransformations are characterized by a low number of specific reactions, whereas metabolic bioconversions need the metabolic system of living and growing cells. The latter can be bacteria, yeasts, or fungi. In contrast to these, enzymatic biotransformations are carried out by resting cells or isolated proteins in different types of bioreactors (41). The production of fine and bulk chemicals via biocatalyzed processes can be competitive with classical chemical processes when economic advantages are given. Further on, ecological benefits such as a reduced carbon footprint might increase the market potential of biocatalytic products, dependent on the actual pressure exerted by the respective governments and societies (Fig. 1).

In contrast to chemical processes, bioprocesses often apply milder reaction conditions and are more selective. On the one hand, this is advantageous because of fewer purification steps, a lower amount of side products, and lower energy consumption. On the other hand, one has to consider the sensitivity of the biocatalyst in view of substrate and solvent tolerance, temperature, and shear force stability, as well as its storage, retention, and recycling. Advances in biocatalyst improvement by recombinant technologies provide the possibility to alternate the substrate spectra, activity, and stability of enzymes, and the young discipline of systems biology allows the optimization of whole microorganisms with respect to a desired product (42).

In sum, the arguments for the usage of enzymes and whole cells in industrial synthesis of bulk and fine chemicals are crucial when high standards regarding selectivity and purity have to be reached. Therefore, requirements for a successful industrial bioprocess are rational design and development starting from basic reactor types, optimizing the setup with respect to the biocatalyst. Fundamental aspects of bioreaction engineering, which need particular considerations, include enzyme kinetics, immobilization of enzymes, and scale-up. Here, the reader is referred to the respective chapters within this book, whereas this chapter deals with the reactor setup and the bioprocess itself.

38.2. CONCEPT AND GENERAL FEATURES OF BIOPROCESSES

A bioprocess is based on a biological catalyst that is used to conduct a chemical reaction leading to a defined product. The choice of the reaction media, the biocatalyst, or the chemical and physical parameters is the natural scientific starting point to establish and optimize a bioprocess (Fig. 2). However, associated reactors, process control, and modeling are engineering scientific starting points to understand and enhance a bioprocess. Within this section the specific requirements of a biocatalytic reaction from a natural scientist point of view are illustrated and discussed, whereas aspects of process engineering are covered in section 38.3.

38.2.1. Special Challenges of Biocatalysis

In the early times of bioprocess engineering, water was used principally for the reaction medium, because it was assumed that a higher stability and activity can be reached in the natural medium of enzymes. Connected to this is a low solubility of organic substrate and products, entailing low yields and productivities that again necessitate extensive product purification. Next to these parameters, biocatalyzed reactions are limited by other factors which directly influence the applied enzymes and microorganisms. These are temperature, pH value, shear forces, foam formation, organic solvents, and so on. In the view of fermentation processes, these factors are oxygen enrichment, mixing, carbon and nitrogen source, and so forth.

Today, it is a matter of common knowledge that enzymes and whole cells can be applied successfully also in organic solvents (13), ionic liquids (58, 69), supercritical solvents (30), and mixtures thereof, as well as in a solvent-free manner (23, 24). Accordingly, the spectrum of possible applications of biocatalysts was enormously increased (see also section 38.5).

The temperature of bioprocesses is a crucial point when high turnover numbers will be reached. The reaction rate of a biocatalyzed reaction follows the Arrhenius equation to a certain point. Similar to other chemical reactions, the activation energy and frequency coefficient are biocatalyst dependent and lead to a rate constant k at a certain temperature, whereas in biotransformations not k is used but v_{\max} .

$$k = b \cdot \exp\left[-\frac{E_A}{RT}\right]$$

This equation can be used only in the case of simple reaction steps and in a certain temperature interval.

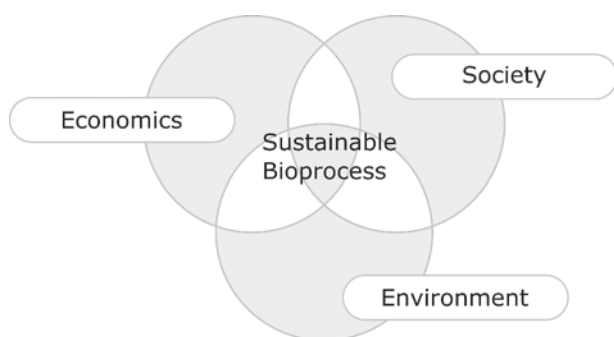

FIGURE 1 Terms of sustainable development.

At an enzyme-dependent temperature, denaturation of the enzyme occurs (Fig. 3) and the reaction rate decreases. Therefore, next to the activity, the enzyme's stability is important, including the half-life time of the biocatalyst.

Regarding the stability of enzymes at increased temperatures, different approaches were carried out to increase the temperature range of bioprocesses. One possibility is using enzymes from extremophilic microorganisms which have been adapted during the natural evolution process to deal with higher temperatures or extreme pH values (47). Another possibility is directed evolution, which can complement the spectrum of natural enzymes by adapting enzymes in the laboratory in view of stability at higher temperature, pH, and solvent tolerance (1). To broaden the applicability at different temperatures, the stability of enzymes can be also improved by immobilization. Next to the effect on the temperature tolerance, immobilization can also help to enable the use of enzymes in different solvents, at extremes of pH and exceptionally high substrate concentrations (18).

However, although the protein literature contains many references to shear denaturation, there are contradictory

reports on this phenomenon with respect to solubilized enzymes (28). The negative effect on immobilized enzymes and whole cells is assured. Another force influencing protein denaturation and enzyme inactivation is the surface tension (6). Therefore, during process design, these criteria also have to be considered, especially when foam formation or shear sensitivity are problems known from preliminary experiments.

38.2.2. Advantages of Biocatalysis

Enzymes catalyze several defined reactions, rather than defined classes of reactions; hence, there is a big potential for enzymes in industrial processes. Compared with classical chemical catalysts, enzymatically catalyzed reactions are and have to be performed under mild reaction conditions regarding, e.g., pH value and temperature. Enzymes catalyze exactly one defined reaction; therefore, in most cases no impurities by side reactions occur. The reaction medium consists of a few components, which have mostly a precise composition, so that purification causes relatively low costs. However, one has to watch out not to add too many salts in the form of buffer and metal salts that need to be removed later during downstream processing. By coupling several enzymatic reactions, sequences can be built up to synthesize also more complex molecules, omitting intermediate purification. However, in practice it has to be considered that by increasing the number of reaction steps, the technical implementation gets more complex, demanding integration of process engineering and biocatalysis at an early time. A further advantage compared with classical chemical catalysts, like acids or heavy metal-based ones, is the lower toxicity of biocatalysts. Although it is known that some enzymes cause allergic reactions, in general, enzymes are not acutely toxic.

38.2.3. Systems Biology and Metabolomics

Metabolic bioconversions need the metabolic system of living and growing microorganisms, e.g., bacteria, yeasts, or fungi. The special challenges of these bioprocesses are

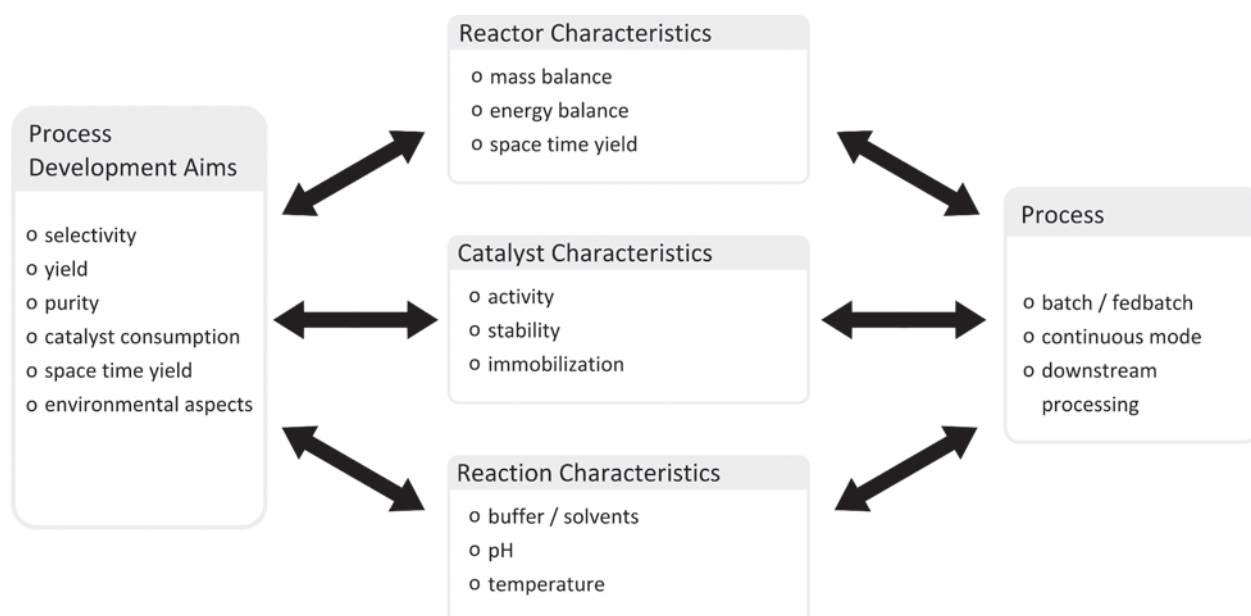

FIGURE 2 Rational process design.

FIGURE 3 Specific activity of immobilized wild-type benzoyl formate decarboxylase at different temperatures (22).

maintaining growing conditions, excluding contaminating organisms, and aerating large volumes of fermentation broth. One disadvantage often found is the extremely low volumetric productivity in combination with the production of undesired side products because of the metabolism of the microorganisms. Therefore, the focus on the overproduction of one specific product by so-called designer bugs is desired.

Traditionally, industrial microorganisms have been developed via multiple rounds of random mutagenesis and selection (2). A goal of systems biology is predictive metabolic engineering, where genes within metabolic pathways are purposefully amplified or deleted based on the consideration of the metabolic network as an entirety (63). However, the application of systems biology to strain development has only just begun to emerge. By combining the results of multiple genome-wide analyses and computational analyses, systems biology can subsequently be used for designing strategies for strain improvement (52). Substantial improvements of analytical hardware allow metabolomics to run routinely now. Data are successfully used to investigate genotype-phenotype relations of strains and mutants. Metabolomics facilitates metabolic engineering to optimize microorganisms for industrial biotechnology and spreads the investigation of biotransformations (48). Metabolomics allows the construction of designer organisms for process application by use of biotransformation and fermentative approaches making effective use of single enzymes, whole microbial cells, and even eukaryotic cells.

Recently, several amino acid producers have been successfully developed by systems metabolic engineering, where the metabolic engineering procedures were performed within a systems biology framework and entire metabolic networks, including complex regulatory circuits, were engineered in an integrated manner. Park and Lee (51) reviewed the current status of systems metabolic engineering for developing amino acid-producing strains. Here, engineering targets are determined by considering entire metabolic and regulatory networks together with midstream (fermentation) and downstream (recovery and purification) processes. The impact on the entire metabolism of altering these targets is examined to provide feedback, and through the iterative mode of operation of metabolic engineering, the ultimate metabolic phenotype desired can be obtained.

38.3. PROCEDURES OF BIOPROCESS DEVELOPMENT

The industrial application of biotransformations is often limited to the transfer of laboratory bench experiments to the cubic-meter scale. The scale-up implies an increase in the volume handled rather than the decrease in the surface-to-volume ratio. The issues involved are, above all, mixing and heat, as well as mass transfer being connected to power consumption and rheology. The basic reactor types and their mode of operation will be discussed with regard to these physical aspects.

38.3.1. Bioprocess Engineering Principles

The increase of mass and heat transfer within the bioreactor and, by this, the increase of the conversion is achieved by a homogenization of the reaction components. Mixing is the uniform distribution of several components in a specific volume leading to minimal differences in chemical composition, physical characteristics (temperature, density, and viscosity), and/or morphology (size and form of bubbles or particles) (8). Both quality of mixing and mixing time are applied to evaluate a mixing process. The specification of the mixing time only has sense when it is combined with the quality of mixing M . This is defined as:

$$M = 1 - \frac{\Delta c}{\Delta c_0}$$

Here, Δc_0 is the difference in concentration at the beginning of the mixing process, whereas Δc is the concentration difference at the time t_c . The reduction of concentration gradient can be described mathematically with adequate accuracy by an exponential function:

$$\frac{\Delta c}{\Delta c_0} = k_0 \cdot \exp\left(-\frac{\Theta}{t_c}\right)$$

It is assumed that differences in density and viscosity can be neglected; hence, mixing time Θ depends on the revolutions per minute n , the stirrer diameter d , and the kinematic viscosity ν .

The basics to calculate ideal reactor types (38) and the choice of an appropriate reactor are discussed below. Here, only the change in the amount of substance and not in energy is considered, whereas the equations are valid both for enzymatic and chemical catalysis. Only the three basic types of reactors are presented here. All others are variations or deductions thereof:

- Stirred-tank reactor (STR)
- Continuously operated STR (CSTR)
- Plug flow reactor (PFR)

There are no mass flows in the STR during operation, meaning that a closed system is present. In contrast, CSTR and PFR are continuously operated reactors; hence, in these open systems, ingoing and outgoing mass flows have to be considered (Fig. 4). The key feature of the STR is the time-independent homogenous mixing in the reactor, diminishing all temperature, pressure, or concentration gradients. In contrast to the STR, the PFR is characterized by a plug flow velocity profile in the reactor where all fluid elements show the same velocity. Mixing in the axial direction can therefore be neglected here under ideal conditions.

The conversions attainable in the different reactor types are influenced by enzyme kinetics. However, STR and PFR are described by the same equation:

$$v_{\max} \cdot \tau = -K_m \cdot \ln(1 - \chi) + c_{S,\text{in}} \cdot \chi$$

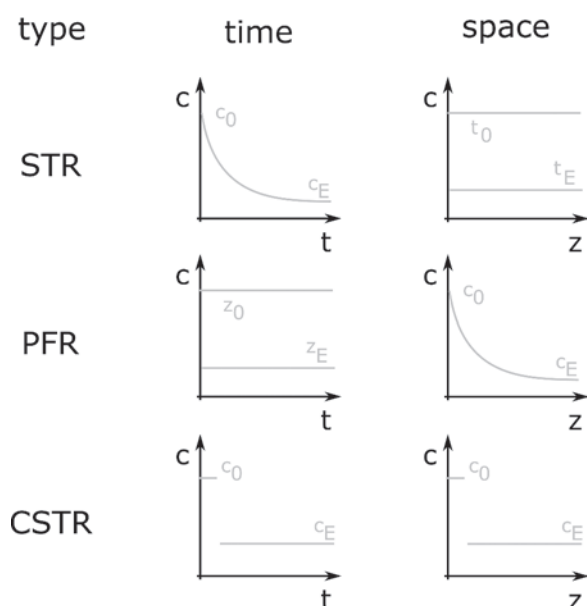

FIGURE 4 Schematic illustration of concentration profiles versus time and space for the different ideal reactor types.

Here, v_{\max} is the maximum velocity of the enzyme, τ is the residence time, K_m is the Michaelis constant, χ is the conversion, and $c_{S,\text{in}}$ is the substrate concentration entering the reactor. Consequently, both reactors show the same performance considering the enzyme kinetics. Thus, batch reactor performance mainly depends on setup time. Longer setup times in the overall process lead to lower performance of the batch reactor. In the case of neglecting setup times, the performance of the batch reactor and PFR is similar. The same conversion reactions inhibited by excess of substrate, and those inhibited by product in the batch reactor or PFR, can be carried out faster in CSTR. Because efflux conditions are present in the CSTR, low substrate and high product concentrations can be obtained. In contrast, the product concentration in batch reactors increases in the course of the reaction; accordingly, the substrate concentration of the inflow of the PFR is high. On passing through the reactor, the substrate is converted into the product; hence, depending on the axial coordinate, different substrate and product concentrations are found.

Furthermore, all conversions with a reaction order higher than 0 run faster in PFR than in CSTR. At high substrate concentrations, enzymes catalyze a reaction kinetics of zero order and at low concentration of first order. The transition is described by the Michaelis-Menten equation. For this reason, to evaluate a given reactor type, $r_{S_0K_m}$, the ratio of initial substrate concentration, c_{S_0} , and the K_m value of the enzyme are the parameters of choice:

$$r_{S_0K_m} = \frac{c_{S_0}}{K_m}$$

For $r_{S_0K_m} \gg 1$ and $c_{S_0} \gg K_m$ within the whole reaction range, the kinetics are of zero order and identical conversions in CSTR and PFR are obtained. This is the case when low K_m values are present or a high conversion is not sought. In other cases, an identical residence time causes a lower conversion in CSTR compared with the PFR.

The enzyme demand of different reactor types is compared by plotting the ratio $e_{\text{CSTR}}/e_{\text{PFR}}$ versus the desired

conversion. Doubling of enzyme activity v_{\max} shows the same effect as doubling residence time τ :

$$\frac{e_{\text{CSTR}}}{e_{\text{PFR}}} = \frac{\tau_{\text{CSTR}}}{\tau_{\text{PFR}}}$$

At a given $r_{S_0K_m}$ value of 100, for example, the reaction has zero-order kinetics over a broad range. Approaching total conversion, the reduced substrate concentration leads to first-order kinetics after passing through a transition phase. Therefore, differences between CSTR and PFR do not occur until very high conversions. The lower the $r_{S_0K_m}$ value, the faster the departure from the ratio $e_{\text{CSTR}}/e_{\text{PFR}}$ of 1 arises at lower conversions. From the very first, the reaction is of first order at a low $r_{S_0K_m}$ value of 0.1, meaning a higher enzyme demand of the CSTR over the PFR at low conversions to obtain equal conversions.

The CSTR outmatches the PFR up to high conversion if strong inhibition by substrate excess, namely, small K_{is}/K_m value, is present. Minor inhibition means that at low conversions the CSTR is favored, whereas at high conversions the PFR is favored. In the case of product inhibition, the PFR shows better reaction performance than the CSTR. At high K_{ip}/K_m values, meaning minor inhibition by the product, the kinetic values are described by the Michaelis-Menten equation; rather, the reaction is of first order. At low K_{ip}/K_m values, the PFR is favored at all conversions because of product inhibition.

In general, the reaction can only be carried out efficiently when $K_{ip}/K_m > 1$. Values of $K_{ip}/K_m < 1$ signify a very strong inhibition preventing high conversions (37). Because the kinetic parameters are constants, high conversions can only be obtained when an adequate process design is applied, e.g., in situ product removal (39). This keeps the product concentration low and will be illustrated in sections 38.4.3 and 38.6.2.

38.3.2. Modeling and Assessment

The insight and understanding of a bioprocess can be enhanced by process modeling, leading to potential improvements and identification of possible difficulties. Furthermore, simulation can supplement experiments and broaden the basis for sound decision making (26, 31). While the general approach is similar, typical bioprocesses differ in their kinetics of product formation, process structure, and operating constraints when compared with chemical processes. The general steps in bioprocess modeling (Fig. 5) are process analysis, model creation, and the consideration of uncertainties in the model (19).

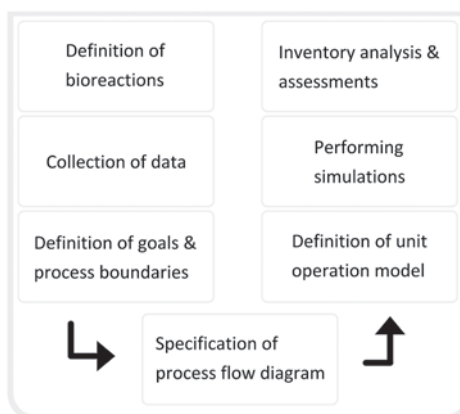

FIGURE 5 The general steps in bioprocess modeling.

For successful modeling, the definition of the modeling goal is crucial; it includes the final product specification and purity, the plant size, the biocatalyst, and the model boundaries. In general, each model has to include all necessary process steps, while keeping complexity at a minimum.

When the goal and the model boundaries are defined, the necessary data have to be collected, which can be derived from one's own experiments or external sources like literature or patents. Parameter values often have to be estimated from different sources or extrapolated from conditions that differ from the expected process, e.g., in scale, process conditions, biocatalyst used, etc. Critical expert assessment of data reliability and applicability is necessary here.

To model a bioreaction, the reaction equations and conditions are derived from the collected data and the general bioprocess knowledge. First, the starting materials needed for the applied biocatalyst are listed. Afterward, parameters like yields, reaction time, final product concentration, by-product formation, etc., are determined. If the reaction data are not known from experiment, a kinetic or a stoichiometric model can be applied to calculate these parameters. Then, the reaction conditions for the process model have to be defined. After this the process flow diagram is assembled and all unit procedures and the process streams of the model have to be specified. Every unit operation has to be described in a model, and the model parameters have to be defined.

The influence of assumptions, estimates, and simplifications on individual steps and the overall performance can be addressed in an uncertainty analysis. Therefore, it is essential to document and explain all assumptions, estimates, and simplifications. This transparent documentation serves as a reference point and enables comprehension and interpretation of the simulation results in the identification of uncertainties. The model is created and finally transferred into suitable software, where simulations are performed. Apart from improving the general understanding of the process, these simulation results are used for further optimization of the bioprocess.

To assess a bioprocess, the understanding of the uncertainties and the identification and quantification of risks and opportunities within a process are crucial. A scenario analysis can compare alternative process flow diagrams, and a sensitivity analysis studies the impact of single input variables, like medium cost or reaction time. In this context, variability is an intrinsic feature of the system and an effect of chance as seen in the actual variation. It cannot be reduced by further studies. Uncertainty is caused by a lack of knowledge about a parameter that does not show variability in reality, but its exact value is not known. Further studies can reduce this type of uncertainty. The variation of model parameters often involves both variability and uncertainty.

Scenario analysis examines variations of the process flow diagram and the process scale. Especially in early process development, there might be a need to compare alternative process flow sheet topologies. For changes in downstream processing, for example, the economic and environmental impact can be derived in a scenario analysis. The base model can be used as a benchmark.

Sensitivity analyses study the impact of a single process parameter on the objective functions of the model. The analysis is usually done within the existing process flow diagram. By comparing the sensitivity of different parameters, the most sensitive can be identified. Special attention must be paid to these parameters in the process development. Sensitivity analysis quantifies the dependence of the

objective functions on single parameters; it may not capture nonlinearities between multiple parameters that may vary simultaneously. However, it does not provide any information about the probability of certain values of the examined parameter. For further reading, the book by Heinzle, Biver, and Cooney is recommended (19).

38.4. TECHNIQUES

38.4.1. Micro- and Minibioreactors

Microbioreactors are characterized by their area of application, by effective heat transfer and ultrafast mixing characteristics, and by their suitability for online monitoring and control (36). Within microprocess engineering, chemical or enzymatic processes are conducted inside small volumes, typically inside channels with diameters of less than 1 mm or other structures with submillimeter dimensions. These processes are usually carried out in continuous-flow mode, allowing a high throughput, and have further benefits like defined residence time setting and highly regular flow profiles.

Microreaction technology is an interdisciplinary field combining natural science and engineering (20, 45). Because there have been demands for innovation in process engineering, particularly for enzymatic reactions, microreaction devices can serve as efficient tools for the development of enzyme processes. The study of individual bioprocess parameters at the microliter scale using either microwell or microfluidic formats can be used to generate quantitative information. Bioprocess design and scale-up based on such broad information can be more rational and effective. Furthermore, automation can enhance experimental throughput, facilitating the parallel evaluation of different process parameters or alternative process flow sheet topologies (section 38.3.2).

Next to the reaction itself, unit operation, e.g., mixing and heat transfer or product purification, can be realized, leading to a complete process on the micrometer level. For further details the reader is referred to Hessel et al. (20).

In contrast, minibioreactors (53) possess volumes below about 100 ml. Different types of these reactors have been constructed:

- Shaken bioreactors (shake flask, microtiter plate)
- Stirred bioreactors (STR, stirred cuvette)
- Other bioreactors (hollow-fiber membrane)

Bioprocess design using micro- or minireactors makes an advanced process control necessary but has a great advantage: the reduction in development time and costs. Minibioreactors can be monitored by special online measurements that allow comprehensive studies with high-priced substrates. Many process parameters can be tested in small-scale devices and later on transferred to large-scale bioreactors. Large numbers of small-scale experiments allow broader screening for appropriate biocatalysts, reaction conditions, and a fast and rational scale-up. Therefore, micro- and minibioreactors offer the potential to speed up the delivery of new products to the market, to reduce development costs, and to increase economic benefit (44).

Besides these advantages in the speed-up of process development, there are some advantages in handling. Microreactors can be applied in those cases where mixing and temperature control are crucial for selectivity and yield. Here, the large surface-to-volume ratio allows an excellent energy and mass transfer. Furthermore, the production of critical components can be advantageous because highly

exothermic reactions—leading to high temperature or high pressure—and highly corrosive or toxic reaction components can be processed more safely.

38.4.2. Miniplant

Often, to reduce development costs of bioprocesses, the miniplant technology is suggested (3). This involves establishing a prospective industrial process on the smallest possible scale, including all operation units and the original product. A direct scale-up from laboratory to production facility can thus be made easier in many cases. Accordingly, by mimicking operative unit production, the miniplant technology should help to simplify the scale-up of (bio)processes.

When a new or changed process is to be established, the desired product and reactants, their physical and chemical characteristics, the reaction and downstream processing pathway, and the sequence thereof have to be known. At the beginning, besides mathematical calculations, experiments also have to be done to obtain data not previously available and, hence, to design operable experimental plants. A key factor is the determination of dimensionless key numbers that enable a scale-independent description of the process. To reduce costs, the experimental plant should be as small as possible, leading to a large scale-up factor. These will show the feasibility of the several process steps and deliver data for target-oriented scale-up.

Thus, important characteristics of an optimal miniplant technology are:

- Fast buildup and reconstruction
- High flexibility to react on different experimental conditions
- Long-time operation

The rate at which biotechnology processes are introduced and used in different chemical markets depends on the technical implementation. For economic success,

TABLE 1 Comparison of time requirements (61)

Step	Pilot plant	Miniplant
Planning	1 year	3–4 months
Purchase/setup	1 year	>3 months
Initiation time	3 months	1 month
Test duration	6–9 months	6–9 months
Total time	3 years	1–1.5 years

a fast introduction to the market (short time to market) is necessary. In addition, costs are reduced when shorter development time can be achieved (5). The application of miniplant technology for biocatalytical processes is a helpful approach to attain this goal.

Roughly comparing the time requirement between pilot plant and miniplant, it is obvious that setup and operation predominate (see Table 1), but the development time in sum can be reduced drastically by applying miniplant technology.

Next to time consumption, the costs for process development are crucial. In Fig. 6 the sum of costs for both the pilot plant and the miniplant are illustrated. Here too, the advantage of the miniplant technology can be seen in a faster achievement of the profit zone (11).

38.4.3. Membrane Bioreactors

Membranes have found a broad range of applications, including the production of drinking water, energy generation, tissue repair, pharmaceutical production, food packaging, and the separations needed for the manufacture of chemicals, electronics, and a range of other products (56). In the manufacturing of chemicals by chemical or biotechnological methods, the combination of catalysts and membrane-based reactors is a key to obtaining

FIGURE 6 Comparison of pilot plant and miniplant: costs for process development versus time (11).

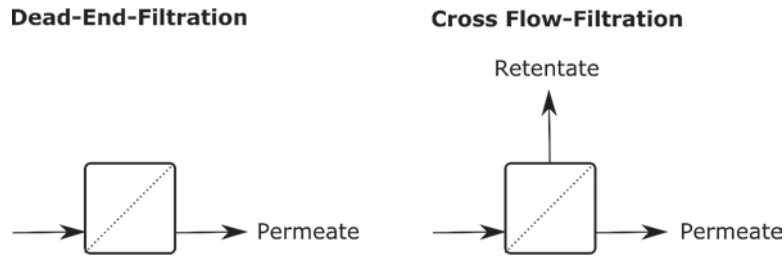

FIGURE 7 Comparison of different membrane process setups.

higher productivities and less waste. Bioprocesses including membrane reactors mimic the biological model of compartmentalization. Here, different reactions and products are separated from each other to minimize interfering reactions and to circumvent by-product formation.

The central point of a membrane bioreactor is the interface, which is formed and stabilized by a thin, partly permeable membrane. This membrane can control the exchange of solvent (conventional or nonconventional), substrates, products, and/or catalysts between two neighboring fluid phases. Here, as in Nature, different forces are found that influence the flow through the membrane. First, there is the viscosity and pressure of the liquid on both sides of the membrane, which influence the flow of the solvent through the membrane. Beyond this, there are forces that limit or allow the passage of solubilized substances. The retention of some of these substances, meaning the selectivity of membranes, is directly influenced by their physical and chemical characteristics. Here, the process engineer has to consider the fluid properties (aqueous phase, organic phase, etc.), the membrane material (hydrophobic, hydrophilic, and selectivity), and the requirement of the process itself.

Different membrane types and driving forces for the filtrations are applied in several processes. The diffusive mass transport via the membrane is mostly very selective but limited by a low flow rate. To increase the flow rate, a higher pressure difference has to be applied. However, porous membranes allow higher permeate flow rates per area because of their membrane structure (46, 60). In view of the conduction of the retentate flow, two operational modes can be differentiated: (i) the dead-end filtration, where the retentate flow is directed vertically on the membrane, and (ii) the cross-flow filtration, where the retentate flow is directed tangentially along the membrane surface (Fig. 7).

Permeation of the solvent through the membrane leads to increasing retentate concentration at the inflow side (74). A boundary and a cover layer are formed, whereby a hydraulic resistance is built up (Fig. 8). This resistance incrementally blocks the permeate flow (J). This polarization of concentration can be counteracted by increasing the tangential flow.

For continuous processes with isolated, solubilized enzymes, the enzyme membrane reactor was designed (73). In this system, a membrane retains the enzyme; on industrial scale, a hollow-fiber module is used. Within this process variant, the substrate is fed to the enzyme solution and the product and nonreacted substrates pass through the membrane. Immobilization of the enzyme directly on the membrane surface is also possible, and in the process, the substrate passes the membrane, reaction occurs, and the product can be obtained in the permeate. The big advantage of such reactors is the operation under outflow conditions in the case of CSTR operation mode,

resulting in minimization of specifically substrate surplus inhibition. Thus, enzyme membrane reactors have found application in the synthesis of pharmaceuticals and the building blocks thereof.

The first industrial application of membrane bioreactors was published by the Degussa Company in the 1980s. This process can be used in the production of *L-tert-leucine*, *L-neopentylglycine*, or *L-5,5-dimethyl-butyl-glycine*, which are building blocks for drug synthesis, especially for the synthesis of antitumor or human immunodeficiency virus protease inhibitors, as well as templates in asymmetric synthesis (7). These amino acids are synthesized starting from ammonia and keto acids. High concentrations of the keto acid trimethyl pyruvate lead to inhibition of the enzyme *L-leucine-dehydrogenase* within the production of *L-tert-leucine*. Furthermore, the productivity of the process is limited by chemical side reactions. Therefore, a continuously operated process in the mode of a stirred tank with an ultrafiltration step is applied. This enzyme membrane reactor enables low concentrations of the substrates and recycling of the enzyme (73).

A big disadvantage in using pressure-driven membrane processes is membrane fouling, which leads to a loss of performance (4, 46). This effect includes:

- Adhesion of particles on the membrane surface
- Adhesion of particles in the pores of the membrane
- Soaking of the membrane
- Chemical reaction of membrane components with the reaction solution

Special surface modifications can reduce this problem. Changes of chemical surface properties as well as changes of the macroporous structure of the material can improve the performance and stability of the membrane. An overview

about the status quo of membrane bioreactor technology is given in reference 15 and more recently in reference 29. A summary of new applications of enzyme membrane reactor technology is found in references 40, 55, and 75.

38.4.4. Separation Technologies

Many different disciplines are involved in bioprocess engineering, but the separation process is the part that most involves the discipline of chemical engineering. To produce a purified product, an effective separation process has to be carried out. This process can be done after the reaction (classical downstream processing) or during the reaction (hybrid separation process). Within biotechnology, many different separation processes are used; chromatographic methods, membrane technologies, and extraction methods are often applied. A detailed discussion of these technologies will not be done in this subsection; the reader is referred to the literature (25, 62). The focus now should be on the choice of an adequate separation technology in connection with a specific reaction. Because inherent limitations are often exhibited in enzymatic biotransformations, specific separation processes have to be established. Some limitations often found are cofactor regeneration, racemic mixtures, equilibrium conversion, by-product formation, inhibition phenomena by substrate/product, or low solubilities.

For the synthesis of 1-phenyl-2-propanol from 1-phenyl-2-propanone, effective cofactor regeneration necessitates a separation of the cofactors from the products to increase the total turnover number (ttn; mole product/mole cofactor) of the cofactor. Therefore, an STR, an ultrafiltration module, a hollow-fiber membrane module, and distillation process are applied; thus, this enzyme bimembrane reactor consists of three loops (Fig. 9). The CSTR is coupled to two membrane modules (33, 34). The aqueous phase from the reactor is pumped in a loop through the ultrafiltration module. The hydrophilic membrane retains the enzymes, and the filtrate is pumped through the second loop. This aqueous solution, containing products, nonconverted reactants, and cofactors, is passed through the lumen of the extraction module. Here, a microporous, hydrophobic hollow-fiber membrane separates the aqueous and the organic phases and the product and nonconverted reactants are extracted, while the charged cofactors are retained in the aqueous phase. Then, the organic solvent is recycled by continuous distillation and the product remains at the bottom of the distillation column. Besides cofactor regeneration, this process also allows the usage of reactants of low solubility. Here, a ttn of up to 1,350 and a space-time yield (STY) of 64 g liter⁻¹ day⁻¹ are reached.

The (S)-enantiomer of *N*-(*tert*-butoxycarbonyl)-3-hydroxymethylpiperidine is produced by stereospecific esterification of the racemic alcohol with succinic anhydride,

FIGURE 9 The enzyme-bimembrane reactor for the synthesis of 1-phenyl-2-propanol consists of STR, ultrafiltration module, extraction module, and distillation column.

FIGURE 10 Synthesis of α -cyclodextrin by selective adsorption applying a batch process. Here, a sequence of STR, heat exchanger modules, and adsorption step is used.

as carried out by Bristol-Myers-Squibb (16). A sequence of an STR, an extraction module, a second STR, and a second extraction module is applied. The enzymatic resolution is followed by separation of the unreacted (*R*)-alcohol by extraction with a basic NaHCO₃ solution. The subsequent hydrolysis of the (*S*)-hemisuccinate with NaOH provides the desired (*S*)-alcohol. To improve the enantiomeric excess and the yield, repeated esterification of the enriched alcohol can be pursued.

Hydrolase-catalyzed reactions lead to limitations regarding the equilibrium in those cases where ester synthesis is carried out, because this condensation reaction produces water. The equilibrium is shifted at high amounts of water toward the reactants; therefore, an efficient separation is necessary to reach high conversions. For this purpose, a process setup with in situ product removal was developed by Unichema Chemie BV (43). The setup is based on azeotropic distillation of the water produced to synthesize isopropyl myristate. This is enabled by a continuous feed of 2-propanol to the reactor, which forms an azeotropic mixture with water. This mixture is distilled, thereby removing the water produced. Afterward, the immobilized enzyme used can be easily separated by filtration. The feasibility of this technique is also illustrated in the synthesis of glucose stearate. A mixture of ethyl methyl ketone and hexane as solvent is used, forming an azeotropic mixture with the water produced (78).

For the case of highly viscous reactants, like polyglycerol and lauric acid, a different process was developed; see section 38.7 (23).

The enzymatic synthesis of cyclodextrins by Mercian Co., Ltd., applying glycosyltransferases, leads to a mixture of α -, β -, and γ -cyclic oligosaccharides and can be carried out in a batch process by use of a sequence of STR, heat exchanger modules, and adsorption step (Fig. 10). To establish economic cyclodextrin production, separation of the cyclodextrins from the reaction medium is essential (67), because the reaction medium contains many by-products and the enzyme is inhibited by a high cyclodextrin concentration. The selective adsorption of α - and β -cyclodextrin on chitosan beads with appropriate ligands enables the separation. To enable effective adsorption, the temperature is lowered to 30°C before the solution is passed through the adsorption column. At this temperature, almost no cyclodextrins are formed; before reentering the reactor, the temperature of the solution is readjusted to 55°C by passing through a heat exchanger. The dissolved enzyme used in

this process does not adsorb on the chitosan beads at the given reaction conditions. A further example of product separation can be reached by crystallization and is applied as in situ product removal in several industrial processes (see section 38.6.2).

These examples demonstrate that optimization of a given process can only be reached if an effective product separation is available. The bioprocess engineering must focus on downstream processing in addition to the reaction progress. Starting at the reaction itself, a selective synthesis circumvents complicated downstream processing. The separation and purification steps must be both addressed within classical downstream processing and integrated by reaction engineering. Adapting the reaction parameters with respect to easy downstream processing enables a reduction of production costs. Further examples can be found in reference 21.

38.5. REACTION MEDIA

The effectiveness of a biotransformation in view of reaction rate, yield, and/or selectivity strongly depends on the medium applied. Here, aqueous, organic, ionic, and supercritical solvents have to be differentiated. In addition, one can use solvent-free systems, meaning a mixture of the reactant. Every medium possesses its specific advantages, which are summarized in Table 2 in comparison with the aqueous medium, whose disadvantages were discussed at the beginning of section 38.2.1. A general discussion can be found in reference 35; for more information about the biotransformations in organic solvents see Faber's textbook (13).

To reduce the risks for humans and the environment, "green chemistry" advises minimizing the use of volatile, toxic organic solvents where possible. One approach is to investigate options for replacing such organic solvents with more environmentally compatible solvents. However, it needs to be taken into account that, when discussing nontoxic alternative solvents like supercritical CO₂, an atmosphere of too much CO₂ is lethal (admissible exposition value, 5,000 ppm). The energy necessary to evaporate a given amount of water is far from being environmentally friendly as well. Moreover, solvent-free synthesis can be applied, which is simpler, because there is no separation of the organic solvent necessary. This strategy can save energy, reduces the amount of solvent waste, and circumvents the risks of handling of organic solvents as well as their disposal (65). Organic solvent use accounts for approximately 80% of mass utilization

in typical pharmaceutical and fine-chemical synthetic processes (76). In addition, solvent-free bioprocesses reach higher volumetric productivities compared with syntheses in organic solvents. Solvent-free synthesis also eliminates costs for solvent supply, solvent separation, and waste disposal.

In the area of ester synthesis, a triolein lipase-catalyzed, solvent-free synthesis process was published in 1990 (12). In addition, monoacylglycerols, diacylglycerols, triacylglycerols, and mono- and dithioesters were synthesized by esterification and transesterification of pure substances or glycerolysis (70, 71). However, the absence of a solvent is disadvantageous in these cases, because the viscosity is higher than in solvent-based processes. Here, the solvent secures a fast mass transfer and a reduction of viscosity (14). In this way a faster conversion at a similar energy input is possible. This means that thorough mixing of reactants, a selective reaction by a biocatalyst, and its high stability are the crucial points in solvent-free bioprocesses. When these requirements are satisfied, solvent-free synthesis can outperform classical synthesis thanks to higher STYs and lower energy consumption.

38.6. OPTIMIZATION PROCEDURES

38.6.1. Diffusion Limitations

Heterogeneous biocatalysis on an industrial scale is only lucrative when high STYs are obtained or, alternatively, an easy separation of the biocatalyst is afforded. The application of immobilized enzymes aims to bind a maximal amount of enzyme per carrier, whereas porous materials, because of their large surface, represent a good carrier material (17). Here, the enzymes can also penetrate into the carrier and bind within the pores. The total surface of such porous carriers is much higher compared with solid ones. Hence, a maximal amount of enzyme can be immobilized on a specific volume of carrier material.

However, diffusion limitation is observed in various degrees in such immobilized enzyme systems. This diffusion limitation reduces overall conversion rates, because enzymes immobilized at the inner surface of the carrier are not optimally passed by the reactant flow. This nonuniform distribution of substrate and/or product between the enzyme matrix and the surrounding solution affects the measured (apparent) kinetic constants (Fig. 11). The substrate molecules reach the enzyme within the pores of a heterogeneous carrier material by film and pore diffusion from the solution. This occurs because the substrate must diffuse from the bulk solution up to the immobilized enzyme prior to the reaction. The rate of diffusion relative to the enzyme reaction determines whether there are limitations on the conversion rate. The flow rate at which the substrate passes over the insoluble particle affects the thickness of the diffusion film. The film diffusion and the pore diffusion determine the concentration of the substrate near the enzyme molecule, and thus, the rate of reaction. Diffusion of large molecules will obviously be limited by steric interactions with the matrix. This leads to a decrease of relative activity of bound enzymes toward high-molecular-weight substrates compared with low-molecular-weight substances.

The experimental determination of the diffusion limitation can be easily carried out by operation of two identical PFRs with different bed heights (second reactor has a doubled height, i.e., a doubled amount of enzyme) in parallel. Under non-diffusion-limited conditions the same conversion

TABLE 2 Reaction media for biotransformations

Medium	Advantage	Reference
Organic solvents	Increased enantioselectivity	49
	Increased stability	36
	Reduced risk of microbial contamination	32
Ionic liquids	Very low volatility	54
	Versatile solubilities	68
Supercritical solvents	High diffusion rates	50
	Nontoxic	27

- 1 mass transport to carrier
- 2 mass transport through boundary layer (film diffusion)
- 3 pore diffusion of substrates
- 4 binding of substrate to enzyme
- 5 enzymatic reaction
- 6 desorption of products
- 7 pore diffusion of products
- 8 mass transport through boundary layer
- 9 mass transport from carrier

FIGURE 11 Processes within the catalytic reaction at porous carriers.

is reached, if the reactor with the doubled bed volume is operated as well with the doubled flow rate. By this means the same residence time is established in both PFRs.

$$\tau = \frac{V}{F} = \text{const.} \Rightarrow \frac{F_1}{F_2} = \frac{V_1}{V_2}$$

In diffusion limitation, different conversions are reached in both PFRs. The reactor with the higher flow rate will reach a higher conversion at the same residence time, since the flux on the carrier surface is higher, lowering the film diffusion.

38.6.2. In Situ Product Removal

A range of conversion between >80% to total conversion is of high interest for industrial processes (8). Here, great changes in the ratio $e_{\text{CSTR}}/e_{\text{PFR}}$ are found, and thus the choice of an appropriate reactor type strongly influences the effectivity of the process. If the reaction equilibrium is on the side of the substrates or the product has an inhibiting effect on the enzyme activity, a selective removal of product can increase the productivity of the reaction system. This can be realized by application of selective membranes, for example, which retain the product but not the enzyme or substrate. In those cases, the use of continuous processes is favored. The increase of conversion by continuous product removal can be exemplified by a simple enzymatic process carried out in a CSTR. The proposed reaction is an irreversible one-substrate reaction showing competitive product inhibition:

$$v = \frac{v_{\text{max}} \cdot c_S}{K_m \left(1 + \frac{c_P}{K_{iP}} \right) + c_S}$$

The selectivities of the product separation step with regard to substrate and product are described by β_S and β_P , respectively. Here c_S and c_R are the substrate and product concentration in the outflow of the reactor:

$$\beta_S = \frac{c_{S,\text{out}}}{c_{S,R}} \quad ; \quad \beta_P = \frac{c_{P,\text{out}}}{c_{P,R}}$$

$\beta_S = \beta_P = 1$ represents a classical STR, where substrates and products are removed in the same degree. In steady state the mass balances are described as follows, where V_R is the reactor volume and $c_{S,\text{in}}$ is the substrate concentration in the inflow:

$$\begin{aligned} \dot{Q}_{\text{in}} &= \dot{Q}_{\text{out}} = \dot{Q}_F \\ 0 &= \dot{Q}_F \cdot c_{S,\text{in}} - \dot{Q}_F \cdot c_{S,\text{out}} + v|_{c=c_{S,R}} \cdot V_R \\ 0 &= -\dot{Q}_F \cdot c_{P,\text{out}} + v|_{c=c_{S,R}} \cdot V_R \end{aligned}$$

It follows from the above:

$$c_{P,\text{out}} = c_{S,\text{in}} - c_{S,\text{out}}$$

Transposing leads to reactor concentration $c_{S,R}$ as a function of kinetic constants, selectivities, and residence time:

$$c_{S,R} = \frac{b}{2a} \pm \sqrt{\frac{b^2}{4a^2} - \frac{c}{a}} \quad \text{with } a = \frac{K_m \cdot \beta_S^2}{K_{iP} \cdot \beta_P} - \beta_S$$

$$b = 2 \frac{K_m \cdot \beta_S}{K_{iP} \cdot \beta_P} \cdot c_{S,\text{in}} + K_m \cdot \beta_S + v_{\text{max}} \cdot \tau - c_{S,\text{in}}$$

$$c = K_m \cdot c_{S,\text{in}} \cdot \left(1 + \frac{c_{S,\text{in}}}{K_{iP} \cdot \beta_P} \right)$$

Productivity can be increased dramatically by selective product removal, where the increase of conversion depends on the degree of product inhibition.

Besides these product inhibitions in thermodynamically unfavorable reactions, a limit to the achievable product concentration may also be imposed. In situ product removal (ISPR) is a useful strategy to overcome such problems via hybrid separation processes, integrating a one-step reaction with the first step of the downstream processing (77). ISPR may be carried out either internally or externally (Fig. 12). When the reaction media are in contact with a second, product-removing phase that is present in the reactor, the setup used for separation of biocatalyst and by-product is internal. An external setup exists when the reaction media are in contact with a product-removing phase within an external unit. In both cases, the ISPR configuration is intended to reduce the product concentration in the reactor, whereas direct and indirect contact with the product-removing phase can be differentiated in both setups. A process configuration with indirect contact of biocatalyst can be done by ultrafiltration for external setups or by membrane technology for internal setups. In all cases, the biocatalytic reaction is influenced with respect to the chemical equilibrium, enabling higher conversions. The choice of the setup depends on the properties of the by-product and the biocatalyst, the number of phases (liquid/liquid; liquid/gas) concerned, and the type of recovery process in use. The techniques used for ISPR depend on the properties of the target product, the expected benefit that ISPR needs to achieve, and the biocatalyst involved (9).

Depending on the form of the biocatalyst (resting cell, isolated enzyme, or immobilized enzyme), different levels of process integration are possible. A complete integration is reached when the reaction and product recovery steps take place within the reactor. Here, a compromise in the case of the pH value or the temperature must be made. To circumvent such compromise, discrete reaction and product

FIGURE 12 Internal and external modes of ISPR operation with direct and indirect catalyst contact. In the internal setup, the reaction media are in contact with a second, product-removing phase that is present in the reactor, whereas in the external setup, the reaction media are in contact via a loop with a product-removing phase in an external unit. Direct and indirect contact can be differentiated in both cases.

removal steps are linked via a recycle loop, but the biocatalyst must be retained. This may involve a second recycle loop, already illustrated above in the production process of 1-phenyl-2-propanol (section 38.4.4).

The potential of crystallization as an ISPR technique for bioprocesses has found application in fine-chemicals production. In chemical engineering, processes are often referred to as reactive crystallization if an internal configuration (Fig. 11) is used (72). For several enzymatic processes, a crystallization step has been integrated with the reaction step by use of either crude or pure enzyme. The reader will find an interesting example in reference 59. In addition, crystallization might be an attractive option in the production of crystalline compounds using whole cells as biocatalyst (9).

The selection of the appropriate separation method is of key importance. Different separation methods have been illustrated above and applied in ISPR (e.g., chromatographic methods, membrane methods, or crystallization). To choose the optimal process, the important criterion is the product concentration. A low concentration will improve the reaction performance, because enzyme inhibition is minimized and the thermodynamic equilibrium is shifted. In addition, high product concentrations simplify the further downstream processing.

38.7. EXAMPLES OF TYPICAL BIOPROCESSES

The enzymatic synthesis of fatty acid ester-based care specialties is a prime example of a modern, innovative,

and sustainable technology (66). The advantages of this process compared with traditional production methods are lower reaction temperature and higher selectivity leading to fewer by-products, fewer purification steps, less waste, and, therefore, an economically competitive bioprocess. These economic and quality aspects led to the implementation of a fixed-bed reactor system for the synthesis of ester oils at Evonik Industries because the enzymatic esterification could yield specialty esters of high quality. Nevertheless, the field of application is restricted by the availability of enzymes on an industrial scale and their thermal stability. Furthermore, the application of a fixed-bed reactor is restricted to raw materials and products with a melting point below 60°C and low-viscous substances, because otherwise no pumping through the enzymatic fixed bed is possible. Therefore, there was a high interest in establishing an alternative process. To overcome limitations due to the high viscosity in the solvent-free esterification of polyglycerol-3 and related polyols, such as polyethylene glycols (PEGs), an alternative reactor concept was developed (23). The new reactor constitutes a bubble column that prevents mechanical erosion of Novozym 435 (lipase B from *Candida antarctica*) found by mechanical stirring of the mixture. In that way, polyglycerol-3 laurate was synthesized at an STY of 3 kg liter⁻¹ day⁻¹ and PEG-55-propylene glycol dioleate was synthesized at an STY of 0.7 kg liter⁻¹ day⁻¹. To prove the broad application range of this system, low-viscous myristyl myristate was synthesized at an STY of 6.7 kg liter⁻¹ day⁻¹, thus outperforming conventional methods such as stirred-tank or fixed-bed.

The newly developed reactor concept is universally applicable to esterification reactions and can be advantageously applied in the synthesis of a broad range of high-quality surfactants.

The product high-fructose corn syrup (HFCS) is used as an alternative sweetener to sucrose or invert sugars in the food and beverage industry (41). HFCS obtained directly by enzymatic isomerization with a content of 42% fructose is used mainly in the baking and dairy industries. This HFCS can be obtained without further downstream processing by a continuously worked fixed-bed reactor setup with a capacity of more than 7,000,000 tons/year. For use in alcoholic beverages, the HFCS is enriched afterward up to 55% fructose by chromatography. The production process of HFCS is based on the isomerization of glucose to fructose by glucose isomerase in the form of immobilized whole cells or enzymes. The biocatalyst is available commercially from different suppliers under various trademarks, e.g., Sweetzyme, Maxzyme, Optisweet, or Sweetase. The reaction enthalpy is slightly endothermic and reversible. The equilibrium conversion is approximately 50% at 55°C; thus, to limit by-product formation, the reaction time has to be kept short. This can be done by using high isomerase concentrations showing half-life times of more than 100 days. Several reactors (typically 20) are operated in parallel containing enzymes of different ages and activities. To maintain productivity the enzyme is replaced when activity is reduced to 12.5% of initial activity. The feed to a single reactor is controlled by the extent of conversion in the reactor. This process setup allows a productivity of 1,000 tons/day.

38.8. DOWNSTREAM PROCESSING

Industrial applications using enzymes as biocatalysts are very diverse. The major market is the use of enzymes within detergents. Other applications are in the food and feed sector, as well as in paper and textile production. Besides this application, there are numerous enzymatic syntheses; e.g., hydrolases are used in the production of bulk chemicals like surfactants and of fine chemicals, whereas lyases like decarboxylases can be used for enantioselective carbon-carbon couplings.

The complexity of the biocatalyst separation is crucial for an effective industrial process. The type of enzyme retention has a strong influence on the costs of the final product, because repetitive use of the enzyme increases the productivity. Within the bioprocess development, there is the question of whether the enzyme will be heterogenized or retained by other approaches (e.g., membranes), whereas the answer is specific for a singular biotransformation. To retain free enzyme, ultrafiltration has to be carried out; in comparison, the filtration of a heterogeneous catalyst is much more simple and allows the use of fixed-bed reactors. The decision about immobilized or solubilized enzymes depends on cost savings resulting from simplified downstream processing by heterogenization. The costs for the production of the enzyme depend on the fermentation scale and yield, as well as the number of purification steps. Nevertheless, these costs have to be considered in both cases; thus, the costs for immobilization depend on the efficiency of the immobilization and the costs for the carrier material. The big advantages of immobilization are the dramatic cost savings because of the repetitive and longer use of the enzyme in synthesis. Here, a long half-life time is afforded to minimize the costs for the final product by increasing the ratio of product mass to mass of catalyst (10, 64).

38.8.1. Integrated Approach and Ideal Reaction Conditions

The classic disciplines of chemistry and biology offer methods for selective catalytic reactions. The task of the process engineer is the transfer of these syntheses from the laboratory scale to the industrial scale, as well as to ensure the feasibility of the bioprocess. Problems often occur that cannot be solved by singular disciplines; therefore, an integration of chemical and biological steps as well as bioprocess engineering is helpful to accomplish the advantages of these disciplines by establishing new reaction sequences. This affords new thinking in process development, especially the realization of hybrid separation methods as illustrated in the section on in situ product removal. The integration of different catalysts necessitates an adequate formulation of the catalyst to establish efficient process management. Furthermore, modeling of these bioprocesses is mandatory to find the bottlenecks and to establish an efficient overall process.

An effective reaction is also required to establish an efficient bioprocess. This is characterized by high end concentrations and high productivity, and at the same time, by low amounts of side products. An early view on the reaction with respect to the product purification can reduce later expenses for product isolation and development and production costs. An additional advantage is the reduced environmental impact because of higher efficiency and therefore less waste.

Effective reactions are characterized by the use of a minimum of reactants but high product amounts. Biocatalytic processes are especially useful to achieve this goal of high atom efficiency. In all bioprocesses, cyclization, retention, and separation of catalyst and product are arbitrary parameters to implement an economically successful bioprocess.

MICROBIAL FUELS (BIOFUELS) AND FINE CHEMICALS

VII

ONE OF THE MOST SIGNIFICANT RECENT DEVELOPMENTS AFFECTING industrial microbiology has been the marked increase in activity and anticipation related to microbially produced chemicals and, especially, fuels. As detailed elsewhere, a dramatic increase in biofuel and related investment by government, large companies, and venture capitalists occurred during 2005 to 2008 (1–3). At the time of writing, research and commercialization activity still continue at a pace unprecedented prior to 2005.

The chapters in this section address some of the key themes that have emerged since the 2nd edition of the *Manual for Industrial Microbiology and Biotechnology* (MIMB) appeared in 1999. One of these themes is the use of high-throughput methods for accessing biodiversity, which is explored in chapter 39 by Carl Abulencia et al., who draw largely on the experience of Verenum Corp. A second, the subject of chapter 40 by Susan T. L. Harrison et al. of the University of Cape Town, is the use of algae for production of fuels, chemicals, and nutritional products. Metabolic engineering has come of age during this time, with chemicals leading the way to a large extent, as amply illustrated in chapter 41 by Parick Cirino of Penn State University. This period has also seen the development of systems biology tools offering researchers access to unprecedented volumes of information regarding gene sequences, gene expression, and metabolite levels. Jonathan Mielenz and David Hogsett, from Oak Ridge National Laboratory and Mascoma Corporation, respectively, address in chapter 42 the use of systems biology tools to further understand the industrial robustness of microorganisms.

Although not a new theme, the conversion of lignocellulose to fuels and chemicals continues to be a prominent focus of industrial microbiologists and biotechnologists, appears close to commercial fruition after many decades of effort, and involves many important microbiological topics that still have much to contribute through yet-to-be-realized advances. Charles Abbas et al. from ADM address some important techniques and practical considerations in chapter 43. In chapter 44, Alexandru Dumitrache and Gideon Wolfaardt of Ryerson University, with Lee Lynd from Dartmouth, consider the surface microbiology of cellulolytic bacteria. Also from Dartmouth, Nicolai Panikov and Lee Lynd address physiological and methodological aspects of cellulolytic microbial cultures in chapter 45.

Further progress and change are sure to characterize industrial microbiology and biotechnology when the 4th edition of MIMB is prepared in the future. Until then, and it can be imagined thereafter, it is hoped that practitioners in the field will find the chapters herein to be informative and useful.

Accessing Microbial Communities Relevant to Biofuels Production

CARL B. ABULENCIA, STEVEN M. WELLS, KEVIN A. GRAY, MARTIN KELLER,
AND JOEL A. KREPS

39

39.1. INTRODUCTION

Microbiology, a field pioneered by Ferdinand Cohn, Louis Pasteur, and Robert Koch in the late 1800s, has seen a renaissance through novel cultivation methods and insight into the tremendous diversity of microorganisms. Ferdinand Cohn discovered heat-resistant endospores of bacilli; Louis Pasteur disproved the theory of spontaneous generation, leading to effective sterilization procedures; and Robert Koch introduced media solidified with agar and the concept of isolating pure cultures of microorganisms. Koch's discovery was a precursor to the development of bacterial taxonomy, genetics, and general isolation of pure cultures (36). The use of solidified media is still the most common technique to isolate pure cultures, as well as to isolate strains from the environment. The development of molecular techniques, focusing on the isolation, cloning, and sequencing of 16S rRNA, a commonly used phylogenetic marker, demonstrated that prokaryotes represent a large portion of the earth's biota. When Carl Woese and colleagues described the main bacterial phyla almost 20 years ago, 11 bacterial phyla were described (36). Two decades of environmental 16S rRNA gene sequencing from many habitats has shown that most of the 54 described bacterial phyla have only a few representatives, and 13 phyla have no cultured representatives (36). Some groups, such as *Acidobacteria* and *Verrucomicrobia*, represent significant proportions of examined ecosystems, with only a handful of isolates obtained in pure culture. The metabolic capabilities of these uncultured phyla are unknown. However, based on the abundance of cellulose within many environments, it could be speculated that genes for cellulose degradation are present in many of these unknown phyla.

39.2. CELLULOSE DEGRADATION IN NATURE

Due to the insolubility of lignocellulosic material, microbes developed various methods of accessing cellulose plant matter. In general, cellulose degradation and utilization are carried out not by a pure microbial culture but by microbial consortia representing both cellulolytic and noncellulolytic organisms, with CO₂ in aerobic environments, and methane and CO₂ in anaerobic environments, as final end products (46). In soil the major source of cellulose is decaying

plant material, rich in lignin and generally low in moisture, often favoring fungi as dominant cellulolytic biota (45). In aquatic environments, plant material is usually low in lignin and degraded within the anoxic zone by a consortium of anaerobic bacteria (46).

In ruminant animals, the retention time of plant material is long enough to allow fiber utilization through fibrolytic microbial populations and degradation of cellulose. In addition, the microbial protein produced during growth of these microorganisms, followed by lysis within the ruminant's abomasum, contributes significantly to the protein nutrition of the ruminant (30, 53).

Insects are the largest group of organisms on earth that host diverse microbial populations (13). Many insects, such as termites or Coleoptera larvae, specialize on a diet rich in lignocellulosic biomass. Until recently, it was unclear whether the enzymes required for cellulose degradation were produced by the termite or the microorganisms present within its hindgut. Tokuda and Watanabe showed a direct role of the symbiotic bacteria in the gut of the termite in cellulose and xylan hydrolysis (71). An extensive metagenomic analysis of the P3 segment of the hindgut of the "higher" termite species, *Nasutitermes*, demonstrated the presence of a large, diverse set of bacterial genes for cellulose and xylan degradation (78). Cook et al. studied the larvae of *Tipula abdominalis*, an aquatic crane fly found in aquatic riparian environments (13). While the larvae feed on coarse particulate organic matter, primarily leaf litter, the larvae themselves do not synthesize cellulolytic enzymes (13). It was proposed that the larvae may benefit nutritionally from fermentation products produced by microorganisms during digestion of plant material. Larval hindgut bacterial isolates demonstrated the ability to degrade model plant polymers such as carboxymethylcellulose, xylan, and others (13). However, all isolations were performed aerobically on model substrates. It would be of great interest to include isolation strategies including anaerobes enriched on the original larva diet, such as leaf litter obtained directly from the aquatic riparian environment.

Lynd et al. described a general trend of increasing growth rate on crystalline cellulose as a function of temperature with an upper limit of about 75°C (46). In general, thermophiles such as *Anaerocellum thermophilum*, isolated from the plant residues of a hot spring in Russia, degrade crystalline cellulose through free primary cellulases, which are distinct

from other multienzyme complexes associated with the cell wall and found in organisms such as *Clostridium thermocellum* (5). Some hyperthermophiles, defined as organisms with a growth temperature optimum at 80°C or above, are able to degrade α - and β -linked glucans and hemicelluloses such as xylan and mannan. None of these organisms, however, effectively degrades crystalline cellulose (5). It is of great scientific interest to discover hyperthermophiles that have the ability to degrade crystalline cellulose.

39.3. MAN-MADE CELLULOSE-DEGRADING ENVIRONMENTS

Man-made environments with a high load of crystalline cellulose are found in compost piles of animal waste, backyard clippings, and wastewater treatment plants. *C. thermocellum* was originally isolated from a cotton bale (18). Many microbial ecology studies have been performed on these types of environments to explore microorganisms performing various steps during lignin and cellulose digestion (44). Shiratori et al. reported the isolation of a novel *Clostridium* sp. that performs effective cellulosic waste digestion from a thermophilic methanogenic bioreactor fed with shredded office paper for methane production (64). In this environment, the conversion of cellulose to methane is mediated by four microbial populations: cellulolytic and noncellulolytic saccharolytic microorganisms, syntrophic hydrogen-generating bacteria, and methane-producing *Archaea*, with the hydrolysis of cellulose being, in general, the rate-limiting step (64).

39.4. PHYLOGENY OF CELLULOSE-DEGRADING MICROORGANISMS IN RELATION TO CELLULOSE DEGRADATION

Using 16S rRNA and 18S rRNA as the most commonly used molecules to classify *Bacteria* and *Eucarya*, the ability to digest cellulose is widely distributed. So far, however, no members of the *Archaea* have been identified with the ability to digest crystalline cellulose (5).

Within the *Bacteria*, there is a clear concentration of cellulolytic organisms within the phyla *Actinobacteria* and *Firmicutes*. Most of the representatives within the *Actinobacteria* are aerobic, while the organisms within the *Firmicutes* are anaerobes. Within the *Eucarya*, cellulolytic organisms are distributed across the fungal kingdom, spanning from Ascomycota to Basidiomycota.

Among the bacteria, there is a distinct difference in cellulolytic strategies between the aerobic and anaerobic groups of microorganisms (46). With very few exceptions, anaerobes degrade cellulose primarily via complexed cellulose systems, while aerobic cellulose degraders utilize cellulose through the production of substantial amounts of extracellular cellulases secreted into the culture supernatant, leading to two primary strategies for crystalline cellulose utilization. Aerobic bacteria and fungi do not adhere to cellulose, produce noncomplexed cellulases, and oxidize hydrolytic products to CO₂ and water (46). Anaerobic bacteria and fungi attach to cellulose, produce primarily complexed cellulases, and secrete a variety of fermentation end products. This fundamental difference between anaerobic and aerobic cellulose-degrading microorganisms has significant impact on isolation and cultivation strategies for various microorganisms. The anaerobic degradation of crystalline cellulose to various fermentation end products, such as small organic acids or alcohols, can lead to product inhibition and changes

in medium conditions, inhibiting growth. In addition, the adhesion of many of these anaerobic bacteria to insoluble substrates such as crystalline cellulose complicates the traditional cultivation of microorganisms and led to the use of soluble model substrates.

In nature, the degradation of lignocellulosic materials is not performed by a single microbial species. In contrast, many cellulolytic species coexist with noncellulolytic microorganisms which grow on the side products of metabolic intermediates, leading to a synergy between cellulolytic and noncellulolytic microorganisms. This synergy has been described in many publications (46).

39.5. QUANTIFICATION OF MICROBIAL CELLULOSE UTILIZATION

To study microbial physiology it is essential to obtain physiology data such as rate of cell growth, substrate utilization and product formation, and cell yields. For microbial utilization of soluble substrates such as glucose or cellobiose these data are available, and the exploration of microbial physiology has shifted to more molecular-level studies (46). However, these types of data are, in general, not available for microbial utilization of cellulose. Growth on insoluble substrates coupled with the growth characteristic of cellulose-degrading microorganisms makes the collection of these types of data challenging. For soluble substrates, cells can easily be quantified through various methods such as direct cell count or optical measurements like light scattering. To determine the cell count of cells grown and adhered to insoluble substrate requires the enumeration of cells on three-dimensional particles. In general, accurate cell counts are normally not possible for cellulosic substrates by conventional methods. Alternative and more indirect methods such as measurement of total protein or DNA are required and complicate the determination of cell growth. Other methods were explored as described by Lynd et al. (46).

The accurate determination of cellulase concentration and the measurement of specific activity are also challenging. Cellulases can be bound to the insoluble substrate, and it is unclear how much of the total cellulase activity is bound to the substrate, bound to the cell, or free within the supernatant. In addition, cellulase systems are composed of multiple proteins that interact by performing complementary functions and in some cases forming multienzyme complexes. These multiprotein complexes are often tethered to the bacterial cell wall and also bind to the insoluble substrate, making quantification extremely challenging. Determination of exact cell counts in conjunction with measuring specific activity of cellulase, cellulase-cellulase, and cellulase-cellulase-cell complexes will be critical to compare novel strains isolated from the environment (46).

39.6. NEW CULTIVATION METHODS

To further explore the diversity of novel cellulose-degrading microorganisms, novel cultivation methods need to be explored. Most of the current strains capable of degrading crystalline cellulose were isolated using traditional techniques. However, it could be assumed that these traditional methods are not suited to isolate strains specialized in degrading crystalline cellulose present in lignocellulosic plant material. New cultivation methods need to be applied without the use of the soluble model substrates used in traditional cultivation methods. Ideally, all steps of isolation, starting with the primary enrichment and finishing with the

purification of the strain, should be performed on relevant insoluble substrates. Relevant substrates include those that mimic natural environments or are used in biorefineries.

The development of novel cultivation methods targeting previously uncultured microbes gained importance with the goal of obtaining information from these uncultured phyla. In general, many of these methods mimic conditions found in nature. So far, only a few of these novel techniques have been applied to isolate lignocellulosic-degrading microorganisms. These techniques could be adapted to lignocellulosic degraders and might serve as platforms for further developments.

The general method to ensure cultivation of a pure strain is to start cultivation from a single cell, resulting in an actively growing colony created by clonal growth. This method dates back to Robert Koch and the plating of microbial cultures on solid surfaces such as agar (37). Even now, in the era of molecular tools and methods such as RNA profiling, metabolomics, and proteomics, the establishment of a pure culture is obligatory for detailed physiological characterization, is important for patent issues, and is critical in the search for multienzyme protein complexes, which are often not easily expressed in recombinant hosts. These goals have been, and are still, the driving force behind the development of novel techniques for the isolation of a pure culture derived from a single bacterial or eukaryotic cell. For cultures grown on soluble substrates the easiest approach, besides plating on agar plates, is serial dilution to extinction. Normally, these dilution series are repeated multiple times. Overall, this method cannot easily be used for the separation and purification of cells grown on insoluble substrates, since cells must first be sheared off the substrate and then separated from the remaining substrates before the dilution series can be generated.

Many of the traditional cultivation methods are not directly applicable and need to be optimized to be applied to insoluble substrates. Soluble model substrates could be used; however, they present their own issues, as discussed above. Alternatively, microbial cell separation methods have been developed and could help to overcome many of these cultivation challenges.

39.7. BACTERIAL CELL SEPARATION AND MANIPULATION

39.7.1. Cell Separation by Cell Manipulator Technologies

Cell separation technologies use optical instrumentation to visualize the specific microorganisms in conjunction with cell manipulation methods. Cell manipulation is dominated by two principal methods: laser manipulation and mechanical manipulation. Ashkin et al. described the use of infrared laser beams for trapping and manipulating biological specimens, such as single cells of *Escherichia coli* (3). The laser manipulation method was further improved by Huber et al. (27). They used a focused laser beam to capture and move archaeal cells within a capillary filled with fresh medium, from one side of the capillary to the other. The neodymium laser is focused by a microscope objective with a computer-controlled microscope stage. A rectangular glass capillary with a predetermined breaking point is used as the separation chamber, which is filled with fresh medium on one end and the mixed microbial population on the other. Cells are visualized through an inverted microscope, enabling the selection of specific cells based on morphology and also

phylogenetic criteria if combined with fluorescent *in situ* hybridization (FISH). A single selected cell is fixed with the laser beam and separated from the mixed culture by moving the microscope stage. The capillary is cut to remove the front end filled with the mixed culture. The end with the individual cell can be used for cultivation or, theoretically, for DNA isolation (27). Schutze et al. described a laser pressure catapulting method, which uses a laser for the microdissection and transfer of single cells (62). This method has been successfully applied for the isolation of single cells from human tissue and the dissection of various cell types. The specimens are spread on a sheet of thin polyethylene membrane, and the single cell of choice is circumscribed with the high photonic energy of a focused nitrogen laser. The selected cell, together with a small surrounding strip of the polyethylene membrane, is cut out; the selected cell adheres to the polyethylene membrane. The laser is then focused below the microdissected target cell, and the microdissected sample is catapulted into a common microcentrifuge tube positioned above the sample with a laser shot of increased energy (62). This method can be applied to any cell size. The laser can separate parts of cells in addition to having the capability to kill unwanted cells. However, this method is limited by the porosity of the polyethylene membrane. At high magnification, necessary to visualize individual microorganisms, the membrane shows a granular structure which lowers the optical resolution to a point that certain bacteria are not visible. Further research and the use of alternative membranes would make this a very powerful cell separation technology. Modern commercial microdissection microscopes are computer controlled and allow for automated cutting of selected particles. Xie et al. reported a reagentless method for identification and discrimination of single bacterial cells in aqueous solutions using a combination of laser tweezers and confocal Raman spectroscopy (79). The optical trapping enables the capture of individual bacteria in aqueous solution in the focus of the laser beam, levitating the captured cell well off the cover plate to minimize unwanted background from the cover plate and environment. Raman spectral patterns excited by a near-infrared laser beam provide intrinsic molecular information. Bacterial cells cultured at stationary phase could be discriminated by principal component analyses as well as hierarchical cluster analysis of their Raman spectra (79). This method, applied to biofilms formed on insoluble substrates, should be able to determine if the biofilm is formed from different species. Combination with an optical tweezer might allow separation of different species for subsequent isolation.

Another cell separation approach is based on microinjectors in combination with the precision of a servo-powered micromanipulator, enabling the easy handling of a single microbial cell (20). Fröhlich and König applied such a system using prefabricated Bacto-tips to isolate and cultivate single cells from the natural environment (19). For the isolation of microbial cells, a commercial micromanipulator equipped with a pressure device and mounted onto an inverse phase-contrast microscope can be used. For the isolation of bacteria, a sterile capillary tube (Bacto-tip) was used, sealed at the posterior end with a droplet of sterile oil. Luttermann et al. (cited in reference 20) described a micromanipulation method for transferring bacteria from agar plates using microcapillary tubes (31). An angled capillary tube was positioned between the condenser and the objective. The agar plate with the selected bacteria was moved below the opening of the capillary tube using

the microscope stage. The aspirated bacterium was placed on the surface of a solid medium or in liquid medium in a microtiter plate. Further experiments would be required to evaluate if bacteria could be removed from solid substrates and placed on fresh lignocellulosic material. Ishoy et al. further improved this technology and developed a system which is based on an inverted microscope, a microinjector, and a micromanipulator (31). The isolated cell was captured in a microcapillary pipette and transferred into an appropriate growth medium. They demonstrated that the micromanipulator system was able to isolate a single cell from a mixed culture without contamination by any of the nontarget cells from the surrounding medium. However, micromanipulation of individual microorganisms can be challenging. Thomsen et al. used the combination of micromanipulation of FISH-labeled filaments or microcolonies in activated sludge samples with reverse transcriptase PCR for further identification (70). This method was more successful on filamentous bacteria, as they were easier to separate from the floc material. However, it was not possible to isolate microcolonies consisting of only a single bacterial species due to the presence of several different species within a microcolony or the contamination of the selected microcolony by surrounding free bacteria (70). One would expect that similar issues would be encountered during separation of microorganisms from the surface of insoluble substrates. A biofilm formed by various microorganisms might make the selection and separation of an individual microorganism challenging. Luo et al. further combined a microfluidic device with a microwell array and an optical tweezer (44). This method was used to manipulate yeast cells, wherein cells were captured by the optical tweezer and separated into microwells for further cultivation. This combined technology might allow the parallel cultivation of many separated cells within the microfluidic microwells. Further research will be required to adapt this technology to the cultivation of cellulose-degrading microorganisms.

39.7.2. Separation of Cells by Flow Cytometry

Another technology widely used for cell separation and cell analysis is flow cytometry. This technology is commonly used in many medical applications to analyze and separate eukaryotic cells, but it is gaining more and more popularity for bacterial applications. Flow cytometry coupled with cell sorting is a powerful fluorescence-based cell diagnostic and separation tool that enables the rapid analysis of entire cell populations on the basis of single cell characteristics. Characteristics can be analyzed simultaneously, including cell count, cell size or content, and responses to fluorescent probes as diagnostics of cell function. Cells in a liquid sample are passed individually in front of an intense light source (laser or laser diode), and data on light scattering and fluorescence are collected (14, 77). Bacteria can be separated and sorted based on the forward- and side-scatter effects alone, even without the use of any fluorescent dyes. We have successfully demonstrated that this technology can be applied to the isolation of single bacteria grown on insoluble substrates (unpublished data). Cells attached to insoluble substrates can be sheared off by vigorous shaking and separated from the insoluble substrates with the remainder of attached cells, by slow centrifugation (unpublished data). The supernatant is applied to cell sorting, and single individual cells are sorted into fresh medium containing insoluble substrates.

Flow cytometry, used in conjunction with FISH, combines identification of specific cells in a mixed culture

with cell separation (35, 63). Raghunathan et al. used flow cytometry to separate single, unstained *E. coli* cells and subsequently amplified the isolated DNA 5×10^9 -fold (54). Podar et al. combined flow cytometry with FISH and multiple displacement amplification to amplify DNA from five sorted bacterial cells belonging to the candidate division TM7, an uncultured division of microorganisms commonly found in different soils (52).

Recently, nanotechnology has made significant progress and miniaturized many standard laboratory procedures. This technology, in combination with rapid development in laser technology, led to the miniaturization of flow cytometry and the development of an integrated microfabricated cell sorter using multilayer soft lithography (21, 22). This integrated cell sorter can be incorporated with various microfluidic functionalities, including peristaltic pumps, dampers, switch valves, and input and output wells, to perform cell sorting in a coordinated and automated fashion with extremely low fluidic volumes. Inexpensive materials and a simple fabrication process allow the production of these devices as disposables, eliminating the danger of cross-contamination from previous runs (22). In addition, the cell sorting device can be directly combined with chemical or enzymatic reactions, such as cell lysis and DNA amplification methods. This approach has recently been used to characterize a different ecotype of TM7 phylum bacteria from the human subgingival microbiota (47). Large, rod-shaped cells, resembling oral TM7 bacteria previously characterized by FISH (29), were separated and lysed in a microchamber, followed by DNA amplification in nanoliter-scale volume to confirm identity and provide access to the genome of the isolated cell. However, the sorting speed of these devices is much lower than that of traditional flow cytometers. At this stage it has not been demonstrated whether these devices can be used for the cultivation of microorganisms in the presence of insoluble substrates. Also, insoluble substrate particles have various sizes which might obstruct the channels of the microfluidic devices.

39.7.3. Novel Microbial Cultivation Methods

The traditional cultivation methods, based on plating of mixed populations of microorganisms on solidified medium such as agar, are selective and biased toward growth of specific microorganisms (15, 29). Traditional media strongly select for microbes that are fast growing, grow to high density, are resistant to high concentrations of nutrients, and are able to grow in isolation. Most microbial cells studied directly in the environment are viable but do not form visible colonies on solid agar plates when cultured. Therefore, it could be argued that these traditional culturing strategies use conditions that are completely different from the normal growth habitat of many microbes and are a major contributing factor to the failure to cultivate most microorganisms in pure culture (15, 72, 73). Janssen and coworkers addressed the issue of inhibition by high concentrations of nutrients in cultivation media and investigated the cultivability of soil microorganisms using diluted nutrient broth (33). Extended incubation times, of at least 10 weeks, were required to allow maximum colony development leading to the isolation of previously uncultured microorganisms (11, 61). Other studies investigated the effect of signal compounds such as cyclic AMP on the cultivation efficiency of aquatic bacteria, showing, in general, an increase in culturability (8, 9, 25). Button et al. developed a dilution cultivation method for growing bacteria from oligotrophic

aquatic environments (10). These findings suggested that most marine bacteria (60%) are viable but reach stationary phase before attaining visible turbidity and are therefore not detectable with traditional techniques. Kaeberlein et al. used natural chemical components to enrich microorganisms directly from the environment (34). Marine organisms were placed in a chamber, separated through a membrane, and deposited into a natural environment. They could demonstrate growth of novel, previously uncultured microorganisms (34). Gavrish et al. further expanded this technology to cultivate filamentous actinobacteria from soil samples based on the ability of these bacteria to form hyphae and penetrate solid environments (23). A similar idea was applied to the cultivation of previously uncultured soil bacteria using a soil substrate membrane system. The system used a polycarbonate membrane as a solid support for growth and soil extract as the substrate. Microcolonies were visualized using total bacterial staining combined with FISH (16).

Connon and Giovannoni described the development of a high-throughput cultivation method enabling the identification of a large number of extinction cultures (12). They combined the concept of extinction culturing in natural medium with the use of microtiter dishes in combination with an automated cell array and imaging process. This combination enabled them to increase the detection sensitivity of cells, leading to a significant shortening in incubation time of cells with low growth rates (10, 12). Zengler et al. developed a high-throughput cultivation approach based on the encapsulation of single microorganisms in microcapsules followed by flow cytometry for the detection of cell growth and cell separation (80). Members of the microbial community, represented in single encapsulated cells, are grown in columns under very-low-nutrient flux conditions using mineral medium supplemented with low concentrations of nutrients extracted from the sampling site. Over time, each cell capable of growth under the conditions in the column forms a microcolony within its enclosure. Using this technology, it was demonstrated that novel, previously uncultured organisms can form microcolonies within the microcapsules

and can generate a pure culture if separated and sorted into microtiter plates (80).

39.8. CULTURE-INDEPENDENT ENZYME DISCOVERY

Culture-independent methods enable the discovery of genes and proteins from microbial species that are uncultivable. Microbes are capable of growth in a variety of environments and conditions, and the stable and active enzymes of microbes growing at the extremes of pH and temperature could have utility in industrial applications. These microbes, however, have proven to be difficult to cultivate (2). Indeed, the overwhelming majority of all bacteria remain uncultivated (56), and the potential of tapping into this majority for industrial enzymes is vast. Explorations of the metagenome—the collective genomes within a microbial community (26) obtained directly from the environment without cultivation—have increased in the last decade (28). Novel enzymes have been discovered (68), and one metagenomic sequencing effort nearly doubled the number of identified proteins (60).

Screening of the metagenome for novel genes and proteins can be accomplished by first cloning the DNA into a library, and also by interrogating the DNA directly. Methods include PCR screening, DNA hybridization, metagenome sequencing and data mining, and genomic library expression screening (Table 1).

39.8.1. DNA Extraction

Culture-independent screening for genes or enzymes is based on the extraction and analysis of a sample community metagenome. The ideal method is to extract the metagenome in its entirety to retain unbiased representation of all microbes present. Methods to extract DNA from soils and sediments are generally classified as direct or indirect extractions (55). The methods differ in the amount of sample required, the size of DNA extracted, and the separation of cells from their surrounding environmental matrix, which affects species representation. Given these differences, the downstream

TABLE 1 Metagenome screening

Method	Benefits	Limitations
Sequencing	High throughput Library construction not required	Hits may be incomplete ORFs Can find only known domains High tech
PCR	Works with small amounts of DNA Can find similar sequences Low tech Library construction not required	Can find only known domains Low throughput
DNA hybridization	Can find similar sequences Low tech	Can find only known domains Hits may be incomplete ORFs Medium throughput Library construction required
Activity	High throughput Hits are active clones Can find enzymes with novel domains	Lower success rate Host must be able to produce active enzyme Library construction required High tech

analytical application must be considered when choosing an extraction method.

39.8.1.1. Direct Extraction

In the direct DNA extraction process the cells are lysed directly within the sample matrix. The DNA is then isolated from the matrix and cell debris (49, 74). The methods for cell lysis include thermal shock, bead mill homogenization, bead beating, microwave heating, and ultrasonication (55). These are preferred to chemical or enzymatic lysis methods because they allow for disruption of the surrounding matrix, allowing for more complete, unbiased lysis of all cells. The liberated DNA is then purified using methods such as silica-based binding, agarose gel electrophoresis, precipitation, and gel filtration. A disadvantage of the direct extraction method is that since the sample is extracted as a whole, any inhibitors present in the matrix, especially humic acids commonly found in soils, accompany the DNA. These substances can inhibit downstream molecular processes such as PCR. Also, DNA from all cells within the sample, including eukaryotic cells, is extracted. Due to the generally larger genomes of eukaryotes and the presence of noncoding sequences, eukaryotic DNA contamination may be undesired. The main consideration of direct extraction is the amount of DNA shearing that takes place with the mechanical disruption of cells and the surrounding matrix, resulting in smaller fragments of genomic DNA. This limits the insert size of genomic clone libraries and precludes the use of fosmid or bacterial artificial chromosome (BAC) libraries.

39.8.1.2. Indirect Extraction

The indirect DNA extraction process separates cells from the sample matrix before lysis (4, 81). Samples are typically blended in a disruption buffer to separate the cells from the matrix while keeping them intact. The cells are then separated from the sample debris by differential centrifugation. The cells are further purified by density gradient centrifugation (4) or the use of a cation-exchange resin (32). The combination of the centrifugations also helps to eliminate the eukaryotic cells from the sample, resulting in a pure prokaryotic metagenome. The purified cells are encased in low-melting-point agarose and then lysed by enzymatic or chemical methods (69). During the lysis and washing steps the immobilization of the DNA in agarose eliminates DNA shearing and preserves high-molecular-weight DNA. The DNA is then released by melting and digesting the agarose with an agarase.

As with direct extraction, there are advantages and disadvantages to indirect extraction. The extraction of high-molecular-weight DNA allows for the construction of larger insert libraries (fasmids and BACs). These libraries enable the screening of longer stretches of DNA, such as those encoding metabolic pathways or multienzyme protein complexes. They also aid in the recovery of full-length open reading frames (ORFs) by increasing the chances of finding a full-length ORF within a clone insert. Since the harsh mechanical methods of direct extraction are not employed, a portion of the cells may not be released from the sample matrix. This leads to overall lower coverage of the community, with rare species possibly unrepresented. The DNA yields from indirect extraction are typically lower than direct extraction. Thus, the sample amounts needed to obtain enough DNA for library construction need to be as much as 10 times higher, if not more, than the amount needed for direct extraction.

39.8.2. Environmental Genomic DNA Screening Methods

39.8.2.1. Sequence-Based Discovery Using Genomic DNA

39.8.2.1.1. PCR Screen

PCR screening is based on amplifying target gene fragments from metagenome DNA templates using degenerate primers that anneal to conserved regions. Gene sequence databases are quite large, and many protein functional domains have well-defined primary amino acid sequences. Thus, a highly conserved target sequence can be defined for many enzyme activities of interest. Once a target is chosen, e.g., a cellulase, the known, sequenced cellulases are aligned to determine any conserved regions. In designing degenerate primers, the primers must be specific enough to amplify only cellulases but general enough to amplify the variety of cellulases that may be present in any sample. Annealing temperatures are typically low, to decrease the stringency of the PCR and to aid in capturing novel genes. The PCR product is a collection of the different cellulases that were amplified in the sample. The product is cloned, and clone inserts are sequenced—with sequence depth determined by the complexity of the metagenome and the number of unique cellulases amplified by PCR.

Since most conserved regions are not found at the start and stop regions of a gene, the amplified products are only gene fragments. These PCR tags can then be used as starting points for complete cloning of the full ORF using thermal asymmetric interlaced PCR or other PCR recovery techniques. Activity of the protein encoded by the ORF must then be confirmed by activity assays. Another limitation to the PCR screening approach is that the only genes that can be amplified are those encoding already known domains with sufficient conservation to allow for degenerate primer annealing.

The main benefit of PCR screening is sample coverage. As long as the sample metagenome DNA is free of PCR inhibitors, 1 ng of template DNA in a reaction is greater than 1,000 times the coverage of a sample containing 1,000 genomes. Relative abundance plays a large role. To discover genes from rare species, and to limit the dominance of genes from abundant species, the lowest number of PCR cycles should be employed and the greater number of clones should be sequenced.

39.8.2.1.2. Hybridization Screen

Another traditional approach for isolating novel coding sequences is to screen a DNA library at low stringency with a DNA probe. While this approach can work with environmental DNA samples, it does have limitations. Recent analysis of a soil sample led to an estimate of 3,555 bacterial operational taxonomic units in that sample (48). If one assumes a typical prokaryotic genome size of 4 Mb, then there would be 1.4×10^{10} bp of sequence information in that sample. A typical small insert library with an average insert size of 5 kb would require screening 1.4×10^7 clones. If one can screen 5,000 colonies per plate, it would require 2,800 plates to screen all the information contained in the plasmid library at $5\times$ coverage. Thus, any standard DNA hybridization probe approach will cover only a very small percentage of the potential within a typical metagenomic library. Such a screen is also limited to finding only sequences related to previously identified sequences and will miss truly novel sequences.

39.8.2.2. Metagenomic Sequencing and Data Mining

Since the first large-scale sequencing of metagenomes (75, 76), a method of data mining metagenome sequences to

discover novel proteins has emerged. Numerous studies of-fering comparisons of metagenomes and functional insights into microbial communities have been published (28, 40, 59) and will continue to be invaluable. In collaboration with the Joint Genome Institute and the California Institute of Technology, Verenum Corp. discovered novel genes encoding lignocellulosic-degrading enzymes from the metagenome of hindgut microbiota of wood-eating higher termites (71). These enzymes have potential applications in the lignocellulosic ethanol industry. With ever-increasing sequencing capacity and technology, data mining for discovery and application of novel proteins for the biofuel, pharmaceutical, chemical, and industrial fields continues to gain ground.

39.8.2.2.1. Library End Sequencing

Traditional dideoxynucleotide chain termination sequencing, or Sanger sequencing, has been the approach to obtain metagenome sequences for the past three decades. This method has also been used for gene pathway and whole-genome sequencing. The metagenomic DNA of a community is randomly sheared or digested and then cloned into a library, with clone insert sizes in the range of 1 to 10 kb for a plasmid library, 32 to 47 kb for a fosmid or cosmid library, and 150 to 350 kb for a BAC library. The clones are plated, and individual colonies are picked and grown. The cloned DNA is extracted from each clone separately, and the end of each clone insert is sequenced. Two sequencing reactions are run for each clone using a forward and a reverse primer, producing a forward and reverse “end read.” The priming sites are situated on the vector sequence nearest to the insert, to minimize known vector sequence in the read. Typical end reads are 500 to 1,000 bp long. Software is used to assemble any overlapping reads to form contigs. Depending on the diversity and abundance of species within a community, contigs may or may not form. Unlike a single genome sequencing effort, the goal of metagenome sequencing is not to “close” the metagenome, or sequence it in its entirety, but rather to gather a sampling of all the genomes present. Data mining of metagenome sequences has been used to discover novel glycosyl hydrolases (7, 78).

The advantage of metagenome data mining is that the genes discovered are not encumbered by the necessity of hybridization to conserved regions, as is the case for PCR and hybridization screens. More genes may be discovered without these constraints. The disadvantages are limited coverage and the relative abundance of species. The amount of metagenome sequenced in the termite gut study and the Sargasso Sea was only a fraction of the total metagenomes present (76, 78). However, from these sequencing efforts numerous novel genes were discovered. In any given community the distribution of species is not equal; there are over- and underrepresented species present. Metagenome sequencing will reveal a greater amount of data from the abundant species, with very little from the rare species. This bias can be overcome by sequencing to a greater depth, if cost is not a factor.

The main disadvantage of metagenome sequence data mining for novel genes encoding active proteins is the paucity of full-length genes discovered. The vast amount of data generated by metagenome sequencing is subject to gene prediction and annotation using software programs that employ different gene prediction methods (40). In most cases the genes discovered will be gene fragments or genes containing partial ORFs. These partial ORFs do not

contain—on one read or contig—the start and stop codons of the gene. The utility of these partial sequences is invaluable for comparative analyses, where genes can be predicted from partial sequence, but limited for obtaining novel proteins from full-length ORFs. When the full-length ORF does exist within the sequence, primers can be designed to the start and stop of the gene and PCR amplified from the genomic DNA or library. The gene may also be created synthetically.

39.8.2.2.2. Full-Length Gene Recovery

The candidate genes discovered by data mining are all hypothetical, subject to vetting in subsequent functional characterization experiments. Many unknowns exist as to the activity of the proteins encoded by sequence data-mined genes. To be active, a gene must contain no debilitating mutations or deletions, contain functional start and stop sites, be capable of expression and proper folding in the expression host cell, and have activity on the chosen substrate. Inactive proteins and their genes may possibly be fine-tuned to produce activity. Indeed, the same issues also apply to genes and proteins in the function-driven approach. However, only those proteins that are active will be discovered through the screen; the number of inactive clones does not affect the workload. In the case of sequence data mining, any gene of interest must be subcloned and tested for expression. Some will be inactive, for any number of the reasons listed above (78). It should be assumed, when embarking on a sequence mining discovery effort, that some portion of the genes discovered will be inactive. When only a partial ORF is discovered, there are a number of methods to obtain the missing sequences—the start or stop codons, or both. The power of library end sequencing is that there is a potentially inexhaustible supply of clone DNA to go back to and obtain the portion that neighbors the end sequence. The clone insert from which a partial end sequence was discovered may contain the entire ORF. A new primer is designed toward the end of the known sequence. It is used to “primer-walk,” or continue sequencing from the known sequence. When the full-length ORF is contained within a clone insert, this is the simplest and least labor-intensive method.

If a partial gene is truncated at the end of a clone insert, other more laborious methods are needed to obtain its full ORF. These methods depend on the use of metagenomic DNA, which may be scarce. The DNA must also be clean and free of PCR inhibitors to work effectively. Environmental samples, especially soils, often contain inhibitors that make these methods of full-length recovery inefficient.

39.8.2.2.3. Next-Generation Sequencing

Next-generation sequencing methods such as pyrosequencing, reverse termination, and amplification by ligation (51) can yield much greater amounts of sequence data than Sanger sequencing. The new technologies have provided substantial increases in predicted gene sequences and the resulting predicted enzyme sequences (7). However, given the relative shortness in the sequencing reads (<400 bp) from all the next-generation DNA sequencing technologies, the sequence data tend to cover only portions of a complete ORF. These short reads limit investigators to discussing sequences in terms of environmental gene tags (7, 39). The methods do enable sequencing directly from extracted metagenomic DNA, bypassing the need to create genomic clone libraries. However, for the purpose of functional gene and protein discovery, the absence of actual

library clones underlying the DNA sequence precludes the relatively easy subsequent clone sequencing efforts to complete partial sequences.

The obvious advantage to highly processive new sequencing technologies is greater coverage of the metagenome, which would yield greater numbers of, albeit partial, genes discovered. Depending on the complexity and relative abundance of a sample, the increased coverage may yield overlapping sequences and contigs, which may include full-length genes. Without contigs, however, the laborious PCR methods mentioned above may be the only way to recover ORFs, using the metagenomic DNA as a template. The large differences in per-base sequencing costs dictate that the new methods will be used, and improvements in average read lengths will lead to larger contigs and better ORF calls (reviewed in reference 40).

In a previous effort that used Sanger-based sequencing methods to identify new cellulases (78), scientists at Verenum Corp. were able to follow up on partial genes and sequence actual clones, express them, and confirm the enzyme activity of 35 of the 44 genes tested. It follows that to most effectively discover novel functional proteins by data mining metagenome sequences, the combination of new and old technologies is needed. This can be done by building up large data sets with next-generation sequencing and then associating these sequences and contigs with actual library clone ends generated by Sanger sequencing.

39.8.2.3. Genomic Clone Libraries and Expression Screening

Direct sequencing of environmental DNA can lead to the identification of novel enzymes but has limitations, as mentioned above. Also, sequence-based discovery still requires subsequent testing of the cloned or synthesized DNA to confirm that the enzyme predicted to be encoded by the gene in question does have the activity of interest. Thus, it is important to have expression systems for testing putative ORFs as well as using the environmental DNA as source material for building libraries in expression vectors suitable for high-throughput activity (24).

39.8.2.3.1. Library Construction

39.8.2.3.1.1. Characteristics of different bacterial cloning. Researchers may now choose from a large variety of bacterial cloning systems available for use in an assortment of *E. coli* strains. These cloning systems cover a full range of potential insert sizes from less than 1 kb to greater than 100 kb.

Each of the available cloning strategies has advantages and disadvantages.

Lambda cloning vectors provide significant advantages over plasmid vectors, such as lack of size bias, easier amplification and screening, and more complete representation because lytic systems have a higher tolerance for toxic proteins. Early versions of lambda vectors were difficult to manipulate in downstream applications such as subcloning and sequencing due to their unwieldy size, nearly 50 kb. However, this issue has been addressed by newer generations of lambda vectors such as Stratagene's Lambda Zap.

Lambda insertion vectors typically accept inserts of 0 to 12 kb, depending on the vector. Stratagene's Lambda Zap vectors combine the high efficiency of a lambda vector system with the versatility of a plasmid system by allowing in vivo excision of cloned fragments into a phagemid

vector. The plasmid form of the clone is recovered in the pBluescript plasmid through a simple in vivo process of coinfecting the appropriate *E. coli* strain with the phagemid and a helper phage.

Cosmid vectors have larger cloning capacities than lambda insertion vectors, up to 45 kb. This has the advantage of allowing large genes or operons to be isolated within a single clone. However, nearly all large-fragment cloning systems have the potential of generating cloning artifacts such as chimeras and can also give rise to a percentage of clones that are unstable and rearrange or delete inserts during cell replication.

39.8.2.3.1.2. Average insert size and representation of the genome. For environmental genomic cloning strategies, microbial sources and preparations can sometimes be directed to enrich for targets of interest. When constructing environmental libraries intended for multigenome-wide studies, the usefulness of the library depends on maximizing the proportion of entire genomes present in the library. The two defining characteristics of library quality are clone insert size and total number of clones containing inserts.

Insert size relates directly to the overall genome coverage of an environmental library, which may include several to hundreds of genomes. Inserts must also be of sufficient size to be useful for downstream analysis such as sequencing. As described above, even larger inserts may be required to identify complex pathways; however, their large size also presents challenges to procedures such as sequencing.

The number of clones or library size also relates directly to the probability of finding clones of interest. As library size increases, the probability of finding the desired segment of any genome within the library increases. This also applies to the probability of finding overlapping clones which make up pathways. One must keep in mind that while larger insert libraries have inherent advantages with genome analysis, they also have disadvantages in downstream manipulation. Consequently, how large does a library need to be to theoretically guarantee that a target will be present? "Genome equivalent" is a term used to describe the depth of genome coverage. Equivalent is calculated as the ratio of the amount of genomic DNA in the library to the amount of DNA in the genome, or the genome redundancy. The calculation of an environmental library's genome coverage involves five factors: (i) genome size of the organisms, (ii) total number of clones in the library, (iii) number of background clones, (iv) average insert size of contributing clones, and (v) with environmental libraries, the number of different genomes present. For example, a soil sample may contain hundreds to thousands of different genomes. A library with 5× genome coverage is generally adequate for finding one or more clones of interest, since more than 99% of the genome should be present.

39.8.2.3.1.3. Amount and quality of DNA required. The quantity of DNA needed to construct a library varies depending on numerous factors, including the cloning system chosen, average size of the genomic DNA prepared, and genome coverage needed. Depending on the experience of the user, multiple rounds of optimization may be needed to achieve an acceptable initial DNA preparation. The ideal preparation of environmentally sourced DNA consists of both sufficient quantity and quality of size-selected DNA for library construction. Regardless of the vector type chosen for library construction, it is helpful to have available environmental source DNA which is at least five times the

size of the desired insert size. DNA of five times the size will allow for random shearing or partial enzyme digestion of the DNA with a high probability of gene representation in the library. For example, lambda insertion libraries which accept inserts up to 12 kb would require 60 kb of source DNA and cosmid libraries with 40-kb inserts would require 200 kb of source DNA.

DNA prepared in liquid format is more susceptible to shearing forces and breakage, although it can be of sufficient length to be suitable for cloning into lambda, cosmid, and fosmid vectors.

39.8.2.3.1.4. The bacterial host strain. There are a variety of challenges to maintaining foreign genomic DNA in a bacterial host. Environmental sources will likely contain both prokaryotic and eukaryotic genomes, adding to the overall complexity of maintaining library representation. Wild-type *E. coli* has evolved numerous restriction, modification, and recombination systems to combat introduction of foreign DNA. Fortunately, a variety of host strains with mutant genotypes is now available for library construction, and these strains minimize such effects.

For instance, disabling *recA* and other related genes in the host strain eliminates most recombination related to repetitive sequences in the genomes of higher organisms. Another common host strain modification includes mutations to restriction systems that degrade foreign DNA. Selection of a suitable host strain is simplified by the general availability of library construction kits which include host strains (Table 2).

39.8.2.3.2. Activity Screening Methods

Expression libraries made from environmental DNA can be screened in several different ways, each differing in the format for keeping individual clones separate and exposing each clone to the substrate. The basic distinctions are between solid agar plate formats and liquid-based microtiter plate formats. Each has its pros and cons. Solid agar plate formats are simple to run and have reasonable throughput but are limited to assays that can be run at lower temperatures and are more amenable to colorimetric substrates that allow direct visual readout of the activity. Liquid-based screens, using microtiter plates, can result in higher throughput because of the use of photonic readouts (fluorescence and luminescence) and robotic systems (24, 65). Liquid-based screens also allow for assay conditions that may not be amenable to host cell growth or agar stability, such as higher temperatures or organic solvent-requiring substrates.

In all the cases, primary screens are conducted with highly complex libraries to identify a clone expressing the

enzyme activity of interest, or hit (66, 67). These primary hits are then subsequently rescreened at much lower complexity to confirm the presence of a clone with the desired activity and to isolate individual clones. In some cases there may be a third or even fourth round of screening at low density to ensure that single clones with the desired activity have been isolated. The final clone is then ready for DNA sequencing. The resulting DNA sequence is scanned for potential coding sequences. The translations of the coding sequences are then searched for similarity to previously identified enzymes or domains using, for example, BLAST (1) and Pfam (17).

39.8.2.3.2.1. Solid-medium screening. Activity-based screening of environmental DNA libraries on solid media such as agar plates is best suited to assays where a colorimetric substrate is available (67). An azo dye-linked xylan was used at Verenum (6) to screen libraries from insect gut contents to discover novel xylanases. Palackal et al. (50), also at Verenum, used the same substrate to isolate a novel cellulase from bovine ruminant gut bacteria. In both cases, bacteriophage lambda plaques were screened by plating the phage in top agar containing the dye-linked substrate. A thermostable α -amylase that is used in the grain ethanol industry was discovered at Verenum using a similar method with dye-linked starch (57). In this case, a nitrocellulose lift was done to replicate the plaques onto a solid support and allow for screening at high temperature ($\sim 75^\circ\text{C}$).

39.8.2.3.2.2. Liquid-based screening. Another method for screening by activity is to use a liquid medium. A library is propagated in plasmid form, and bacterial clones are grown and assayed for the novel activity (65). Typically the library is plated out and colonies are picked into microtiter plates for culturing. The substrate is subsequently added, and the microtiter plates are tested for generation of the expected product. Colorimetric substrates are useful because the products can be detected with a basic spectrometer; however, they can have problems with background noise, low sensitivity, and linearity. Fluorometric assays are also used and have the benefits of higher sensitivity, better linearity, and lower noise. Kim et al. (38) used a fluorogenic compound to screen environmental DNA from a soil sample to find a β -glucosidase. They used 4-methylumbelliferyl β -D-cellobioside as a substrate to screen a metagenomic expression library arrayed into 96-well microtiter plates, visualizing the product using UV light. Robertson et al. (58), from Verenum, used a variant of this method to select for the clone of interest. They developed a strategy to find nitrilases by growing the cells expressing the environmental

TABLE 2 Bacterial cloning systems

Vector	Max capacity (kb)	Avg insert size (kb)	Growth format on agar plates	No. of clones required for $10\times$ representation ^a	Typical no. of clones in a library constructed from 1 μg of size-selected DNA (under good conditions)	Source
ZAP Express	12	5	Plaques or colonies if excised	400,000	2,000,000	Stratagene
Uni-ZAP XR	10	5	Plaques or colonies if excised	400,000	2,000,000	Stratagene
pWEB	45	40	Colonies	50,000	20,000	Epicentre
EpiFos	45	40	Colonies	50,000	20,000	Epicentre

^aEnvironmental source containing 100 genomes = 200,000 kb (assuming 2-Mb genome).

DNA library in a medium where the only nitrogen source was a nitrile. After up to 5 weeks of culturing, several flasks were identified that contained actively growing cultures. They were subsequently streaked for single-colony isolation and confirmation of the activity, yielding 137 novel nitrilases. The efficiency of microtiter plates for screening has increased from the original standard of 96 wells up to 1,536 wells per plate in the same area as occupied by the 96-well version. The GigaMatrix[®] technology (42, 43), invented at Verenum (41), dramatically increased that efficiency by using a microtiter plate that contains up to 1,000,000 wells in the same footprint. GigaMatrix[®] has been used to isolate proteases, cellulases, β -xylosidases, and α -L-arabinofuranosidase (42).

Microalgal Culture as a Feedstock for Bioenergy, Chemicals, and Nutrition

SUSAN T. L. HARRISON, MELINDA J. GRIFFITHS, NICHOLAS LANGLEY,
CARYN VENGADAJELLUM, AND ROBERT P. VAN HILLE

40.1. INTRODUCTION

40.1.1. Benefit of Algal Culture for Renewable Products

Interest in algal culture stems back to the 1940s (15, 48) and formed a key component in the early developments of the bioprocess engineering discipline. Recently, renewed interest in algal research has centered on its potential role as a renewable feedstock for energy and commodity products while utilizing solar energy to fix CO₂. Algae also have a role in the production of niche fine chemicals and nutraceuticals.

Algal culture can be used to extend resources beyond those conventionally exploited by agricultural systems owing to algal culture using marginal land areas and water bodies. This prevents direct competition with food crops. While the theoretical efficiency of photosynthesis has been estimated at about 10% (19), plant crops typically yield an efficiency of 1 to 3%, while algal systems can approach the 10% level under low light conditions (<1,000 μmol photons m⁻² s⁻¹) (9). This underlies the improved productivities of microalgal culture. In the biotechnology context, this can be demonstrated by comparing algal oil productivities with those of seed crops. Typical values for seed crops range from 0.6 liter m⁻² year⁻¹ (palm oil) through 0.1 to 0.2 liter m⁻² year⁻¹ (rapeseed, sunflower, and jatropha) to 0.04 liter m⁻² year⁻¹ (soya) (44). By contrast, algal oil productivities of 4.7 to 14 liters m⁻² year⁻¹ have been reported (45). Furthermore, ready access of the unicellular systems to water and nutrients as well as continuous harvesting of algae contributes to these superior productivities.

40.1.2. Potential Algal Product Range

Commercial interest in algal culture originated with low-value products, focusing on biomass as a source of protein or a source of energy. The large-scale application has been restricted by the cost of production of algal biomass, which ranges from US\$15 to \$20 kg⁻¹ where open culture is feasible to US\$50 to \$600 kg⁻¹ for selective cultivation of fastidious algae in closed systems (12). The current product range has been expanded to include fine chemicals and secondary metabolites as products of higher value as well as bioenergy products, the latter typically coupled to wastewater treatment or using carbon credits to offset costs.

The range of high-value algal products includes health foods, food additives, aquaculture supplements, and growth

regulators. Examples are given in Table 1. In these cases, product value affords opportunity for controlled growth in sophisticated bioreactor systems.

While commodity products such as protein, algal oil, and bioenergy products remain of great interest, these require improvements in productivities to be economically feasible as independent products. Currently they are produced as by-products or coproducts where economically feasible. Here the potential value of algal biomass as an energy source should be noted, as it has a lower heating value of 21 MJ kg⁻¹ (Phyllis database for biomass and waste [<http://www.ecn.nl/Phyllis>]), comparing favorably with conventional biomass resources.

40.2. ALGAL RESOURCES

40.2.1. Overview of Algal Types With Respect to Product Range and Requirements

The term "algae" is loosely used to describe a huge variety of prokaryotic (strictly termed cyanobacteria) and eukaryotic organisms with wide-ranging morphologies and phylogenies. Microalgae are generally small, photosynthetic, heterotrophic or, occasionally, phagotrophic, and unicellular or colonial aquatic plants. The term is typically extended colloquially to include the cyanobacteria. Macroalgae are larger (can be seen without the aid of a microscope), multicellular, and eukaryotic and often show some form of cellular specialization. Some of the more well-known microalgal types are described in Table 2.

40.2.2. A Decision Framework for Algal Species Selection for Desired Product

The choice of algal species is a primary critical decision in any algal enterprise. Success requires selection of a species with both the appropriate productivity and the right characteristics for specific culture conditions. To assist the decision-making process, a decision-making framework is useful. Data on candidate algal species are collated for comparison and assessment. Product value is key in determining the relative weighting of traits of interest in algal culture and product recovery (e.g., capital cost tolerated, need for sterile processing, harvesting, and product liberation) and their influence on process economics (for a good review on this, see reference 11).

For large-scale outdoor pond culture typical for low-value products, one or more of the following traits are desirable in

TABLE 1 Examples of currently commercially available algal products^a

Product metabolite	Commercial application(s)	Microorganism	Production system(s)	Geographical location(s)
β-Carotene	Pigment, vitamin A precursor	<i>Dunaliella salina</i>	Open ponds and raceways	Australia, China, India, Chile, United States, Israel
Astaxanthin	Pigment	<i>Chlorella</i> , <i>Haematococcus pluviialis</i>	Circular ponds	Taiwan, Japan, United States, Thailand
Phycocyanin	Blue colorant	<i>Spirulina</i>	Open ponds, natural lakes	
Eicosapentaenoic acid	Medical use	<i>Phaeodactylum tricornutum</i>		
Docosahexaenoic acid	Functional food	<i>Isochrysis galbana</i> , <i>Cryptocodinium</i>	Heterotrophic fermentation	United States
Fatty acids	Animal nutrition	<i>Isochrysis galbana</i>	Open ponds, PBR ^b	
Biomass	Health food	<i>Spirulina</i>	Open ponds	

^aSee reference 15.^bPBR, photobioreactor.

the algal species: fast growing, robust, optimized for the local culture conditions, able to thrive under conditions providing a niche habitat (thereby minimizing contamination), tolerant of a range of temperatures, and tolerant of a range of light intensities. Growth in an extreme environment (e.g., high temperature, pH, or salt) reduces contamination and predation, as a restricted spectrum of organisms grow

under such conditions. This has largely contributed to the successful culture of *Dunaliella salina* (high salt tolerance) and *Spirulina* (high pH and salt). In smaller-scale, closed photobioreactors, the environment can be better controlled to minimize contamination.

Productivity, the product of growth rate and product content or concentration, has been demonstrated as an

TABLE 2 Characteristics of some algal groups relevant to microalgal biotechnology

Group (common name)	Description	Morphology	Dominant storage product	Well-known organisms	Applications ^a
Chlorophyta (green algae)	Diverse group. Origin of higher plants. Usually photoautotrophic but can be heterotrophic.	Large range of cellular structures—unicellular flagellates to complex multicellular arrangements. Cell walls contain cellulose.	Starch (α-1,4-glucan)	<i>Chlamydomonas</i> , <i>Chlorella</i> , <i>Scenedesmus</i> , <i>Spirogyra</i> , <i>Volvox</i>	<i>Chlorella</i> is commercially grown as nutraceutical and aquaculture feed. <i>Haematococcus pluviialis</i> is used to produce astaxanthin. <i>Dunaliella salina</i> is grown for β-carotene.
Cyanobacteria (blue-green algae)	Nonmotile, gram-negative, prokaryotic eubacteria. Most widely distributed algal group. Dominate particularly in oceans. Important component of picoplankton.	Can be unicellular, filamentous, or colonial.	Starch and cyanophycin (arginine and asparagine polymer)	<i>Spirulina</i> (<i>Arthrospira</i>), <i>Anabaena</i> , <i>Oscillatoria</i>	<i>Spirulina</i> biomass sold commercially to health food and nutraceutical market.
Dinophyta (dinoflagellates)	Important components of microplankton. Nutritionally diverse. Half the known species are obligate heterotrophs.	Typically unicellular flagellates. Have armor-like cell covering beneath cell membrane.	Starch (α-1,4-glucan)	<i>Gymnodinium</i> , <i>Cryptocodinium cohnii</i>	Known for blooms and toxin production; many exhibit bioluminescence. Responsible for red tides. Some species produce DHA.

(Continued on next page)

TABLE 2 (Continued)

Euglenophyta (euglenas)	Occur in freshwater, brackish water, and marine environments, mostly in soils and mud, especially in highly heterotrophic environments. Obligate mixotrophic, as require B vitamins. Colorless. Species are phagotrophic. More closely related to trypanosomes than any other algal group.	Unicellular or colonial flagellates.	Paramylon (β -1,3-glucan)	<i>Euglena gracilis</i>	Unique cellular and biochemical features; may have pharmaceutical applications.
Haptophyta (also known as Prymnesiophyta)	Generally marine. Mostly photosynthetic but can be heterotrophic or phagotrophic.	Largely motile unicells. The best-known haptophytes are coccolithophores, which have an exoskeleton of calcareous plates called coccoliths.	Chrysolaminaran (β -1,3-glucan)	<i>Pavlova lutheri</i> , <i>Isochrysis galbana</i> , <i>Prymnesium parvum</i>	Several species grown as food for fish and other aquaculture organisms such as bivalves and abalone.
Heterokontophyta (includes brown algae, golden algae, and diatoms)	Large group containing the <i>Chrysophyceae</i> , <i>Xanthophyceae</i> , <i>Eustigmatophyceae</i> , and <i>Bacillariophyceae</i> (diatoms). Largely marine, but some freshwater varieties.	Cells with two different flagella (as opposed to isokont—two the same). <i>Bacillariophyceae</i> are unicellular, brown cells with a silica cell wall (unique type of casing made of two frustules that fit together like a lid on a box).	Chrysolaminaran (β -1,3-glucan)	<i>Amphora</i> , <i>Nitzschia</i> , <i>Thalassiosira pseudonana</i> , <i>Phaeodactylum tricorutum</i> , <i>Nannochloropsis</i>	Several species grown as aquaculture feed; others known for EPA production.
Rhodophyta (red algae)	One of oldest and largest groups of algae. The accessory pigments phycobiliproteins give them their red color.	Free-living, unicellular.	Starch (α -1,4-glucan)	<i>Porphyridium purpureum</i>	Some species secrete calcium carbonate—could be used in CO ₂ sequestration. Most economically important macroalgae are from this family, e.g., dulse (<i>Palmaria palmata</i>), nori (<i>Porphyra</i>), and species used to make agar, carrageenans, and other food additives.

^aDHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

important characteristic which should be considered in preference to growth rate, biomass concentration, and product content individually (23). Biomass harvesting represents a significant capital and operating cost in the algal process owing to the typically low biomass concentration and associated large culture volumes. The alga may be selected for properties to simplify harvesting, e.g., filamentous morphology, large cell size, high specific gravity, and cell surface properties that promote flotation or autoflocculation. The liberation of intracellular products is facilitated by a species that can be easily disrupted. This is influenced by cell wall type and size. Typically, algal species are more difficult to disrupt than bacteria or yeasts (5), a notable exception being *Dunaliella*. Other desirable characteristics include tolerance of shear force, the ability to outcompete contaminants, the production of autoinhibitors, and a high rate of CO₂ uptake (particularly for CO₂ sequestration applications).

The desirable algal characteristics should be ranked relative to other species, ideally by numerical quantification. These features are weighted depending on their importance and relevance to issues such as cost and impact on the large-scale feasibility of establishing a process for the product under consideration. The composite weighted score for each species allows direct comparison. The use of published information to compare species can present challenges. For example, data are often presented using different units of measurement, without sufficient information for their interconversion unless broad assumptions are made (e.g., conversion between areal and volumetric productivities cannot be made without information on culture depth). Studies may have been conducted to meet distinct objectives, using different strains (not always identified) and degrees of optimization of the culture conditions. Furthermore, species may have different inherent optimum nutrient levels and pH, temperature, and light requirements, and they may not reach their maximum potential under standard conditions.

40.2.3. Acquiring Algae from Culture Collections and Natural Habitats

Microalgae grow in almost every habitat in the world. They can be isolated from rivers, lagoons, dams, pools, salt lakes, oceans, springs, soils, rocks, animals, plants, and even snow and ice. There are two main types: planktonic (floating) and benthic (attached to a solid substrate). Samples should be labeled with locality, date of collection, and as much information on the environment as possible, e.g., whether the water is salt, brackish, or fresh; temperature; and whether the algae are free-floating or attached.

Algal samples can be stored in glass or plastic bottles, vials, or bags. Wide shallow containers are better than tall narrow ones, as they facilitate gas exchange. Samples should be examined under the microscope for initial identification and choice of isolation method. The isolation techniques described below can be used to eliminate predators and obtain monocultures of algae or, preferably, axenic cultures, i.e., single algal species also free of bacteria and other microorganisms.

Single colonies can be isolated by streaking samples onto agar plates, incubated in the light. These isolated colonies may then be used to inoculate liquid media. However, not all algal species grow on agar media. Further, solid media may also facilitate the growth of bacteria and fungi, so colonies should be transferred with care to fresh plates as soon as they appear (days to weeks). An alternative method to obtain pure culture, not utilizing solid media, is serial dilution. Cell concentration is determined by direct counting

and appropriately diluted such that a single algal cell can be transferred into a test tube, flask, or multiwell plate. Several tubes or flasks should be seeded, as some may contain no cells, while others will contain more than one. On the basis of probability, some should contain a single cell and hence yield an axenic culture containing a single algal species. Nutrient enrichment of the culture medium can be used to create an environment where certain species grow in preference to others. These may include the addition of ammonia, selenium, soil-water extract, macronutrients, organic substrates, or trace metals. Isolation by micropipette can be achieved using a glass pipette or fine capillary tube. This fine tip is used to isolate single cells from a drop of liquid to a multiwell plate, agar, or microscope slide. Transfer through a series of sterile droplets is used to dilute the sample until a single cell can be selected. Alternatively, unwanted cells can be removed from the droplet, leaving the target cell free of contaminants. The diameter of the pipette opening should be at least twice that of the cell to prevent shear damage. To remove adhering material from filamentous algae, a hook can be prepared on the end of a Pasteur pipette and used to drag the filament into and through an agar plate. Flow cytometry with cell sorting is recognized as a high-throughput automated technique for isolation of single cells. Density centrifugation can be used to separate the species of interest from contaminants of different size or density. Certain flagellates are known to swim toward or away from light. This can be used to isolate them by application of a focused light source to one end of a channeled culture, through phototaxis. Chemical agents such as germanium dioxide can be used to kill diatoms contaminating cultures of other algal species. Similarly, antibiotics are often effective at eliminating cyanobacteria. A combination of antibiotics or other antimicrobial agents can be used to reduce the number of bacteria in an algal culture without killing all the algae. Exposing the culture to UV light can also be used to eliminate bacteria, based on their different response to UV light from algae. The lower end of the UV-B spectrum and UV-C light are most effective, and exposure times vary from 1 to 30 min.

Typically, a selection protocol composed of the following steps, in the order given, is used for isolation and purification of microalgae to achieve a virus-free, axenic culture (adapted from reference 27).

1. Examination for predators and debris
2. Size/density separation
3. General enrichment (most algae) or selective enrichment (certain species)
4. Isolation by agar streaks, micropipetting, dilution, flow cytometry, centrifugation, etc., to achieve an algal monoculture
5. Antibiotic or UV treatment to achieve axenic culture
6. Further treatment to remove viruses

Pure algal monocultures can be ordered from culture collections around the world. The site http://en.wikipedia.org/wiki/List_of_algal_culture_collections provides a list of appropriate culture collections. Popular ones include the CSIRO culture collection in Australia (<http://www.marine.csiro.au>) and the collections of the University of Göttingen (<http://www.epsag.uni-goettingen.de>) and University of Cologne (<http://www.ccac.uni-koeln.de>) in Germany, the University of Toronto in Canada (<http://www.botany.utoronto.ca/utcc>), Algobank in France (<http://www.unicaen.fr/ufr/ibfa/algobank>), the National Institute for Environmental Studies in Japan (<http://mcc.nies.go.jp>),

the Culture Collection of Algae and Protozoa in the United Kingdom (<http://www.ccap.ac.uk>), and UTEX in the United States (<http://web.biosci.utexas.edu/utex/>).

40.2.4. Culture Maintenance

The most common maintenance method for microalgal cultures is routine serial subculturing, also known as routine serial transfer (39). A culture in late log or stationary phase is subcultured into fresh growth medium (35). The newly transferred cultures are usually placed on lighted shelves until a desired colony size or culture density is achieved, and then they are stored away from light until needed. Indirect natural daylight or solely artificial light can be used for maintaining cultures. In some instances, a day/night cycle of 12 h each is used (1). The transfer time varies with species from 2 weeks to 6 months. Serial transfer is used to maintain healthy physiologically, morphologically, and genetically representative populations. Therefore, a balance is required between sustaining active stock cultures and extending the period between transfers. The serial transfer method is labor-intensive and expensive for maintaining a large number of strains. Other limitations include possible loss of important morphological features or physical traits and the possibilities of contamination and mutation (35, 39). Despite these limitations, a number of the large international culture collections such as the Culture Collection of Algae and Protozoa in the United Kingdom, Canadian Phycology Culture Centre in Canada, and UTEX in the United States still employ this method. Microalgal strains which grow readily on agar are maintained on agar slants. Long-term culture storage methods such as encapsulation and cryopreservation have been investigated in order to prevent genetic drift (18). The encapsulation method entraps microalgal cells in a calcium alginate gel to extend transfer time to 12 to 36 months; however, it is very labor-intensive and not suitable for large numbers of strains (18, 39). Under cryopreservation, algae are held at an ultra-low temperature while remaining capable of survival upon thawing. Most cryopreservation techniques include two steps: slow cooling at $1^{\circ}\text{C min}^{-1}$ in a -86°C freezer, followed by submersion in liquid nitrogen. This has been used successfully for a range of cyanobacteria and unicellular microalgae (1, 18). However, many large and complex algae cannot be cryopreserved, as the mechanism of cell injury during freeze-thaw cycles is not fully understood (18). Microalgal strains which grow readily on agar can be cryopreserved directly on agar. The most commonly used cryoprotectant for microalgae is methanol, not glycerol, which is used conventionally for bacteria. The viability of strains after cryopreservation varies, and it is recognized that the technique of cryopreservation will benefit from further development.

Recently, a new method of maintaining microalgal cultures was proposed, employing dual-layer 96-well microtiter plates (39). The cultures were successfully maintained by immobilization onto membrane filters fitted to individual wells (source layer), allowing passage of nutrients from the underlying growth medium (substrate layer) housed in the bottom of the chamber. Numerous axenic cultures were maintained in this manner.

40.3. BASIC REQUIREMENTS OF ALGAL CULTURE

40.3.1. Identifying Key Culture Variables

While optimal microalgal culturing systems vary greatly with application, the following characteristics should be

FIGURE 1 Parameters that can be manipulated in algal culture. (Adapted from reference 25.)

considered for culture system design and operation: provision of CO₂ and removal of O₂, provision of nutrients, temperature, pH control, salinity, light provision, mixing, mass and heat transfer, and hydrodynamics. The interaction of these variables is illustrated in Fig. 1. Their optimal and tolerated ranges tend to be species specific.

40.3.2. Light—Provision and Its Intensity

Sufficient light is vital for photosynthesis, the sole source of energy and carbon for autotrophic algae. As the depth in the cell culture increases, the penetration of light through the system decreases. This creates two effective lighting regions in a culture. In the photic volume, light is sufficient for photosynthesis, while in the dark region light intensity is below the threshold value for photosynthesis and photolimitation occurs. The cycling of cells between these volumes can increase algal productivity (42). By increasing the ratio of surface area to volume in the culture system, the exposure of the culture to light is increased. Furthermore, penetration of light through the culture decreases exponentially with increasing cell concentration (42) and is a decreasing function of liquid depth and absorbance capacity of the suspending medium and an increasing function of irradiance intensity. The combination of these parameters alters the ratio of photic and dark regions and is recognized as important for achieving high algal growth rates (15, 42).

Increasing the incident irradiance on the system to overcome photolimitation in dense algal cultures improves light penetration through the photic volume, increasing the algal growth rate (22) until the threshold value is surpassed beyond which photoinhibition occurs (9, 24). This threshold value for photoinhibition is highly dependent on algal species, previous culturing conditions, and the hydrodynamic regime within the system, the last affecting light cycling. An example of this is illustrated in Fig. 2. Many algal species cannot tolerate direct sunlight. Light intensities generally employed in the laboratory are 100 to 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (about 5 to 10% full sunlight, 2,000 $\mu\text{mol m}^{-2} \text{s}^{-1}$). Many algae have been reported to grow better under a light:dark cycle (between 16:8 h and 12:12 h) than continuous light; however, contradictory reports are also found.

Most green algae rely primarily on the pigments chlorophyll *a* and chlorophyll *b* to harvest light for photosynthesis. The absorption spectra of chlorophylls *a* and *b* show strong absorbance in the blue (410 to 500 nm) and red

FIGURE 2 Dependence of photosynthetic rate on light intensity, illustrating limitation and inhibition.

(620 to 700 nm) regions and very low absorbance in the green region (500 to 600 nm) (31). Another well-studied pigment, β -carotene, exists in nearly all algal strains and absorbs light between 400 and 500 nm (31). The efficiency at which light is harvested by a certain pigment varies with the wavelength of light supplied (31). Although studies undertaken focus on the quantity of light supplied to cultures, the quality of this light should also be of concern.

Measurements of solar irradiance show a relatively even distribution of radiation across the visible spectrum (31). Most types of lightbulbs, on the other hand, emit light in a more confined region of the visible spectrum (22). Some of the most commonly suggested bulbs for algal cultivation on a laboratory scale are fluorescent tubes, metal halide bulbs, standard incandescent bulbs, and halogen lamps (10, 14, 22). Both standard incandescent bulbs and halogen lamps emit small amounts of blue light, while metal halide bulbs emit small amounts of red light. Fluorescent tubes offer the most practical lighting option, as they put out small amounts of heat. In addition, fluorescent tubes have become available with modified phosphor coating emitting a more evenly distributed spectrum similar to natural daylight; however, they have a relatively low light output (22). More work is needed to establish to what extent the quality of light affects algal growth.

40.3.3. Hydrodynamics—Mixing and Mass Transfer

When a microalgal culturing system is designed, it is important that the hydrodynamic regimes in the system be considered, primarily to prevent settling, expose algae to light, and enhance mass and heat transfer, especially gas-liquid mass transfer. Dead zones in the photobioreactor can result in undesirable settling of the cells (15). Appropriate mixing and circulation times are required, as is optimum cycling between light and dark zones. Care must be taken not to subject shear-sensitive cells to excessive shear stress, as this can cause decreased growth rate, metabolic activity, and even cell disruption (53).

40.3.4. CO₂ Provision and Gas-Liquid Mass Transfer

The rate of transfer of CO₂, the primary carbon source in gas-sparged autotrophic systems, from the gas into the liquid frequently limits the rate of growth of algal biomass (48). New culturing systems designed to facilitate CO₂ mass transfer at a sufficient rate to satisfy the cell growth rate are required. The rate of CO₂ mass transfer (CTR), given

in equation 1, from gas to liquid is dependent on the concentration driving force between the saturation (C_s) and instantaneous (C_L) CO₂ concentrations in the liquid and the volumetric mass transfer coefficient (k_La) (31).

$$CTR = k_La.(C_s - C_L) \quad (1)$$

The volumetric mass transfer coefficient describes the CO₂ mass transfer capability of a particular system and is a strong function of bubble size, agitation rate, temperature, and superficial gas velocity through the system (31). It can be estimated from a number of empirical correlations (52). Typical values reported for algal photobioreactors range from 0.002 to 0.020 s⁻¹ (48). The saturation concentration is directly proportional to the concentration of CO₂ in the gas stream and can be calculated using Henry's law (31). This indicates that mass transfer limitations can be partially alleviated by using CO₂-enriched gas. It must be noted that the recovery of CO₂ from the gas stream is incomplete owing to the need for a driving force for mass transfer. Further, where CO₂-enriched gas is used, the fractional recovery of CO₂ from the gas stream may be expected to decrease despite improved gas transfer rates. The extent of the recovery is a function of the residence time of the gas stream in the reactor.

40.3.5. Nutrient Provision—Medium Requirements

Microalgal medium is composed of macronutrients, microelements, and vitamins. Macronutrients are required in relatively large amounts and include nitrogen, phosphate, and silicon, the last required only for diatoms, silicoflagellates, and some chrysophytes. Nitrogen is typically provided as nitrates, ammonia, or urea, while phosphorus is provided as potassium phosphate. Silicon, added as Na₂SiO₃·9H₂O, enhances precipitation and hence should be minimized. Macronutrients are generally required in a ratio of 16N:16Si:1P for diatoms, although typically a single macronutrient is set as limiting (3).

Microelements are required in trace amounts. They are usually prepared as a stock solution of chloride or sulfate salts of zinc, cobalt, manganese, selenium, and nickel and kept in solution by a chelator such as EDTA. Iron is also added to marine culture media, usually as a separate solution.

Three vitamins are generally used for algal culture: B₁ (thiamine), B₁₂ (cyanocobalamin), and H (biotin) (51). Many algae require only one or two of these, although all three are typically supplied at the laboratory scale. Stock solutions of vitamins should be filter sterilized and added to media after autoclaving, as they are destroyed by heating.

Comprehensive listings of media, trace elements, and growth factors are given by Andersen (3). Frequently used laboratory media for freshwater and marine algae are listed in Table 3.

Freshwater media, tailored to specific algal needs, typically include macronutrients, a micronutrient mix, and distilled water, with a buffer if necessary. The pH of the

TABLE 3 Frequently used general-purpose media for microalgae^a

Freshwater	Marine
Bristol medium	F/2 medium
Bold's basal medium	Enriched seawater medium
Proteose medium	Erdschreiber's medium
Soil extract medium	Artificial seawater medium

^aRecipes available on the UTEX website: <http://web.biosci.utexas.edu/utex/>.

media is adjusted to specification prior to sterilization by heat or filtration. Several media include a soil extract, made by heating, boiling, or autoclaving soil in water and then filtering. This contains a complex mixture of nutrients and is useful when precise knowledge of medium composition is not necessary.

Two main types of marine culture media can be identified, natural and artificial. Natural media use seawater, while artificial seawater recipes attempt to mimic the composition of natural seawater using laboratory chemicals. Natural or simulated seawater forms the basis of the media, to which nutrients, microelements, and vitamins are added.

Natural seawater is collected offshore to avoid pollution and variation in composition. The salinity and nutritional value of collected seawater may vary depending on season and collection point and should be tested. Seawater should be filtered as soon as possible (using 0.45- or 0.22- μm -pore-size filters) and stored at 4°C in the dark. If the exact composition of the medium is important, artificial seawater should be used.

Seawater is often heat sterilized at 121°C. Precipitation of salts may occur during this process, rendering key nutrients unavailable to the algae. The removal of CO₂ during heating with a concomitant pH increase to above pH 10 causes precipitation. Adding acid or a buffer or saturating the medium with CO₂ before autoclaving can reduce precipitation. Rapid cooling of medium also reduces precipitation. Alternatively, other sterilization techniques such as filtration, pasteurization, or microwaving can be used.

Several algal species can be grown heterotrophically, obtaining carbon and energy from an organic carbon source instead of, or in addition to, photosynthesis. This is advantageous, as it reduces and in some cases eliminates the requirement for light. A list of commercially important algal species that can be grown on organic carbon sources such as glucose, acetate, ethanol, glycerol, yeast extract, and various amino acids is given by Lee (33).

40.3.6. Physiological Culture Conditions: Temperature, pH, and Salinity

The optimal temperature for algal species is often related to the environment in which they naturally occur. Temperatures between 16 and 35°C are most common, although polar algae may grow at less than 10°C and growth of thermophilic algae is reported to 62°C, depending on the species (14, 29). Deep-ocean species (e.g., picoplankton) generally prefer lower temperatures than freshwater pond species (e.g., *Chlorella*).

The pH range of most algae lies between pH 7 and 9. CO₂ supply and consumption largely determines the pH of a culture owing to its speciation on dissolution.

While salinity may be used as a selection pressure for halophilic algae of interest, it may also inhibit the growth of nonhalophilic, freshwater algal species. Control of salinity is important in systems where evaporative losses are significant and the makeup water contains dissolved solutes (seawater, brackish water, wastewater, and brines). Marine algae are reasonably tolerant to changes in salinity. Optimal levels are generally slightly below that of seawater, 20 to 24 g NaCl liter⁻¹. Halophilic species such as *Dunaliella* undergo lysis in the absence of salt.

40.4. ALGAL CULTURE SYSTEMS

40.4.1. Laboratory Culture Systems

Many types of photobioreactors are suitable for laboratory culturing of algae. Their suitability depends on application. Shake flasks and sparged bottles provide very simple systems for algal culturing but generally result in low rates of mass transfer. Algae can be grown in bubble columns; however, external or internal loop airlift reactors are more effective as photobioreactors for algal growth owing to the development of defined flow patterns with a concomitant increase in mass and heat transfer (30). Flat plate reactors increase the ratios of surface area to volume and result in high volumetric algal productivities (15). They remain impractical in small spaces. If larger-scale laboratory cultivation is required, open raceway ponds can be used where sterilization is not required.

40.4.2. Large-Scale Culture Systems

Large-scale cultivation systems fall into two main categories: outdoor ponding systems and closed photobioreactors. Commercial-scale operations for low-value products typically require the ability to produce tons of algal biomass. Based on productivity values reported for most species, this requires culture volumes ranging from 10,000 to in excess of a million liters (13). For this reason, almost all commercial microalgal enterprises employ relatively low-cost open ponding systems. While naturally occurring shallow ponds may be used, in most cases ponds are constructed. Constructed ponds vary in complexity from large unlined, unmixed ponds, frequently used for *Dunaliella* cultivation, to mechanically agitated, circular or raceway ponds. Rectangular ponds, up to 1 ha in size, divided by a central baffle and agitated with a single paddle wheel represent the most efficient and widely utilized design. These have been applied at a scale of 5,000 tons of algal biomass per year. Photobioreactors are typically closed, or mostly closed, systems which facilitate a far greater degree of control, resulting in significantly enhanced productivities. Increased capital and operating costs, influenced by the construction materials and energy requirements, currently limit their operation to high-added-value compounds. In Table 4, the benefits and disadvantages of open ponding systems and closed reactor systems for algal growth are compared.

The range of reactor configurations includes tubular, flat plate, and cylindrical systems. Example productivities reported in these systems are given as a function of size and light path across the systems in Table 5.

A number of design considerations are relevant to both types of large-scale culture systems. These include light provision, algal circulation, regulation of pH and temperature, and minimization of contamination. The efficient provision of CO₂ and removal of O₂ are more critical for photobioreactor systems, given the enhanced productivities (8).

Chlorophyll is characterized by a high extinction coefficient, meaning that it is very efficient at absorbing light (31). As a result, light penetration is limited at high algal concentrations. Consequently, the effective depth of open ponds is limited to a maximum of 20 to 30 cm for the majority of commercially important species, with this depth depending on appropriate mixing. Mixing is critical in open ponds to prevent biomass settling, temperature and oxygen stratification, and cyclic exposure to light. Biomass productivities up to 10-fold higher have been recorded in well-mixed systems relative to similar unmixed ones. The most

TABLE 4 Comparison of open and closed reactor systems for algal growth^a

Reactor type	Advantages	Disadvantages
Open ponds	Lower cost to establish Low operating cost Suitable for mass cultivation	Low biomass concentrations (0.1–0.5 g liter ⁻¹) Poor productivity Limited control of culture conditions Weather dependent Easily contaminated Occupy large land areas High evaporative losses
Closed photobioreactors	Improved control of culture conditions Reduced contamination Increased biomass concentration (2–8 g liter ⁻¹) Increased productivity Reduced land area required Reduced evaporative losses	Increased cost of manufacture Buildup of dissolved oxygen which may cause inhibition Fouling of walls by biomass limits light penetration, hence requiring cleaning Increased shear stress

important engineering considerations related to mixing in open ponding systems are reviewed by Borowitzka (13). Photobioreactors are often illuminated using artificial light sources, and most designs are configured to reduce light path length to a minimum. Mixing is most often achieved using the airlift principle. Control of pH and temperature is possible in photobioreactors but is limited in open systems, where evaporation and subsequent changes in salinity are more important.

Contamination and predation are important considerations for open systems, where maintenance of axenic cultures is impossible. Most of the species currently cultivated at a commercial scale are grown under highly selective conditions of high pH (*Spirulina*), salinity (*Dunaliella*), or nutrient loading (*Chlorella* and *Nannochloropsis*). Cultivation of genera such as *Haematococcus*, or lipid-producing species, under more benign conditions has been prone to contamination in pilot-scale operations. Predation by shrimp, rotifers, and amoebae can significantly reduce algal productivity, but in most cases these can be controlled by short-term adjustment of pH or elevation of salinity levels (7). Closed photobioreactors are less prone to gross contamination, although care must be taken to avoid contamination with competing algal species.

Prevailing climatic conditions are an important consideration for large-scale open ponding systems, particularly where drying of the biomass is required. Excessive humidity prevents efficient solar drying, while areas with high rainfall are unsuitable due to dilution, particularly in the case of halophilic species. Arid regions may appear attractive due to increased sunlight and a longer growing season; however, evaporative water loss from shallow ponds may make these systems unsustainable unless cultivated on a readily available, nonpotable water source. Further, where saline water is used, evaporation may cause concentration of salts.

40.5. MEASURING BIOMASS AND PRODUCT FORMATION

40.5.1. Measuring Biomass Concentration

Microalgal biomass concentration is typically presented as either cell concentration (cells per milliliter) or biomass concentration, normally in terms of cell dry weight per volume (kilograms per cubic meter). The most direct method of quantification remains direct cell counting, using specialized cell counting chambers and an optical microscope. The counting chamber consists of a microscope slide into which a grid representing a specific volume has been etched. Cells are counted within a predetermined number of fields on the grid, and the concentration is calculated using the specific volume of the fields. A stain, such as Lugol's solution, may be added to assist visualization and reduce motility. Direct counting is time-consuming, can be subjective (particularly when concentration or dilution of the sample is required), and may not be appropriate for colonial or filamentous algae. Some of these disadvantages can be overcome using automated particle counters, typically Coulter counters, or flow cytometry. Both of these approaches are increasingly used.

Gravimetric methods of biomass quantification are relatively simple but can be time-consuming. Cells are separated from the liquid medium (typically by centrifugation or filtration), washed to remove dissolved solids, dried, and weighed. Biomass is calculated by subtracting the mass of

the preweighed tube or filter. This method is most suitable for axenic cultures, and replicate samples should be taken to account for inherent variability. Its accuracy is limited where dilute algal cultures are used.

In order to interconvert algal cell concentrations on a number and mass basis, it is necessary to determine a mass per cell for the particular species and culture conditions of interest through the determination of the cell concentration by both approaches. The typical absence of such data in the literature restricts overall data comparison.

As both direct counting and gravimetric methods are time-consuming, it is often desirable to use a proxy method, quantitatively correlated by means of a standard curve. Popular proxy methods include measuring optical density or extracted pigment concentration. Optical density is measured at 580 nm to minimize the impact of pigment content of the cells. Chlorophyll pigments in suspensions are typically quantified at 450 nm rather than 680 nm, avoiding impact of turbidity at 660 nm, while carotenoids are measured between 480 and 520 nm, as shown in Fig. 3. The correlation of these methods must be evaluated on a species-by-species basis. Bacterial contamination, precipitation, and medium turbidity interfere with absorbance, while physiological status and life cycle can affect pigment content.

Recent developments in the field of molecular biology have allowed quantification of microbial species using quantitative PCR (28). The process requires complete DNA extraction from all component species and relies on specific amplification of a portion of a selected gene, typically the 16S or 18S rRNA gene or intergenic spacer region. A fluorescent DNA binding dye or reporter probe is added to the PCR mixture, and the increase in signal intensity with successive cycles can be used to quantify the template concentration. While the technique is powerful, allowing simultaneous quantification of several species, and is not affected by bacterial contamination of the culture, it is expensive. Further, it is effective only if the gene sequence of the target organisms is known and specific primers or probes have been designed (34).

40.5.2. Algal Kinetics and Productivity

Where asexual cell division leads to exponential growth, the algal growth may be described by the Malthus equation (equation 3). The rate of growth is then reported as doubling time, T_d (in hours or days), or specific growth rate, μ (per day). These are related through equation 4.

$$dN/dt = \mu N \quad (3a)$$

$$N_t = N_0 e^{\mu t} \quad (3b)$$

$$\mu = \ln(2)/T_d \quad (4)$$

N_0 is the initial cell concentration (as cell number; similarly, we can write the equation in terms of X , the cell concentration on a mass basis), and N_t is the cell concentration at time t . Where the culture is exposed to continual lighting, these equations may be used in the same manner as heterotrophic bacterial growth. However, where a diurnal pattern is used, data collection for determination of growth kinetic constants must take this pattern into account, sampling at the same point in each photoperiod.

Volumetric biomass productivity, Q_x (in grams per liter per day), provides a measure of space-time effects and is the

FIGURE 3 Average absorbance across the range of visible light wavelengths for five microalgal species (*Chlorella*, *Scenedesmus*, *Nannochloropsis*, *Isochrysis*, and *Phaeodactylum*).

product of the specific growth rate, μ (per day), and biomass concentration, X (in grams per liter):

$$Q_x = \mu X \quad (5)$$

Biomass productivity may be reported on an areal (grams per square meter per day) or volumetric (grams per liter per day) basis. The choice of unit depends on the purpose of the study (e.g., optimizing areal footprint versus water requirements), but for purposes of comparison across reactor

types, volumetric productivity seems the most appropriate. In order to convert areal productivity to volumetric productivity, culture depth is required; however, this is frequently not reported.

Where a product other than the algal biomass is of interest, product productivity is an important characteristic. This is the product of biomass productivity and product content. Use of specific growth rate, biomass concentration, and product content individually are of limited value

FIGURE 4 Correlation between algal oil productivity, biomass productivity, and oil content under nutrient-replete conditions (23).

TABLE 6 Typical algal growth rates and example product contents and productivities^a

Algal class (no. of species considered)	Doubling time (h)	Specific growth rate (day ⁻¹)	Biomass productivity (g liter ⁻¹ day ⁻¹)	Lipid content (% dry wt)	Lipid productivity (mg liter ⁻¹ day ⁻¹)
Green algae (17 species)	24 (6–72)	0.69	0.24	23 (13–31)	66
Cyanobacteria (5 species)	17 (7–32)	0.96	No data	8 (5–13)	No data
Other taxa, including Dinophyta, Heterokontophyta, Haptophyta, Rhodophyta, and Euglenophyta (33 species)	18 (5–44)	0.92	0.22	25 (11–51)	44
Freshwater spp. (22 species)	20 (5–72)	0.83	0.26	22 (5–36)	54
Marine spp. (33 species)	19 (7–44)	0.88	0.21	24 (7–51)	41

^aResults are given as average of species number indicated and as range, the latter in parentheses. Adapted from reference 23.

as indicators of algal productivity. For example, a culture with a high product content but low growth rate could yield less product per unit time than a faster-growing species with a lower product content. These relationships have been explored for algal oil production as a feedstock for biodiesel production through literature review by Griffiths and Harrison (23) and are summarized in Fig. 4.

A selection of typical growth rates, lipid contents, and productivities are given in Table 6 for illustration. A review of these on a species basis is presented by Griffiths and Harrison (23).

40.6. MAXIMIZING CO₂ FIXATION

The equilibrium concentration of CO₂ in water at 25°C is approximately 10 μM. This is significantly lower than the K_m (CO₂) of Rubisco, the primary CO₂-fixing enzyme of most microalgae. Many cyanobacteria have K_m values in the region of 200 μM. Furthermore, oxygen is a competitive inhibitor of the carboxylase activity of the enzyme. As a result, most microalgae and cyanobacteria grow under CO₂-limiting conditions. Algae contain a carbon concentrating mechanism, built around the enzyme carbonic anhydrase (CA), which catalyzes the reversible decomposition of bicarbonate (38). External CA elevates the CO₂ concentration at the cell surface, facilitating diffusion into the cell, where the intracellular pH promotes bicarbonate formation. Internal CA catalyzes the same reaction and elevates the CO₂ concentration around the Rubisco, enhancing CO₂ fixation. The carbon concentrating mechanism is particularly well developed in organisms adapted to grow under alkaline conditions where the inorganic carbon speciation strongly favors bicarbonate.

In closed photobioreactor systems, the equilibrium concentration can be increased by using CO₂-enriched air (see item 40.3.4). Increasing the dissolved-CO₂ concentration leads to acidification of the medium. This can be compensated for by the alkalinity generated from nitrate accumulation (8) or controlled by coupling CO₂ addition to an automated feedback system. Achieving this in open ponding systems is more difficult due to reduced gas-liquid contact time. The most commonly employed strategies are improving passive mass transfer by increasing the contact area between the atmosphere and pond surface and active injection. The use of diffusers to reduce bubble size, spoilers to increase turbulence around the injection point, and airlifts to induce defined circulation patterns may further improve mass transfer. The decoupling of CO₂ dissolution

from the algal reactor through the use of scrubbers is of increasing interest for algal applications motivated by CO₂ sequestration or cycling.

40.7. MAXIMIZING PRODUCT FORMATION—ALGAL LIPID AS AN EXAMPLE

The aim of many microalgal biotechnology applications is to maximize productivity, which is influenced by the biology of the organism as well as the culture conditions and operating mode. The goal of optimizing culture conditions is to reach the maximum production biologically possible by the species of interest while considering ease of product recovery. Further improvement requires genetic modification.

Successful optimization of product formation requires an understanding of the flow of material from carbon and energy sources to biomass and product formation at a biochemical level. Metabolic flux analysis can be used to model the movement of materials through metabolic pathways. Metabolic pathways are complex interacting networks; however, they can be simplified by identifying the key enzymes, branch points, and bottlenecks through assessing the time scale of the reactions and identifying nodes at which biological control is exerted most strongly. The simplified pathway, typically representing about 30 reactions, is subjected to integrated kinetic modeling. Metabolic modeling can help to identify the important controlling factors in a pathway of interest and hence to design interventions that influence the flux toward desired products (for more information, see reference 47).

As an example, the optimization of lipid productivity in algae is considered. Here the goal is to maximize the flow of photosynthetic products to lipids rather than carbohydrates, pigments, proteins, and other products. This comes at the expense of cell growth and maintenance. By understanding the flux through these pathways and the partitioning of precursor metabolites such as pyruvate and acetyl coenzyme A (acetyl-CoA) at branch points, the desired pathway can be balanced to provide sufficient growth while optimizing lipid production.

Lipid synthesis is an energy-intensive process and relies on carbon compounds generated from CO₂ by photosynthesis, as well as energy and reducing power [in the forms of ATP and NAD(P)H, respectively]. There are several branch points at which metabolic intermediates are partitioned between synthesis of lipids and other products, such as carbohydrates and proteins, as illustrated in Fig. 5.

FIGURE 5 Simplified metabolic pathway illustrating CO₂ fixation and metabolism to biomass and triacylglycerides. TCA, tricarboxylic acid.

Acetyl-CoA is a central metabolite for lipid synthesis as well as the entry point into the tricarboxylic acid cycle for generation of energy and biosynthetic precursors for proteins and nucleic acids. Light determines the amount of CO₂ taken up and hence the total carbon available for anabolism. Introduction of an organic carbon source into the medium can enhance lipid formation and reduce dependence on light in heterotrophic species. At the other end of metabolism, rates can be accelerated by removing the product, e.g., designing algal species that secrete lipid.

Nitrogen deprivation is well known to enhance lipid formation in certain algae by limiting protein formation, thereby reducing growth. By reducing the carbon and energy flux into proteins, these resources are channeled into lipid and carbohydrate production. The extent and timing of nitrogen removal must be carefully balanced to maximize the number of cells as well as their lipid content. This illustrates the value of a comprehensive understanding of metabolic pathways and their control for application of the rational design approach to product optimization through both the physiological and molecular routes.

40.8. CHARACTERISTICS OF ALGAL SUSPENSIONS AND THEIR INFLUENCE ON HARVESTING BIOMASS FOR PRODUCT RECOVERY

Algal cultures are typically restricted to a low biomass density to facilitate light penetration. Typical volumetric biomass concentrations reported in large-scale processes range from 0.3 kg m⁻³ to some 5 kg m⁻³. This algal biomass is harvested and concentrated by solid-liquid separation prior to use of the biomass as product or extraction of the product. Owing to the dilute nature of the biomass, the limited driving force for separation, and the large volumes

to be processed, this separation can contribute as much as 20 to 30% of the total cost of producing the biomass (26). The value of the end product therefore influences the choice of harvesting method. Furthermore, harvesting is critical to the overall dewatering step. Short-sighted savings in harvesting could result in higher drying and end-product extraction costs later in the process train.

Physical properties of the algal cell that can be exploited for solid-liquid separation include cell density, size, charge, and surface properties. Algal cells range in size from 3 to 30 μm. Their size is influenced by growth conditions (2, 50). Example cell sizes are given in Table 7. Filamentous algae such as *Spirulina* present a larger effective size, facilitating collection by filtering. As typically found for microbial biomass, limited density difference exists with respect to water, with typical densities of 1,030 to 1,050 kg m⁻³. Cell surface properties, such as zeta potential and hydrophobicity, influence flocculation and flotation and may be a function of growth conditions.

Size-based separation by dead-end filtration is infrequently used for algal separation (37). Where filtration is used, cross-flow filtration shows the greatest potential, as it prevents fouling of the filter with cells and is optimized as a function of pressure. In the harvesting of filamentous algae, such as *Spirulina*, screen filtration is used with larger pore diameters than the cellulosic or polycarbonate membranes used for bacterial harvesting (46). Therefore, the effectiveness of filtration is strongly influenced by the morphology of the species being cultivated.

Cell density coupled with cell size determines the settling velocity of the cell, which can be used in either gravity or centrifugal sedimentation. Gravity sedimentation in settling tanks is suitable for processing large volumes of fluid, and the units are relatively inexpensive to construct and operate. The resulting concentrate retains a relatively high

TABLE 7 Typical algal cell size^a

Algal species	Cell diam (μm)	Cell vol (μm ³)
<i>Chlamydomonas</i>		1,080–6,200
<i>Chlorella</i>		34

<i>Rhodomonas salina</i>	10–15	
<i>Scenedesmus</i>		48
<i>Synechococcus</i>	1–2	1.3
<i>Tetraselmis</i>	12–14	1,275

^aData from references 2, 3, and 50.

fluid content, and the tank itself takes up a large area. Centrifuges enable rapid separation and produce a concentrate of lower moisture content but are energy intensive. Guidelines for recovery of microalgal biomass via centrifugation are provided in reference 17.

For both filtration and settling, recovery can be enhanced by flocculation. Algae carry a negative surface charge, which keeps them apart (37). A multivalent cation or bioflocculant (40) can be used to neutralize this charge, allowing algal flocculation and increasing their effective size. The effect of flocculant addition on further downstream processing and toxicity should be considered (40). Flocculation can also be induced by altering the pH to the isoelectric point of the cell surface. Care must be taken to avoid cell lysis and the release of intracellular products during cell harvesting (37, 40).

Flotation provides an alternative harvesting method. This uses the cell surface properties in terms of both hydrophobic properties and charge of the algae cell wall to attach selectively to rising air bubbles. These surface properties may be altered through manipulating growth conditions or the addition of collectors. Flotation has been investigated as a method for removal of algae in water treatment. The efficiency of separation is dependent on bubble size and contact time. Flotation of algae has been demonstrated through autoflotation (using oxygen evolved on algal culture), dispersed air flotation, and dissolved air flotation (16, 43, 49, 54).

40.8. FUTURE CHALLENGES

Algal biotechnology presents a valuable range of products, ranging from energy products through commodity products to high-value products for medical use. Currently the exploitation of algal biotechnology is in its infancy, with a great range of biodiversity remaining to be explored. While the production of high-value products using photobioreactor systems is economically feasible, exploitation of algal systems for commodity products is limited to extreme environments providing a competitive advantage. Using algae to produce commodity products requires improve-

ment of algal productivity through overcoming mass transfer and light limitations. Further to this, the significant downstream processing costs incurred require emphasis on both improving product concentration and identifying low-energy unit operations suited to the efficient processing of large volumes of algal suspensions.

Metabolic Engineering Strategies for Production of Commodity and Fine Chemicals: *Escherichia coli* as a Platform Organism

PATRICK C. CIRINO

41

41.1. INTRODUCTION

Metabolic engineering encompasses a dynamic field of research that increasingly influences the development of microbial strains for industrial applications. Metabolic engineering efforts pertaining to industrial microorganisms are typically intended to improve (i) productivity and/or the yield and titer of a desired product, (ii) ability to utilize inexpensive raw materials, and (iii) robustness under production conditions. Achieving these goals is facilitated by increasing understanding of cellular metabolism, gene regulation, enzyme kinetics, and allosteric regulation. Advances in molecular biology methods and functional genomics tools promote more efficient manipulation of these biological processes.

This chapter presents a summary of examples in which various metabolic engineering strategies were employed to improve microbial production of small molecules having a range of commercial value (commodity and fine chemicals). Specifically, notable achievements in engineering the biotechnological workhorse organism *Escherichia coli* for chemical production are described. While metabolic engineering approaches have been applied to a great variety of microorganisms (e.g., *Corynebacterium*, lactic acid bacteria [LAB], *Zymomonas mobilis*, *Saccharomyces cerevisiae*, *Pichia pastoris*, etc.) (12, 13, 17, 31, 33, 34, 61, 62, 70, 78), *E. coli*'s metabolic versatility, genetic amenability, fast growth, and track record of engineering success (49, 66) have made this organism the most popular host for both proof-of-concept demonstrations and successful applications of metabolic engineering, often resulting in dramatic improvements in strain performance.

Described below are examples in which *E. coli* metabolism was engineered for overproduction of acetate, pyruvate, D- and L-lactate, succinate, L-alanine, L-valine, L-threonine, shikimic acid, *cis,cis*-muconic acid (ccMA), carotenoids, mevalonate, and amorphaadiene. The genetic techniques employed can be summarized as chromosomal gene deletions, plasmid-based or chromosomal insertion-based heterologous gene expression, adaptive strain evolution of growth-coupled product formation, targeted enzyme evolution for improved flux through a nonnative pathway, optimization of pathway expression in response to the flux capacity of the cell, and fine-tuning the relative expression levels of genes in a synthetic operon. While not comprehensive, the selected examples of metabolic engineering illustrate the diversity of tools available, the variety of

accessible transformations and compounds, and the versatility of *E. coli* as a platform organism and as a system for developing metabolic engineering strategies that pave the way for future developments. Many reviews describe additional metabolic engineering efforts toward the microbially based industrial production of commodity and fine chemicals such as indigo, 2-keto-L-gulononic acid (precursor to ascorbic acid), and the exemplary case of 1,3-propanediol production from glucose (13, 49, 86).

41.2. ORGANIC ACIDS

In terms of commodity chemicals, metabolic engineering has found the most application and success toward the production of small organic acids and amino acids (perhaps with the exception of engineering *E. coli* to produce 1,3-propanediol from glucose), owing largely to the natural coupling between growth and production of these compounds through fermentation. Recent progress in microbial production of acetate, pyruvate, lactate, and succinate is first described here, followed by examples of increased amino acid production. These examples represent a category of metabolic engineering applications in which the host organism is made to overproduce a native metabolite (rather than inserting heterologous pathways for foreign compounds). These may appear to be relatively simple demonstrations of targeted strain improvement, since the host organisms naturally produce the compound of interest. Genetic modifications primarily involve redistribution of carbon flux through increased expression of enzymes which may be bottlenecks in product formation, as well as deletion of pathways that compete for carbon and result in by-products. However, these examples also address the often challenging tasks of overcoming native mechanisms of feedback inhibition and regulation in response to metabolite accumulation and of functionally expressing foreign genes.

Figure 1 depicts the major pathways in *E. coli* central carbon metabolism involved in production of the metabolites described. Many of the corresponding genes shown in Fig. 1 are targets for deletion or amplification in the examples described.

41.2.1. Acetic Acid

Acetic acid (CH_3COOH) is produced commercially primarily for use in polymer production and as a solvent.

synthase complex (*atpFH*) that released the (still functional) ATP synthase from the cell membrane, not only uncoupling proton translocation from ATP production but also promoting cytoplasmic ATP hydrolysis. This provided the added benefit of increased glycolytic flux and acetate production rates as a result of the low ATP yields. Strain TC36 resulting from these efforts is devoid of plasmids, foreign genes, and antibiotic resistance markers and grows well in mineral salts medium without complex nutrients (9). Acetate was produced as the sole product, with up to 86% of the theoretical maximum from glucose (0.67 g acetate/g glucose). In a fed-batch fermentation supplied with 5 % dissolved O₂, TC36 produced 878 mM acetate (~53 g/liter), with a volumetric productivity of ~1.4 g/liter · h (notably much higher than values reported for native acetogens) (9, 29).

41.2.2. Pyruvic Acid

Pyruvic acid (CH₃COCOOH) serves as the biological precursor to many bio-based commodity chemicals (e.g., ethanol, lactate, 1,3-propanediol). In addition to its commercial use as a synthetic precursor to several amino acids, including L-3,4-dihydroxyphenylalanine (40), pyruvate offers potential as a platform chemical for production of a variety of renewable fuels and chemicals. Pyruvate is also marketed as a weight control supplement. Traditionally, pyruvate has been synthesized chemically from tartaric acid (85). While microbially based processes increasingly gain a competitive edge, the general requirement for complex and expensive culture ingredients has hampered their commercial success. Recent metabolic engineering efforts similar to those applied for acetate production have proven useful for overproduction of pyruvate from glucose by *E. coli* grown aerobically in inexpensive, mineral salts medium.

Ingram and coworkers constructed a strain similar to TC36 (see above) but with additional deletions in the genes encoding pyruvate:quinine oxidoreductase (*pox*) and acetate kinase (*ack*), the two primary sources of pyruvate conversion to acetate (8). The resulting strain, TC44, produced up to 749 mM pyruvate (~66 g/liter) in fed-batch culture and achieved a maximum volumetric productivity of 1.21 g/liter · h and a yield of 0.76 g/g glucose. Up to 62 mM of contaminating acetate also accumulated in the broth.

A similar approach to pyruvate overproduction was reported by Takors and coworkers, who constructed a strain containing gene deletions that disabled conversion of pyruvate to lactate (*ldhA*), acetyl-CoA (*aceEF* and *pfl*), phosphoenolpyruvate (PEP) (*pps*), and acetate (*pox*) (84). The strain grows in minimal glucose medium supplemented with acetate (it is acetate auxotrophic). A maximum molar yield of 1.78 mol pyruvate/mol glucose (0.87 g/g) was reported (85), along with a maximum pyruvate titer of 62 g/liter and a volumetric productivity of 1.75 g/liter · h (84).

In a final and again similar strategy, Altman and coworkers combined the same mutations as for the acetate-auxotrophic strain (*ldhA*, *pfl*, *pox*, *pps*, and *aceEF*), with deletions in the (F₁F₀)H⁺-ATP synthase complex (*atpFH*) and in the redox-sensitive global regulatory protein ArcA, which is known to control gene expression of respiratory pathways (91). The resulting strain, ALS1059, achieved 90 g/liter pyruvate, with an overall productivity of 2.1 g/liter · h and a yield of 0.68 g/g glucose in the presence of 5 mM betaine as an osmoprotectant and under acetate-limited growth (91).

41.2.3. Lactic Acid

Lactic acid [C₃H₆O₃; CH₃CH(OH)COOH] finds a wide range of applications in the food and chemical industries (67). Polylactic acid is a biodegradable polymer finding increasing applications and replacing petrochemical products, resulting in growing demand for lactic acid production. Physical properties of polylactic acid are dependent on the relative amounts of D-lactic acid and L-lactic acid in the polymer, so it is important to provide these isomers in the desired ratio. The environmentally friendly solvent ethyl lactate is also gaining popularity. LAB are Generally Regarded As Safe (GRAS) and are the primary source of lactic acid from sugar fermentation (17, 66, 67). Disadvantages to the use of LAB for commodity chemical production include their requirement for expensive complex nutrients and their inability or poor ability to ferment pentose sugars. In addition, these organisms typically produce racemic mixtures of lactic acid and suffer from significant inhibition as the product accumulates in the fermentation broth. Microbially based commercial production of lactic acid would ideally involve the efficient conversion of a variety of sugars derived from hemicellulose to a single isomer with high volumetric productivity and yield. While many improved mutant strains of LAB have been developed over the years and directed metabolic engineering efforts have been increasingly successful toward LAB as new tools and knowledge are furnished (17), the unprecedented wealth of metabolic knowledge and genetic engineering techniques available for *E. coli*, along with its native ability to metabolize both pentose and hexose sugars, has made this organism a widely studied alternative host for homolactate production, as discussed below (note that engineered yeasts have also been considered for lactate production [13]).

Dien et al. constructed an *E. coli* strain carrying deletions in genes encoding pyruvate formate lyase (*pfl*) and the native D-lactate-producing lactate dehydrogenase (*ldhA*), resulting in strain NZN111, which is unable to grow fermentatively (19). They then used plasmid-based heterologous gene expression to introduce an L-specific lactate dehydrogenase (*ldhL*) gene from *Streptococcus bovis* (81) into this strain, resulting in the ability to grow anaerobically and ferment either glucose or xylose to L-lactic acid. *E. coli* preferentially metabolizes glucose over other sugars through a complex mechanism known as catabolite repression, which is at least partly controlled by the PEP-dependent glucose phosphotransferase system (PTS) (16). A more desirable property for industrial fermentation of biomass-derived sugars is the ability to simultaneously utilize pentose and hexose sugars. The authors constructed a mutant of NZN111 in which the gene (*ptsG*) encoding IIBC^{Glc} of the PTS is disrupted, in an effort to partially alleviate glucose-dependent catabolite repression (18). The resulting strain (ND19) had a yield of 0.77 g L-lactic acid/g sugar when fermenting an equal mixture of 10% glucose and xylose in complex medium (containing tryptone and yeast extract).

Ingram and coworkers constructed a series of *E. coli* strains that efficiently ferment glucose and sucrose into optically pure D- or L-lactic acid (27, 90). Their efforts included directed gene deletions to eliminate loss of carbon to by-products (*pfl*, *frd*, *adh*, and *ack*), heterologous expression of an L-specific lactate dehydrogenase from *Pediococcus acidilactici* (*ldhL*) that was chromosomally inserted in place of the native *ldhA* gene (for the case of L-lactate production)

(89), and many rounds of growth-based metabolic evolution in which serial subculturing was used to enrich for spontaneous mutations that both increased growth and improved volumetric productivity and lactate production. Addition of 1 mM betaine as a protective osmolyte significantly improved lactate production and tolerance to high concentrations of lactate and sugars in mineral salts medium (88). Flux through the methylglyoxal bypass was identified as the source of low levels of chirally impure lactic acid (both isomers can be produced via methylglyoxal), and deletion of *mgsA* (encoding methylglyoxal synthase) ensured chiral purity of both D-lactate (using the native *ldhA*) and L-lactate (with *ldhL* in place of *ldhA*) (27).

The culmination of the Ingram group's lactate strain development, which includes the accumulation of as-yet-uncharacterized random mutations resulting from adaptive growth evolution at multiple stages of strain design, is strain TG108, which produced >1.2 M L-lactic acid with a maximum volumetric productivity of ~2.7 g/liter · h, and strain TG114, capable of producing >1.2 M D-lactic acid with a maximum volumetric productivity of ~3.2 g/liter · h (27). Cultures of these strains completely utilized 10 to 12% (wt/vol) glucose in 48 h using mineral salts medium containing glucose and 1 mM betaine, with yields of up to 98% and chiral purities of >99%. An important distinction between the adaptive evolution strategy used in the Ingram studies and the more traditional microbial evolution experiments applied for industrial strain optimization is that in the former case, detailed understanding of the central metabolic pathways leading to straightforward strain engineering steps was necessary to constrain the metabolic network and ensure coupling between cell growth and lactic acid production. The increasing availability of affordable genome sequencing in the postgenomic era provides tremendous opportunities for understanding the mechanisms of strain adaptation and further improving subsequent strains through more rational approaches.

In a final example, Zhu et al. developed a strain having deletions in all major genes responsible for pyruvate metabolism, other than *ldhA* (i.e., *aceEF*, *pfl*, *pox*, and *pps*) (92). This strain requires acetate for aerobic growth due to inactivation of both pyruvate dehydrogenase and pyruvate formate lyase and is unable to grow under anaerobic conditions. The authors used an aerobic growth stage to generate the biocatalyst, followed by a nongrowing anaerobic stage for conversion of glucose to D-lactate. Residual acetate following the growth stage was determined to be the primary source of contaminating succinate in the fermentation broth, and inactivation of fumarate reductase by deleting *frd* genes helped to reduce succinate formation. By minimizing residual acetate at the end of the growth stage, their final strain produced 138 g/liter lactate representing 97% of all carbon products, with a yield of 0.99 g/g glucose and a productivity of 6.3 g/liter · h during the anaerobic stage (92).

41.2.4. Succinic Acid

Succinic acid (C₄H₆O₄) serves as a precursor to a variety of other commodity chemicals such as butanediol, tetrahydrofuran, and γ-butyrolactone; can be used as a monomer toward biodegradable polymer synthesis; and finds applications in the food, pharmaceutical, and cosmetics industries (47, 78, 79). Commercial demand for succinic acid is far from mature and is expected to increase dramatically as petrochemical prices increase and as more efficient routes to renewable succinate production are developed. A variety of naturally occurring organisms produce succinate as a major

but not solo fermentation product, and some strain development efforts have focused on improving yield and purity from these organisms (47, 69). Noteworthy are the efforts of Lee and coworkers, who isolated the high-succinate-producing bacterium "*Mannheimia succiniciproducens*" and subsequently performed genomic, transcriptomic, and proteomic analyses and developed genetic tools enabling metabolic engineering of this organism (37). However, as is the case with so many target products, *E. coli* has served as the primary host for metabolic engineering efforts toward efficient conversion of sugars to succinate. Again, the ability to perform this conversion using inexpensive, minimal medium ingredients is essential.

The theoretical yield of succinate from glucose depends on whether additional CO₂ or external reductants are also supplied. Regardless of the pathways used, CO₂ fixation is required to achieve theoretical maximum yields, since all glucose is first converted to the three-carbon metabolite PEP (Fig. 1). Glucose-derived carbon can yield 1.5 succinate per glucose, while CO₂ supplementation increases the theoretical yield to 1.7 mol/mol. A yield of 2 succinate per glucose is theoretically possible, provided the organism is appropriately engineered to balance CO₂ fixation and trafficking of reducing equivalents from an external source such as H₂ toward succinate production, resulting in the redox-balanced reaction

E. coli has been engineered to produce succinate under both aerobic and anaerobic conditions. A mutant of strain NZN111 (*pfl ldhA* double deletion strain described above for L-lactate production) showing dramatically enhanced anaerobic growth on glucose and producing high levels of succinate (0.92 mol/mol glucose in rich medium) (20) was found to carry a mutation in the PTS system gene *ptsG* (11). While the mechanisms leading to fast anaerobic growth and succinate production are not well understood, altered PEP levels, the consequential regulatory effects, and flux through PEP carboxylase clearly play important roles in this mutant strain (named AFP111). That initial discovery prompted a series of subsequent studies with *ptsG* mutant strains. To increase flux of three-carbon intermediates to succinate via the reductive branch of the TCA cycle (i.e., oxaloacetate), Altman and coworkers expressed *pyc*, encoding the pyruvate carboxylase enzyme from *Rhizobium etli*, in AFP111 (Fig. 1) (74, 75). Succinate production was compared under exclusively anaerobic growth and dual-phase conditions (aerobic growth followed by anaerobic production). Using dual-phase, fed-batch fermentation with complex medium and supplementation with MgCO₃ (source of CO₂), succinate was produced to a titer of 841 mM (~98 g/liter), with an average volumetric productivity of 1.31 g/liter · h and a yield of 1.68 mol/mol glucose (75).

San and coworkers constructed a strain for aerobic succinate production by preventing oxidation of succinate to fumarate (*sdh* genes were deleted) and preventing acetate secretion (*ack*, *pta*, and *pox* were deleted) (41–43). To prevent loss of carbon through the oxidative branch of the TCA cycle, aerobic flux to succinate should be routed through the glyoxylate bypass. The gene *iclR*, encoding the repressor of the glyoxylate bypass operon, was therefore deleted, promoting expression of the genes encoding isocitrate lyase (*aceA*) and malate synthase (*aceB*). Finally, a PEP carboxylase from *Sorghum vulgare* (*ppc*) (catalyzing conversion of PEP to oxaloacetate) was overexpressed, and PEP consumption during glucose transport through the PTS

was prevented by deleting *ptsG* (43). The resulting strain produced ~500 mM succinate (58 g/liter) during aerobic growth in complex medium, with an average volumetric productivity of ~1.1 g/liter · h and a yield of ~0.9 mol/mol glucose (41). The same laboratory also developed similar strains for anaerobic succinate production (63). Strain SBS550MG contains deletions in *adh*, *ldhA*, *ack*, and *pta* (to prevent fermentation to ethanol, lactate, and acetate) and contains the *iclR* deletion for activating the glyoxylate bypass. Plasmid-based expression of pyruvate carboxylase (*pyc*, this time from *Lactococcus lactis*) resulted in the anaerobic production of 340 mM succinate (~40 g/liter) from glucose with CO₂ supplementation using a rich growth medium, with a final yield of 1.6 mol/mol glucose, near the theoretical maximum of 1.7 mol/mol (63). This strain apparently balances fluxes through the reductive branch of the TCA cycle (where oxaloacetate is replenished via carboxylation of PEP and pyruvate) and the glyoxylate bypass, such that redox balance is achieved through succinate production, with net consumption of CO₂.

To avoid scale-up complications related to poor growth in the absence of expensive growth nutrients, Jantama et al. focused on the use of a mineral salts-based defined medium for conversion of glucose to succinate (30). They combined direct genetic modifications (similar to those used for the previously described succinate-producing strains, but without addition of plasmids or foreign genes) with a metabolic evolution strategy similar to that described above for lactic acid-producing strains. The experiments started from strain KJ012, having deletions in *ldhA*, *adh*, and *ack*. While a moderate succinate producer when growing in rich medium, this strain grew much slower and produced much less succinate than the wild-type strain (*E. coli* C in this case) when using minimal medium (6 mM succinate for KJ012, compared to 49 mM for the wild type). Metabolic evolution via serial dilution was then employed, with culture conditions and transfer times appropriately changed throughout the process to accommodate the adapting strain phenotype. It is important to note that as was the case for growth-based evolution of lactate producers, rational metabolic engineering was first required to constrain the metabolic network such that growth is coupled to succinate production. The result of this first set of transfers, strain KJ017, showed much higher growth and succinate production in the minimal medium but also produced formate. Formate production was next eliminated by deleting *pfl*, resulting in acetate-auxotrophic strain KJ032. Another round of serial dilutions with gradual decreases in acetate used to supplement the culture medium eventually yielded strain KJ060, having no acetate requirements. Subsequent modifications included deletion of *mgsA* (encoding methylglyoxal synthase) to eliminate residual lactate production and *pox*, followed by further rounds of metabolic evolution to improve growth.

Throughout this work, several unexpected metabolic changes were noted, such as increased malate production due to the *mgsA* deletion and reduced malate secretion with the *pox* deletion. Most noteworthy from these studies is the drastic difference in strain performance in minimal versus complex media, and the power of adaptive strain evolution to overcome these metabolically complex (and not understood) limitations. In the end, the best succinate-producing biocatalyst produced 733 mM succinate (0.90 g/liter · h, 1.4 mol/mol glucose), with 39 mM malate and 250 mM acetate produced as by-products, while a high-malate-producing strain produced 516 mM malate, with significant succinate, pyruvate, and acetate as by-products (30).

Elimination of coproducts for higher-purity succinate or malate production from minimal medium cultures presents opportunities for further strain optimization.

41.3. AMINO ACIDS

Microorganisms have been used for the production of amino acids for many decades. A variety of amino acids find applications in industries including food, animal feed, pharmaceuticals, and cosmetics (38). While *Corynebacterium glutamicum* strains gained early popularity for their ability to produce large quantities of glutamate and lysine, *E. coli* strains have also proven effective hosts for overproduction of many amino acids (38, 78). Whereas microbes were traditionally improved for amino acid production using strain adaptation techniques (random mutation and auxotrophic selection procedures) (52), recently, metabolic engineering and systems biology approaches have been effectively applied to *C. glutamicum* (for lysine, serine, tryptophan, isoleucine, and threonine), LAB (for alanine), and *E. coli* (for threonine, phenylalanine, alanine, and valine) (14, 17, 38, 52, 53, 62, 70, 78). Considering the low titers of amino acids obtained from wild-type *E. coli* cultures, improvements of this host through metabolic engineering have been impressive, as described below.

41.3.1. Alanine

Just as the research teams of Altman and coworkers and Ingram and coworkers reported similar approaches to engineer *E. coli* for pyruvate and lactate overproduction (as described above), these two groups also took similar approaches for overproduction of L-alanine from pyruvate, by the action of a nonnative, heterologously expressed NADH-linked alanine dehydrogenase (*alaD*) (Fig. 2).

The Altman approach was to eliminate all major metabolic routes of aerobic and anaerobic pyruvate assimilation. Pyruvate-overproducing strain ALS929 carries deletions in *pfl*, *pps*, *pox*, *ldhA*, and *aceEF* and has an acetate-auxotrophic requirement for aerobic growth (68). In a two-phase production strategy similar to that described above by the same laboratory, strain ALS929 expressing plasmid-borne *alaD* from *Bacillus sphaericus* was first grown in complex medium under aerobic conditions, with glucose plus acetate feeding to control the growth rate. Following this biocatalyst production stage (~25 h), the culture was switched to anaerobic conditions and additional glucose was fed to the system for conversion to alanine. A 23-h production phase was sufficient to deplete all glucose and produce 88 g/liter D,L-alanine (not optically pure), with a yield of ~1 g/g glucose (68).

Starting from lactate-overproducing strain SZ194 (*pfl*, *frd*, *adh*, and *ack* deletions) (89), Zhang et al. replaced the native *E. coli* *ldhA* gene (encoding lactate dehydrogenase) with the *alaD* gene from *Geobacillus stearothermophilus*, such that *alaD* was regulated by the native *ldhA* promoter (87). Deletion of the methylglyoxal synthase gene (*mgsA*) eliminated low levels of lactate production (refer to above description for construction of lactate strain TG108), and the catabolic alanine racemase gene (*dadX*) was deleted to prevent conversion of L-alanine to D-alanine (87). Since alanine production replaces the role of lactate dehydrogenase in NADH oxidation, the supply of ATP for anaerobic cell growth from glycolysis is obligately coupled to alanine production. Therefore, as in the previous studies from this group described above, strains that were rationally engineered to ensure coupling between growth and product formation were subsequently subjected to metabolic evolution by selecting for faster-growing mutants on minimal glucose

FIGURE 2 L-Alanine production from pyruvate by alanine dehydrogenase (*alaD*).

medium through serial transfers. Resultant strain XZ132 produced <1.3 M L-alanine from 120 g/liter glucose in batch fermentation in mineral salts medium, with an average volumetric productivity of <2.4 g/liter · h (87). The yield was 0.95 g L-alanine/g glucose, with >99.5% chiral purity. Results from this work appear superior to other attempts at microbial production of L-alanine. Chromosomal expression of the foreign *alaD* gene was sufficient for supporting the high levels of glycolytic flux, so this strain did not require plasmid maintenance or antibiotics. The authors also point out that L-alanine production by XZ132 exceeded the performance of their previously reported pyruvate-producing strain (TC44, described above), suggesting an alternate route to pyruvate production via enzymatic hydrolysis of L-alanine.

41.3.2. Valine

Amino acid metabolism is known to be tightly regulated in *E. coli*, such that supply and demand are tightly coupled. This regulation was avoided in the alanine studies described above because a heterologous and unregulated pathway was used for the nonnative conversion of pyruvate to alanine. In contrast to that approach, Lee and coworkers sought to engineer *E. coli* for L-valine and L-threonine production via their native pathways (36, 51). In addition to the common strategy of deleting competing pathways, their efforts required alleviation of natural regulatory mechanisms designed to prevent loss of carbon and energy through amino acid overproduction. To identify the correct genetic targets, a variety of systems biology and metabolic modeling tools were combined with in-depth knowledge of amino acid metabolism to methodically construct L-valine- and L-threonine-overproducing *E. coli* strains.

In their first example, known mechanisms of regulation of L-valine production, such as feedback inhibition and gene repression, were eliminated by genetic modification (51). Acetohydroxy acid synthase (AHAS) catalyzes the conversion of pyruvate to 2-acetolactate in the L-valine biosynthetic pathway. Previous research identified point mutations in AHAS that relieve L-valine-mediated feedback inhibition, and these mutations were added to the *E. coli* chromosome. The expression of AHAS isoenzymes was enhanced by replacing native promoters known to be subject to transcriptional attenuation with a strong constitutive promoter (*tac*), as well as by amplifying AHAS activity through plasmid-based expression. Pathways known to be competing with L-valine biosynthesis were next blocked by gene deletion (*ilvA*, *leuA*, and *panB*). The transcriptomes of the wild-type and intermediate valine-producing strains were compared to identify additional genes whose upregulation may further boost valine production. The genes selected for amplification encoded a leucine-responsive global regulator (Lrp) and an L-valine exporter (YgaZH). Finally,

in silico gene knockout simulations using a stoichiometric model of *E. coli* metabolism (adapted from reference 60) were used to study the effects of various genetic modifications on valine production. This model-driven approach identified three additional gene deletions (*aceF*, *mdh*, and *pfkA*) to further enhance valine production. The final strain resulting from these systematic efforts produced 7.55 g/liter L-valine, with a yield of 0.378 g/g glucose in batch fermentation (51).

41.3.3. Threonine

A similar systems-based metabolic engineering approach was taken for L-threonine production (36). Collectively, relief of built-in negative regulation by point mutation and promoter replacement, deletion of genes involved in threonine degradation and biosynthetic precursor competition, transcriptome profiling of wild-type and intermediate threonine-producing strains to identify gene amplification targets, and in silico flux response analysis to help optimize amplified gene expression levels resulted in a genetically defined *E. coli* mutant able to produce 82.4 g/liter threonine in fed-batch culture, with the high yield of 0.39 g/g glucose (36).

41.3.4. Unnatural Amino Acids

Unnatural amino acids are attractive synthetic building blocks for pharmaceuticals and for incorporation into proteins for structure and function studies and for added stability or to introduce unique functionality (77). Whereas unnatural amino acids are typically produced by chemical synthesis, Maier developed an *E. coli* fermentation-based process for production of unnatural L- α -amino acids by metabolic engineering of the cysteine biosynthetic pathway (44). As depicted in Fig. 3, O-acetylserine sulfhydrylases encoded by *cysK* and *cysM* catalyze the final step of cysteine biosynthesis using sulfide as the nucleophile and ultimate source of cysteine sulfur. The known relaxed specificity of these enzymes for the nucleophilic substrate enables the use of externally supplied substrates (thiols, selenols, and N-heterocycles), leading to the synthesis of unnatural amino acids. O acetylation of serine by the serine acetyltransferase (encoded by *cysE*) is the committed step in L-cysteine synthesis and is subject to L-cysteine (product) inhibition. A feedback inhibition-resistant mutant of *cysE* was therefore isolated (*cysE^{fbn}*) and overexpressed during nucleophile feeding. Using this strategy, along with optimized biotransformation procedures that included a two-stage process to avoid feeding of toxic nucleophiles during growth, the author was able to produce a wide variety of unnatural amino acids (up to 13 g/liter), including the valuable S-phenyl-L-cysteine which serves as a building block for a commercially important human immunodeficiency virus protease inhibitor (32, 44).

FIGURE 3 Engineering the cysteine biosynthetic pathway (starting from serine) for production of unnatural amino acids (AA). The *O*-acetylserine sulphydrylases encoded by *cysK* and *cysM* utilize sulfide as a cosubstrate to produce cysteine, but the enzymes have relaxed specificity such that addition of select, nonnative nucleophiles (R-H) results in production of unnatural amino acids. *cysE^{fbr}* encodes a feedback-resistant variant of serine acetyltransferase.

41.4. PRODUCTS OF THE AROMATIC AMINO ACID PATHWAY

Frost and coworkers have devoted two decades of research toward engineering the aromatic amino acid biosynthetic pathways of *E. coli*. Their efforts have resulted in the biological production of a variety of aromatic compounds, products that otherwise require petroleum-derived aromatics such as benzene for chemical synthesis, and other valuable metabolites that are difficult to isolate from natural resources (1, 6, 21, 26, 28, 39, 50, 58). Of primary importance has been shikimic acid, which is a key starting material for the synthesis of the neuraminidase inhibitor Tamiflu®, an orally effective anti-influenza agent (35). Isolation of shikimic acid from plants has been considered commercially cost-prohibitive, while high-level production from bacterial culture is cost-effective.

41.4.1. Shikimic Acid and Quinic Acid

As shown in Fig. 4, shikimic acid is produced by *E. coli* as an intermediate toward the production of aromatic amino acids and aromatic vitamins. The genes *aroK* and *aroL*, encoding enzymes downstream of shikimic acid, were deleted (21). The reaction catalyzed by 3-dehydroquinate (DHQ) synthase (encoded by *aroB*) was identified as a rate-limiting step in shikimic acid production (15), so an extra copy of *aroB* was integrated into the *E. coli* chromosome. The aromatic amino acid pathway starts with the condensation of PEP and erythrose-4-phosphate (E4P) to 3-deoxy-heptulosonate-7-phosphate (DAHP), catalyzed by DAHP synthase (encoded by *aroF*), and this reaction is tightly regulated (allosterically) through feedback inhibition by aromatic amino acids. Using a strategy similar to that described above for amino acid overproduction, a feedback-resistant mutant of *aroF* was overexpressed in the

strain, along with an additional gene encoding shikimate dehydrogenase (*aroE*). As a result of these modifications, the *E. coli* strain converted glucose to 27 g/liter shikimic acid in fed-batch fermentation with defined medium (21). Quinic acid was produced as a significant by-product (12.6 g/liter), as a result of a side reaction between shikimate dehydrogenase and DHQ. By changing the glucose feeding strategy during fermentation, the authors were able to shift the shikimate/quinic molar ratio to 11.8:1 (although with a net lower yield of shikimate), thus allowing for easier recovery of shikimic acid by crystallization.

Quinic acid (shown in Fig. 4) is also a high-value pharmaceutical precursor, and high levels of this product without shikimic acid by-product were obtained by deleting the gene *aroD* in the strain described above, resulting in production of 60 g/liter quinic acid plus 2.6 g/liter DHQ in 60 h from a fed-batch fermentation of glucose (21).

Further improvements in flux through the engineered aromatic amino acid synthesis pathway focused on increased availability of upstream intermediates. Overexpression of the pentose phosphate pathway enzyme transketolase (*tktA*) increases E4P availability (22), causing metabolic competition for PEP to become a limiting factor in DAHP synthesis. A major source of PEP competition is PEP-dependent glucose uptake and phosphorylation via the PTS. To improve PEP availability, PTS uptake of glucose was eliminated by *pts* gene deletions, and PEP-independent glucose uptake and phosphorylation were enhanced by heterologous expression of the *Z. mobilis* *glf*-encoded glucose facilitator protein (for which glucose diffusion is the mechanism of transport) and *glk*-encoded glucokinase (for ATP-dependent glucose phosphorylation) (10). These efforts resulted in production of 87 g/liter shikimic acid from glucose in fed-batch culture supplemented with yeast extract.

As an alternate approach to relieving the demand for PEP, a novel enzymatic step toward DAHP was introduced into the

FIGURE 4 Engineered biosynthesis of shikimic acid, quinic acid, and ccMA from the *E. coli* aromatic amino acid synthesis pathway. PCA, protocatechuic acid.

shikimate pathway (57, 59). Ran et al. sought to replace PEP with pyruvate in an enzyme-catalyzed condensation with E4P to synthesize DAHP. 2-Keto-3-deoxy-phosphogalactonate (KDPPGal) aldolase (DgoA) naturally catalyzes the reversible cleavage of KDPPGal to pyruvate and glyceraldehyde-3-phosphate (G3P). Directed evolution of DgoA activity toward E4P was accomplished by screening mutants based on their ability to improve growth of DAHP synthase-deficient *E. coli*. Successful recovery of novel DgoA variants resulted in an effective bypass route to DAHP, which could prove useful for improved production of shikimic acid as well as a variety of other compounds derived from the pathway, including adipic acid, catechol, vanillin, and pyrogallol (59).

41.4.2. Adipic Acid

Adipic acid (shown in Fig. 4) is used in the manufacture of nylon and is traditionally synthesized from benzene, with

release of harmful N_2O as a by-product. Adipic acid can also be easily synthesized chemically from ccMA (shown in Fig. 4). Niu et al. modified the *E. coli* aromatic amino acid biosynthetic pathway for the conversion of the native intermediate 3-dehydroshikimic acid (DHS) to ccMA (50). This was accomplished by expressing the genes *aroZ* from *Klebsiella pneumoniae* (encoding DHS dehydratase), *aroY* from *K. pneumoniae* (encoding protocatechuic acid decarboxylase), and *catA* from *Acinetobacter calcoaceticus* (encoding catechol 1,2-dioxygenase) in a strain lacking *aroE* and carrying extra copies of *aroB* and *tktA*. The reactions catalyzed by these enzymes are depicted in Fig. 4. These strain modifications resulted in production of 37 g/liter ccMA from glucose in 48 h (50). Additional efforts from the Frost laboratory include *E. coli*-based conversion of glucose to *p*-hydroxybenzoic acid (12 g/liter) (6) via the aromatic amino acid pathway.

FIGURE 5 Biosynthesis of 2,3-*trans*-CHD starting from chorismate. The genes *entC*, *entB*, and *entA* encode isochorismate synthase, isochorismatase, and 2,3-dihydroxybenzoate synthase, respectively, which catalyze the corresponding reactions depicted.

41.4.3. 2,3-*trans*-CHD

In a final example of engineering the *E. coli* aromatic amino acid pathway, Franke et al. sought to overproduce (*S,S*)-2,3-dihydroxy-2,3-dihydrobenzoic acid (2,3-*trans*-CHD), which serves as a valuable chiral intermediate toward synthesis of a variety of biologically active natural products (25). As depicted in Fig. 5, 2,3-*trans*-CHD was produced by deleting *entA*, encoding 2,3-dihydroxybenzoate synthase, while overexpressing the genes *entB* and *entC*, encoding isochorismatase and isochorismate synthase. The resulting strain produced 2,3-*trans*-CHD in concentrations up to 4.6 g/liter (25).

41.5. ISOPRENOIDS

Isoprenoids (or terpenoids) represent a wide variety of specialty and pharmaceutical compounds synthesized biologically by the assembly of two or more branched, five-carbon isopentenyl pyrophosphate (IPP) subunits (7). As depicted in Fig. 6a, IPP is synthesized through two distinct routes involving either the synthesis of D-1-deoxy-xylulose-5-P (DXP) from pyruvate and G3P or the synthesis of mevalonic acid from acetyl-CoA. IPP is then isomerized to dimethylallyl pyrophosphate (DMAPP) by the enzyme IPP isomerase (*idi*), initiating chain elongation via condensation reactions

FIGURE 6 (a) Two different pathways to IPP; (b) pathways to carotenoids.

between DMAPP and IPP. As depicted in Fig. 6b, a single condensation yields the 10-carbon intermediate geranyl pyrophosphate (GPP), which can be transformed into a variety of 10-carbon natural products known as monoterpenes. Addition of another IPP to GPP yields the 15-carbon farnesyl pyrophosphate (FPP), which can be transformed into products such as quinines, sterols, and sesquiterpenes. Another IPP addition to FPP yields the 20-carbon intermediate geranylgeranyl pyrophosphate (GGPP), which can be converted to diterpenes and carotenoids.

41.5.1. Carotenoids

Carotenoids are a class of typically tetraterpenoid (40-carbon) pigments that act as light-harvesting and light-protecting agents, antioxidants, and anticancer compounds and serve as valuable synthetic precursors (48). Early metabolic engineering efforts to develop microbial strains for isoprenoid production focused on production of carotenoids, as reviewed by Barkovich and Liao (7) and Misawa and Shimada (48). In general, these involved heterologous expression of bacterial *crt* genes from the naturally carotenogenic *Erwinia* species for production of lycopene, β -carotene, and zeaxanthin in *E. coli* and other bacteria (Fig. 6b). *E. coli* has limited supplies of IPP, DMAPP, GPP, FPP, and GGPP, and strategies to improve carotenoid production using the native DXP pathway in this organism have focused on increasing the supply of IPP and DMAPP building blocks by increasing expression of native genes (*idi*, *dxs*, or *dxr*), as well as expressing the multifunctional GGPP synthase (*gps*) from the archaeobacterium *Archaeoglobus fulgidus* and optimizing heterologous expression of the various downstream *crt* genes (7, 46, 48, 64, 76). The optical properties of carotenoids make them easy targets for high-throughput screening, and as a result, various enzymes involved in carotenoid synthesis have been engineered using combinatorial directed evolution techniques, leading to improved production as well as synthesis of novel natural compounds in *E. coli* (65, 73, 76).

Synthesis of IPP in *E. coli* requires G3P and pyruvate (Fig. 6a). Farmer and Liao showed that lycopene production in *E. coli* overexpressing *dxs*, *idi*, *gps*, and *crtBI* could be improved by altering the flux distribution between pyruvate and G3P (24). Increasing the availability of PEP by overexpressing PEP synthase (*pps*) or by deleting pyruvate kinase (*pyk*) led to improved lycopene production by directing excess pyruvate to G3P and balancing the availabilities of the two precursors for IPP synthesis. One drawback to the continuous expression of heterologous pathways is the metabolic burden imposed on the cells. For example, continuously overexpressing the genes involved in lycopene synthesis is likely to diminish the availability of important precursor metabolites that serve as substrates to the same pathway (e.g., pyruvate and G3P). The expression levels of pathway enzymes may at times be far in excess of the pathway's metabolic flux capacity. To improve the efficiency of lycopene production in *E. coli*, Farmer and Liao designed a dynamic genetic control system, such that the expression of rate-controlling enzymes involved in isoprenoid synthesis (*idi* and *pps*) is regulated in response to the availability of precursors required for synthesis of IPP and, ultimately, lycopene (23). Acetyl phosphate (AcP) concentrations provide a measure of excess glucose flux (overflow metabolism), and AcP was chosen as the molecule to signal availability of energetic precursors derived from glucose metabolism. The Ntr regulon of *E. coli*, which normally plays a role in adapting to nitrogen depletion, was modified to control

gene expression in response to AcP. In the native system, the nitrogen sensor protein NRII controls phosphorylation of the regulatory protein NRI, whose phosphorylated form (NRI-P) activates expression from promoter *glnAp2*. However, in the absence of NRII, the phosphorylation state of NRI depends on AcP levels. Therefore, by placing expression of *idi* and *pps* under the control of *glnAp2* in an NRII-deficient strain, expression of these genes is activated in response to precursor availability. Using this approach, the authors were able to drastically improve final lycopene titers from batch cultures compared to control strains in which *idi* and *pps* were continuously expressed from a *tac* promoter. Whereas cells without the dynamic controller secreted large amounts of acetate, and constitutive expression of *pps* caused a growth deficit, AcP-dependent expression of *idi* and *pps* alleviated metabolic imbalance and growth retardation. The sum of their efforts was a >18-fold increase in the lycopene carbon yield on glucose and an ~3-fold decrease in acetate secretion in batch cultures containing 1.5% (wt/vol) glucose. The productivity was 0.16 g/liter · h, with a final lycopene titer of ~150 mg/liter.

Stephanopoulos and coworkers used a global stoichiometric network model of *E. coli* metabolism, modified to include the lycopene pathway (*crtEBI* operon), to identify single and multiple gene deletion targets that would improve lycopene production (2). Using this model-driven, optimization-based design approach, a total of seven single or multiple gene deletions were predicted and experimentally validated to increase lycopene production by increasing the supply of precursors and cofactors important for lycopene synthesis. An alternate approach used to identify gene knockout targets involved visual screening for increased lycopene production by cells carrying transposons randomly inserted into their chromosomes (thereby randomly disrupting genes in the genome). This strategy yielded three additional gene knockout targets (4). They next screened for further improvements in lycopene production from strains carrying all combinations of the two sets of knockout targets identified from these two different strategies (64 unique knockout combinations), resulting in new gene deletion combinations representing "global maximum" strains with twofold-improved lycopene production over the parental strain (4). High-density fermentations led to production of ~220 mg/liter lycopene from ~27 g (dry cell weight)/liter (3).

41.5.2. MVA Pathway Engineering for Artemisinin Production

To achieve an adequate supply of IPP to a heterologous isoprenoid pathway in *E. coli*, as an alternative to relying on the native DXP-dependent pathway, which likely suffers from limitations owing to native feedback control mechanisms, Keasling and coworkers expressed the foreign mevalonate-dependent (MVA) pathway in this organism (45). An eight-gene biosynthetic pathway combining genes from *E. coli* and *S. cerevisiae* was divided into a "top" operon that transforms acetyl-CoA to mevalonate in three enzymatic steps and a "bottom" operon that converts mevalonate to IPP, DMAPP, and/or FPP (depending on the construct). Coexpressing these operons in a mutant *E. coli* strain carrying a lethal deletion in an essential gene in the endogenous isoprenoid biosynthetic pathway (*ispC*) complemented the deletion, demonstrating a functional MVA pathway. However, the resulting excessive accumulation of intermediates produced through the heterologous biosynthetic pathway was toxic. The top and bottom operons were next coupled to expression of a codon-optimized variant

of amorphadiene synthase, which catalyzes conversion of FPP to amorphadiene, the sesquiterpene olefin precursor to the antimalarial drug artemisinin. This alleviated the growth inhibition and resulted in high-level production of amorphadiene from rich medium supplemented with glycerol. Peak amorphadiene production from the complete MVA pathway was 36- and 10-fold improved over peak production by similar strains using the native DXP pathway and an engineered DXP pathway, respectively (45).

Following this initial study, Keasling and coworkers reported a variety of additional efforts to further enhance flux through the MVA pathway for production of amorphadiene. While supply of mevalonate was identified as a limiting step in amorphadiene production, simply increasing expression of the top operon (to increase mevalonate production) led to reduced growth and productivity (56). Accumulation of the mevalonate precursor 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA; synthesized through the top operon by HMG-CoA synthase) was identified as a source of inhibition. Mevalonate production was improved threefold by amplifying the expression of HMG-CoA reductase (which converts HMG-CoA to mevalonate) relative to the expression levels of the upstream enzymes that produce the intermediate from acetyl-CoA (56).

In an alternate approach to optimizing the expression levels of individual enzymes in the MVA pathway, Pfleger et al. inserted between the top operon genes combinatorial libraries of tunable intergenic regions containing genetic control elements that include mRNA secondary structures, RNase cleavage sites, and ribosome binding site sequestering sequences (55). Intergenic region libraries were first screened for their ability to satisfy a mevalonate-auxotrophic requirement in engineered *E. coli* cells (54). Combinations of intergenic regions conferring enhanced mevalonate production were then identified using a fluorescence screen that involved constitutive green fluorescent protein expression from a mevalonate auxotroph. This novel strategy of optimizing expression of multiple genes in a biosynthesis pathway resulted in approximately 10-fold-improved mevalonate production (55). Further improvements have included optimizing promoter strengths and plasmid copy numbers of genes in the bottom pathway (5), replacing the top operon genes encoding HMG-CoA synthase and HMG-CoA reductase from *S. cerevisiae* with the genes from *Staphylococcus aureus* (72), and optimizing fermentation conditions, resulting in production of >25 g/liter amorphadiene by fermentation in defined glucose medium (72).

Prior to these efforts, artemisinin production relied on extraction from plants, with low yields. The ability to synthesize large quantities of the artemisinin precursor amorphadiene from inexpensive carbon sources using microbial culture presents revolutionary opportunities to treat malaria in the developing world at drastically reduced costs. Moreover, similar efforts following these examples should result in microbial production of other terpene-based natural products having important biological activity and potential to treat disease but traditionally obtained in low yields from plants. As a final example, the heterologous MVA pathway in *E. coli* has been applied to the production of β -carotene, resulting in 465 mg/liter β -carotene from batch culture supplemented with glycerol (83).

41.6. CONCLUSIONS

Since the successful engineering of *E. coli* metabolism for conversion of glucose to the nonnative product 1,3-propanediol (13, 49), a commodity chemical now used in

the industrial manufacture of renewable polymers, the field has seen tremendous advances in genomics, systems biology tools and information, and synthetic biology tools that facilitate genetic engineering. As a result, microbial metabolic engineering continues to gain momentum, with increasing frequency of success. This chapter has highlighted successful applications of metabolic engineering toward the goal of microbially based industrial chemical production and has demonstrated the diversity of strain modification strategies that can be applied to achieve overproduction of native and nonnative metabolites by *E. coli*. From these examples, it is clear that the likelihood of success increases with awareness of natural diversity (e.g., accessible enzyme functions), rate-limiting steps and pathway bottlenecks, and mechanisms of inhibition. Noteworthy are the power of combining rational and evolutionary approaches and the value of molecular tools that enable fine-tuning of gene expression.

Improving Microbial Robustness Using Systems Biology

JONATHAN R. MIELENZ AND DAVID A. HOGSETT

42

42.1. MICROBIAL ROBUSTNESS IN INDUSTRIAL PROCESSES

What is robustness regarding microorganisms and microbial processes? We define robustness to be a collection of properties a microorganism has that allow it to grow, conduct biochemical processes, and survive in a changing environment better than less robust microorganisms. Robustness requires the microbe to be able to rapidly adjust to different stresses derived from temperature and pH changes, nutritional limitations, presence of chemical toxins, and pathogen attacks such as by viruses and phages, while both surviving and continuing to function (Table 1). Indeed, these adaptations theoretically could result in a microbial strain that is less competitive under nonstressed conditions. Still, these characteristics are sought for industrial and environmental processes such as large-scale fermentations or bioremediation applications. Robustness is not necessarily a requirement for highly productive microorganisms that are developed for well-controlled environments, although robustness is nevertheless quite beneficial there too. Therefore, robust microbial processes are sought for all microbial processes used in the medical, food, feed nutrition, cleaning, chemical, bioenergy, and environmental industries. In this chapter, we aim to outline aspects of microbial robustness desirable for specific industries and processes and examine the current status and potential benefits of application of systems biology analysis tools to further improve these processes.

42.1.1. Biological Robustness

While robustness is a key recognized property of biological systems, the term “robustness” is frequently applied across a broad range of biological attributes, ranging in scale from genes to biological populations. For example, an enzyme can be described as robust if it performs its function across a wide range of conditions, such as pH and temperature, although optimal (peak) activity is defined by a narrow range of pH and temperature, and stability is temperature dependent (Mosier and Ladish, 2009). Likewise, the genetic makeup of an organism can be regarded as robust if it contains redundant genes and pathways for key metabolic activities or incorporates sophisticated metabolic control schemes. Additionally, “robustness” is used to describe both the ability of biological systems to respond rapidly to perturbations and their ability to adapt to evolutionary pressures

on a much longer timescale. Such broad use of the term underscores the significance of understanding biological robustness and has motivated several attempts to more precisely define the term (117).

In the context of industrial microbiology, the value of robustness can be seen across processes, organisms, and biological scales. It is a topic of both fundamental and applied value, the centrality of which has been essentially rediscovered with the development of systems biology tools. For example, robustness of even very simple biochemical networks has been shown to be important to bacterial chemotaxis, circadian rhythms, and the yeast cell cycle (10, 13, 116). Such analyses draw heavily from the network theories and computational tools applied previously to physical networks and incorporate consideration of dynamic stability, control theory, and biochemical “noise” (66, 69, 80).

This application of systems biology and network theory to biological robustness has generated valuable insights that may potentially be useful in identifying or developing industrial organisms with improved robustness. At the genetic level, latent metabolic pathways have been shown to be as important as excess metabolic capacity when organisms adapt to the loss of key metabolic enzymes (31). Perhaps not surprisingly, such metabolic flexibility often exists around core metabolic pathways that synthesize or utilize metabolites essential for biomass formation under all environmental conditions (5, 63). For example, high-throughput, integrated “omics” tools were used to evaluate *Escherichia coli* strains with disrupted glycolytic and pentose phosphate pathways. Despite the alterations to these central metabolic networks, the organism was able to reroute fluxes and exhibited only minor changes in gene transcription and protein expression (57).

In many organisms, genotypic variation far exceeds phenotypic variation, and a great many genes and gene variants can be considered inconsequential in terms of normal function. However, such variants may impart phenotypic or evolutionary capacitance, which enables the organism to behave in a normal phenotypic manner even when environmental conditions or mutations would otherwise make the system less robust (11, 84). While such phenotypic capacitance is not yet well understood, it may play a significant role in determining the robustness of industrial organisms designed around so-called “minimal” genomes and metabolic functionality. In a practical example of

TABLE 1 Preferred characteristics of a robust microorganism

Able to use inexpensive organic and inorganic sources of nitrogen and other nutrients
Able to utilize multiple complex carbohydrates as substrates for carbon and energy
Able to withstand a temperature or pH shock with minimal loss in viability
Multiple restriction modification systems to minimize virus and other external genetic attacks
Presence of metabolic and genetic redundancy for core biological processes
Able to enter dormant state to survive inhospitable environments or nutrient limitations
Ability to withstand brief oxygen deprivation or exposure for aerobes or anaerobes, respectively
Able to multiply rapidly and respond appropriately to changing environments
Reaches and maintains very high viable cell density
Able to withstand high levels of metabolic products and input inhibitors

robustness of enzymes, substitution of several amino acid residues was sufficient to enhance the stability of an alkaline protease 10-fold (43). Hence, robustness comes from a range of potential biochemical, metabolic, and genetic characteristics.

Robustness gained through genetic or metabolic redundancy is not without trade-offs, as such redundancy requires that an organism have additional genetic complexity, that it utilize more sophisticated regulatory networks, and that it carry a greater metabolic burden. These extra burdens exert pressure on biological systems to find an efficient and effective balance between redundancy, adaptability, and robustness. One possible means for accomplishing this balance is reliance upon a few simple yet complementary strategies for responding to predictable environmental stresses, such as nutrient limitation. Elementary node analysis of *E. coli* central metabolism, when applied in such a case, indicates that while only a very small fraction of permissible metabolic pathways are ecologically competitive, they represent enough diversity to account for the observed range of metabolic responses (16). In this way, a robust response results from the combined application of only a few metabolic strategies.

42.1.2. Genetic Adaptability

A key aspect of attaining robustness is a population's ability to adapt genetically to perturbations to the environment to not only survive but also possibly thrive due to improved fitness. Evolutionary geneticists distinguish adaptation as different from natural selection primarily in that adaptation includes mutations that in and of themselves do not result in large genetic changes but individually move an organism to a more fit optimum (101). Such a process may have been involved in evolution of the very successful variety of beverage yeast, which is discussed below, that developed over time through genetic paths that will remain unknown. An ongoing difficulty is that beneficial, adaptive mutations are difficult to study due to low frequencies (on the order of 4×10^{-9} per cell and generation), and they are difficult to identify compared to deleterious mutations (auxotrophy and loss of other critical functions) (52). Using phage evolution in the laboratory, Wichman et al. determined that fitness can be the result of multiple mutations, many defined as adaptive yet resulting in a similar improved organism or, in this case, a phage genome (130). In their study, they examined the adaptation of ϕ X174 to high temperature and an altered host. They found that two different lines had 15 mutations and documented the specific amino acid changed within five proteins. Most interestingly, they determined

that seven of these mutations were precisely identical as to amino acid affected and the nature of substitution, but critically, the order of their appearance was very different, suggesting that no single change or order of adaptation was decisive regarding ability to survive in a stressful environment. In the case of bacterial evolution, a laboratory 3-liter fermentor of *E. coli* approaching stationary phase ($\sim 2 \times 10^9$ cells/ml) should contain at least one mutation in every one of the $\sim 4,600$ genes in the genome. Using this microorganism, two different studies analyzed adaptation of *E. coli* across hundreds of generations under specific adaptive pressures. The authors concluded that many of the genomic changes are highly reproducible although not identical as with the aforementioned study, improving *E. coli* with many mutations that had small impacts and few "silver bullets" resulting in sudden fitness (52, 141). So such a population will likely contain many silent or nearly silent mutations from an evolutionary standpoint, many of which have the potential to improve the fitness when responding to metabolic challenges or perturbations.

42.2. SYSTEMS BIOLOGY TOOLS

Systems biology tools include measurement of the level of transcripts, proteins, and metabolites in a biological system at any moment in time. With rapid sampling, these tools can be used to paint a picture of the basal operation of cellular functions in a temporal context, including gene and protein expression plus carbon and metabolic flux. Similarly, the cellular response to an external change such as environmental alterations, metabolic limitations, or exterior assaults by pathogens or infective agents can be measured and compared with respect to the basal metabolism to detect genetic and metabolic responses to the new situation. Consequently, these tools are ideal to begin to further define the nature of "robustness" in microorganisms, and cellular and genetic characteristics that comprise this beneficial survivability. Certainly, a metabolic model of such robust microorganisms should have components not found in many "lesser" microorganisms. Systems biology tools have been the subject of a number of excellent reviews (1, 61, 64, 66) and so are reviewed here only briefly.

42.2.1. Genomic Analysis and Resequencing

The genetic sequence of the organism under analysis is a fundamental requirement for systems biology tools. Fortunately, the technology for sequencing is continuing to evolve rapidly from the "ancient" gel-based sequencing to fluorescent-tag-based sequencing to the evolving Roche

454 Genome Sequencer FLX™ and FLX Titanium™ and the Applied Biosystems SOLiD™ instruments. Interestingly, large numbers of repeated sequences can compromise assembly of contiguous sequences (contigs), especially for newer short-contig sequencing technologies. Even with the acquisition of genomic data, fully assembled, the function of many genes will remain unknown or hypothetical within all genomes, including that of very-well-studied organisms such as *E. coli*, due to the lack of homologous genes found in other organisms. Therefore, gene annotation remains one of the most limiting factors for genome analysis. At this writing, there are approximately 761 bacterial genome sequences, 55 archaeal microorganism genomes complete, and 100 animal and plant genomes complete. Table 2 highlights a sampling of the numerous microorganisms with fully sequenced and annotated genomes, along with areas of research that motivated their genomic analysis. Each of these microorganism's genomic data fulfill a fundamental requirement for application of systems biology tools to investigate these many important research topics.

Genome resequencing refers to determination of changes to a previously known genome sequence after a designed modification and/or evolution of the genome. An obvious example is a mutagenesis and selection procedure, but also interesting is detection of changes after multiple generations under mild selection pressure, including continuous culture. With proper genome sequence knowledge completed at the outset of a designed selection, as opposed to a genome sequence available from public data banks, there is a good likelihood a relatively limited number of genetic changes, whether they are single nucleotide polymorphisms or deletions or genome rearrangements, will be identified, providing valuable information regarding genetic changes relative to phenotypic changes. For example, the power of genome resequencing is described in the amino acid production section. In short, the genome sequence permitted specific rebuilding of a production strain, avoiding existing unintended potentially deleterious genetic changes found in the conventionally developed amino acid producer.

42.2.2. Transcriptomics for Gene Expression

Given availability of a genomic sequence, microarray gene expression analysis has made it possible to determine differences in gene expression under two or more conditions. Briefly, a microarray contains presynthesized oligonucleotide segments of selected regions of the genome, usually all the open reading frames/genes in the genome. The mRNA is isolated from an organism and converted into labeled DNA segments by enzymatic synthesis, producing genetic probes that represent the genes active under the selected condition. These labeled DNA segments derived from the mRNA are used to challenge the microarray by hybridization. If a gene is active, the mRNA is present as its labeled DNA equivalent, which will hybridize to the microarray oligonucleotide segment representing that gene. Since the locations of all selected genes are known on the microarray, hybridization and therefore expression of each of the genes can be determined. As an example, using a bacterial culture, genes expressed by a wild-type strain can be compared to a mutant to detect those genes not expressed or those whose expression has changed due to the mutation. Additionally, microarrays are very valuable to determine temporal expression of genes, for example, during the course of fermentation. Since thousands of genes are active during normal metabolism of an organism, a very large number of signals will be detected by the microarray.

The best microarray data come from differential expression of clearly definable differences, as with the example mentioned above, and completed with multiple biological and technical replicates to provide statistical validation of the results. As the technology matures, the number of arrays and replicates of arrays that can be placed on one analysis slide has grown considerably, providing tens of thousands of gene spots per microarray, yielding multiple gene coverage for simpler genomes with one microarray.

An additional tool, serial analysis of gene expression (SAGE), is used to evaluate gene expression patterns in a comprehensive manner (125). The technology relies upon the uniqueness of an ~14-bp segment (called a tag) from a gene obtained from expressed mRNA. The multiple tags are amplified and linked together for sequencing. The key advantage is that genes can be identified by these small sequences that can be linked together, allowing a sequencing run to identify dozens of genes expressed at a particular time. Using homology searching, the cells that are being examined do not require a genomic sequence because sequences of related (micro)organisms or homologous genes from anywhere could be used to identify the tagged gene. This technology has been useful for analysis of *Saccharomyces cerevisiae* and other yeasts (125, 126), as well as other cellular systems, including cancerous cells. Like all new techniques, improvements have been made with longer tags (25 to 27 bp) called super-SAGE, allowing better identification of gene location (90), and other variants aimed at microRNA expression quantitation, especially for cancer research (140).

42.2.3. Proteomics for Protein Synthesis

Proteomic analysis involves the examination of the proteins present in an organism. While early work was based on two-dimensional gels, technological improvements in genomics and mass spectrometry (MS) have permitted identification of the majority of proteins present in simple microorganisms, far more than before. For example, gel-based techniques required sufficient protein to form a detectable spot and required its structural characteristics to permit it to be within the pH and molecular weight range separable in the gel. While shotgun proteomics requires the partial purification of proteins, the technology permits many more proteins to be identified than by gel-based methods. The key to the technique is the ability to cleave the proteins specifically by site-specific proteases that generate peptides of predictable molecular weight. The peptides are separated by high-performance liquid chromatography (HPLC) and detected by either matrix-assisted laser desorption/ionization or electrospray ionization possibly coupled with time-of-flight technology (2). Computer analysis is required to connect the hundreds of peptides of specific molecular weight to the protein encoded by the genome of the targeted organism. MS protein identification can be challenging when there is extensive posttranslational modification of proteins by phosphorylation, glycosylation, transferases, or other modifications that increase the peptide molecular weight, making the computational identification of those peptides impossible without additional treatment of the protein sample. Interestingly, coupled with genomic data, experience has shown that proteins expressed from microorganisms resident in a complex matrix such as soil or biomass can still be identified in the presence of these environmental "contaminating" proteins, making proteomic technology very powerful for dissection of complex biological materials (108, 132).

TABLE 2 Examples of industrial organisms with completed genome sequence and potential areas of applied use^a

Organism	Use(s)
<i>Acidithiobacillus ferrooxidans</i>	Bioleaching, bioremediation
<i>Acidothermus cellulolyticus</i>	Bioremediation, environmental
<i>Actinobacillus succinogenes</i>	Succinic acid production
<i>Anaerocellum thermophilum</i>	Energy production
<i>Anaeromyxobacter</i> sp.	Bioremediation, environmental
<i>Arabidopsis thaliana</i> ^b	Model plant species
<i>Arthrobacter chlorophenolicus</i>	Bioremediation, environmental
<i>Aspergillus niger</i> ^b	Citric acid production, enzyme production
<i>Aspergillus oryzae</i> ^b	Beverage alcohol, food industry
<i>Bacillus amyloliquefaciens</i>	Antibiotic production, suppresses plant pathogens
<i>Bacillus licheniformis</i>	Biotechnological, enzyme production
<i>Bacillus subtilis</i>	Biotechnological, enzyme production
<i>Bacillus thuringiensis</i>	Insect pathogen
<i>Bradyrhizobium japonicum</i>	Soybean nitrogen-fixing symbiote
<i>Caldicellulosiruptor saccharolyticus</i>	Cellulases, biofuels
<i>Cellvibrio japonicus</i>	Cellulases, biofuels
<i>Chlamydomonas reinhardtii</i>	Model plant species
<i>Clostridium acetobutylicum</i>	Acetone, butanol, ethanol production
<i>Clostridium beijerinckii</i>	Acetone, butanol, ethanol production
<i>Clostridium cellulolyticum</i>	Cellulases, biofuels
<i>Clostridium phytofermentans</i>	Cellulases, biofuels
<i>Clostridium thermocellum</i>	Cellulases, biofuels
<i>Corynebacterium efficiens</i>	Amino acid production
<i>Corynebacterium glutamicum</i>	Amino acid production, food industry
<i>Desulfovibrio vulgaris</i>	Bioremediation, environmental
<i>Escherichia coli</i>	Biomaterials, biofuels, biochemicals
<i>Geobacter</i> sp.	Bioremediation, microbial fuel cells
<i>Gluconobacter oxydans</i>	Vitamin C production
<i>Hydrogenobaculum</i> sp.	Hydrogen production
<i>Klebsiella oxytoca</i>	Biofuels
<i>Lactobacillus casei</i>	Lactic acid production
<i>Lactobacillus delbrueckii</i> subsp. <i>bulgaricus</i>	Lactic acid production
<i>Lactobacillus plantarum</i>	Lactic acid production, food industry
<i>Lactococcus lactis</i>	Cheese production
<i>Mannheimia succiniciproducens</i>	Succinic acid production
<i>Methanocaldococcus jannaschii</i>	Methane production
<i>Methanosarcina barkeri</i>	Methane production
<i>Methanospirillum hungatei</i>	Methane production
<i>Nostoc (Anabaena)</i> ^b	Alga model organism
<i>Pichia stipitis</i> ^b	Energy production, biofuels
<i>Populus balsamifera</i> subsp. <i>trichocarpa</i> ^b	Biomass source
<i>Ralstonia eutropha</i>	Bioplastic producer
<i>Rhizobium leguminosarum</i>	Bean nitrogen-fixing symbiote
<i>Rhodobacter sphaeroides</i>	Bioenergy, biohydrogen
<i>Rhodospseudomonas palustris</i>	Hydrogen production
<i>Saccharomyces cerevisiae</i> ^b	Biofuel production, food industry
<i>Sinorhizobium meliloti</i>	Alfalfa nitrogen-fixing symbiote
<i>Streptococcus thermophilus</i>	Yogurt production
<i>Sphingomonas (Pseudomonas) elodea</i>	Biogum production

TABLE 2 (continued)

Organism	Use(s)
<i>Streptomyces avermitilis</i>	Antibiotic production
<i>Streptomyces coelicolor</i>	Antibiotic production
<i>Thermoanaerobacter ethanolicus</i>	Biofuels
<i>Thermoanaerobacter pseudethanolicus</i>	Biofuels
<i>Thermobifida fusca</i>	Cellulases, biofuels
<i>Trichoderma reesei</i> ^b	Enzyme production
<i>Vitis vinifera</i> L. ^b	Grapes and wine
<i>Yarrowia lipolytica</i> ^b	Citric acid production
<i>Xanthomonas campestris</i>	Biogum production
<i>Zymomonas mobilis</i>	Biofuels

42.2.4. Metabolomics

Biological systems are constructed of chemical molecules either obtained from the environment (i.e., food) or synthesized from portions of these input materials by cellular metabolism. While much can be learned from examination of gene expression and the resulting protein expression, identification of the chemical molecules that comprise internal cellular metabolism can be critical to understanding regulation of cellular gene and protein/enzyme expression. Metabolomics aims to accomplish this by use of advanced separation and detection tools to identify small metabolic molecules. Typically, a sample is taken and quickly extracted to remove the small-molecule metabolites by use of very cold solvents, such as methanol, to halt metabolic activity as quickly as possible. Special approaches are needed for charged molecules or those not readily solubilized by cold solvents. As metabolism is dynamic, temporal sampling of a biological system in rapid succession can detect changes in metabolic processes which can confer robustness after the organism is challenged by inhibitors or other stressful or selective conditions. These small molecules are typically separated by chromatography (gas chromatography, HPLC, or capillary) and detected by either nuclear magnetic resonance spectroscopy or MS, which are particularly suited to small molecules, with modifications to separate charged molecules such as phosphorylated molecules common in cellular processes. Unlike with the previous “omics,” the genome sequence is not required to delve deeply into the metabolism of biological systems using metabolomics (89).

42.2.5. Fluxomics for Metabolite Flow Analysis

Analysis of the flow of metabolites within an organism is termed fluxomics and is a natural extension of metabolomic analysis. Indeed, temporal analysis of the metabolome comprises the fluxome, with flow of cellular small molecules delineated in a linked metabolic pathway, permitting analysis of the flow of materials, as shown in *Saccharomyces cerevisiae* (14). Pathway engineering in combination with fluxomic analysis provides a powerful approach by which to understand the changes engineered into a metabolic chain of reactions. Such understanding can be critical to understanding an organism's ability to survive stresses and is therefore closely aligned to understanding differences between robust (micro)organisms and more sensitive relatives. Fluxomics has been helpful for production of small molecules such as amino acids and is being used to analyze production of ethanol production from both corn starch and cellulosic feedstocks.

42.2.6. Metabolic Model Development

Metabolic models are valuable tools to begin to structure and test understanding of cellular processes. Models can have different degrees of complexity and can attempt to model the whole cell or, more often, specific aspects of cellular processes such as carbon flow, DNA replication, or bacterial sporulation. As computational power has grown, the possibility to model hundreds of genes and enzymes and link them to the fluxome has become realistic. Models provide platforms to test interactions of different cellular processes using multiple approaches including all the “omics” tools described briefly above. Metabolic modeling is particularly useful for fermentation chemicals such as organic acids, alcohols, and amino acids, as outlined below.

42.3. INDUSTRIAL ENZYME PROCESSING AIDS AND PRODUCTION STRAINS

Industrial enzyme production is a mature industry that contributes to numerous products and processes, including food production, improved cleaning products, pulp and paper processes, textiles, animal feed, and niche markets such as chemical detectors, research enzymes, and chiral chemical processes. Due to their complex structure, enzymes are synthesized exclusively by biological processes. Microorganisms are most commonly used for enzyme production, although there are examples of enzymes isolated from plant and animal sources. Since enzyme production is largely a microbial process, highly productive fermentation processes have been developed yielding enzymes in excess of 50 g of protein per liter, which is now required in many instances to be commercially competitive.

Bringing an enzyme to the commercial market requires a number of steps. Initially an enzyme must have catalytic and stability characteristics that meet the requirements of the application for which they are destined. Such functional criteria are typically very stringent, especially now with the many enzymes that have been developed over the last three decades (106). For example, early commercial enzyme producers quickly realized that process knowledge was essential, consistent with the formation of the strategic partnership between Procter & Gamble and Genencor International developed in the 1980s for development of detergent enzymes. This partnership permitted Genencor to understand the very stringent requirements needed for a successful and superior detergent and processing enzymes needed in Procter & Gamble product lines. As is discussed in some detail below, Henkel KGaA (Düsseldorf, Germany), Staley/Tate & Lyle, and CPC

International are three of a small number of companies that developed in-house capability for enzymes used in detergent and sweetener applications. Proprietary details for “doing the laundry” or production of high-fructose corn syrup were readily available to in-house microbiologists/geneticists seeking improved enzymes for their processes. This proprietary process knowledge has been one of the significant hurdles facing nascent enzyme companies, such as Diversa/Verenium, Dyadic, Direvo, and Maxygen, whose products must compete with and hopefully displace carefully crafted existing enzyme products that are commercially successful using existing processes with attendant depreciated capital.

Selection of an enzyme that provides the best match to existing or anticipated process needs is critical, as it provides the springboard for both enzyme improvement and high-level production. Enzyme production has been accomplished through the use of convenient, reasonably productive original host microorganisms such as *Bacillus* or *Streptomyces*, as well as filamentous fungi such as *Aspergillus niger*. However, it was understood early on that improved production can be accomplished better by transferring the enzyme structural gene to a new, more suitable host, such as genetically modifiable fungi or bacteria, initially with associated production improvement by simple gene dosage. Such gene cloning opened the doors to genetic improvement by numerous approaches, including random gene mutagenesis, site-directed modification, gene and nucleotide shuffling, and gene recruiting. Productivity improvements were gained by modification or recruitment of regulatory sequences, most prominently a paired promoter/Shine-Dalgarno sequence with a strong terminator, but more sophisticated improvements continue to be developed (113).

Selection of the best microbial production host organism is extremely critical, since follow-on genetic and fermentation process development will be built around this organism. Approaches have taken and continue to take two general forms. The first is the development of a process around a microorganism that can easily be genetically modified, with the expectation that deficient characteristics can be genetically improved. The alternate approach is the selection of a robust host microorganism that has a known track record of functioning in an industrial process, and struggling with the usually difficult task of genetically modifying a microorganism for which the requisite tools are not developed. Both approaches have merit, and their selection often hinges upon the value of the product as well as the complexity of the protein regarding required posttranslational modification. For example, *E. coli* K-12 was chosen by Eli Lilly as the host for production of human insulin even with its lack of protein transport and potential for endotoxins because the high value of the product supports more expensive, highly regimented regulation-driven reproducible production and downstream processing. By contrast, industrial carbohydrases, such as glucoamylases, and cellulases continue to be produced by filamentous fungi, even with the associated complexity of production due to required extensive posttranslational modification and since their applications do not require highly purified enzyme products.

42.3.1. Detergent Enzymes and Production Strains

As mentioned previously, robust production strains are highly beneficial economically because their performance in industrial fermentors, 50 m³ and larger, is predictable and dependable. Henkel KGaA, as the largest producer of laundry detergent in Europe, was faced with the need to produce an improved detergent protease to replace their in-house-produced *Bacillus licheniformis* alkaline protease

P300 or to purchase a protease from an enzyme manufacturer such as Novo Nordisk at a higher price. The current production host had been subjected to multiple rounds of random chemical mutagenesis, which yielded a strain able to produce active protease at economically competitive levels. In-house research identified a more effective protease from *Bacillus lentus* which passed required stability tests in company applications laboratories, which included the required perborate bleach and temperature stability needed for European laundry practices. The structural gene for the protease was cloned, and production in *Bacillus subtilis* rose modestly but did not match the productivity of the older enzyme, P300 (133), being produced on a large scale from *B. licheniformis*, a well-characterized high-yielding enzyme producer. To take advantage of this production strain, the *B. lentus* protease gene was cloned behind the P300 protease promoter and Shine-Dalgarno ribosome binding sequence (133). However, it was not known whether the signal sequence for the *B. lentus* enzyme would function as efficiently in the new industrial host, so the new protease gene was either left linked to the resident homologous secretion sequence or attached to the *B. licheniformis* P300 secretion sequence prior to cloning into the robust, dependable production host, *B. licheniformis*. Results showed that the secretion sequence homologous to the host and the new structural gene was significantly more productive, permitting the well-characterized production process to now produce a superior alkaline protease at protein concentrations obtained previously with the inferior enzyme. Subsequently, the genetic construction was inserted in the chromosome after multiple rounds of site-directed mutagenesis, yielding one of the best alkaline proteases for detergent applications, all being produced by the original superior production host strain (43, 44).

While production of alkaline proteases, such as described above for Henkel KGaA, involves quite mature technology where possibly only small incremental improvements remain, much can be learned from analysis of the production process with common heterologous host-enzyme combinations using systems biology tools. For example, sequencing of the genome of the production strain will yield valuable hints as to why this host organism is so effective in protein production under industrial conditions. Furthermore, with the genome sequence available, it could be determined if the protein production proceeds consistently throughout the fermentation run using both transcriptomic and proteomic approaches, although the latter will be a challenge in the presence of very high levels of protease. Certainly protein synthesis has a high energy demand, and potential limitations in synthetic capability may become evident with gene expression analysis. For example, a detergent protease expression was modeled for mass flux looking at enzyme synthesis (15). Furthermore, Henkel, as an oleochemical company, could benefit from this information were they to want to produce lipases or other enzymes for detergent, chemical, or personal-care businesses with a well-understood host organism.

42.4. FERMENTED BEVERAGE INDUSTRY

One of the oldest uses of microorganisms is production of fermented beverages by yeasts and other microorganisms, which has evolved from a spontaneous process to the current well-developed art and science of production of wine, beer, and processed fermentation beverages such as various liquors. Indeed, alcoholic fermentation was used by early societies to preserve beverages from fresh fruits and other sources of fermentable sugars. For example, *Zymomonas* has

long been used for production of pulque from fermented agave sap and has appeared as a troublesome contaminant in wine making. *S. cerevisiae* and other yeasts have been used for wine and beer production since antiquity (9, 92). Currently the technology is very advanced, with dramatic improvements in quality and quantity due to improved processing equipment and selection and development of improved fermentation yeasts. Indeed, studies using systems biology tools are beginning to delineate differences between laboratory yeast strains and those developed through the ages as robust fermentative strains that permit the production of high-quality alcoholic beverages.

Laboratory strains of *S. cerevisiae* have been the subject of intense analysis since the genome sequence was determined in 1996 (45, 134); such analysis includes generation of a metabolic network model for a portion of the intracellular metabolism, including over 700 genes/open reading frames, or about 16% of the genome (32). For example, the linkage of transcriptomic analysis with the metabolome during a sudden increase in carbon source (glucose) in *S. cerevisiae* showed that within 5 min, the organism can respond to addition of glucose both with increased intracellular metabolites and with activation of genes associated with purine synthesis due to the sudden demand for ATP (71). Interestingly, the demand for the energy carrier's metabolites was severe enough that the mRNA degradation rate increased to provide purine building blocks, giving a clue with respect to the extent of cellular metabolism reprogramming expected due to a sudden change in the external environment. Finally, a comprehensive multiomic study correlating the gene expression (transcriptome), protein expression (proteome) and the external and internal metabolome with a chemostat-grown *S. cerevisiae* strain permitted the delineation of some of the details of growth control of this laboratory yeast (19). Genes associated with growth under nutrient-limited and -sufficient conditions were identified, as well as stress- and stimulus-related genes, and provided a guide for integrated systems biology analysis of a complex biological system and possible approaches to understand how robustness can be detected and quantified in a cellular system.

Regarding robustness, laboratory yeasts cannot successfully compete with commercial wine and fermentation yeasts, which have been selected to be very hardy and survive a very stressful environment while rapidly fermenting metabolizable sugars to ethanol. When a yeast is pitched into a wine must, it is suddenly exposed to very high sugar levels (i.e., >22% sugar by weight) with associated high osmotic pressure, plus low pH (pH 3 to 4) due to high organic acid levels, especially for white wines. Relatively low nitrogen levels and high levels of sulfur dioxide used to kill indigenous yeasts and bacteria present with incoming grapes plus the onset of anaerobiosis (105) provide other stresses. Beer production exposes the beer yeast to a similar environment, with the exception of minimal sulfur dioxide levels, but can include limitations in expression of genes associated with membrane synthesis that require small levels of oxygen (106). As a result of this stressful and inhospitable environment, yeasts have presumably evolved that are quite different from laboratory *S. cerevisiae*.

Transcriptome and proteome tools require a genome sequence for gene identification. Wine and beer yeasts, including *Saccharomyces bayanus*, *Saccharomyces kudriavzevii*, *Saccharomyces mikatae*, *Saccharomyces paradoxus*, and *Saccharomyces pastorianus* (*Saccharomyces carlsbergensis*), are among the approximately 117 *Saccharomyces* genomes being sequenced which will greatly facilitate systems biological analysis (www.genomesonline.org; www.genolevures.org).

Wine production often uses *S. cerevisiae* or *S. bayanus*, while beer yeasts comprise a wider group of *Saccharomyces* species. Initial analysis has shown considerable genome and chromosome rearrangement, and there is considerable divergence between beer yeasts for top-fermenting ales and bottom-fermenting lagers (62, 70, 115), providing for different characteristics among fermentation strains likely to affect the resulting product. The availability of a large and growing number of genome sequences, with multiple strains being sequenced from the aforementioned species, will greatly broaden the potential for understanding the value of the genetic differences found in industrial yeasts.

During wine production there is no need for starter cultures, as dry wine yeasts are typically pitched into the must, where they have to quickly adapt to very different environments upon rehydration. Having been produced in a rich and rapidly fermenting aerobic fermentor, harvested, and spray dried, the starter yeasts find themselves now in a high-sugar, acidic, anaerobic, rather toxic milieu comprising the wine must. Surprisingly, a few studies have failed to detect activation of classical stress response genes, which might be expected under these conditions. The rehydrated yeasts undertake activation of anaerobiosis genes, glycolytic genes, and catabolism repression due to the high sugar levels (98, 111), suggesting that these yeasts have been selected to avoid an energy-consuming stress response in favor of quickly adapting to the environment of an industrial wine yeast, i.e., are able to undertake fermentation in the environment and not become the classical "stuck" fermentation common to laboratory yeasts when facing high sugar levels. As the fermentation proceeds, an additional stress is self-introduced as the ethanol levels rise due to fermentation. Indeed, levels above 25% (by weight) sugar are common with wine production yielding over 12% ethanol, a level that is highly toxic to laboratory yeasts and nearly all bacteria. One common response is accumulation of the sugar trehalose, as well as expression of genes related to membrane fitness and electron transport and, finally, generalized stress response genes (110, 124). Cellular metabolism slows down in late stationary phase due to minimal sugar and nitrogen and high levels of ethanol in readiness for harvesting of the product by the enologist.

By comparison, a true wild-type yeast isolated from a spontaneous grape fermentation caused by a yeast resident on the grape exterior was analyzed for protein changes during fermentation (121). During the fermentation, when the glucose level dropped significantly, there was a dramatic decrease in protein synthesis for about 50 proteins and evidence of proteolytic activity. Also noted was upregulation of classical stress response genes, a response not seen in selected wine yeast strains, indicating that the natural yeast indigenous to vineyards was not as robust or resilient as selected commercial wine yeasts.

Beer yeasts are more diverse and, as mentioned above, have multiple fermentation modes divided at least between top- and bottom-fermenting yeasts plus other proprietary fermentation approaches. Analysis of brewing yeasts has shown chromosomal diversity regarding structure and number, as first noted by Casey (17). Using comparative competitive genomic hybridization techniques, various laboratories have found that wine and lager yeast chromosomal structures have distinct site-specific changes in a number of genes at or near the mating type (MAT) loci (12, 53, 70). These hybridization studies have identified regions of *S. cerevisiae*-like and non-*S. cerevisiae*-like genes, suggesting interspecies mating and hybridization, which lead generally to two situations. First, an addition of large regions of chromosomes after

mating clearly accelerates evolution of traits that can be advantageous if selection pressures are imposed. Additionally, analysis of industrial yeast strains has shown them to have poor mating and sporulation ability, providing genetic isolation eventually. This provides for stability and maintenance of traits such as robustness in the face of the challenges of alcoholic beverage manufacture, for example, but makes conventional strain improvement via natural gene transfer difficult. The use of genetic engineering to further improve yeast strains for beverage fermentation can, therefore, be limited to modern genetic engineering approaches, raising concerns regarding genetically modified organism (GMO) application for products destined for human consumption. The application of systems biology tools such as those underway with laboratory strains (19, 32) can be applied to wine and especially lager beer production to build an integrated metabolic model of gene response and metabolite flows as the fermentation process proceeds. With such a model, non-GMO approaches can be used after identification of genes that should be either removed (knockout) or overexpressed to improve further the robust industrial nature that the brewmaster has selected through time.

42.5. AMINO ACID PRODUCTION

Amino acid production is a mature industry, with very large volumes of selected amino acids being produced primarily for food and feed applications. For example, lysine is deficient in corn-based rations for animals, so a number of companies such as Ajinomoto, ADM, Cargill, Kyowa Hakko Kogyo, and DSM produce lysine as well as glutamic acid by microbial fermentation with additional amino acids, including threonine and phenylalanine. *Corynebacterium glutamicum* has been developed for very-large-scale fermentations (>50 m³) using low-cost substrates with current production of glutamic acid reaching 1.5 tonnes annually, primarily for food use, and lysine production of more than 600,000 tonnes as a feed additive.

Historically *C. glutamicum* was identified as a glutamic acid producer, and this discovery started the continued development of this microorganism for industrial processes, with many years of conventional mutagenesis and selection. Early work included the use of amino acid analogues to select for overproduction (115) and improved fermentation yields were improved with time. Fermentation conditions were developed that took advantage of the flexible nature of *Corynebacterium*. For example, many corynebacteria do not demonstrate diauxic lag for use of multiple carbohydrates beside glucose and as gram-positive microorganisms are associated with a very broad and diverse substrate utilization potential. Due to these advantages, such microorganisms, which include *Brevibacterium*, have been developed as producers of multiple amino acids, with the advantage of employing similar fermentation regimens for different amino acid products.

C. glutamicum was first used for glutamic acid production in the late 1950s, and work to increase yields was begun using fermentation process development and strain improvement, the latter with conventional mutagenesis and screening with amino acid analogues. Strain improvement continued as gene cloning and expression contributed to productivity, which included early flux analysis and substrate pathway modification for higher yields (51, 65). While the productivity of these conventional and genetically improved *C. glutamicum* and related *Brevibacterium* organisms provided sufficient economic productivity, the advent of genomic sequencing opened additional investigative avenues of strain improvement using

systems biology tools (60). For example, initial comparative analysis of related genomes revealed that the ability of *Corynebacterium efficiens* to produce amino acids at higher temperatures was due to both higher G+C content and altered codon usage, providing a beneficial change to production at higher temperatures, and likely improved stability to temperature spikes, an important aspect of robustness.

Industry and academia have used microarray technology that followed the emergence of genome sequences. Microarrays generate hundreds to thousands of signals, often leading to data overload and potentially reducing the perceived value of this tool. However, with well-designed experiments, a specific metabolic quandary was solved by microarray analysis involving valine production. The sequenced *C. glutamicum* strain ATCC 13032 was genetically modified to overproduce valine, and unexpectedly it was discovered to be inhibited by exogenously added valine (as was a related lysine producer). Microarray analysis comparison of the overproducing valine strain with the wild type detected an isoleucine limitation overcome by adding isoleucine, thus identifying an actionable outcome for further genetic engineering (74). As another example, microbial genome sequencing permitted an additional unique approach to strain building. It is well known that conventional mutagenesis followed by screening permitted significant progress in developing industrial fermentation strains, but it often resulted in unrelated deleterious mutations causing poor growth and stability. Whole comparative genomic analysis of a *C. glutamicum* production strain was used to examine the lysine pathway, along with transport and supportive genes. Initial work was limited to specific genes, but further research used the full-genome analysis, which detected many mutations in the conventionally derived strain, along with the identification of key genetic changes that caused overproduction of amino acids. These specific mutations predicted to be critical to amino acid production were recruited for “genome-based strain reconstruction” in which the critical mutations were added to an unmutated *C. glutamicum* strain, which resulted in a much more robust rapidly fermenting production strain with no known detrimental mutations (88, 99).

In addition to genetic analysis, analysis of the intermediate metabolites is progressing with advanced analytical tools with increasing sensitivity. For example, an automated method for gas chromatography-MS analysis of *C. glutamicum* metabolites able to detect over 1,000 compounds with conclusive identification of a selected 164 of these has led to improved understanding of internal metabolism (118).

These examples highlight the growing potential of the “omics” toolbox that can be beneficially applied to industrial microbes that were developed before the advent of genetic engineering. Competing with these efficient industrial coryneform bacteria for amino acid production is *E. coli*, which was investigated as a preferred host for phenylalanine production by GD Searle in the 1980s for NutraSweet production. Apparently it was decided that *E. coli* was advantageous due to its ease of genetic modification and that strain development research could overcome economic advantages of the competitor’s *Corynebacterium* and *Brevibacterium* strains. This approach discounted any apparent benefits from robustness of the gram-positive microorganism, likely due to patent concern, with the conclusion that *E. coli* could be developed for high levels of phenylalanine production quickly. Interestingly, GD Searle successfully developed *E. coli* as a phenylalanine producer from two different directions. The first included conventional mutagenesis and selection with amino acid

analogues at their Harbor Beach, MI, facility. Subsequently the unpublished cloning of the entire phenylalanine pathway was completed by a research team led by S. Primrose in the Searle High Wycombe, England, research facility (33), leading to another *E. coli* production strain for phenylalanine. The initial nonrecombinant *E. coli* strain went into production, providing important knowledge regarding large-scale *E. coli* phenylalanine production. Among the knowledge gained from this work is the lack of robustness of *E. coli* regarding phage infections, as early fermentations were plagued by viral attacks due to a nearby waste treatment facility, until additional engineering modifications were added to ensure sterility of incoming air. Indeed, this is a real concern for any bacterial fermentation process that is potentially worse for *E. coli* hosts due to ubiquitous coliform-containing waste management facilities. This new information was undoubtedly included in facility designs as the fully recombinant strain went into production by Searle in their Georgia facility. This example demonstrates that nonindustrial microorganisms can be harnessed successfully and compete with robust counterparts if proper facility and process practices are included.

42.6. XANTHAN PRODUCTION

The origins of the industrial production of bacterially derived biogums, such as xanthan, can be traced back to work done in the 1950s at the U.S. Department of Agriculture Laboratory in Peoria, IL. Current production of xanthan gum for use in foods, pharmaceuticals, cosmetics, oil drilling, and industrial processing amounts to more than 50,000 tonnes per annum globally. Xanthan production leaders include companies such as CP Kelco, ADM, Cargill, Danisco, Jungbunzlauer, and Deosen, the majority of whom have been shifting production capacity to China to remain competitive in this growing but cost-sensitive market (25).

The production of xanthan gum by *Xanthomonas campestris* has been extensively studied and is the subject of several good reviews (30, 41). Produced aerobically via submerged fermentation, xanthan is a large, anionic, water-soluble heteropolysaccharide with a primary structure containing repeated pentasaccharide units of glucose, mannose, and glucuronic acid. Even early mucoid isolates of *X. campestris* were capable of producing >50 g/liter xanthan, so much of the development of the xanthan process has focused on industrial scale-up and application development, especially as a food ingredient. The development of techniques for large-scale xanthan production have focused on overcoming the challenges inherent in the highly viscous fermentation, including controlling dissolved oxygen, temperature, and pH as the acidic polysaccharide is produced (87). Xanthan gum fermentations exhibit a strong dependence on oxygen transfer rate, as it affects cell growth and xanthan production rates, as well as the mean molar mass of the xanthan produced. As the fermentations are viscous, typically >100 cP, various carbon and nitrogen feeding strategies are used to maintain productivity during the course of fermentation (30, 41). As the commercially relevant properties of the xanthan gum differ among strains, cultivation techniques, and purification schemes, these have also been investigated in detail (30, 37, 112).

The genomes of three strains of *Xanthomonas campestris* pv. *campestris* have been published since 2002 (24, 107, 128). While the genomic information has been primarily interrogated to better understand the pathogenicity of the microbe, which is the causal agent for black rot disease in crucifers, the genome sequences have also been utilized to

reconstruct the metabolic pathways for synthesis of xanthan and its precursors, as well as to perform comparative genomic analyses (128). The reconstruction of the xanthan pathway was nontrivial, for while the genes responsible for xanthan gum production were first reported in the 1980s, the number of cyclic metabolic pathways involved in xanthan synthesis complicates stoichiometry. In addition to providing insight into xanthan synthesis, the genome provides evidence for a large number of carbohydrate import systems. Following publication of the genome, the links between the import systems and specific carbohydrates have been further elucidated using transcriptomic data (114).

While structured kinetic models of *X. campestris* growth and xanthan production have been developed and shown to be useful in predicting bioprocess performance, the development of a genome-scale metabolic model has not yet been reported (39, 40, 83). Metabolic flux analyses have been developed and utilized to evaluate an advanced reactor configuration, to evaluate the energetics of xanthan synthesis, and to increase understanding of the relationship between nutrient addition and product attributes (30, 50, 81). Proteomic analysis has also been utilized with *X. campestris*, although the focus has been largely restricted to its role as a phytopathogen (20, 129). The presence of copious amounts of exopolysaccharide creates challenges in the “omic” investigation of *X. campestris*, as it can interfere with standard techniques for proteomic, transcriptomic, and metabolomic sampling and analysis. To overcome this issue, researchers have utilized modified methods or non-mucoid strains (20, 82). To make real progress with “omics” tools, method development aimed at extraction of genetic transcripts and microbial proteins for transcriptomic and proteomic analysis, respectively, must be accomplished. Once these methods are available, a full “omic” analysis of gum synthesis will be possible and potentially yield a metabolic model with hopefully actionable outcomes to further improve a very unique microbial fermentation process.

42.7. CELLULOSIC ETHANOL PRODUCTION

The conversion of cheap, abundant cellulose biomass into alcohol fuels has been pursued for more than a century. Like ethanol derived from cane and corn, ethanol derived from cellulose will require low-cost operations possible only in very large, simply designed fermentation equipment. However, while relatively inexpensive, cellulose feedstocks are much more difficult and costly to process than feedstocks providing starch or sucrose. Taken as a whole, the robustness challenges of cellulose ethanol production are numerous (Table 3).

Cellulosic biomass is composed mainly of cellulose, hemicellulose, and lignin. While precise compositions vary significantly across types of cellulosic biomass, such as grasses and trees, typical dry biomass is >50% carbohydrate by weight, with lignin comprising between 20 and 35%. While the major portion of biomass is typically cellulose, composed of $\beta(1\rightarrow4)$ -linked D-glucose units, a significant portion is composed of pentose-rich polysaccharides such as xylan and arabinan, or hexose-rich polysaccharides such as galactan and mannan. In part due to the presence of lignin, which sheathes cellulose fibrils and is cross-linked within the hemicellulose, the biological breakdown of lignocellulosic biomass is challenging. To attain the conversion rates and yields required of industrial fermentation processes, this recalcitrance to biological decomposition must be overcome.

TABLE 3 Robustness challenges in biomass ethanol production

Type of challenge	Description
Substrate	
Concentration	Processes employing prehydrolysis require rapid growth at high initial sugar concentrations. Processes featuring simultaneous saccharification release sugars slowly, typically over several days. Process economics favor very high solid concentrations, often >20% (by wt), resulting in limited free water, difficult mixing, and potential for local accumulation of sugars and/or ethanol.
Heterogeneity	Biomass feedstocks exhibit considerable compositional variability. Processes require the use of both pentose and hexose sugars.
Environment	
pH, temp, nutrients	Low-cost, large-scale fermentation systems have minimal mechanical mixing, resulting in potentially large spatial variations in pH, temperature, and nutrient availability.
Product accumulation	Process economics favor ethanol titers in excess of 6% (vol/vol). High concentrations of dissolved carbon dioxide can be anticipated due to equipment scale and mixing.
Infection	Scale, feedstock, and equipment limitations increase the likelihood of bacterial and phage infections.
Biomass-derived inhibitors	
Cellulose	Many pretreatments convert a portion of the hexose sugars into HMF, levulinic acid, and formic acid.
Hemicellulose	Many pretreatments convert a portion of the pentose sugars into furfural; acetyl groups are converted to acetic acid.
Lignin	Many pretreatments convert a portion of the lignin polyphenolics into vanillin, 4-hydroxybenzoic acid, 4-hydroxybenzaldehyde, and syringaldehyde.

As early as 1900, concentrated acid was employed to hydrolyze cellulose into glucose. However, low yields and high cost led researchers to look for other means of liberating sugars from cellulosic biomass. Most current research is focused on processes that employ pretreatments which disrupt the lignocellulosic structure prior to biological conversion to ethanol. A wide variety of pretreatment approaches have been proposed, including processes that operate at low pH (dilute acid and sulfur dioxide), high pH (ammonia and lime), and near neutral pH (liquid hot water and steam explosion). In other processes, such as wet oxidation, pH is a matter of choice (103). In addition to disrupting the cellulosic structure, the low-pH pretreatments hydrolyze the hemicellulose fraction and yield monomer sugars such as xylose. Pretreatments at high pH tend to solubilize lignin, without hydrolyzing the hemicellulose to a significant degree. The various approaches to pretreatment and their performance trade-offs are the subject of several good reviews (36, 49, 95). Pretreatments vary in terms of their ability to enhance enzymatic digestibility of different cellulosic feedstocks, but for most cellulosic feedstocks of interest, one or more pretreatments have been shown to be effective at rendering the cellulosic biomass digestible (135, 136).

While the various pretreatments improve biomass digestibility, many of them also make the biomass hydrolysates inhibitory to the growth of the fermentative microorganisms. Growth inhibition by biomass-derived inhibitors has been a recognized challenge since the earliest days of concentrated acid hydrolysis (79). Various means of detoxification have been tried, including overliming and activated carbon treatment of liquid hydrolysates and neutralization and washing of the insoluble materials. While several of the methods have been shown to be effective at reducing inhibition, their cost has motivated efforts to both minimize the production of inhibitors during pretreatment and identify or develop robust organisms capable of tolerating biomass-derived inhibitors (76, 94).

The exact identity and mechanism of the biomass-derived inhibitors are not well understood. Degradation products of glucose and xylose, such as 5-hydroxymethylfurfural (HMF) and furfural, have been a focus of attention for many years. The same is true of lignin degradation products such as vanillin and syringaldehyde. However, recently developed analytical methods capable of quantifying a wide range of potentially inhibitory water-soluble compounds have made it clear that dilute-acid-pretreated biomass hydrolysates have many more potential inhibitors (21, 22). The inhibitor profile following alkaline pretreatments differs considerably from that following pretreatments at lower pH and can result in pretreated biomass with low toxicity. For example, both wheat straw pretreated by alkaline wet oxidation and corn stover pretreated using ammonia fiber expansion have been shown to exert little or no inhibition on *S. cerevisiae* (67, 77). For ammonia fiber expansion and other mild types of pretreatments, such as liquid hot water (93), carboxylic acids such as acetic and formic acids are the primary biomass-derived inhibitors.

Among the potential inhibitors, furfural and HMF have received the most attention. Examination of furfural and HMF toxicity in yeasts led to the recognition that both compounds are converted to their corresponding alcohols during the course of the fermentation (86, 97, 127). While the sensitivities and responses to furfural and HMF vary widely among yeast strains, under anaerobic conditions, cell growth is typically inhibited until the conversions to the less toxic alcohol derivatives are complete (38, 93, 102, 119). In *S. cerevisiae* the reduction of the aldehyde group is catalyzed by one or more alcohol dehydrogenases, using both NADH and NADPH as cofactors (85). Researchers at Lund University utilized mRNA expression profiles to identify *adh6* as the gene responsible for conveying NADPH-dependent HMF conversion. Later, the same group identified a second, NADH-dependent alcohol dehydrogenase using electrospray ionization-MS and demonstrated that overexpression of the two alcohol dehydrogenases in a laboratory strain of

S. cerevisiae markedly improved anaerobic fermentation in the presence of HMF and furfural (6, 73, 104). The bacterial ethanologens *Zymomonas mobilis*, *E. coli* KO11, and *Klebsiella oxytoca* P2 have also been evaluated with respect to furfural and HMF toxicity and conversion. As with the yeast, the bacteria appear to detoxify the aldehydes by converting them to their respective alcohols (47, 109, 139).

While the appearance of HMF and furfural in pretreated biomass is associated with the degradation of otherwise fermentable carbohydrates, the presence of acetic acid is an unavoidable outcome of the depolymerization and hydrolysis of hemicellulose. Microbial sensitivity to acetic acid is strongly pH dependent, as toxicity is well correlated to the protonated form of acetic acid. Acetic acid toxicity has been shown to be significant for *E. coli* and *Z. mobilis*, as well as *S. cerevisiae* (38, 78, 102, 109). Interestingly, a gene that provides sodium acetate resistance in *Z. mobilis* has been identified by resequencing the genome of a mutant strain, in conjunction with transcriptomic profiling and genetic studies (S. Brown, Oak Ridge National Laboratory, personal communication). Microarray analysis of *S. cerevisiae* grown in glucose-limited chemostats showed hundreds of up- and downregulated transcripts when exposed to acetic ethanol at sublethal levels (1). Analysis of *S. cerevisiae* strains adapted to acetic acid, utilizing either whole-genome microarrays or lipidomics, highlights the adaptive importance of membrane composition and ion pumps (42, 137).

Microbial inhibition due to lignin-derived inhibitors such as vanillin, 4-hydroxybenzoic acid, 4-hydroxybenzaldehyde, and syringaldehyde has also been shown to be significant (26, 68, 75, 139). While genetic elements responsible for tolerance to these compounds have not been reported to date, this can be expected to change. For example, recent analysis of an *S. cerevisiae* deletion library identified 76 mutants with increased sensitivity to vanillin. The analysis indicated a key role for ergosterol biosynthesis, as well as for genes in the functional categories for chromatin remodeling and vesicle transport (29).

In addition to the robustness challenges posed by inhibitors deriving from pretreated biomass, microorganisms to be used in cellulosic ethanol production also need to be able to withstand high levels of ethanol and dissolved carbon dioxide. In cellulosic ethanol production, like starch- and sugar-based processes, attaining high ethanol concentrations has a significant impact on production costs. Existing commercial ethanol processes often achieve ethanol yields in excess of 10% (vol/vol), with much of the ethanol production occurring after cell growth ceases. High partial pressures of CO₂ accompany high ethanol titers, especially in large-scale ethanol production processes where economic considerations include very large (>500,000-gal) fermentation vessels with very limited agitation.

The effects of dissolved carbon dioxide on microorganisms have been studied at length, including its impact on aerobic and anaerobic yeast cultivations (28, 58). High levels of dissolved CO₂ have been shown to influence cell growth and protein production in aerobic systems as well as cell growth and product formation in anaerobic ethanol production processes (72, 96, 120). Analysis of these systems using microarrays has led to new insight into the underlying genetic mechanisms of CO₂ inhibition at the regulatory and transcriptional levels (3, 96). The physiological effect of dissolved carbon dioxide has also been examined in continuous cultures of the bacterial ethanol producers, including *Z. mobilis* and *Clostridium thermocellum*, although without the benefit of systems biology tools.

Ethanol tolerance has been of applied and fundamental interest since before the modern era of biotechnology, especially in wine making. Several good reviews have been written on ethanol tolerance in yeasts and other industrial organisms, which highlight the impact of ethanol on cell membranes, glycolysis, end product distribution, and cell growth (18, 23, 54, 56). Despite years of study, the biological mechanisms involved in ethanol tolerance, and how they are affected by temperature, medium composition, and genetics, remain the subject of some debate.

Genetic-level understanding of alcohol tolerance in yeasts has been significantly advanced through the use of systems biology. In 2006, separate groups published studies in which *S. cerevisiae* deletion libraries were screened for ethanol tolerance. While dozens of genes were correlated with ethanol sensitivity, genes encoding proteins involved in vacuolar function were identified by both groups as being critical in ethanol tolerance (35, 123). Since the initial reports, screening of more comprehensive libraries has expanded the list of genes which potentially influence ethanol tolerance (138).

Microarrays have also been employed in examining the response of yeast to ethanol. Alexandre et al. showed that more than 3% of the genes in the yeast genome are upregulated within 30 min of an ethanol challenge (4). Similar challenge experiments with a variety of alcohols showed significant upregulation in genes associated with stress response, glycolysis, metabolism of energy reserves, and synthesis of amino acids (34). Transcriptional profiling has also been applied to evaluate the difference between ethanol-adapted and parental yeast strains during growth in the presence of elevated ethanol. Genes related to ribosomal proteins were highly upregulated in the ethanol-tolerant strain. In addition, when cultivated under ethanol stress, both parental and adapted strains showed upregulation of genes associated with mitochondrial ATP generation and oxidative stress response (27). The number of transcriptional differences seen in response to short- and long-term ethanol exposure underscores the complexity inherent in yeast fermentations. Further evidence of this can be seen in research showing that modifications in global transcriptional machinery can impart significant improvements in overall ethanol and stress resistance (7, 8).

Systems biology tools have also been applied to evaluation of ethanol-adapted and parental of bacteria, such as *C. thermocellum* and *E. coli*, engineered for ethanol production. When performing transcriptional profiling to compare ethanol-adapted and parental strains of *E. coli*, researchers found that gene expression levels for more than 5% of the genome differed significantly. Among the affected genes were those involved in aromatic amino acid transport and synthesis, cell structure, energy metabolism, and stress response (46). In proteomic analysis of a *C. thermocellum* strain adapted to grow in 5% ethanol, the majority of membrane proteins were shown to be differentially expressed. Most of the expression difference was the result of downregulation of membrane proteins, especially those related to carbohydrate transport and metabolism (131). Subsequent resequencing, using 454 pyrosequencing and microarray-based comparative genome sequencing, revealed hundreds of mutations between the ethanol-adapted strain and the ATCC type strain from which it was derived (Brown, personal communication). Undoubtedly, additional systems biology investigations will reveal additional clues regarding the response of ethanologens to this important industrial chemical.

The development of processes for biomass ethanol production will require strains that tolerate the combined effect of ethanol, acetic acid, and degradation products arising from biomass pretreatment. While the impact of individual inhibitors on growth and product formation may not severely impair performance, the effect of the combined stresses may be more than additive (59, 100, 102). So the quintessential multiple-inhibitor-resistant super-robust ethanologen has yet to be obtained.

In biomass ethanol production, economic considerations necessitate the use of organisms capable of fermenting both cellulose- and hemicellulose-derived carbohydrates, including cellobiose, glucose, xylose, arabinose, galactose, and mannose. In practice, this requires broadening the range of sugars fermented by proven ethanol-producing organisms, enhancing ethanol production in organisms natively capable of using numerous biomass-derived sugars, or both. While metabolic engineering to obtain these improvements falls beyond the scope of this chapter, it is the subject of several good reviews and an area of active, ongoing research that includes multiple examples of successful application of systems biology tools (48, 55, 91, 122).

42.8. SUMMARY

Development of a vigorous, rugged microorganism by adaptation or as the result of directed selection is of selective value to microbes and economic value to industrial microbiologists. This robustness will have many characteristics derived from a combination of selection/adaptation and genetic changes, resulting in better survivability under stressful conditions. One of the best examples of robustness is yeast strains derived for beer and wine manufacture through the centuries which resulted in many phenotypic and genetic changes in the yeasts, leading to very beneficial survival responses during alcoholic fermentation. Similarly, engineered microorganisms for enzyme or other products are being developed to be very rugged and potent, which is part of the definition of robustness, but this microbial soundness requires a protected, engineered production environment to maintain and demonstrate their hardiness. Still, in either situation, the microorganism's response to the environment, however controlled, can be dissected and defined in ever-increasing detail by employing systems biology tools. This process starts with identification of gene and genome changes, and resultant data are used for analysis of both expression of genes and attendant proteins and their impact on the flux of metabolite in the cell and environment. As these differences become known, new or expanded modification strategies can be planned to further improve the microbe's robustness as needed for each industry.

Bioethanol Production from Lignocellulosics: Some Process Considerations and Procedures

CHARLES A. ABBAS, WU LI BAO, KYLE E. BEERY, PAMELA CORRINGTON, CONSUELO CRUZ, LUCAS LOVELESS, MARTIN SPARKS, AND KELLI TREI

43

43.1. INTRODUCTION

The current emphasis on environmentally friendly liquid transportation fuels has caused a renewed interest in bioethanol and, in particular, lignocellulosic feedstocks for the production of bioethanol. As a result, research into the development of an economic process for the bioconversion of lignocellulosics has accelerated (21). The primary areas of research crucial to improved process economics consist of feedstock selection, pretreatment, hydrolysis of the pretreated feedstocks, and developing an optimized fermentation process that uses newly engineered ethanologens capable of utilizing various biomass-derived sugars (1). Faced with the above challenges, biotechnologists and engineers are addressing these issues in an integrated fashion by combining many of the above steps, thereby reducing the need for costly processing scenarios (52). For those new to this area of research, this chapter addresses in a stepwise and practical manner some of the general considerations, procedures, and approaches that can be used in process optimization.

43.2. FEEDSTOCK SELECTION

Choosing a lignocellulosic biomass feedstock is an important step in the biochemical conversion of biomass to ethanol. Feedstock composition dictates the choice of pretreatments. The hemicellulose, cellulose, lignin, silica/ash, starch, and moisture content all need to be taken into consideration.

A feedstock high in lignin, such as wood or corn stover, requires a more severe pretreatment and also requires a higher enzyme usage, as lignin inhibits cellulase activity by adsorbing the enzymes (49, 55, 56). A feedstock high in silica, such as rice straw or rice hulls, needs to be discounted, as the silica will be inert, at best, throughout the pretreatment. A feedstock high in starch, such as corn fiber hulls, will require a less severe pretreatment to avoid excessive degradation of the glucose from the easily hydrolyzable starch. Another factor is moisture, and agricultural processing by-products such as corn fiber hulls and sugarcane bagasse will already contain a high content of water. The initial moisture content and chip size have both been shown to have an impact on the efficiency of the bioconversion of softwood lignocellulosics (17). This needs to be factored into the pretreatment step, and it can aid specific types of pretreatment processes, such as dilute acid, ammonia recycle percolation, and steam explosion, among others. Total car-

bohydrate content is important, as that is the only portion of the feedstock that can be converted to ethanol biochemically. However, the lignin in the biomass surrounds the carbohydrate to protect the carbohydrate from degradation and to offer structural rigidity to the plant; therefore, lignin composition is also important. More important than all of the compositional considerations is economics. Feedstocks such as wheat straw have use as animal bedding, while other higher-protein, ruminant-digestible feedstocks, such as corn fiber hulls, soybean hulls, or wheat middlings, are used as animal feed. These types of feedstocks will have a much higher value than wood chips, corn stover, or switchgrass; however, the total carbohydrate content is also higher than that of wood or corn stover, so more ethanol production is possible per ton of biomass feedstock. Table 1 shows the approximate compositions of various biomass feedstocks, including grains, oilseeds, agricultural processing by-products, agricultural residues, energy crops, and wood.

43.3. PRETREATMENT SELECTION

After the selection of feedstock, the selection of the pretreatment method is the next difficult choice. There are many types of pretreatment, some severe and some mild, ranging from hot-water treatment to thermochemical, organosolv, or ionic liquid treatments. The pretreatment may be expected to release fermentable sugars by the chemical treatment alone or in combination with an enzyme hydrolysis step. Generally, the treatments are aimed at either disrupting or solubilizing the hemicellulose, cellulose, lignin, or a combination of the three (Table 2). The following sections detail these approaches.

The selection of the pretreatment step also depends upon the composition of the feedstock in question. Various levels of cellulose, hemicellulose, lignin, ash, silica, nitrogen, and moisture will require various pretreatment conditions and chemicals to ensure the most optimum pretreatment for that feedstock.

Typically, the first step in feedstock pretreatment aims to increase surface area. The larger the surface area of the feedstock, the more area which is available for chemical reactions. Particle size is one determinant of surface area, but the situation is complicated because internal surface area is much larger than external surface area for many pretreated feedstocks, and accessible surface area is affected by the size

TABLE 1 Compositions of various biomass feedstocks

Feedstock	% of indicated ingredient						
	Cellulose	Hemicellulose	Starch	Fat	Ash	Protein	Lignin
Corn	2.0	7.6	72.0	4.4	1.6	9.1	1.0
Corn fiber hulls	16.0	40.0	18.0	3.0	3.0	11.0	4.0

^aNA, not applicable.

^bDDG/DDGS, distillers dried grains/distillers dried grains with solubles.

of the adsorbing species. Grinding to reduce particle size is very costly from an energy standpoint (7, 27).

Another important factor to consider is the length of time for the pretreatment. In general, times that are too short result in solids that are not sufficiently reactive, while times that are too long result in unwanted reactions such as degradation of sugars and formation of inhibitors. The various pretreatments range from seconds for dilute acid, ammonia fiber explosion (AFEX), and steam explosion to days and weeks for lime pretreatment (28, 34, 36, 63).

43.3.1. Pretreatments with Acids

Acid pretreatments include both processes featuring the addition of acids and processes without added acids in which the pH is lowered due to release of acetic acid in the course of pretreatment. This family of pretreatments brings about decrystallization and swelling of the cellulose structure as well as hydrolysis of hemicellulose polysaccharides (and, to a much lesser extent, cellulose). Although little or no lignin is solubilized by acid pretreatment, the state of lignin is significantly altered in the course of melting and recondensation. Hydrolysis of hemicellulose leads to soluble oligosaccharides and free sugars being generated (2), while the hydrolysis of the cellulose leads to swelling of the cellulose matrix, but very few soluble maltooligosaccharides, due to the highly crystalline nature of cellulose (23). The acid pretreatments also disrupt the lignin, which allows for enzymes to effectively hydrolyze the cellulose (70).

These pretreatments can be characterized and compared by calculating the severity factor (R_0) for the pretreatment (40). The formula for severity factor is

$$R_0 = t \times \exp\left[\frac{(T_H - T_R)}{14.75}\right]$$

where t is reaction time in minutes, T_H is hydrolysis temperature in degrees Celsius, and T_R is a reference temperature, most often 100°C.

If acid is used in the pretreatment, a modification of the severity factor is used: the combined severity factor $CS = \log_{10}(R_0) - \text{pH}$.

Generally the range for pretreatment by dilute acid, hot water, or steam explosion is 150 to 200°C, with 0.15 to 3% acid for 1 to 30 min. Other studies have examined pretreating biomass feedstocks under autoclave conditions (24, 53). Figure 1 shows the relationship between severity factor and amount of solids solubilized and monomeric arabinose yield for corn fiber. It can be seen that as the severity factor is increased, the monomeric arabinose yield (the hemicellulose side chain sugar) and the total solids solubilized both increase linearly over the range of severity factors shown.

43.3.2. Pretreatments with Bases

Pretreatments using bases, such as AFEX (61), lime pretreatment (34), and ammonia recycle percolation alone or followed by a successive treatment with hydrogen peroxide (32, 35, 41),

TABLE 2 Pretreatment selection and impact of pretreatment on lignocellulosics

Process	Solids loading (%)	Cellulose	Hemicellulose	Lignin
Dilute acid	10–40	Some depolymerization	80–100% solubilization to monomers	Little or no solubilization but extensive redistribution
Steam explosion at high solids	20–40	Some depolymerization	80–100% solubilization to monomers or oligomers	Little or no solubilization but extensive redistribution
Hydrothermal	10–30	Some depolymerization	80–100% solubilization to >50% oligomers	Partial solubilization (20–50%)
Organic solvents with water (organosolv)	10–30	Some depolymerization	Substantial solubilization to near completion	Substantial solubilization to near completion
Wet oxidation	6–15	Some decrystallization	30–90% solubilization depending on severity	20–50% solubilization depending on severity
AFEX	60–90	Substantial swelling	Solubilization from 0–60% depending on moisture with >90% oligomers	Some solubilization (10–20%)
Sodium hydroxide or ammonia	10–30	Substantial swelling	Substantial solubilization, often to >50%	Substantial solubilization, often >50%
Lime pretreatment	10–30	Substantial swelling	Substantial solubilization (>30%) under some conditions	Partial solubilization (40%)
Concentrated acid	10–30	Substantial solubilization	80–100% solubilization	Extensive redistribution

work mainly by swelling the biomass and modifying or solubilizing the hemicellulose and lignin (70). By removing the bonds between the lignin, hemicellulose, and cellulose, the cellulase enzymes can effectively hydrolyze the cellulose (34).

43.3.3. Other Pretreatments

Wet oxidation, organosolv, and ionic-liquid-based pretreatments modify the biomass in different ways than the acid

and base pretreatments. Wet oxidation works by solubilizing the hemicellulose and lignin and cleaving the bonds between the three fiber components. This works best when wet oxidation takes place under alkaline conditions (44).

Organosolv removes lignin nearly completely, by first hydrolyzing the alkyl aryl ether bonds in the lignin and then solubilizing the remaining lignin fragments (16). The lignin can be separated from the residual solids and

FIGURE 1 Severity factor impact on solubilization and arabinose release from the corn fiber hull hemicellulose arabinosylan.

precipitated from the solvent/water system. This allows the enzymes to attack the remaining carbohydrates.

Ionic liquids are a recent development in the lignocellulosic biomass conversion arena. This technology works by completely dissolving the carbohydrate portion of the biomass and leaving the lignin as a solid. The soluble carbohydrates can be chemically hydrolyzed in the ionic liquid to create water-soluble oligosaccharides for use as a chemical or fermentation feedstock (57). The difficulty of this type of pretreatment is recovery of the expensive, and often environmentally hazardous, ionic liquid.

43.4. ENZYME SELECTION AND HYDROLYSIS

Following pretreatment of a lignocellulosic feedstock, an enzymatic step can be employed to further hydrolyze the solubilized material and residue into simple sugars. These sugars are then, in turn, used by the microbes in fermentation to produce a desired biobased product such as ethanol. The enzymatic hydrolysis step is one of the major obstacles to the industrial production of bioethanol from a process efficiency and economic standpoint (1). Therefore, optimizing the enzyme hydrolysis blend for a given feedstock is critical to an industrial process. Choosing and optimizing the right blend of enzymes for an industrial process depends on many factors, such as feedstock composition, pretreatment method used, overall process design, enzyme reaction efficiency, and cost of enzymes (1, 72).

43.4.1. Substrate Preparation

The substrates of the enzymatic reactions (the pretreated feedstocks) are derived from diverse sources of materials which undergo different methods of pretreatments as described in section 43.3. The diversity in feedstock and pretreatment methods generate substrates for enzymatic hydrolysis with different physical and chemical properties (1). Properties such as particle size, solid and liquid and/or moisture content, degree of crystallinity, chemical composition, polymer size or length of fiber filaments and degree of substitution, and the specific type of chemical bonds all dictate the kind of enzymes and dose of each enzyme required to hydrolyze the substrates (17). The slurry generated from pretreatment usually includes a variety of carbohydrates, such as cellulose fibers, soluble oligosaccharides, and some simple free sugars, as well as other compounds that are derived from lignin (1). Hydrolysis of the cellulose and oligosaccharides with different compositions and chemical bonds requires specific cellulosic enzyme cocktails, as these enzymes act in a synergistic fashion. Optimizing the cocktail or components of enzymes for a given substrate is necessary to quantitatively depolymerize the carbohydrates at an acceptable rate (72). When lignin is present in high concentrations, as in the case of wood-derived feedstocks or agricultural residues (see Table 1), inhibition of cellulases and hemicellulases is a common occurrence (10). Some differences in lignin inhibition of enzyme activity following feedstock pretreatment have been shown (10). The addition of nonionic surfactants has been shown to have a positive impact on enzymatic conversion of softwood lignocellulose by reducing the amount of enzyme necessary and by enhancing the rate of conversion (13, 37). Screening for weak lignin-binding cellulases is one approach that has been proposed to deal with the interference of this polymer so as to improve the activity of cellulases on lignocellulosics (12).

The whole slurry after pretreatment can be fractionated into a cellulose stream and a hemicellulose stream prior to selective enzyme treatment (hemicellulases versus cellulases) to improve the effectiveness of the hydrolysis step. This requires the use of different enzyme blends for the different fractions. Fractionation can consist of a liquid-solid separation step such as filtration or centrifugation. If filtration is employed, the cake or solid retentate contains mostly fractured and cellulosic fibers. An enzyme cocktail consisting mostly of cellulases should be considered for the hydrolysis of this residual solid material. The filtrate or permeate will consist mostly of soluble oligosaccharides of hemicellulose. A blend with mostly hemicellulases should be selected for this fraction. In some cases where the hydrolysate is derived from agricultural residues or processing by-products that contain starch such as corn fiber and wheat middlings, a glucanase-type enzyme such as glucoamylase is also essential to hydrolyze the residual starch present in the soluble fraction.

43.4.2. Enzyme Selection Criteria

Enzyme samples to be tested can be obtained from enzyme suppliers such as Novozymes, Genencor (Danisco), and other smaller companies. These companies have developed several commercial cellulase blends (Table 3) that can be evaluated for a given pretreated feedstock. In general these blends contain high cellulase activity and are produced by fermentation using the fungus *Trichoderma reesei* (46, 59). By comparison, hemicellulases are derived from different fungi and bacteria (8, 38, 47, 68). In addition to cellulase and xylanase activities, several secondary activities may also be produced during fermentation, which may be necessary for optimum cellulase hydrolysis of a pretreated lignocellulosic feedstock (11, 47). Variability in the enzyme blends is due to the choice of microorganisms and differences in fermentation parameters. Therefore, dissimilar protein compositions are observed among different commercial xylanase blends (Fig. 2). For this reason, it is crucial to ensure that all needed activities are present in the chosen blend.

A cellulase blend usually contains endo- β -glucanases and exo- β -glucanases (47, 72). The combined activities can hydrolyze the solid cellulose fibers into glucose in a stepwise fashion. The endoglucanase reacts first with the cellulose chain to cleave an internal β -glucosidic bond, thus creating two new chain ends, one reducing and one nonreducing. The exoglucanases then cut the polymer from the reducing end or nonreducing end to make cellobiose, which is eventually hydrolyzed by the β -glucosidase into glucose (6, 43, 48). The inhibition of cellulases and β -glucosidases by increased glucose content during enzymatic treatment has been well described (71). The cellulase complex from *T. reesei* has been well characterized by several research institutes and is produced by several manufacturers, listed in Table 3. A variety of cellulase enzymes from other sources, especially those from thermostable microbes, have also been evaluated for the ability to hydrolyze cellulosic fibers (67). While the list of commercially available blends is limited, there are many more cellulases and hemicellulases in development that can be considered for evaluation on these substrates.

Commercial hemicellulase mixtures can have multiple activities and are not as well defined as the cellulase mixtures. Most pretreatment methods employed to specifically release hemicellulose create soluble oligosaccharides and do not release all the hemicellulose. This hemicellulose is still attached to the lignin component of the cellulose

TABLE 3 Some commercial enzyme products available for testing

Enzyme name	Function	Source	Temp (°C)	Best pH	Supplier
Cellic Ctec	Cellulase	<i>T. reesei</i>	50	5	Novozymes
Celluclast 1.5L	Cellulase	<i>T. reesei</i>	Up to 70	3.5–5.5	Novozymes
GC220 (C2)	Cellulase	<i>T. reesei</i>	Up to 70	3.5–5.5	Genencor
Multifect GC	Cellulase	<i>T. reesei</i>	Up to 70	4	Genencor

fiber matrix. The hemicellulase blend is then necessary to disintegrate those soluble and insoluble polymers into usable carbohydrates. The hemicellulose is composed of many different monomers, such as xylose, arabinose, mannose, galactose, and other C₅ or C₆ chemicals (67). These sugars are linked together by a variety of chemical bonds, and these bonds may require application of different enzymes. A typical hemicellulase blend contains exo- and endoxylanases and arabinofuranosidase. Because of the highly substituted and branched nature of hemicellulose, other enzymes, such as mannanase, polygalactouronase, rhamnosidase, and ferulic esterase or other esterases, could sometimes be required for different substrates.

In addition to the carbohydrate hydrolytic enzymes, there are several other types of enzymes that could play a role in the process and have a synergistic effect. Examples of this

are the wood rot fungus-derived oxidases that have been proposed to have a function in the degradation of lignin compounds. The activities of these oxidases by in vitro assays on the intact lignocellulose material are not easily detectable (25). Evaluating the function of these enzymes on the pretreated substrates can be useful in assessing the impact of pretreatment on a lignocellulosic feedstock (1). Also, an acid protease has been shown to have some synergistic effect on the hydrolysis of some selected polysaccharides from a variety of feedstocks (W. L. Bao, unpublished data).

43.4.3. Enzyme Mixture Optimization

Due to the recalcitrant nature of lignocellulosic feedstocks, the compositional variation within the feedstock, and differences in enzyme sources, enzyme mixture optimization is necessary to the processing of each pretreated substrate. For

FIGURE 2 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of commercially available cellulosic enzymes. Lane 1, molecular mass marker; lanes 2 to 6, commercial xylanases; lanes 7 to 11, commercial cellulases.

the downstream processes, separate hydrolysis and fermentation and simultaneous saccharification and fermentation, the enzyme blend should have high catalytic efficiency. A long reaction time contributes to additional cost of the process and increases the chance of contamination. Therefore, the ideal enzyme blend should hydrolyze most of the substrates with minimum enzyme concentration at a high rate. According to published reports and due in part to the U.S. Department of Energy's funding of cellulase development work, the cost of production of commercial cellulosic enzymes has dropped significantly in recent years (72). In spite of this, the cost of these enzymes is still a prohibitive factor in the process. To achieve additional cost reduction, further research and development work and enzyme blend optimization are needed. Blend optimization is one of the ways that end users can minimize the amount of enzyme in processing of lignocellulosics and thereby decrease cost.

Blend optimization includes finding the right enzymes for the substrate and fine-tuning the amount of each enzyme in the blend. This can be achieved by utilizing tools that are available for experimental designs, statistical analysis, and computer modeling (15, 66). Approaches include testing different enzyme sources in order to find the right mix for the substrate. Once the right mix is determined, different compositions of the blend should be tested for optimization. The hydrolysis data can be plotted on a graph to establish the dosage effect of each enzyme. By using this method, the optimum blend can be determined (Fig. 3).

43.4.4. Detection of Enzyme Products

Several analytical methods can be used to test the catalytic efficiency of enzymatic hydrolysis of cellulosic substrates, some of which are described below. The enzyme products can be analyzed on silica thin-layer chromatography plates, where sugars are visualized by sulfuric acid charring at high temperature. The glucose can also be determined by the Yellow Springs Instrument Company's (Yellow Springs, OH) biochemical analyzer, which is an instrument that utilizes

glucose oxidase to measure the amount of glucose in a solution. The phenol-sulfuric method can be used for the total soluble carbohydrate analysis (20), as can enzymatic assays using hexokinase and glucose 6-phosphate to measure glucose concentration. Finally, high-performance liquid chromatography (HPLC) or gas chromatographic (GC) methods can be used for quantitative carbohydrate determination (3).

43.4.5. Other Considerations

The cost of enzymes can be reduced by modification of the enzymes or fermentation organisms, such as enzyme display on the membrane surface of yeasts and transformation of expressed enzymes into yeasts (19, 29, 39, 64, 65). Current research includes the use of membrane separation to recycle the biomass-degrading enzymes and on enzyme immobilization to extend the lifetime of enzymes for the hydrolysis of cellulosic material (9, 26, 58, 62). Enhancement of enzymatic hydrolysis has also been shown using simultaneous ball milling in combination with added cellulases (42). Other developments in protein engineering include the development of artificial enzymes or high-throughput screening platforms. These methods hold some promise for improving the catalytic activity of enzymes or the rapid discovery of better enzymes (22, 51). Whether these new approaches can be applied successfully remains to be demonstrated.

43.5. TESTING PROCEDURES FOR ETHANOLOGENS ON HYDROLYSATES

Improved ethanologens can be created by classical mutagenesis and/or genetic engineering approaches. Ethanologens can also be obtained from numerous sources, which include proprietary and public culture collections. A partial list of ethanologens of interest is provided in Table 4. These ethanologens can be tested for performance on feedstocks prepared as described in sections 43.3 and 43.4. Laboratory testing of ethanologens on hydrolysates proceeds by experiments in

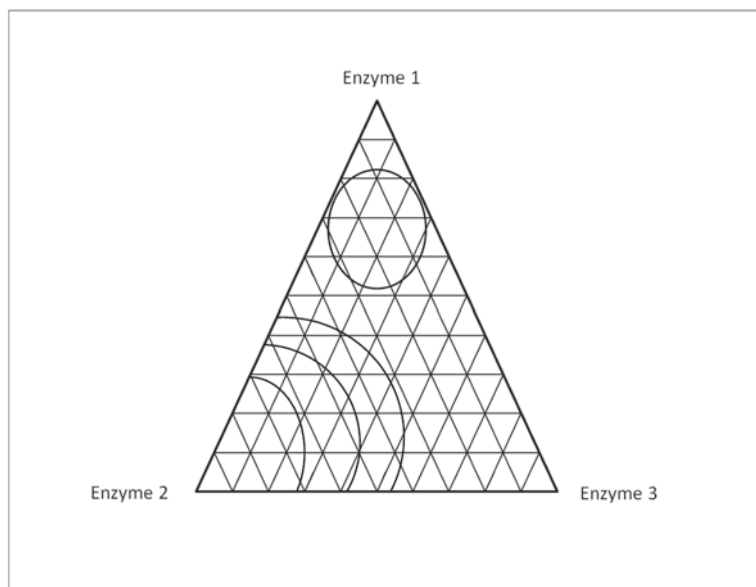

FIGURE 3 Ternary plot for enzyme blend optimization. Three enzymes, each with 10 concentrations, can be tested and plotted in the same experiment. Product (glucose or other sugars) concentration is plotted on the graph, and each line represents a concentration range.

TABLE 4 Properties of leading candidate microorganisms for industrial production of ethanol from xylose

<i>Saccharomyces cerevisiae</i>	–	+	+	+	>15

shake flasks and fermentors. Shake flasks are often used as a prescreening method before moving organisms to bench-scale fermentors. Successful ethanologen strains will proceed to the commercial-scale plant. Some benefits of using shake flask experiments to screen ethanologens include the following.

- Simplicity of planning
- Fast results
- Minimal cost due to the small scale and the simple equipment required
- Sufficient flexibility to run in batch format or as cascades which mimic continuous processes

Some of the issues to consider in choosing an ethanologen include the ability to ferment completely feedstock components, resistance to inhibitors, and the ability to thrive at temperatures and pH levels compatible with enzyme activity (4, 5, 14, 19, 30). Table 5 lists some of these considerations.

43.5.1. Shake Flask Protocol

Successful fermentations depend on the inoculation of a sufficient number of healthy cells into a fermentation broth. This is achieved by growing the inoculum in an enriched seed medium before starting the fermentation. The fermentation itself can use either an enriched medium with the addition of cellulosic material (33, 50) or a minimal medium with the addition of particular carbohydrates. Antimicrobials and antifoaming agents may be added as deemed necessary. The preparation of a seed medium for shake flask evaluation proceeds as follows.

1. Ethanologens should be grown in an enriched medium such as YPD broth for yeast (usually 1% yeast extract, 2% peptone, and 2% dextrose) (18) and tryptic soy broth or RM broth (yeast extract, KH_2PO_4 , glucose, and other sugars) for bacteria. Cultures are incubated at an optimal temperature and agitation for the specific organisms.
2. Determine broth cell counts using a hemacytometer or automated cell counter, and determine cell mass by spectrophotometer. Adjust inocula so that all flasks have comparable cell counts or masses.

After the seed stage, fermentation tests proceed as outlined below.

1. Add the desired amount of cellulosic hydrolysate to YP broth (1% [wt/vol] yeast extract and 2% [wt/vol] peptone) or other medium with or without dextrose supplementation, depending upon the content of the cellulosic hydrolysate, in order to achieve a targeted broth concentration of dextrose.

2. Adjust the pH of the fermentation medium using ammonium hydroxide, potassium hydroxide, and calcium hydroxide or sodium hydroxide for an acid hydrolysate or sulfuric acid for an alkaline hydrolysate to a level which is acceptable to the chosen ethanologen and the required enzymes.
3. Add enzymes to hydrolyze any complex carbohydrates that have not been hydrolyzed by pretreatment protocols.
4. Inoculate enriched fermentation medium with the seed medium using comparable cell concentrations in each flask. Wash cells with sterile water several times before inoculation if the fermentation broth is a minimal medium.
5. Incubate flasks at the appropriate temperature and agitation. This agitation will be typically slower than that used when culturing the seeds because the intent now is to produce ethanol rather than cell mass.

During the fermentation, samples are taken daily and analyzed by HPLC or GC. One HPLC method employed by Agblevor et al. (3) analyzes sugars using an acetonitrile-water mixture as mobile phase, a column packed with a proprietary bonding material, and both a low-temperature evaporative light-scattering detector (ELSD-LT) and a refractive index detector. Figures 4 and 5 show chromatograms of standard sugar mixtures and a pretreated corn stover liquid fraction, respectively, analyzed by this method. Ethanol can be analyzed by centrifuging and filtering samples before injecting them into a GC system (50). The measurement of dry solids in the fermentation medium can be accomplished rapidly using a moisture balance set at 110°C. For these measurements, 1- to 2-g samples are

TABLE 5 Evaluation scheme for improved ethanologens for scale-up testing

Organism of choice is obtained by genetic engineering, mutagenesis, and selection or a combination of two using high-throughput screening approaches.
Single isolates or clones that meet a set of criteria that range from robustness, tolerance to hydrolysate, and fermentation of sugars of interest are further screened in shake flasks.
The most promising isolates or clones are evaluated further in bench-scale fermentors to better define process parameters for scale-up purposes.
The pool of single isolates or clones is then limited further to a small pool that can be tested in pilot plant fermentors.
A single isolate and/or clone that meets overall desirable process criteria is moved on to a production facility.

tared on the balance pan, the lid is closed, and measurement is made by pushing a start button and waiting several minutes until the reading stabilizes. An alternate method that provides greater accuracy uses an oven. In this method, preweighed and oven-dried disposable sample pans are used and the oven temperature is set in the range of 75 to 85°C. After determining the weight of the disposable sample pan containing a glass fiber pad, a sample is added and the weight is determined. The pan is placed in an oven until the weight of the dried sample remains unchanged. The pan is then removed from the oven and cooled in the desiccator. The weight of the pan and dried material is measured and dry solids are calculated as follows:

$$\left\{ 1 - \left[\frac{(\text{wet sample mass} - \text{dry sample mass})}{(\text{wet sample mass})} \right] \right\} \times 100$$

Dry solids are typically determined for fermentation medium at the outset and at the end of the fermentation. When using a pretreated feedstock that is high in suspended solids, total dry and soluble solids can be determined before and after enzyme hydrolysis. This is often done for material balance determinations.

43.5.2. Small-Scale Fermentor Protocols

Small-scale fermentation is carried out in fermentors varying in size from a few hundred milliliters to 6 liters. Small-scale fermentation is generally the next step in testing a strain or process conditions before testing at a pilot plant scale. Due to variances in agitation and aeration, difficulty in pH control in shake flasks, osmotic pressure, and nutrient distribution, in many cases strains perform differently in fermentation vessels than in shake flasks.

The goal in fermentation experiments in bench-scale vessels is similar to that in shake flasks. Fermentors are used to establish performance of selected strains on hydrolysate media without the limitations encountered in shake flasks. To accomplish this purpose, we test various media with different levels of hydrolysate to determine the performance of an ethanologen under difficult growth conditions in the presence of increasing levels of inhibitors. The following steps are usually followed.

1. Grow the organism in seed medium from a freezer vial lot representing plant media with a small percentage of hydrolysate for 18 to 21 h.
2. Measure seeds for optical density and viable cell count in order to inoculate the main fermentors to about 10^7 cells.
3. Prepare main media and add α -amylase if starch is present prior to heat sterilization in an autoclave.
4. Prior to inoculation, do the following.
 - a. Set target temperature for experiment in fermentors.
 - b. Set target pH (using the above-mentioned acids, preferably those used in the plant) in fermentors. Measure external pH to calibrate the pH probes in fermentors.
 - c. Set target agitation in fermentors.
5. Take initial sample before inoculation of fermentation media and add glucoamylase, cellulases, hemicellulases, and other enzymes; incubate overnight at the same fermentation temperature.
6. Inoculate the fermentors.
 - a. Start pH control to maintain set pH.
 - b. Start temperature control to maintain set temperature.
7. Add enzyme blend to fermentors.
8. Take a postinoculation sample to measure initial ethanol that is carried over from the seeds as well as to monitor sugar consumption.

9. Sample the fermentors at least every 12 h, if not more frequently.
 - a. Read external pH.
 - b. Read biochemical analyzer for dextrose.
 - c. Read Brix measurement. (Degrees Brix is a measurement of the dissolved sugar-to-water mass ratio of a liquid. It is measured with a refractometer.)
 - d. Spin down samples and freeze supernatant for analytical submission.
10. At 48 h, measure the final volume of the fermentation.
11. Submit all samples, including the seed samples and the initial uninoculated control sample, for the following analysis: ethanol, glycerol, acetic acid, lactic acid, glucose, xylose, arabinose, mannose, fructose, galactose, and any other sugars or inhibitors that are likely to be present in the media or fermented by the strain being tested.

43.6. FERMENTATION METHODS

Once the appropriate organism and feedstock are selected, the method of fermentation must be chosen. Lignocellulosic hydrolysate fermentation or bioconversion may be achieved by either solid-state or submerged-liquid fermentation (4, 19, 31).

Solid-state fermentation consists of the direct inoculation of dry hydrolysate cake or partially digested precipitate. This method holds tremendous potential for the production of enzymes and various other fermented products (60). Tray, packed-bed, fluidized-bed, and rotary-drum fermentors are common vehicles of solid-state fermentation.

Although there are economic advantages to the use of solid-state fermentation, e.g., the cost of water and extraction are minimized, process limitations in the current methods of solid-state fermentation may favor submerged-liquid-broth fermentation for hydrolysates. Due to the high solids of the cake and reduced surface area created by the tray and packed-bed methods of solid-state fermentation, microbial growth and bioconversion occur mainly on the substrate's surface. Aeration and homogenous distribution of pH, nutrients, moisture, and temperature may pose an obstacle to adequate fermentation (54).

Carbohydrates in hydrolysates may be metabolized using the four main forms of liquid fermentation: batch, fed-batch, semicontinuous, and continuous. Continuous fermentation can be carried out in a single reactor, also referred to as a chemostat reactor, as described by Brandberg et al. (14), or in a cascade mode as detailed below. Tolerance of ethanologens to inhibitory compounds in lignocellulosics can be improved by cell recycling (30, 45).

43.6.1. Batch Method

During batch fermentation, pretreated substrate/slurry and supplemental nutrients are combined in the initial media. Possible growth inhibitors formed during the pretreatment (acids, hydroxymethyl furfural, and furfural) may also be present at levels higher than during continuous fermentation. It may be necessary to increase cell inoculation dosages and adjust the pH when fermenting pretreated biomass using the batch method. The main advantage of the batch process is that cleaning of the equipment can be done after each fermentation; therefore, process vulnerability to yeast and enzyme contaminants is reduced. The main disadvantage is the increased downtime necessary to clean and sterilize fermentors.

43.6.2. Fed-Batch Method

The fed-batch method is similar initially to the batch method; however, pretreated solids/slurries and other nutrients are

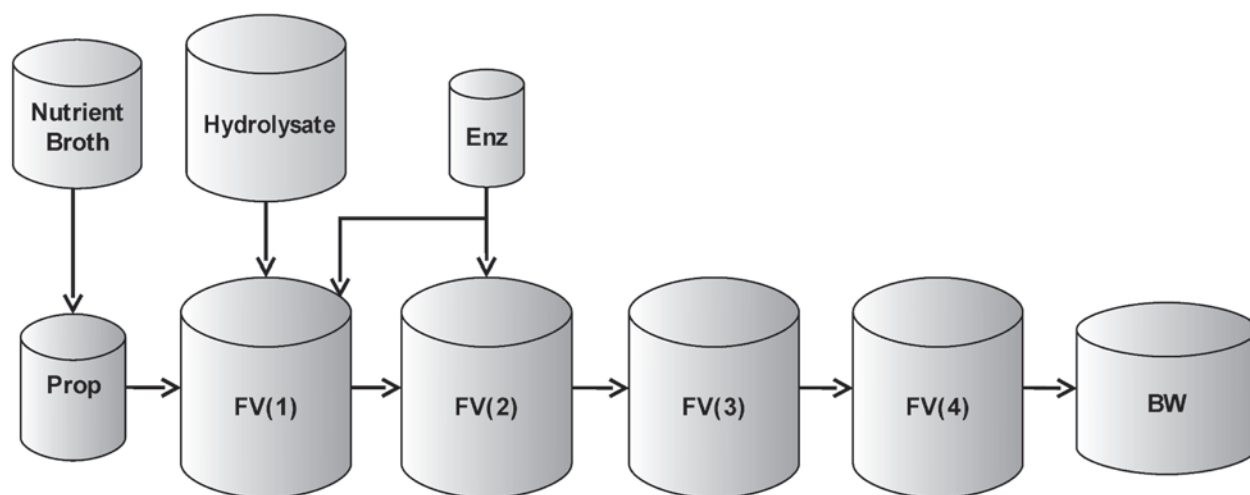

FIGURE 6 Cascade testing: illustration of a continuous setup for testing of ethanologens on a hydrolysate stream derived from a lignocellulosic. Prop, propagation; Enz, enzyme; BW, beer well; FV, fermentation vessel.

fed continually to prevent a plateau in the growth curve. The feed rate greatly influences cell viability. The pH must be adjusted based on the inclusion rate of the hydrolysate. An alkaline solution may be used to adjust the pH for acid hydrolysates or an acid solution for alkaline hydrolysates to a range of 3.5 to 7, depending on the fermentation organism.

43.6.3. Continuous-Cascade Method

Fermentation in the continuous-cascade configuration consists of a series of tanks (or flasks, depending on experimental scale) into which are pumped pretreated lignocellulose and nutrients at crucial stages in the fermentation process. An example of cascade design follows. The first tank typically serves as a propagator and is inoculated with the ethanologen culture being tested. Overflow from this tank is pumped into a second tank as illustrated in Fig. 6. The second tank is also fed hydrolysate and a blend of enzymes to aid in the gradual release of available sugars. The third tank receives overflow from the second tank as well as additional enzymes. The fourth tank holds overflow from the third tank. Surplus broth from the fourth is pumped to the fifth. Overflow from the fifth tank is pumped into the beer well and is recycled back to the propagator. If necessary, and in order to maintain a high cell viability count in the cascade, an overflow loop from the final collection tank (beer well) with supplemental nutrient solution can be fed to the propagator.

In the bench-scale experimental setup illustrated in Fig. 5, the temperature is controlled using a circulating water bath and the flow rate through the cascade is adjusted using peristaltic pumps calibrated for the residence time sought. Stir plates maintain medium to low agitation within each flask during bench-scale experiments to circulate the yeast and hydrolysate media. The main advantages to the cascade process are as follows.

- Less downtime for maximum use of equipment. Maximum heat load can be targeted to specific fermentors for cost savings.
- Easily scaled down to a bench-scale experiment in which variables such as flow rates, feeds, etc., are evaluated at a relatively low cost (relative to production scale).

The primary disadvantages are as follows.

- Cleaning the equipment may be problematic.
- The system is vulnerable to shifts in external temperature.
- More vigilance is required by operators to monitor potential problems in the system.
- The system is highly vulnerable to yeast and enzyme contaminants.

43.6.4. Semicontinuous-Cascade Method

Semicontinuous fermentation is similar to continuous-cascade fermentation; however, a fraction of the culture is replaced with fresh medium at regular intervals (69). The greatest disadvantage is the removal of cells when culture is replaced with medium.

43.6.5. Other Specific Considerations

- Stover hydrolysate exhibits properties of a non-Newtonian fluid; this should be considered when selecting tubing and pump methods.
- Fermentation vessels (flasks, tubing, etc.) should possess resistance to chemical erosion due to content of the hydrolysate.
- The optimal hydrolysate concentration is dependent on the organism's tolerance of inhibitors.

43.7. CONCLUDING REMARKS

In the past decade, significant advances have been made in the pretreatment and hydrolysis of a wide range of lignocellulosic feedstocks. Development of improved biocatalysts (enzymes and ethanologens) and the pace of discovery of new ones have also increased. When combined with improvements in design and engineering of processing facilities, these advances have set the stage for the construction of pilot- and demonstration-scale plants to validate this new technology. Beyond these developments, significant reduction in processing costs must be made to ensure that the cost of producing cellulosic ethanol is competitive with that of bioethanol produced from conventional feedstocks such as corn, sweet sugar beets, and sugarcane. Improving

the logistics and sourcing of lignocellulosic supplies is still necessary for future large-scale production and expansion of this emerging industry.

Surface Microbiology of Cellulolytic Bacteria

ALEXANDRU DUMITRACHE, GIDEON M. WOLFAARDT, AND LEE R. LYND

44

44.1. INTRODUCTION

Cell-enzyme-substrate interactions may be major determinants for the efficiency of cellulose hydrolysis during biomass conversion. These associations, where the substratum serves as the attachment support and carbon source for the cells as well as the substrate for saccharolytic enzymes, differs substantially from those in biofilms typically studied on inert interfaces. While the microbiology associated with bioprocess technology traditionally focused on suspended populations, there is evidence that biofilms may be central elements of cellulolytic microorganisms' life cycles. Delineating the underlying fundamentals of such biofilms should advance bioconversion technology and specifically contribute to realizing the potential of cellulosic biomass as a feedstock for renewable fuel production. In this chapter, biofilm structure and cell behavior in fully hydrated, undisturbed biofilms of *Clostridium thermocellum* are considered as a means to study biofilm formation by these anaerobic thermophiles.

44.2. CELLULOSE CONVERSION FROM A BIOFILM PERSPECTIVE: A NEW FRONTIER

44.2.1. The Biofilm Mode of Microbial Existence

Bacteria are often studied in a planktonic mode as suspended cells growing in a liquid culture; however, in most natural environments, up to 95% of bacteria are present in surface-associated biofilms (38). Sessile bacteria thrive in multicellular communities associated with phase interfaces, which convey advantages over the planktonic life form, most notably protection against environmental factors such as extreme conditions, host immune response, predation, and antimicrobial stress. The classical biofilm is a microbial assemblage of adherent cells, situated (most commonly) at a liquid-solid interface and encased within a matrix of extracellular polymeric material. It may be noted that this definition is applicable to microbial aggregates and flocules (7). Biofilm translocation to new niches is generally understood to occur when cells become planktonic and then recolonize new interfaces or, in the case of some flagellated bacteria, by a massive coordinated group behavior called swarming motility (54). Other surface-associated methods of translocation have been described (16). Taken to the extreme, the planktonic mode of bacterial life can therefore be viewed as

primary mechanisms of cell translocation from one surface to another (55); however, from a holistic perspective, both biofilm and planktonic phenotypes are seen as integrated components of the prokaryotic lifestyle (51). Many studies suggest that the profiles of gene transcription are significantly different for adhered and nonadhered cells (45) and that cell-to-cell signaling is a required condition for biofilm formation (9, 46).

44.2.2. Cell-Cellulose Interactions in Nature

Close associations between cellulolytic organisms and their substrates have been reported in the literature. For example, a survey of 13 cellulolytic and 10 noncellulolytic strains of *Ruminococcus albus* showed that most cellulolytic strains bind to the substrate, whereas most noncellulolytic strains do not; however, the extent of bacterial adhesion was not well correlated with culture cellulolytic activity (36). Recent evidence demonstrates the strong correlation between first-order hydrolysis rates of cellulose with the concentration of sessile bacteria rather than with the concentration of total or planktonic biomass after inoculation with enriched leachate and rumen fluid (20).

In the case of *C. thermocellum*, cellulolytic enzyme complexes, defined as cellulosomes, were found to form large clusters embedded in the cell surface layer, appearing as protuberances in electron micrographs. Mutants isolated based on their inability to bind cellulose were found to lack such protuberances of cell-bound cellulosomes and to display reduced cellulose hydrolysis rates (1–3). Further study led to a comprehensive description of the macromolecular cellulosome architecture. A key feature of this architecture is a noncellulolytic scaffoldin protein including a cellulose-binding domain, dockerin domains to which catalytic components bind, and a type II cohesin region that mediates binding to the cell surface (4). Other investigations using electron microscopy revealed that such cell surface "protuberances" are present on the surfaces of a variety of cellulolytic bacteria (gram positive or negative, thermophilic or mesophilic, and aerobic or anaerobic) but are not found in noncellulolytic bacteria or on cellulolytic bacteria grown under conditions that are known to repress cellulase synthesis (17, 25).

Rumen bacteria are known to strongly attach to grass particles and model cellulosic substrates. Electron micrographs of the cellulolytic rumen bacterium *Fibrobacter*

succinogenes show tight adherence to the cellulose fibers, with erosion of the substrate visible beneath the cells (12). Glycosylated residues of cellulose-binding proteins, some of which have endoglucanase activity, isolated from the cell envelope of *Fibrobacter intestinalis* DR7 were suggested to have an important role in the adhesion of cells to cellulose (35), and electron micrographs of adherent *Ruminococcus flavefaciens* cells have shown the presence of a discernible exopolysaccharide (EPS) matrix, presumably responsible for nonspecific adhesion (24). A glycocalyx, thought to be responsible for substrate adherence through its constitutive polymeric elements, has also been identified in the anaerobic cellulolytic *R. albus* 7. Variable-pressure scanning electron microscopy revealed the formation of thin cellular extensions that mediate substrate attachment, followed by the development of a ramifying network that connects individual cells to one another (56). Additionally, in the gram-positive strain *R. albus* 8, a novel type of cellulose-binding protein (CbcC) belonging to the Pil protein family has been isolated with similarity to the type 4 fimbrial proteins of gram-negative pathogens. *R. albus* 8 was found to employ a fimbria-mediated attachment to cellulose (37).

Adhesion to the substrate and the formation of a cellulose-enzyme-microbe ternary complex has been suggested to provide a series of advantages to the cellulolytic organism, which include enzyme concentration at the cellulose surface, fast sequestration of oligomeric hydrolysis products, protection from predation (grazing protozoa) or bacteriophage attack, and, in the case of ruminal bacteria, protection from rumen proteases (30). The benefits seem to outweigh the extra energy demand for the biosynthesis of glycocalyx precursors and of cellulose binding factors, which, for example, in the case of the nonprotein fraction of EPS, has been shown to represent $\leq 4\%$ of the total anabolic ATP expenditure of *C. thermocellum* (56).

Overall, substrate adherence by anaerobic cellulolytic species is primarily attributed to (i) the cellulase complex (cellulosome) through the carbohydrate binding module, (ii) the glycosylated moieties of catalytic or noncatalytic cellulose-binding proteins in the cell envelope, (iii) the carbohydrate epitopes of the bacterial glycocalyx, and (iv) fimbriae or other proteinaceous appendages. The actual strategies employed by individual species may be a combination of the above mechanisms, as suggested for adherent rumen cellulolytic bacteria (34); however, further research is needed to extend this knowledge to other naturally occurring anaerobic bacteria.

44.3. CONCEPTUAL AND POTENTIAL METHODOLOGICAL OVERLAP BETWEEN BIOFILM RESEARCH AND BIOMASS PROCESSING

44.3.1. Tools for Discovery and Current State of Biofilm Research

Modern biofilm research has relied primarily on a few major approaches: genetic screening of mutants (22, 23), the application of confocal laser scanning microscopy in conjunction with fluorescent molecular probes and digital image analysis (26, 33), and, to a lesser extent, biophysical studies that measure adhesion kinetics and cohesive strength (e.g., the quartz crystal microbalance technique, atomic force microscopy, or optical tweezers) (42). Other approaches with demonstrated or suggested utility for biofilm research include measurement of biofilm respiratory activity (50); quantification of cell mass and numbers

(19); and biochemical, spectroscopic, and chromatographic analyses of cells and EPS composition and structure (47).

Biofilm formation has been proposed as a model system for the study of microbial development. Reviewing a large number of studies from the preceding 10 years, O'Toole et al. (41) concluded that biofilms are a stable point in a biological cycle that includes initiation, maturation, maintenance, and dissolution and that most microorganisms appear to be able to make the transition to a surface-associated life, regardless of their physiological capabilities. The number of biofilm-related studies has indeed grown at an impressive rate during the last two decades in diverse fields such as medical, natural, and engineered systems. A recent keyword search revealed that the number of articles published in the scientific literature containing the term "biofilm" in the abstract steadily increased from less than 200 per year in 1993 to more than 2,000 per year in 2008. Research that started as primarily microscopic observations of attached cells now involves a range of tools and techniques to analyze spatial relationships, gene expression, and metabolic activity, and as a result, the structure-function relationships of biofilms are increasingly better understood.

The same is not true for cellulolytic biofilm research, for which there are only a few reports that describe the role of biofilms in cellulose hydrolysis, and among those, the focus is primarily on natural processes and degradation of cellulose-based waste. Adhesion by *C. cellulolyticum* to cellulose in order to overcome carbon starvation was addressed by Gehin et al. (13), who demonstrated higher levels of adhesion by cells in the exponential growth phase than those in the stationary phase. They further suggested that spores may play a role in increased adhesion towards the late stationary phase. The positive correlation between cell activity and adhesion to cellulose in the exponential growth phase suggests that biofilm formation facilitates cellulose degradation, which is in line with the phenomenon of enzyme-microbe synergy described by Lu et al. (28). In the latter, the effectiveness of a cellulase system is significantly enhanced when it functions as part of a cellulose-enzyme-microbe complex. Rotter et al. (48) developed a model to evaluate the importance of parameters and processes in the modeling of cellulose degradation. Although this model focused on landfill and anaerobic digesters, their assumptions and conclusions may be relevant to cellulolytic processes in general. The authors' major concern with the most commonly used approaches for modeling cellulose-utilizing bacteria is that hydrolysis is typically described as a zero- or first-order reaction that is independent of the planktonic biomass, implying that the impact of bacterial growth is negligible and that enzyme-producing cells are in excess. It is argued that these assumptions represent an oversimplification, as there is no concrete evidence that the cellulolytic cells indeed have direct access to cellulose particles. Furthermore, referencing Schwarz (49) and Lynd et al. (30), the authors indicated that cell-enzyme-cellulose binding may indeed be essential for the microbially mediated cellulose hydrolysis process to proceed. Although subsequent models incorporated cell-cellulose binding, the authors indicated that these models do not take spatial separation between bacterial cells and cellulose into account, nor do they consider interaction between the attached and suspended populations. In response to these potential shortfalls, the model developed by Rotter et al. (48) incorporates the potential for colonization of the cellulose substrate by suspended bacteria, which then become the primary agent of hydrolysis, including controlling the rate of hydrolysis. At this point it should be emphasized

that this model focuses on landfill and anaerobic digesters, thus with an ultimate goal of complete hydrolysis of biomass to simple products such as CO₂ and CH₄, mediated by complex microbial communities with a high degree of cooperation, cometabolism, and often competition, which is in contrast to bioprocesses where biomass conversion is perceived through the activity of single species, native or engineered, or potentially through synergy of well-defined microbial consortia, in some cases supplemented with selected hydrolytic enzymes. It therefore remains to be determined to what degree models that are based on biofilm characteristics generally attributed to degradative microbial communities can account for or predict cellulose degradation by *C. thermocellum* and other cellulolytic strains with industrial potential—the need for cooperation and sequential degradation that is typically described for the biofilm mode of existence may not be relevant for cellulolytic organisms where it appears that specialized species have evolved independently to overcome the challenge of growth on a single refractory polymer.

McAllister et al. (31) summarized findings by various groups that showed distinct populations in the rumen ecosystem: the nonattached organisms in the ruminal fluid and two subpopulations attached loosely (can be removed by gentle washing) and firmly to feed particles. While these attached subpopulations accounted for 70 to 80% of the microbial matter in the rumen, and were responsible for up to 80% of endoglucanase, 70% of amylase, and 75% of the protease activity in the rumen, the subpopulation associated with the ruminal fluid was linked with the important role of colonizing newly ingested feed particles. The demonstration that hemicellulase and cellulase activities were notably higher in the particulate fraction of ruminal contents than in the fluid suggested that biofilm populations are responsible for the majority of feed digestion in the rumen.

A study of the colonization potential of naturally occurring, mixed species in the anaerobic layers of a landfill site made use of an adapted aerobic flow cell to promote strict anaerobic conditions (21). The culture chamber, designated as an anaerobic continuous-culture microscopy unit, was a miniature, self-sealing, oxygen-impermeable, transparent reactor that could be fit on a microscope stage. The investigators used inocula of enriched collections from the anaerobic layers of a landfill site, which were injected at the outflow port of the flow chamber to avoid passive transport of organisms by the media flow and to ensure that any observed attachment upstream was due to some active motility or transposition event. The colonization process on biodegradable and nonbiodegradable materials was monitored over time by capturing phase-contrast micrographs and calculating the rate at which the biofilm front advanced. Fluorescence microscopy and the natural coenzyme F₄₂₀ autofluorescence were used to track and quantify the localization of methanogenic bacteria. It was found that wood, cotton, and polyester fabric remained poorly colonized or not colonized after weeks of incubations, whereas the nonbiodegradable glass, plastic, and polyethane were readily and heavily colonized. However, the study acknowledged that enrichment for butyrate- and hexanoate-degrading methanogens could have excluded cellulolytic organisms from the flow cell inocula, which could explain the lack of cellulose colonization.

The use of flow cells to grow pure cultures of the oral bacterium *Porphyromonas gingivalis* under anaerobic and microaerophilic conditions was described by Hansen et al. (15). Their findings show poor biofilm formation after 18 h

of growth under low oxygen concentrations (1 to 2 ppm) and improved growth in anaerobic culturing. To ensure anaerobic culture conditions, an inflatable glove chamber was used to isolate the medium flask (kept under continuous N:CO₂ sparging) and the flow cell from the normal atmosphere environment. Biofilm formation was visualized with fluorescence tagging and confocal laser microscopy. Their extensive literature review revealed that relatively few attempts have been made to grow anaerobic biofilms, with little evidence that the most commonly used anaerobic chemostat technology had been extended to obtain in situ observations.

A recent study in which microbial attachment and cellulose degradation in leachate and rumen systems were evaluated in situ and in real time acknowledges the potential and utility of using flow cell concepts in the study of anaerobic biofilms (39). In their system, a flow cell, which contained immobilized cellulose fibers on the underside of the glass coverslips, was connected to an anaerobic medium flask (containing crystalline cellulose) in a closed loop so that its content was continuously recirculated through the flow chamber. The medium flask was inoculated with rumen fluid or anaerobic leachate from a municipal solid-waste digester and during the incubation the extent of cellulose solubilization was estimated by nitrogen/chemical oxygen demand balance. Concurrently, phase-contrast microscopy was used to estimate the extent of biofilm formation at the cellulose interface inside the flow cell. The study aimed to correlate the imaging of cellulolytic biofilms with process performance data in real time, and the results suggested that the rumen culture formed thicker and more stable biofilms than the inoculum from digester leachate, which were consistent with the higher rates of cellulose solubilization in the rumen reactors. It was also acknowledged that the presence of multilayer biofilms could be partly due to the interactions between the species within the microbial consortia and that close interactions between bacteria and cellulose particles are required for efficient cellulose degradation.

44.3.2. Biofilm Equilibrium: Reactive Versus Inert Attachment Substrates

Studies on biofilms have overwhelmingly focused on the association of cells with inert surfaces, where the nutrients are obtained from the bulk liquid phase (thus supply to the basal biofilm layers, i.e., at the biofilm attachment interface, is diffusion dependent). This model is representative for engineered systems such as industrial bioreactors for the treatment of waste effluents, natural systems such as biofilm deposits on a riverbed, or biofilms with relevance to medical applications such as those developing on implants and prosthetics. Biofilms on inert surfaces typically have multiple layers of cells, and their form and function are dependent on the large variability in concentration and bioavailability of nutrients (29). It is generally expected that the nature of the attachment substrate, whether it is biotic or abiotic—reactive or inert—has an impact on biofilm form and function, and therefore on the overall metabolic activity of the associated microbial communities. However, there is a paucity of comparative analyses between bacterial colonization of inert and reactive surfaces, with a few studies suggesting an overlap between the mechanisms contributing to biofilm formation at these interfaces. For instance, studies of the mutualistic interaction between plant roots and *Pseudomonas putida* showed the presence of genetic determinants that similarly influence adhesion on plant surfaces and inert abiotic material (58). Insertional mutations

affecting flagellar genes or the large adhesin LapA decreased adhesion to corn seeds as well as abiotic surfaces. In contrast, a mutant of the cytochrome oxidase assembly has deficient bacterium-plant interactions only, while a lipopolysaccharide biosynthesis-impaired phenotype presents reduced adhesion in the rhizosphere but initiates attachment to plastic faster than the wild type. These examples suggest that bacterial adaptation to the sessile state can be dependent on the physicochemical properties of the attachment interface and be governed by surface-specific or global molecular mechanisms. Microbially influenced corrosion represents a good example of biofilm formation at a reactive interface where sulfate-reducing bacteria have been shown to play a primary role in anaerobic environments by metabolically producing sulfide ions to form sulfide iron deposits and by secreting hydrogenase enzymes that adsorb on steel surfaces. These elements are responsible for the catalysis of cathodic proton reduction, which is generally understood as microbial corrosion (6, 8). Recently, corrosion induced by direct microbe-cathode interactions has been linked to *Geobacter sulfurreducens*, which, when grown in a medium with low electron donor concentrations, was found to interact directly with the attachment surface by extracting electrons required for its metabolism from the cathode through membrane-bound redox compounds (32). Other organisms, termed electricigens, are well known for their potential to oxidize organic matter and to transfer the electrons produced directly to solid electrodes (27).

Cellulolytic organisms occupy a special niche where (the primarily) insoluble cellulose serves both as the carbon source and as biofilm solid support, theoretically providing optimal conditions for biomass accumulation with preferential access to the primary substrate. It can be expected that continuous-flow cultures of planktonic cellulolytic cells would have reduced hydrolysis with lower retention rates which are inversely proportional to cell and substrate dilution. Bacterial populations attached to inert surfaces that hydrolyze the cellulosic substrate at distance would suffer from hydrolytic end product loss by dilution. Attachment to and proliferation at the cellulosic source are thought to be beneficial due to reduced microbial biomass loss and the potential capture of the enzymatic hydrolysis products. In *C. thermocellum*, polycellulosomal structures have been demonstrated to exist at the cell surface, forming multiple protuberances (2). Electron micrographs of antibody-labeled cells adherent to cellulose indicated that the protuberances undergo structural conformations to form fibrous contact corridors connecting the cell and the substrate at distances of more than 500 nm (this being, to our knowledge, the only reference of measured cell-substrate gap in the literature). These protracted protuberances were proposed to assist in channeling the products of cellulose hydrolysis to the cell to be taken up via the appropriate transport mechanisms (4), potentially providing a competitive advantage for the adherent bacterial cells.

44.3.3. Microbial Dynamics: Cooperation Versus Competition

In evolutionary ecology, Darwin's concept of selection is applied to individual species. However, within a community, the biological complexity at the different levels of organization pose notable challenges to selection theory. Caldwell et al. (5) proposed that communities are considered as units of proliferation (hence units of evolution) to offer alternative or additional community-level testable hypotheses. They introduced a proliferation hypothesis as an evolutionary

model, which recognized the possibility of simultaneous propagation and reproductive success at different levels of organization (e.g., genes, cells, communities, and ecosystems) rather than at the level of individual organisms. In line with classical evolution, this theory involves the assumption that organisms are more successful by adapting through genetic mutation and recombination. However, it also assumes that adaptation is enhanced by association and copropagation; i.e., self-replicating molecules associated as macromolecules, macromolecules as prokaryotic cells, eukaryotic and prokaryotic cells as communities through behavioral changes, or communities propagated more efficiently as a result of association to form ecosystems. The symbiotic relations in the microbial consortium of the rumen ecosystems are exemplary for the evolutionary success with adaptation at multiple levels of organization. The rate of fiber digestion in the rumen content, rich in organic matter at pH 5.5 to 6.9 with low redox potential, is affected by many factors which include the nature of the species of anaerobic and facultative anaerobic organisms and their degree of adaptation to the diet.

In line with the proliferation theory described above, species which carry traits unnecessary for their survival in isolation, but beneficial for a consortium, are considered an evolutionary success for reproduction. Here the focus is not solely at the organismal level, as implied by the selection theory, but rather at the community level. For example, in the case of *C. thermocellum*, the enzymatic subunits of the cellulosome are complex proteins containing one or more catalytic domains in the form of glycosyl hydrolases, which include cellulases, hemicellulases (xylanase, mannanase, chitinase, and lichenase), and carbohydrate esterases (4). The hydrolytic products of hemicellulolytic activity are not utilized by *C. thermocellum* and thus suggest that these enzymes' function may be to facilitate a better exposure of cellulose in the complex cell wall, or that these cellulosomal elements are the coevolutionary result of the symbiotic interaction in mixed cellulolytic communities. These examples demonstrate the complex nature of microbial interactions. This complexity poses numerous challenges to bioprocessing aimed at cellulose conversion but at the same time offers a broad range of possibilities. Realization of this potential will depend on the development of strategies that will make it possible to manipulate microbial cell-enzyme-substrate interactions; studying these processes from a biofilm perspective may be an important first step towards this goal.

44.4. BIOFILM FORMATION BY *C. THERMOCELLUM*

44.4.1. Experimental System

While studies on microbial cellulose degradation are numerous, the principal approach to understanding organism behavior and cellulose colonization has been by direct visualization, in which slurry samples are collected from fermentation reactors and subjected to light and fluorescence microscopy, fluorescence in situ hybridization, and electron microscopy (4, 40, 52), or indirectly by molecular and biochemical probing of batch cultures (14). Arguably, these methods have a destructive nature associated with sample preparation and can skew the associated observations on the complexity of adherent structures. A major limitation remains the lack of detail about colonization patterns or spatial relationships. The use of flow cells involves in situ observation of biofilms that can be made in real time under flow conditions. The flow chamber allows the growth of microbial biofilms on solid

surfaces under controlled conditions and their microscopic visualization through a transparent window under fully hydrated conditions and in a nondestructive manner, with the possibility of repeated observation over long cultivation periods and the extrapolation of behavioral changes (44).

We have successfully used flow cells (57) with modified chamber design (Fig. 1) to study associative behavior during microbial cellulose utilization by *C. thermocellum*. For this purpose, solid cellulose (cotton fibers) was immobilized inside flow chambers and served as the single, insoluble source of cellulosic carbon for the bacteria. Continuous-flow experiments were carried out under an N_2 atmosphere and under a normal oxygen atmosphere. Growth in flow cells kept under a nitrogen atmosphere was possible with the use of an anaerobic cabinet equipped with an incubator and was suited for experiments where occasional observation and evaluation were desired or where sample collection and flow cell analysis over time were not limited by the confined chamber space. The continuous-flow system was composed of a vessel containing RM medium (43, 53), silicone tubing, a flow cell, a peristaltic pump, and an effluent waste container. The complex synthetic RM medium, lacking Avicel, was prepared by a modified Hungate technique (18) and stored for up to 48 h to allow the photocatalytic reduction of oxygen by L-cysteine HCl. Exposure of media to a higher light intensity (11) hastened the reduction time. The tubing system and the flow chamber were sterilized by pumping a 10% sodium

hypochlorite solution at approximately 40 ml/h for 30 to 60 min and was then washed out with sterile distilled water overnight at 10 ml/h. Sterile medium was pumped in at 40 ml/h for approximately 2 h with the flow chamber kept in the incubator at 60°C. Cultures of *C. thermocellum* were transferred (10 to 30% [vol/vol] inocula) into the flow chamber via sterile syringes and needles, and the medium was kept stationary for 60 min to allow potential cell-surface interactions to occur. Thereafter, flow was initiated and maintained at constant rates for the duration of the experiments at 10 ml/h. The cultures were examined at various stages of growth ranging from 24 to 120 h for microscopic investigations. Sample preparation and staining procedures are detailed below.

Growth of *C. thermocellum* in flow cells maintained outside of an anaerobic chamber was possible with the use of a modified continuous-flow system design (Fig. 2) and was suited for experiments where sample collection and repeated flow cell measurements required the use of devices not fitted for an anaerobic chamber (e.g., real-time microscopy, CO_2 measurement, and flow cytometry). Under ambient atmosphere, the system described above was modified to accommodate an oxygen-free medium source in a unidirectional flow system and a set of sample collection devices on the effluent side. External ports were protected with 0.2- μ m-pore-size filters to ensure sterility (not shown in Fig. 2), and the silicone tubing was replaced with Norprene because of its much lower gas permeability.

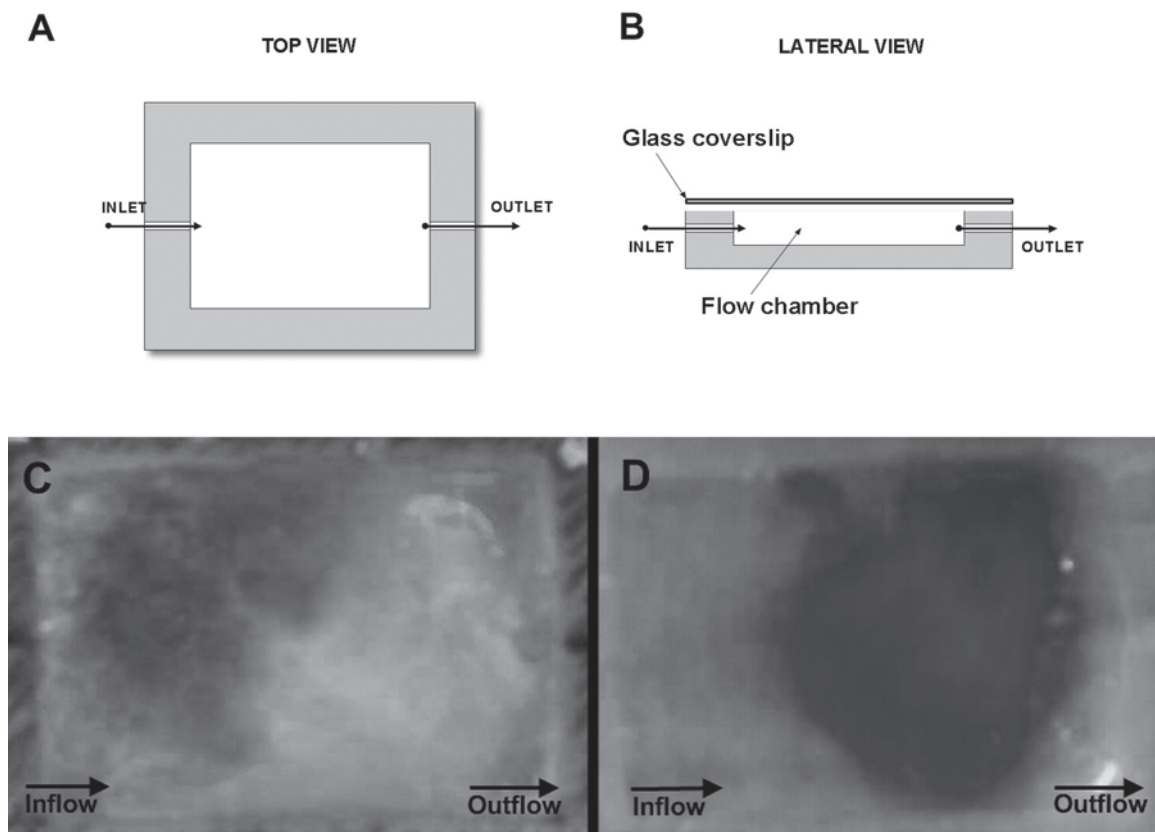

FIGURE 1 Schematic flow cell design showing top view (A) and lateral view (B) and typical *C. thermocellum* continuous-flow culture growth within flow cells showing the initial growth (dark areas) pattern around the inoculation site (C) with subsequent spreading to uncolonized regions and the depletion of its only cellulosic carbon source, which serves as the attachment substratum (D).

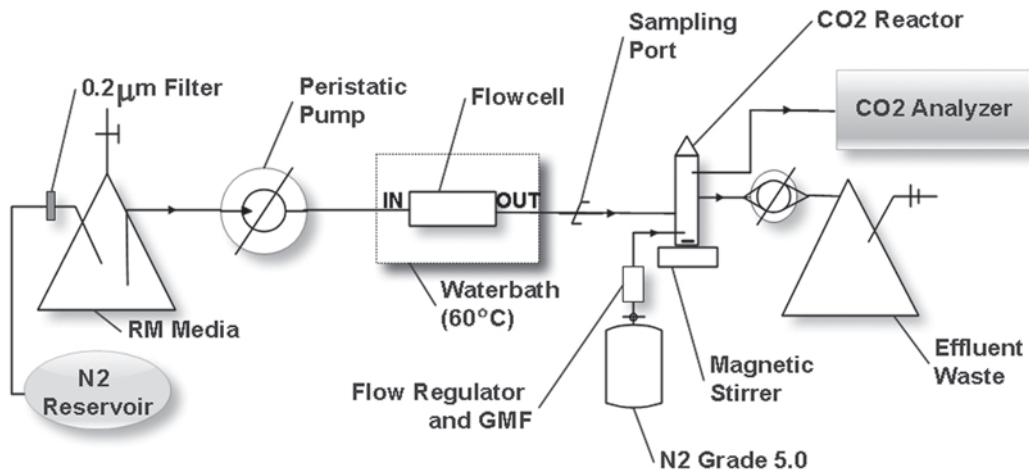

FIGURE 2 Schematic diagram of a continuous-flow system used under normal atmosphere for growth of anaerobic, thermophilic *C. thermocellum* cultures. A sampling port allows the aseptic collection of liquid effluent samples, and a “CO₂ exchange reactor” purged with N₂ gas and coupled to an infrared analyzer allows real-time measurements of dissolved CO₂ in the effluent. GMF, gas mass flowmeter.

Continuous-flow cultures of *C. thermocellum* were analyzed in situ with the confocal laser scanning microscope by fitting the flow cell directly onto the microscope stage. Stain (fluorescent probe) stocks and the working solutions derived from them were prepared with ultrapure sterile deionized water as detailed in Table 1.

For the preparation of culture samples, volumes of stain working solutions were transferred very slowly via needles directly into the flow cell while the medium flow was halted.

The amount of stain injected was dependent on the flow chamber size. The working solutions were tested across the range of concentrations provided in Table 1, but typically a middle-range value was used. All the stains were tested separately and in combinations of two or more. A typical combination of two consisted of a nucleic acid stain supplemented with a secondary stain targeted against carbohydrates or lipids. Noninvasive imaging of the undisturbed anaerobic cultures was performed through the thin glass coverslip of the

TABLE 1 List of stain stocks and working volumes used on continuous-flow cultures of *C. thermocellum* in confocal laser scanning microscopy^a

Stain ^b	Stock concn	Working solution (μl/1 ml H ₂ O)	Target(s)
Syto9	3.34 mM	2–5	Nucleic acids
Propidium iodide	20 mM	2	Nucleic acids
FM 1-43	1 mg/ml	4–20	Cell membrane (outer leaflet)
FM 4-64	2 mg/ml	4–20	Cell membrane (outer leaflet)
Conjugated lectins	1 mg/ml	4–20	
ConA-FITC + TRITC			α-Glucose and α-mannose
PSA-FITC			α-Mannose
DBA-FITC			N-Acetylgalactosamine
PNA-FITC			Galactose
UEA-FITC			Fucose
LEA-FITC			N-Acetylglucosamine
WGA-TRITC	5 mg/ml	1–4	N-Acetylglucosamine
Acridine orange	0.25 mg/ml	10	Nucleic acids
Ethidium bromide	10 mg/ml	2–10	Nucleic acids
Nile red	1 mg/ml	100	Intracellular lipids

^aFinal volumes of the working solutions are represented as the solvent volume.

^bAbbreviations: ConA, concanavalin A; FITC, fluorescein isothiocyanate; PSA, *Pisum sativum* agglutinin; DBA, *Dolichos biflorus* agglutinin; PNA, peanut agglutinin; UEA, *Ulex europaeus* agglutinin; LEA, *Lycopersicon esculentum* agglutinin; WGA, wheat germ agglutinin.

FIGURE 3 Confocal laser scanning micrographs of *C. thermocellum* biofilms growing on solid cellulosic substratum. Attachment to abiotic surfaces was recorded when the solid cellulosic support had been considerably depleted. Cells were stained with Syto9, and cellulose was stained with wheat germ agglutinin-TRITC.

flow cell. The optical properties of the objectives and the glass cover thickness determined the vertical working distance within the chamber. The confocal microscopy optical slicing feature along the z axis allowed the postacquisition reconstruction of orthographic projections of the scanned fields and high-resolution three-dimensional volume rendering.

44.4.2. Cell Organization

Growth in flow chambers was found to begin at the site of inoculation and then progressively spread and colonize the available adjacent cellulosic surface areas, with concomitant depletion of the solid substratum. Biofilms were observed at various degrees of cellulose colonization, from scattered cell groups to regions with very high cell densities, covering the entire surface area of the fibers. Occasionally, attachment to inert glass surfaces was recorded in late growth stages, primarily around substrate depletion zones (Fig. 3).

Typical *C. thermocellum* biofilm morphology was characterized by accumulation of terminal endospore and rod-shaped vegetative cells at the cellulose surface forming a single layer of cells with various degrees of density and with multiple cell orientations. Cells with terminal endospores invariably exhibited an end-on attachment with spores away from the cellulose surface (Fig. 4), and vegetative cells during division appeared to have a parallel orientation to the substrate. Cells divided along their longitudinal axis while attached, thus forming the typical long chains of cells described in previous work (10), which were also encountered in the flow cell effluent. Each individual cell appeared to be in close proximity to the cellulosic interface, as shown in the orthographic projections along the xz and yz planes. A typical biofilm matrix (consisting of multiple cell layers and an extensive EPS matrix) was absent. Notably, cell yield to the suspended phase (typically $\geq 10^5$ cells/ml after 24 h) occurred soon after initial attachment and persisted through all stages of biofilm development.

FIGURE 4 Confocal laser scanning micrograph of *C. thermocellum* cells colonizing a cellulose substrate (fiber) showing spores (arrows) with distinct end-on attachment on the non-sporulating side. Cells were stained with Syto9, and cellulose was stained with wheat germ agglutinin-TRITC. The circles indicate dividing cells with parallel orientation to the attachment interface. Objective, 63×1.2 water immersion.

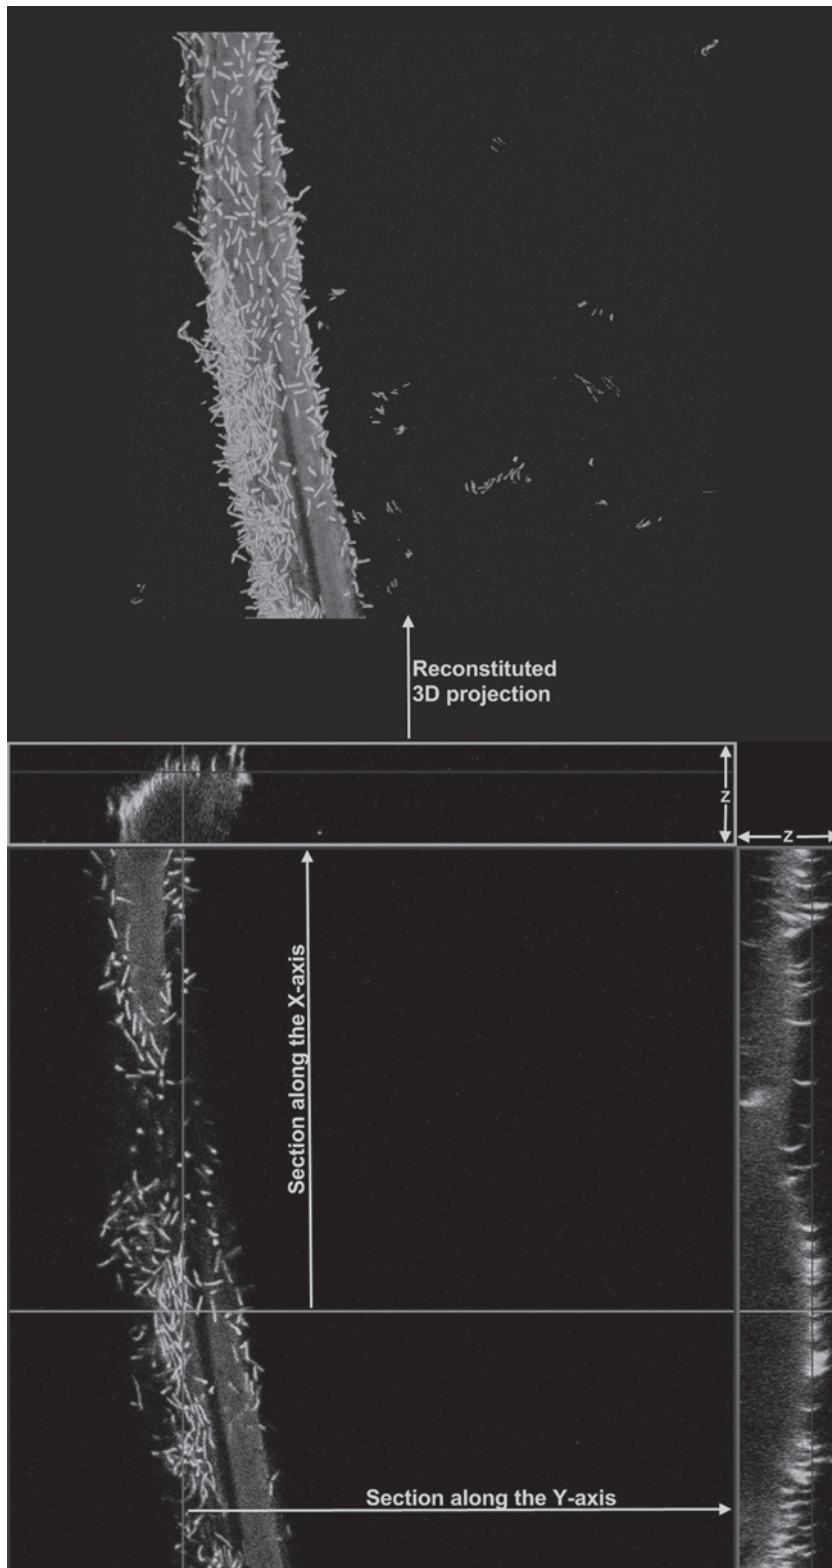

FIGURE 5 Confocal laser scanning micrograph of *C. thermocellum* biofilm developing on a cellulose fiber, seen from the top-down view of a three-dimensional projection (top); sectioning through the projection along the x and y axes in the z plane (bottom) revealed the distance between cells and substrate, which was recorded to be lower than the $0.44\text{-}\mu\text{m}$ z -scaling limit of the scanning microscope. Cells were stained with Syto9, and cellulose was stained with wheat germ agglutinin-TRITC.

44.4.3. Form-Function Relationship

In situ microscopic imaging of fully hydrated cultures of *C. thermocellum* growing on cellulose revealed biofilm clusters where each cellulose fiber was colonized with various degrees of cell density and distribution. Each flow cell thus hosts independent biofilms in different stages of development. Confocal laser scanning and postacquisition image analysis allowed us to observe development over time to obtain a better understanding of biofilm formation by *C. thermocellum*: following initial attachment, cells divide along the longitudinal axis, thereby increasing the biofilm cell density laterally but not orthogonally relative to the surface. It further appeared that biofilm development was coupled with the continuous recruitment of cells from the planktonic mode. The fact that adherent cells were always visualized in monolayers, with various orientations to the attachment substratum, supports the idea that the cellulolytic organisms benefit from a close proximity to the cellulosic source for efficient substrate utilization, as opposed to the acquisition of diffuse hydrolysis products from the bulk liquid phase (or the leaching of hydrolytic products from enzymatic cellulolysis). Invariably, cellulose colonization progresses from localized patches of adherent cells to the complete coverage of the entire surface area. Many of the cells during the initial stages of colonization have spores, suggesting that these cells might be involved in biofilm translocation to uncolonized regions and that sporulation may be regulated by surface conditions or by cell-to-cell interactions in the biofilm layer. Carbohydrate- and protein-targeted staining in continuous-flow biofilms failed to reveal a typical EPS matrix interconnecting the adherent cells. However, tetramethyl rhodamine isocyanate (TRITC)-conjugated concanavalin A, with primary sugar specificity for α -glucose and α -mannose, did bind to the outer regions of biofilm cells, which suggests the presence of a glycocalyx. Previous electron microscopy findings suggest the existence of protracted polycellulosome protuberances at the surface of the adherent cells, mediating the contact between cellulose and the microbe (2). We propose that a glycocalyx layer is also involved in the cell-substrate interaction, as evidenced by observations of microbe adherence to inert surfaces in regions where cellulose was believed to have been in contact with the inert interface. Attachment to inert material suggests the existence of secondary, nonspecific binding mechanisms mediated, for example, by the constituents of a glycocalyx. Orthographic projections (Fig. 5) along the xz and yz planes of colonized cellulose fibers scanned along the vertical axis with a scaling of $0.44 \mu\text{m}$ between sequential images in the xy plane revealed no visible separation between the microbes and the interface, confirming a cell-substrate gap no larger than $0.44 \mu\text{m}$.

The role of spores in translocation, cellular division, and biofilm lateral sprawling along the liquid-cellulose interface with subsequent detachment events and substrate depletion can be further understood by the use of time-lapse microscopy, a technique not previously applied in the study of thermophilic anaerobic organisms. The formation of monolayer biofilms of strongly adherent cellulolytic cells, emphasizing the intimate association with the carbon substrate, can be further investigated in biofilms formed by microbial consortia, where targeted staining techniques have to be developed to enable the in situ localization of cellulolytic microbes in the consortial structures, which have previously been reported to form multilayer biofilms (39).

C. thermocellum is one of the potential candidates for strain development through recombinant and classical strategies for application in consolidated bioprocessing aimed at large-scale conversion of renewable biomass into biofuels and other products. The numerous examples of biofilm formation in the literature, and the observed association between *C. thermocellum* cells and substrate, make this organism a suitable model to delineate cell-cellulosic substratum associations and to optimize the tools to study this phenomenon in other cellulolytic cultures and consortia with potential for application in biomass conversion.

Physiological and Methodological Aspects of Cellulolytic Microbial Cultures

NICOLAI S. PANIKOV AND LEE R. LYND

45

45.1. INTRODUCTION

Microbial cellulose utilization is a key part of the global cycle, important for the production of ruminants and ensiling, and promising for new industrial processes for production of fuels and chemicals from solar energy captured in chemical form by photosynthesis. In all of these contexts, isolation, cultivation, and characterization of cellulolytic microbes is of interest. Yet physiological understanding of microbial cellulose utilization substantially lags behind that of utilization of soluble substrates. This is due both to the complexity of cellulose utilization and to the methodological challenges associated with its study (15). To illustrate these points, we note the following.

- Cell concentration and growth rate measurement are routine for microbial cultures grown on soluble substrates, but this is not the case for cultures grown on cellulose.
- We know of no controlled comparisons of the rate of cellulose utilization by cellulolytic microorganisms. Whereas highly standardized methods such as the filter paper assay are developed for measuring the specific activity of cellulose-solubilizing enzymes (9), there are no such standardized methods for cellulose-solubilizing microbes.
- The widely used Monod model for kinetics of microbial utilization of soluble substrates was proposed in 1942 (18). By contrast, kinetic models for enzymatic hydrolysis of cellulose are in a nascent stage of development (31), and incorporation of enzyme-level models into kinetic models for microbial cellulose utilization has yet to be attempted. Moreover, foundational concepts associated with soluble substrate utilization such as exponential growth and a substrate concentration-independent affinity constant have seldom been demonstrated experimentally for microbial cellulose utilization and are questionable on mechanistic grounds (15).

Fermentation technique specifically developed for cellulose fermentation has been covered in several extensive reviews (6, 15, 34) and numerous experimental studies (1–4, 7, 11, 13, 20, 24, 25, 28, 29, 33). Drawing from both this prior work and our own experience, we address in this chapter three aspects of cultivating cellulose-utilizing microbes: (i) growth media, (ii) fermentation equipment for small-scale laboratory cultivation, and (iii) methods to monitor cellulose consumption and fermentation dynamics with online and offline instrumental techniques. Data relevant

to item iii are presented for *Clostridium thermocellum*, an anaerobic, thermophilic bacterium with among the highest rates of cellulose utilization reported (15).

45.2. GROWTH MEDIA

45.2.1. General Principles

As discussed elsewhere (22), growth media used to culture heterotrophic microorganisms for fundamentally oriented studies should contain a carbon and energy source, sources of all inorganic elements present in cells (macro- and microelements), and essential organic growth factors (vitamins and amino acids) which the organism is unable to synthesize from simple precursors. The temperature, pH, and redox potential must also be maintained in a range compatible with the organism of interest.

The concentration of the i th nutrients in growth media (s_i^0) can be found from a mass balance equation if the desired cell density (x^*) of cultured organisms is specified:

$$s_i^0 = s_i + (x^* - x_0)/Y_i$$

where x_0 is the initial cell density (inoculum concentration), s_i is residual concentration of the i th nutrient when growth stops, and Y_i is respective cell yield (grams of cells/grams of nutrient). Although it is usually desired that s_i be close to zero for economic reasons, the value of s_i should be chosen such as to prevent growth rate limitation. Typical cell yield values for energy sources are 0.1 g of cellular biomass synthesized/g of cellulose consumed, although higher apparent yield values can be observed under some conditions for cellulolytic anaerobes (15, 26, 32). For nutrients which are not energy sources, such as sources of N, P, K, S, Mg, Ca, Fe, and trace elements, the consumed elements are incorporated into cell mass; therefore, the Y_i value can be calculated from published data on elemental composition of the organism of interest or a similar organism:

$$Y_i = 1/\sigma_i$$

where σ_i is intracellular content of the respective element per unit of cell dry weight. For example, the N content (σ_N) in *C. thermocellum* is about 0.1 g of N/g of cell dry weight; therefore, $Y_N = 1/0.10 = 10.0$ g of cell dry weight/g of N. To produce 2 g/liter of cell mass, one has to use medium containing at least $2/10.0 = 2 \times 0.10 = 0.2$ g of N/liter, which is equivalent to 0.94 g/liter of $(\text{NH}_4)_2\text{SO}_4$. In prac-

tice, this minimal amount should be at least doubled to ensure lack of growth rate limitation.

Common undesirable secondary reactions accompanying preparation of chemically defined media are precipitation of insoluble salts formed after mixing of soluble ingredients, e.g., formation of NH_4MgPO_4 , $\text{Ca}_3(\text{PO}_4)_2$, $\text{Fe}_3(\text{PO}_4)_2$, etc.; caramelization (Shiff base formation between sugars and NH_2 group); and spontaneous oxidation of reduced medium components, e.g., $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$. One strategy to avoid these reactions is to separately sterilize reactive medium components. Precipitation of di- and trivalent metals by PO_4^{3-} and SO_4^{2-} can be prevented by addition of chelating agents, mainly citric or nitroloacetic acid. EDTA is less appropriate because of its inhibitory effect on cellulases (5). Autoxidation is eliminated by purging of media with O_2 -free gases (CO_2 and N_2) in the presence of reducing agents.

The choice of cellulose-containing substrate is a key aspect of medium formulation for cellulolytic microorganisms. Model substrates containing essentially pure cellulose, e.g., Avicel (FMC Corp.) and Sigmacel (Sigma Chemical), have significant merits for fundamental studies in that they have reproducible properties and are commonly accessible. Solka Floc (International Fiber Corp.) is one of a few commercially available model lignocellulosic substrates. Forage samples are readily obtained for studies related to animal feeding for which a real-world substrate is desired, although reproducibility between samples is likely to be an issue. For studies aimed at conversion of pretreated lignocellulosic materials, both access and reproducibility are significant issues, as such materials are not commercially available to our knowledge.

45.2.2. Published Growth Medium Recipes and Protocols for *C. thermocellum*

Table 1 lists six nutrient media for *C. thermocellum* including brief protocols. It may be seen that medium composition varies widely dependent upon the specific purposes of cultivation experiments. In addition to their relevance for *C. thermocellum* and the particular media listed, aspects of the following discussion may be of more general interest for other organisms and media.

MTC and MJM were designed to support high cell densities accompanying growth at high cellulose concentrations (30 to 100 g/liter). These media (especially MTC) are the most concentrated of those considered, and they include up to 3 g/liter of citric acid to prevent precipitation of Mg, Ca, Fe, and trace elements. MJM is simpler and does not contain yeast extract (YE), NaHCO_3 , or Na_2SO_4 ; as a result, its use is recommended for "clean" experiments in instrumentally controlled bioreactors when uncertain effects of undefined growth supplements or high ionic strength are not desirable (experiments aimed at quantitative analysis, isolation and purification of extracellular metabolites, uptake kinetics, off-gas analysis, spectrum of C and N sources, etc.). On the other hand, MTC is more appropriate for experiments aimed at obtaining high cell densities either in pH-controlled fermentors or in serum vials without pH control due to the strong buffering effect of bicarbonates. Very dilute MM and MDM media do not contain chelating agents; therefore, they are simpler to prepare, less expensive, and good for strains sensitive to salts. On the other hand, these media can be expected to fail to support high growth rates in continuous culture or complete utilization of more than 3 g/liter of cellulose.

Trace elements can sometimes be omitted without any noticeable effect on cell growth, and such effects are often only observed when ultrapure chemicals, water, and gases are employed. Many investigators choose to use a standard mixture of trace elements to prevent unintentional growth limitation.

Recipes for trace element stock solutions (Table 1) are based on either chlorides or sulfates of trace metals. For pure cultures that do not reduce sulfate, there is likely to be little difference between chlorides and sulfates. For experiments involving enrichment of mixed microbial consortia, chloride ions are expected to be relatively inert, whereas sulfate provides an electron acceptor for sulfate-reducing bacteria. Stock solutions of trace elements (usually concentrated 1,000-fold) are typically stabilized by acidification to pH 1.5 by HCl or by addition of nitroloacetic acid, which prevents precipitation of hydroxides.

Defined mixtures of vitamins (e.g., as developed for *C. thermocellum* by Johnson et al. [10]) are often preferred relative to undefined growth factors such as YE for several reasons: (i) elimination of variation from one batch of YE to another (we have observed, for example, that some batches of YE contain glucose, whereas others do not); (ii) a much smaller background of organic constituents, which is good for experiments involving quantification and characterization of cells, enzymes, and metabolites; and (iii) avoidance of complications due to metabolism of organic growth factors. The concentration of vitamins varies in different medium recipes and is 10 to 100 times higher in MTC than in the other media listed. Even at such high concentrations, added vitamins do not significantly affect the mass balance of microbial growth.

To maintain anoxic conditions, both cultivation vessels and growth medium reservoirs (for continuous culture) should be purged with O_2 -free gases: He, Ar, N_2 , or CO_2 . Use of He is justified when gas phase is continuously monitored by mass spectrometry in a SIM mode (single ion monitor); otherwise, N_2 and CO_2 are preferred, as they are cheaper and more nearly replicate the gas phase composition that would be observed under most conditions of interest in nature or industrial processes. Within our experience, use of a CO_2 gas phase frequently encourages growth and shortens the lag phase, although continuous use of CO_2 flushing makes it impossible to monitor CO_2 , which may be desired. A good compromise can be to use 100% CO_2 at startup and then switch to an N_2 purge stream. We have found that if continuous CO_2 monitoring is not desired, a purge gas is not required for *C. thermocellum* and many other known cellulolytic microbes. It should be noted that the H_2 partial pressure can influence the ratio of fermentation products produced (1, 13).

The order of mixing of individual ingredients is an important consideration when preparing media. For instance, addition of FeSO_4 to even slightly buffered neutral solution before citric acid can cause precipitation, but if citric acid is added first, then precipitation does not occur. Filtration can be a good substitute for autoclaving because it prevents numerous side reactions. Millipore disposable filters provide a high rate of filter sterilization, e.g., less than 10 min for a 20-liter carboy in our experience.

45.3. CONTROLLED CULTIVATION OF BACTERIA ON MEDIA CONTAINING SUSPENDED CELLULOSE

45.3.1. General Problems of Using Suspended Media

Methodological challenges associated with microbial cultivation on suspended substrates (cellulose and pretreated wood) have been reviewed (15) and investigated experimentally (14, 26). Key technical obstacles associated with microbial cultivation on insoluble cellulose particles include the following.

- Solid particles make difficult or even impossible the direct assessment of microbial growth by all of the best-developed

^aMTC. Autoclave separately sources of C; N; Mg, Ca, Fe, and L-Cys; and the rest of ingredients. The vitamins and trace elements are filter sterilized and combined with the sources of C; N; Mg, Ca, Fe, and L-Cys; and the rest of the ingredients.

^bMJ-medium. Cellobiose and Mg-Ca-Fe salts mixture are autoclaved separately as 10-fold-concentrated solutions and then mixed with filter-sterilized vitamins.

^cMM, minimal medium. CO₂, 100% in gas phase.

^dMM, minimal medium. The basal medium, adjusted to pH 6.7, is autoclaved for 10 min to remove dissolved gases and purged with CO₂. The cooled solution is mixed anaerobically with Na₂CO₃, dispensed into bottles, and autoclaved for another 20 min. A total of 4 g/liter of cellobiose is added after autoclaving.

^eThe modified Dehority medium. Autoclave for 15 min separately YE, L-Cys, and the rest of ingredients, and then add YE and L-Cys into the rest of the ingredients aseptically and expose to bright light to accelerate the action of reducing agent.

^fMJM, the modified JM medium developed at Dartmouth College. A carboy with 5 to 20 liters of deionized water, resazurin, and cellulose powder is autoclaved for 60 min. Solutions containing (i) Mg, Ca, Fe, and citrate and (ii) the rest of ingredients are adjusted to pH 6.8 and pumped to the carboy through the filter.

and most widely used techniques for soluble substrates: microscopic counts, a Coulter Counter, turbidity, and dry-weight measurement.

- The presence of solids gives rise to significant culture heterogeneity even in the presence of intensive agitation. In contrast to soluble substrates, microbial utilization of cellulose by *C. thermocellum* and other cellulolytic anaerobes is accompanied by formation of biofilms (see chapter 44, this volume) and aggregates containing cellulose particles and cells in various ratios and arrangements. Growth conditions are different for planktonic cells and cellulose-adhered cells, and potentially on the inside and outside of substrate-cell aggregates. Thus, the aggregated behavior of a cellulose-utilizing microbial culture is the weighted sum of the behavior of different interconvertible subpopulations which experience different environments and are in different physiological states.
- Sedimentation of solids makes it hard to maintain consistent delivery of substrate and removal of substrate and cells and can cause operational difficulties such as clogging of lines. Nonrepresentative solids removal, either in sampling or in effluent removal for continuous culture, can easily occur and greatly complicates and confounds interpretation of data.

Avoiding sedimentation and related difficulties is addressed in detail below.

45.3.2. Basic Fermentation System for Batch and Continuous Cultivation of Cellulolytic Bacteria

Figure 1 gives an overview of a fermentation system based on the BIOSTAT® Aplus bioreactor (Sartorius Stedim,

<http://www.sartorius-stedim.com/index.php?id=9196>). The system described could also be based on other small-scale (0.5- to 5-liter) bioreactors, e.g., from Applikon, New Brunswick Scientific, Dargip, and other manufacturers. Bioreactors from all these manufacturers have built-in computer control of pH, agitation speed, temperature, volume of cultural liquid (foam/level control), and pO₂. For anaerobic microorganisms, measurement of O₂ is not needed, and the vacant port could be used to accommodate another probe, for example, the optical near-infrared (NIR) sensor DO4 (Dargip, Jülich, Germany). In addition, systems from the manufacturers listed all contain an acid pump to neutralize excessive alkalinity. In our experience, cellulose fermentation almost never causes alkalization, and two active pumps (for base and acid) can create undesired situations such as activation of the acid pump to compensate base overshoot. We have thus found it preferable to disable acid addition functionality and utilize the respective built-in pump for other purposes such as automatic sampling of the culture for offline analyses (see below).

Four environmental parameters (temperature, pH, mixing rate, and level of liquid) are controlled as described by the manufacturer (e.g., <http://www.sartorius-stedim.com/biostat-aplus/documents.html>). Brief additional comments are given below.

- We have found temperature sensing using a regular thermistor and warming by a resistive “heating blanket” to be quite satisfactory. A water-jacketed heat exchanger (available in BIOSTAT® Qplus reactor) is more expensive but is better suited for quick visual inspection of culture (color, aggregation, and possible film growth). Neither a heating blanket nor water jacket is fast enough to prevent cooling during repetitive batch culture (see

FIGURE 1 Scheme of bioreactor designed for quantitative physiological studies of cellulose fermentation. 1, Medium carboy continuously stirred with magnetic stirrer to maintain microcrystalline cellulose in suspended state; 2, N₂ tank equipped with pressure regulator; 3, mass flow controller maintaining constant gas flow (40 to 200 ml/min) through reactor headspace (FMA5512; Omega); 4, manifold of three-way solenoid valves directing gas flow from several (6 to 12; 1 is shown) individual bioreactors to a QMS100 mass spectrometer (high-pressure gas analyzer; Stanford Research Systems); 5, manual sampling port, standard 60-cc syringe connected to neoprene tubing via female Luer connector; 6, automated sampling device consisting of solenoid valve and pump delivering 2- to 15-ml samples at regular intervals to the set of test tubes placed in refrigerated fraction collector (Bio-Rad); 7, liquid level sensor, based on conductivity principle, is used to maintain constant volume of the bioreactor during continuous cultivation; when the volume reaches the threshold level and the sensor's tip touches liquid, the conductivity in the circuit jumps and activates the harvesting pump, pushing excessive cultural liquid to the waste bottle; 8, the condenser functions as a barrier for intensive medium evaporation; 9, pH probe and online optical NIR sensor (OD4, Daspig); 10, Sartorius-Stedim BIostat APlus controlling unit; 11, optional peristaltic pump; 12, tubing line used to discard cells which can be replaced by tangential filtration unit.

below), for which an additional heat exchanger is required if near-constant temperature is to be maintained.

- During autoclaving, the tip of the pH probe should stay submerged in liquid. The user can change the quality of pH control by changing the time delay between signal and base pump response as well as the tolerance limit (allowable mismatch between actual and preset pH values).
- Mixing control is advisable to regulate dependent upon growth stage of the culture. Immediately after inoculation, mixing should be low or eliminated to encourage colonization of cellulose particles by bacteria. Growing

fermenting culture should be agitated with a speed of 150 to 300 rpm. More rigorous mixing (up to 500 rpm or higher) appears to be tolerated and supports high mass transfer rates, which are needed in kinetic studies when metabolic activity is measured based on gas production. Another justification for a high mixing rate can be removal of H₂, which is a strong regulator of fermentation stoichiometry (see above). Except for these situations, intensive mixing is not in general necessary for anaerobic cellulose-utilizing microbes, in contrast to the situation with aerobic microorganisms, which are easily limited by insufficient oxygen mass transfer.

FIGURE 2 Modification of the level control of a Sartorius-Stedim bioreactor (Dartmouth design). 1, Cultural liquid (electroconductive); 2, metal headplate; 3, stainless steel pipe used as level sensor and harvest tubing; 4, Teflon pipe (insulator); 5, flexible rubber tubing which allows changing the position of the pipe by moving it up and down without compromising the sterility of the fermentor; 6, temperature probe (electroconductive). When the liquid level is below the sensor, the electric circuit is open, the current is zero, and the pump is idle. At the instant of contact, the circuit is closed and the harvesting pump is activated.

- Level control is used to keep a constant volume in continuous culture (chemostat or auxostat mode of cultivation; see below). Sartorius provides a short (~3-in. length) conductivity sensor which activates the harvest pump instantly when the sensor tip touches culture liquid. We constructed a level sensor of varying length (Fig. 2); it can be pushed down into the vessel to decrease the volume (taking care to cover newly exposed sensor surfaces with a flexible rubber sleeve) or withdrawn to increase the culture volume.

45.3.3. Modification of the Basic Fermentation System To Meet Requirements of Suspended Solid (Cellulose and Pretreated Wood) Fermentation

It is desired that solids be fully suspended in the bioreactor, in the medium reservoir (for continuous culture), and during medium delivery and withdrawal). However, significant deviation from uniformity in spatial distribution of particles can occur in narrow tubing carrying slurry from the medium reservoir to the bioreactor and in vertically positioned pipes inside both vessels (Fig. 3). In these unmixed parts (stagnation zones), we always observe some sedimentation. While the use of large-diameter tubing decreases

the risk of clogging, it also tends to exacerbate nonuniform distribution of particles because fluid velocities are lower.

To prevent particle sedimentation in practice, Weimer et al. (26) successfully applied a “segmented gas/liquid delivery system” entailing dividing feed slurries into small (~20- μ l) discrete liquid segments separated by intervening gas bubbles. We have successfully employed a simpler approach consisting of a pump activated for 7 s (flow rate, ~10 ml/min) and then turned off for 40 to 100 s depending on the residence time desired. The on/off cycling is repeated ad infinitum using cheap and robust electronic time relays (e.g., NIST traceable lab controller; Cole-Parmer). We have found that this pulsed method completely prevents sedimentation even in tubing with multiple bends. Although technically intermittent, it can be considered practically continuous substrate delivery because the cycle period (~1 min) is much shorter than bacterial generation time, varying in the chemostat from 2 to 30 h.

There are several other general rules which help to achieve uniform distribution of suspended cellulose during continuous cultivation. The tubing connecting the reservoir with the fermentor should be as short and straight as possible, with predominantly vertical or downward-sloped orientation and avoiding folds and loops. It is strongly recommended to avoid diameter changes, as these tend to cause particle accumulation and tubing blockage (Fig. 3B). To stop solids sedimentation within vertical pipes inside the nutrient reservoir (Fig. 3C), we have found it effective to curve upward the end of the pipe by 5 to 10 mm to prevent exiting of particles back to the carboy. To prevent unintended return of cells and residual cellulose to the fermentation vessel (Fig. 3D), the open end of the vertical harvesting pipe should be positioned at the gas-liquid interface rather than below the liquid surface; this condition is satisfied when the harvesting pipe is used to control the level in the fermentor (Fig. 3). Uniform substrate dispersion can be verified by running tests with continuous culture for 1 to 2 days before inoculation by cellulolytic microorganisms. The concentration of solids is determined by dry-weight or total organic carbon (TOC) analysis (see below) in periodically withdrawn subsamples; the uniformity is confirmed if the solid concentration remains the same in the reservoir, culture vessel, and product bottle. Another test is to establish whether the solid concentration is uniform with respect to height in the carboy or fermentor (16).

45.3.4. Diversity of Cultivation Techniques as Applied to Cellulose Fermentation

The fermentation system shown in Fig. 1 can be used for diverse cultivation regimens: batch, repetitive batch, simple chemostat and chemostat with cell recycle, pH auxostat, CO₂ auxostat, D-stat, and others. Definitions and purposes of various cultivation methods together with respective mass balance equations have been reviewed elsewhere (20, 21). Table 2 lists six cultivation techniques (batch and repetitive batch, chemostat, cell recycle, pH auxostat, CO₂ auxostat, and D-stat) in terms of substrate and cell fluxes (Fig. 4). Long-term continuous cultures are accompanied by autoselection, in which spontaneous mutants with changed properties replace the original inoculum strain. The outcome of autoselection depends on the type of continuous cultivation. The “Goals” column of Table 2 lists anticipated results of autoselection and summarizes its potential biotechnological benefits.

45.3.4.1. Batch and Repetitive Batch Culture

When bioreactors are run in batch mode, it is desirable to prepare the nutrient reservoir with medium sufficient for several cycles. The first cycle is usually a preliminary

FIGURE 3 Managing suspended solids in continuous culture. (A) Schematic illustration of forces affecting solid particles moving through narrow tubing: advective forces (vectors parallel to flow direction) are interacting with gravitational forces (vertical vectors), and as a result, solids sediment at the bottom of tube folding (enclosed area). (B) Sedimentation is maximal at junction point of wide and narrow tubing. (C) Wrong (crossed) and correct shape of the vertical pipe used to pump out substrate slurry. With a straight pipe inside a reservoir, the stirring of the carboy does not prevent sedimentation of particulate material back to the reservoir (arrows). The circular end of pipe completely stops sedimentation. (D) Wrong (crossed) and correct way of solids recovery (cells plus unused cellulose) from the fermentation vessel. Unintentional recycling of solids occurs because of their sedimentation in a vertical harvesting pipe (the tip of this pipe is positioned below the gas-liquid interface). Recycling is completely prevented if the harvesting pipe is positioned at the gas-liquid interface: sedimentation is blocked by gas bubbles, and the harvesting pipe serves as a level sensor (see also Fig. 2).

cultivation to “wake up” inoculum material stored frozen under glycerol. The duration of the lag phase is not fully predictable and can last up to a week in our experience. Once the culture is growing rapidly, it can be diluted by fresh medium to initiate the second cycle of batch fermentation. Multiply repetitive batch cultures can be used to monitor autoselection, evolution of microbial communities, etc. Fresh medium is normally kept at room temperature. For thermophilic species like *C. thermocellum*, it should be warmed up to 55 to 60°C immediately before addition to the fermentor. This can be accomplished with a heat exchanger operating along the tubing line from the reservoir to the culture vessel. A standard chemical condenser of appropriate internal diameter can be inserted in the tubing line with hot water (65 to 75°C) circulated through the condenser’s water jacket during medium delivery.

All other elements of the cultivation system shown in Fig. 1 can be used for repetitive batch culture without major modification. The peristaltic pump (Fig. 1, item 11) is turned on only at the end of the growth cycle to replace spent medium. The range of online and offline parameters measured during cultivation is optional.

Protocol for Startup of Batch Culture

1. Assemble, clean, and sterilize fermentation system shown in Fig. 1.
2. Prepare sterile medium according to one of the protocols outlined in Table 1.
3. Connect the sterilized medium reservoir to the fermentor via a Luer connector and start purging the fermentor and medium reservoir with N_2 at a rate of 100 ml/min or higher. Fill the vessel with the required amount of medium (typically 1 liter). Turn on the control panel of the BIOSTAT Aplus; start agitation (200 rpm), pH, and temperature control.
4. When the medium in the fermentor is completely reduced (resazurin turns colorless), the temperature is 60°C, and the pH is around 6.8, inoculate the fermentor with exponentially grown cells. Use a sterile disposable syringe and a Luer port on the fermentor.
5. Reduce the purging rate to ~20 ml of N_2 /min in the medium reservoir and fermentor. Stop agitation and leave the culture overnight. It is recommended to start off-gas recording immediately for early detection of metabolic activity.

TABLE 2 Various cultivation techniques and their possible goals

Cultivation method	Operation conditions	Goals
Chemostat	$F = \text{constant}, x = x_{out}, p = p_{out}$	Continuous conversion of cellulose to fermentation products, minimizing residual concentration of substrate
Batch and repetitive batch	$F = \begin{cases} 0 & \text{if } 0 \leq t \leq T_1 \\ A > 0 & \text{if } T_1 < t \leq T_2 \end{cases}$ <p>where A is liquid replacement rate (100–200 ml/min) at the end of growth cycle, T_1 (20–50 h): removal of 90–95% of spent liquid with following addition of fresh medium to 100%, the replacement time ($T_1 - T_2$) is ~ 0.5 h.</p>	Discontinuous or pulsed fermentation (in the case of repetitive batch); selection pressure minimizes lag phase and maximizes growth and colonization of cellulose particles
Cell recycle	$F = \text{constant}, x \gg x_{out}, s \geq s_{out}, p = p_{out}$; cells and residual cellulose are returned to the fermentor by tangential filtration, while fermentation products are continuously washed out.	Continuous fermentation with deep substrate conversion in the absence of severe product inhibition
pH auxostat	$x = x_{out}, p = p_{out}$; F is generally not constant but rapidly merges to steady state under absence of perturbations. Fresh medium is used to titrate metabolic acidity to keep pH constant.	Continuous fermentation at intermediate degree of substrate conversion. Increase of buffer strength results in higher degree of cellulose conversion. Selection of fast growers.
CO ₂ auxostat	$x = x_{out}, p = p_{out}$; F is generally not constant but tends to steady state, similar to pH auxostat. The medium flow is instrumentally stopped if the CO ₂ level is below preset value. CO ₂ formation rate is constant.	Continuous fermentation favoring fast-growing cells. Degree of substrate conversion is proportional to selected CO ₂ level. The multistability is possible with two or more steady states at the same CO ₂ level and different x_{out} and s_{out} .
D-stat	$F = \text{constant}, x = x_{out}, p = p_{out}$; added medium contains inhibitor (in the main reservoir or in the second small carboy). Its concentration varies stepwise or smoothly as time gradient.	Continuous fermentation aimed at selection of product-resistant strains or strains tolerant to exogenous toxins (e.g., wood pretreatment by-products)

FIGURE 4 Schematic representation of cultivation system listed in Table 2. F , medium flow rate; s_0 , feed substrate concentration; s , residual substrate concentration; x , cell mass concentration in fermentor; x_{out} , cell concentration in outflow liquid; p , metabolic products in fermentor; p_{out} , products in outflow liquid.

6. Check growth the next day: CO₂ and H₂ level above background level, acidification (pH drop down and/or amount of 1 N KOH automatically added), changes in color, and formation of slimy aggregates. Start agitation and increase the purging rate to 50 to 100 ml/min if growth has started. Start measuring the optical density with an online probe.
7. When the culture is growing vigorously (close to maximal rate of gas production and KOH titration rate), dilute it with fresh medium to initiate the second cycle. Increase the purging rate to 200 ml of N₂/min, and turn on the harvest pump (50 to 100 ml/min), remove 90% of cultural liquid, and add fresh medium with passage through a heat exchanger. Make sure that the temperature for the culture does not drop below 55°C. Agitation, temperature, and pH control is continued during feeding, ensuring that the tip of the pH probe remains submerged.
8. Monitor growth as required, including offline analysis and sampling with the fraction collector (see below). Start the next cycle before or after substrate depletion as indicated by constancy of optical density and slight increase of pH usually observed upon substrate exhaustion.

45.3.4.2. Chemostat Culture

Chemostat culture is carried out similarly to batch culture, except that the pump delivers suspended medium continuously or in short pulses as described above. To determine medium flow rate, one can use a 60-cc syringe permanently connected via a T-piece in the tubing leading from the feed reservoir to the pump. Growth medium may be drawn into the syringe, and the time required for the feed pump to empty the syringe may be determined under conditions where no flow is coming from the medium reservoir. More advanced automated determination of flow rate may be carried out by recording the volume of culture effluent, a built-in function of the BIOSTAT Aplus. The logged time series is numerically differentiated (e.g., with "SLOPE" or "LINEST" function in Microsoft Excel) to obtain the flow rate. Correction must be taken for any manually withdrawn samples or evaporation (usually a small fraction if the condenser runs at 5 to 10°C). A third method is to weigh periodically the carboy with medium or take a reading of the residual volume. All three methods should give reasonable compatibility.

45.3.4.3. pH Auxostat

The main operational difference between a pH auxostat and a chemostat is that fresh medium is delivered by the base pump rather than the peristaltic pump (Fig. 1, item 11). The bottle with 1 N KOH is disconnected or might be used only at startup. The pH auxostat keeps the pH at a constant level preset by the experimenter. However, the biomass level and degree of cellulose conversion are not simple functions of the pH. In practice, one can start pH auxostat cultivation by preliminary batch experiment without autotitration but with instrumental recording of the pH and biomass concentration (x). The growth rate progressively declines because of medium acidification. On the plot " x vs pH," select the required x level and then use the respective pH as the preset value. If a higher biomass is desirable, then increase the buffer strength of the medium by increasing the K₂HPO₄ concentration or adding nonassimilable buffer (morpholinepropanesulfonic acid [MOPS]) (Table 1).

45.3.4.4. CO₂ Auxostat

A robust and relatively inexpensive CO₂ analyzer (e.g., LI-800; LI-Cor, Lincoln, NE) can be attached to the fermentor exhaust gas line (Fig. 1) instead of or in addition to a mass

spectrometer. This CO₂ sensor contains built-in "low-alarm" and "high-alarm" outlets generating an electrical signal at 5 V when the current CO₂ levels are, respectively, below and above the preset value. The high alarm (excessive CO₂ production) turns on a relay which activates the pump delivering medium from the reservoir. Dilution of the culture decreases the CO₂ level until the preset value is restored. An appropriate National Instrument data acquisition system can be used to log the amount of pumped liquid to calculate the medium flow rate (F_s) and then dilution rate ($D = F_s/V$, where V is culture volume). N₂ purging of the fermentor's headspace must be perfectly constant (we use the FMA5512 Omega mass flow controller), with a residence time of about 1 min (e.g., a purging rate of 200 ml/min in a fermentor with a headspace of 200 cc). The CO₂ auxostat is more easily adjusted to the desired level of steady-state cell mass and cellulose conversion than is the pH auxostat because CO₂ is stoichiometrically related to cell yield and substrate consumption.

45.3.4.5. Biomass Recycling

To recycle microbial biomass, the fermentation system (Fig. 1) may include a tangential filter (Sigma) as shown schematically in the flow diagram in Table 2. Initially the culture is run in a chemostat mode, the peristaltic pump (Fig. 1, item 11) continuously adds medium, and the harvest pump removes excessive liquid as regulated by the level sensor. To continue the process with cell recycle, the tubing line (Fig. 1, item 12) is closed, and instead the cultural liquid is directed to the loop containing the tangential filter. Solids, including cells and unutilized cellulose, are returned to the fermentor, while clear filtrate flows to the effluent collection vessel. With low substrate flow rates (~50 ml/h), a standard harvest pump (e.g., from a BIOSTAT Aplus) can be used for filtration activated by the level sensor in the same way as it is done in simple chemostat mode.

45.3.4.6. D-Stat

A D-stat maintains a constant dilution rate in the presence of changes (either stepwise or continuous) in any environmental factor (pH or temperature) or inhibitor concentration. This technique has been described in the literature (12, 21). Although we have not tested this technique in our laboratory at Dartmouth College, we can propose its straightforward realization as follows. The fermentation system (Fig. 1) is appended with a second medium reservoir containing the same medium plus inhibitor (ethanol, acetate, lignin derivatives from wood pretreatment, etc.) equipped with an additional pump. Two pumps work concurrently to keep a total flow constant while their ratio is varied; it would be reasonable to increase the inhibitor concentration gradually to avoid undesirable washout of cells. Another option is to activate the second pump in response to a CO₂ or pH sensor only when the culture retains an adequate level of metabolic activity. In this case, we would have a hybrid of a chemostat, auxostat, and D-stat.

45.4. MONITORING OF GROWTH

45.4.1. Online Methods

45.4.1.1. Gases and Volatile Compounds

Analytical chemistry of gaseous and volatile products is well developed, with several gas analyzers on the market. We have positive experience in using the portable quadrupole mass spectrometer QMS100 (high-pressure gas analyzer; Stanford Research Systems, Sunnyvale, CA) and infrared

analyzers LI-800 and LI-840 (LI-Cor). Gas exhaust from several fermentors may be fed through a solenoid multiplexer into one master gas analyzer, and data can be logged to a computer using either custom or standard software. A one-out-of-eight gas line serves as background (N_2 -flushing line). The difference in gas exhaust versus background multiplied by N_2 flow rate gives the formation rate of the respective gaseous product. Although fermentation generates a wide spectrum of volatiles (ethanol and other alcohols, aldehydes, and volatile fatty acids), their direct detection with mass spectrometry is not a trivial task. The main obstacle is low vapor pressure and binding of these compounds to the walls of capillary tubes. However, detection of true gases— H_2 , CO_2 , CH_4 , and CO —is achieved satisfactorily even without gas chromatographic separation based on unique m/z values or their unique combinations. Example data are shown in Fig. 5 for a *C. thermocellum* batch culture producing CO_2 and H_2 from cellulose.

45.4.1.2. Titration Rate

The cumulative amount of alkali used to neutralize metabolic acidity may be recorded by standard MFCS software. Differentiation of the logged data gives rates of base addition (milliliters of KOH per hour) which provide a measure of the instantaneous metabolic activity of growing microorganisms. It should be realized that identifying particular biochemical processes responsible for acidification can be nontrivial. The common assumption that metabolic acidity is proportional to formation of acidic fermentation products is often wrong, as indicated by the observation of similar pH drops for cultures producing neutral products (ethanol, propanol, and glycerol) and organic acids (lactate, acetate, and propionate). The global ionic balance of aerobic growth indicates that NH_4^+ uptake is the main reaction causing acidification (16, 17), primarily because of high requirements in N of all bacteria and the high cell yield of aerobic microorganisms. In practice, titration rates often correlate closely with growth and fermentation rates (Fig. 5; compare titration rate with rates of gas production), particularly when the pH is controlled. Titration rate is probably the most inexpensive and easiest way of online monitoring of the fermentation dynamics.

45.4.1.3. Optical Probes

NIR optical probes (absorbance at 800 to 1,000 nm) are commonly used in fermentation research to record turbidity in solid-free media and are used to infer cell density. In our laboratory, we have used Optek and Daspip NIR probes for recording turbidity dynamics in cellulose-containing media. During batch fermentation, the decline in turbidity caused by solubilization and uptake of cellulose is four to five times stronger than the increase in turbidity by growing cells. Therefore, NIR probes originally designed for cell mass recording can be applied for measurement of residual cellulose (and probably pretreated wood) after calibration.

45.4.2. Offline Methods

45.4.2.1. Autosampling

Since batch fermentation of cellulose commonly requires 20 to 50 h, manual sampling is very tedious. To address this, we have adapted a system based on a fraction collector (e.g., BioFrac fraction collector; Bio-Rad, Hercules, CA) which preserves sterility and does not require prior flushing of tubes to remove material from previous sampling. The method is illustrated by Fig. 6. The fermentation vessel is continuously purged by N_2 , which enters into the culture

through two lines, one of which is periodically closed by a solenoid valve for 20 to 40 s (NIST electronic time relay); during this period an auxiliary pump is activated to deliver 4 to 10 ml of sample into a sample tube in a refrigerated collector. The valve is open but the pump keeps going for several seconds to force out the residual liquid and clean the tubing for the next sample. Samples can be collected every 1 to 2 h and are kept at 3 to 5°C for 1 to 2 days in tightly capped plastic tubes before analysis.

45.4.2.2. Cell Mass and Residual Cellulose C

The mass concentration of microbial biomass in cellulose-containing slurries can be estimated by analysis of some specific cellular constituent: DNA, membrane phospholipids, proteins, particulate N, muramic acid, etc. The conversion factor from these biochemical proxies to cell mass is generally not constant, the highest variability being reported for phospholipids and cell wall constituents, while DNA, cell proteins, and cell N display the lowest degree of variation. Below we outline protocols for cell N measurement designed to be amenable to a moderately high throughput (a few minutes per sample).

Since the mass fraction of nitrogen in cells (e.g., 10%) is much higher than in most cell-free cellulosic substrates, nitrogen can be used as a proxy of microbial biomass in studies of cellulose-utilizing microorganisms (14). Soluble N-containing compounds (NH_4^+ , extracellular amino acids and proteins, and products of cell lysis) can be removed by washing pellets. If it is desired to differentiate microbial biomass from cellulase, a direct measurement of cellulase concentration (e.g., enzyme-linked immunosorbent assay and quantitative proteomic analysis) is required as developed by Lynd and Zhang (15a) and Zhang and Lynd (30).

Protocol for Cell N and Residual Cellulose C Analysis

1. One milliliter of culture is centrifuged and the pellet is washed twice with deionized water. We find that vacuum suction via a stainless steel needle removes the liquid phase as fully as possible, leaving an intact pellet.
2. The pellet is quantitatively transferred to 20 ml of water and placed in the autosampler of a TOC/N analyzer (e.g., Shimadzu OCT-2) with suspension maintained via a magnetic stirrer. The Shimadzu TOC/N analyzer (model TOC-V combustion analyzer with TNM-1 total nitrogen option) performs full catalytic combustion of organic matter to CO_2 and N_2O , which are then quantified, respectively, by NDIR and chemoluminescence detectors.
3. Calculation of the total pellet C (TPC) and total pellet N (TPN) in suspension is done from peak area versus standard solution of glycine (1,000.0 mg/liter, acidified to pH 1.5 by H_3PO_4). For a cellulosic substrate containing no nitrogen, and cells with mass fractions of 0.46 and 0.12 for carbon and nitrogen, respectively, calculations are as follows: cell mass concentration = $TPN/0.12$. Residual cellulose C = $TPC - TPN \cdot 0.46/0.12$. An example of fermentation dynamics inferred based on TPC and TPN is shown in Fig. 5.

45.4.2.3. Other Offline Analytical Methods

We omit here explicit description of several other standard procedures which should be highly recommended as additional valuable characteristics of bacterial growth on cellulose:

- High-performance liquid chromatographic analysis of cellulose degradation products (cellobiose, glucose, and cellodextrin[s]) and fermentation products—ethanol, lactate, glycerol, acetate, formate, and other fatty acids (see example in Fig. 5).

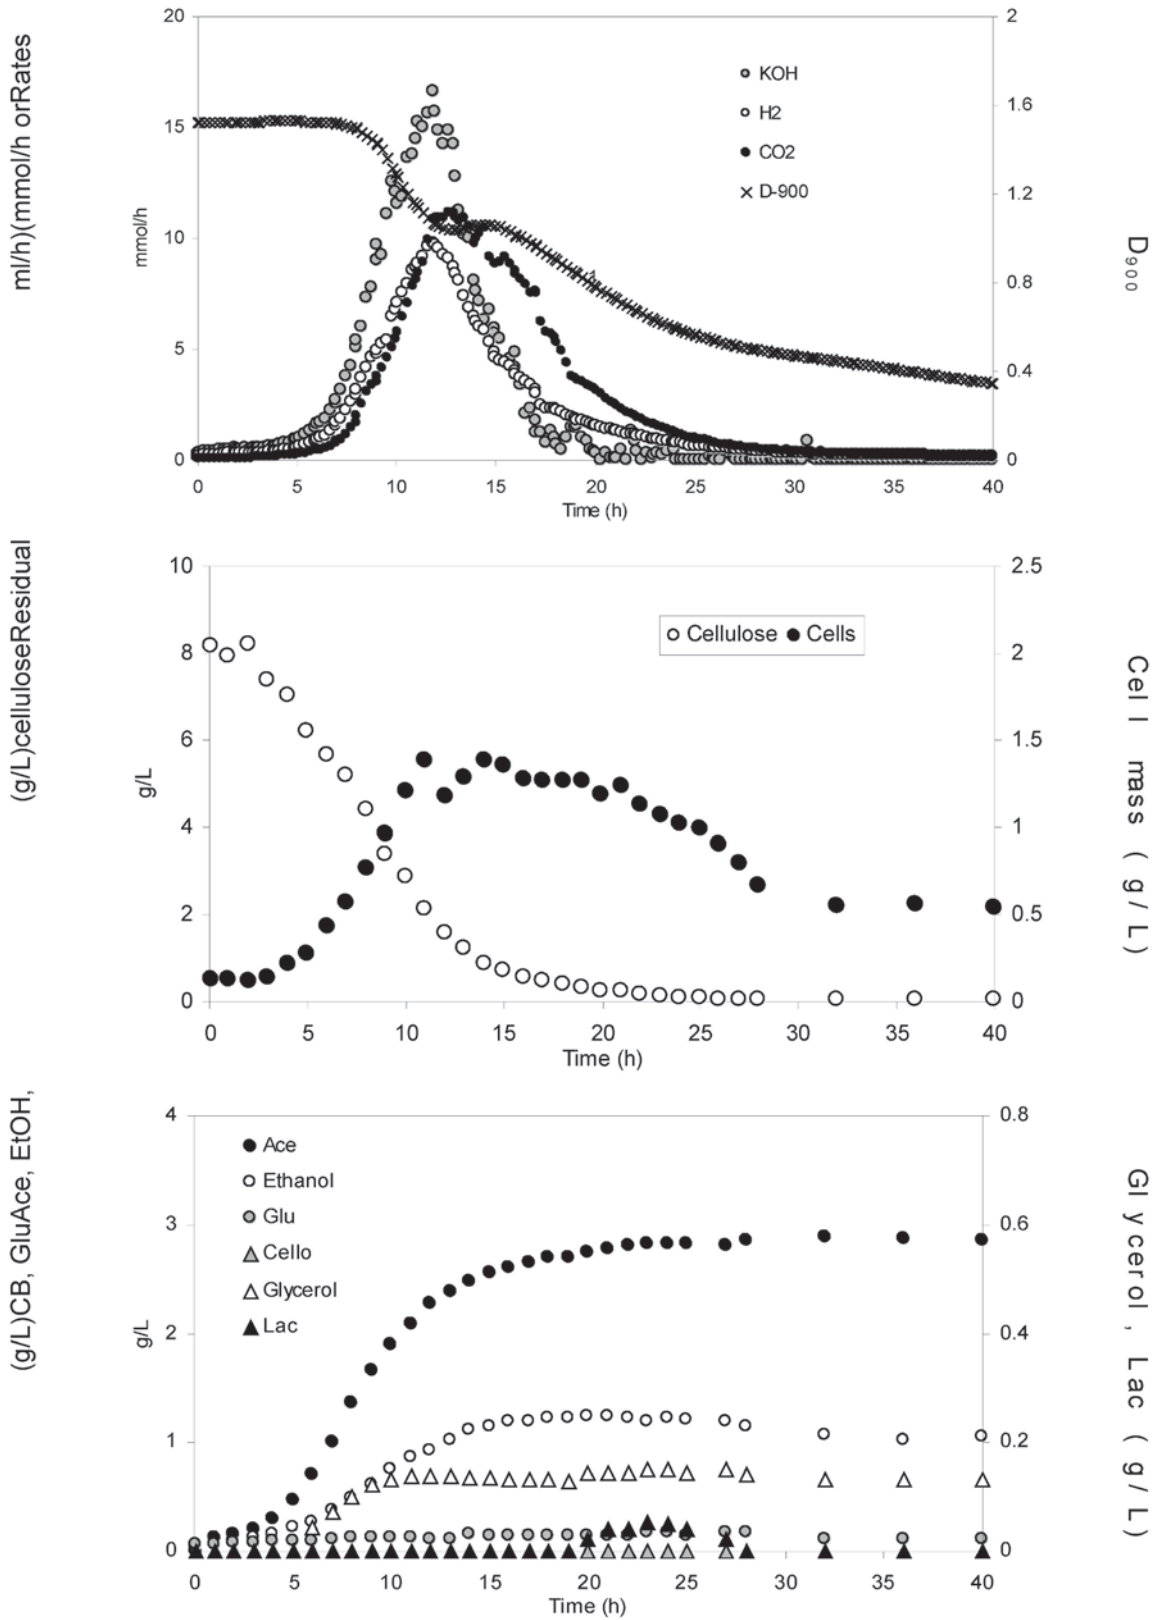

FIGURE 5 *C. thermocellum* batch growth on Avicel, 10 g/liter. (Top) Example of online monitoring of gas production, titration rate, and turbidity; (middle) residual cellulose and cell biomass based on analyses of pellet C and N (example of offline growth monitoring in samples taken with fraction collector); (bottom) high-performance liquid chromatography data for the same experiment.

FIGURE 6 Automated sampling which requires no preliminary tubing flushing. (Top) Configuration of the system between samplings (sampling frequency is typically every 1 to 2 h); the regulating solenoid valve is open and pump is idle. (Middle) The first sampling phase: the valve is closed and the pump is active. Cultural liquid is delivered to a tube kept in a refrigerated fraction collector. (Bottom) The second sampling phase: the valve is open and N_2 gets in and interrupts the flow of cultural liquid; however, the pump keeps going for 5 to 10 s and cleans up the peripheral part of the sampling loop. Unidirectional flow of liquid and positive pressure gradient guarantee the sterility of the entire sampling line. This device can be used in a manual mode as an alternative to traditional sampling with disposable syringes or vials. In this case, the pump is activated manually and N_2 flow is stopped with a clamp instead of a solenoid.

- Pellet proteins with bovine serum albumin as standard by the Lowry and BCA methods (BCA Protein Assay Reagent [bicinchoninic acid], Thermo Scientific)
- Total carbohydrate content by quantitative saccharification as glucose released by differential acidic hydrolysis

Part of the experimental studies described in this chapter were supported by DOE (BESC), NSF (award 0732966, support of development of gas analysis) and Mascoma.

BIOLOGICAL ENGINEERING AND SCALE-UP OF INDUSTRIAL PROCESSES

VII

THIS SECTION CONTAINS CHAPTERS THAT FOCUS ON THE MAJOR ELEMENTS of biological engineering and scale-up that are considered key for industrial process success. The chapters are authored by a mix of academic and industrial practitioners, noted for their extensive experience and valuable insights as well as valuable direct “hands-on” perspectives.

The section begins where most bioprocess development efforts start. The selection of raw materials and subsequent medium development for industrial fermentation processes has been, and continues to be, the foundation of sound bioprocess performance. Samun K. Dahod, Randolph Greasham, and Max Kennedy include recent best practices relating to raw-material quality and performance in their chapter 46. As of this writing, there are some significant examples of raw-material issues that have disrupted biopharmaceutical processing at more than one company, indicating the importance of achieving robustness as well as productivity from raw material selection.

Bioreactors are the main focus of the next two chapters. Microbial fermentation scale-up is described by Xiaoming Yang in chapter 47. Wan-Seop Kim describes cell culture bioreactors in chapter 48. Both of these industrial authors include material that focuses on the importance of scaling down as well as scaling up bioprocesses with fidelity of process performance. As Quality by Design efforts continue to emphasize acquiring process understanding at multiple scales, bioprocess practitioners need to appropriately identify scale-dependent and scale-independent process parameters for further study.

Continuous-culture principles are the subject of chapter 49, written by An-Ping Zeng and Jibin Sun. This chapter remains particularly timeless since the pharmaceutical industry in general, and the biopharmaceutical industry in particular, continue to wrestle with the question of whether batch or continuous processing is more effective. Continuous culture also has remained one key method to efficiently study and optimize process parameter set points or feed compositions.

Precise measurement and consistent control of the cellular environment have been the goal of bioprocess engineers for decades. In chapter 50, Adelyma Arroyo of Genentech describes advances in sensor and sampling technologies, and David Hopkins, Melissa St. Amand, and Jack Prior describe bioreactor automation in chapter 51. These industrial authors describe the wide variety of sensor and automation philosophies currently available for implementation to match bioprocessing monitoring demands. The biopharmaceutical industry and academics working in this field consistently have been effective partners with equipment and instrument manufacturers. The end result has been a continued, decades-long, extensive selection of reliable sensor offerings.

This section ends with chapter 52, on purification and characterization of proteins, authored by Ulrich Strych and Richard C. Willson. The quality of the product produced is perhaps the most important aspect of a bioprocess and the key to evaluating bioprocess success. Strych and Willson describe the available process and analytical methods appropriate for use as the protein becomes progressively more purified.

In summary, the field of bioprocessing is continuing to evolve, but at vastly different speeds depending on the

specific area being examined. Although the fundamentals have remained relatively constant, their wide application to different process elements remains astonishing. The goal of the authors contributing to this updated section was to assist readers in making these applications successfully. In turn, it is hoped that the readers of this third edition of the *Manual of Industrial Microbiology and Biotechnology* can pave the way for continued enhancement of these applications and progression of these fundamentals for use by future readers.

Raw Materials Selection and Medium Development for Industrial Fermentation Processes

SAMUN K. DAHOD, RANDOLPH GREASHAM, AND MAX KENNEDY

46

46.1. INTRODUCTION

The fermentation medium forms the environment in which the fermentation microorganisms live, reproduce, and carry out their specific metabolic reactions to produce useful products. The importance of this environment cannot be overemphasized when it comes to the development of a productive fermentation process. Over the years, substantial progress has been made in developing fermentation medium design as a systematic science. However, experienced industrial microbiologists and biochemical engineers will be the first to point out that this field is as much an art as it is a science. In most industrial fermentations, where the product is something other than the cell mass itself, there are two distinct biological requirements for medium design. First, nutrients have to be supplied to establish the growth of the organism. Second, after growth is established, proper nutritional conditions have to be provided to maximize product formation. Besides these obvious biological requirements, one needs to worry about selection of nutrient components that are cost-effective, readily available, and consistent from lot to lot. In recent years, as integrated approaches to fermentation and downstream processing have been developed, it has also been recognized that the fermentation medium should not unduly hinder the downstream processing and, if possible, should even facilitate downstream processing. For new fermentation processes brought up from microbiology laboratories, considerable flexibility and latitude in medium design are possible. The process is not locked into a fixed set of raw materials (for example, due to a Food and Drug Administration [FDA] filing), and the medium components can be freely selected for the sole purpose of maximizing the product yield and minimizing the cost. For an established fermentation process, the choice of medium components may be limited by such factors as FDA filing, the cost structure for the product, and the requirements of downstream processing. In spite of these limitations, continued medium development remains a necessity so that an established product retains its competitive edge in the marketplace.

While literature reports for medium development in specific fermentation processes are plentiful, a general treatment of broad principles involved in fermentation medium development is comparatively harder to find. Readers may find the reviews by Kennedy and Krouse (9) and Corbett (4) informative.

This chapter focuses primarily on raw materials and medium development for microbial fermentation processes. Although general principles also apply to it, mammalian cell culture will not be emphasized. This chapter is not intended to provide a literature search or a review of specific medium types used in specific fermentation processes. Rather, it is designed to provide practicing microbiologists and biochemical engineers with a rational basis for medium development and improvement. At the start of the chapter, chemically defined fermentation media are considered. Then, various commercially available ingredients for key nutrient components of traditional complex fermentation media are described in generic terms. This discussion is followed by a discussion of general considerations and a set of guidelines for medium development and improvement. The information provided is derived from experiences in the fermentation industry, and little effort has been made to cite references for specific examples and dicta mentioned in the chapter, even though similar information may also be presented in the literature.

46.2. CHEMICALLY DEFINED FERMENTATION MEDIA

Chemically defined media have been used routinely in the laboratory to study the microbial biosynthesis of primary and secondary metabolites. A key characteristic that has made these media desirable is consistency of performance. Although chemically defined media may be used to study the biosynthesis of the metabolites, complex media are usually used to produce them. Today, most fermentation processes employ complex media. However, chemically defined media are becoming popular where process consistency is very important, such as the production of biologics. Frequently, the process for making the biologic is considered part of the product definition. In addition to enhancing process consistency, chemically defined media have several other favorable characteristics, including better control and monitoring of the fermentation process, rapid scale-up, reduced sensitivity to large-scale sterilization conditions, and simplification of downstream processing. Concerns associated with these media include medium cost and development time as well as cell growth and production levels. Some of these concerns are being favorably addressed by the availability

of more-sophisticated analytical tools to quickly analyze initial complex medium components, the use of statistical design of experiments to rapidly develop and optimize media, and the use of the well-established technique of nutrient feeding to circumvent nutrient toxicity at high concentrations and to enhance productivity.

There are several approaches one may employ to develop chemically defined media. One is to perform a thorough search of the literature for chemically defined media that support growth of the microorganism of choice or a closely related one. Once identified, it may be optimized using statistical design of experiments. Another approach is to simulate complex medium ingredients using modern analytical tools. For example, in the medium supporting biotin production, histidine and methionine were found to replace the complex component casein hydrolysate. In general, monosodium glutamate and ammonium sulfate have proven to be good replacements for complex nitrogen medium ingredients. A third approach is to develop the initial medium composition based on the typical elemental formula of the cell being $C_6H_{11}NO_3$ with a molecular weight of 161 including ash (the cell dry matter is 90% organic and 10% ash) (18) and the elemental composition of the cell as presented in Table 1 (20).

For example, to estimate the amount of glucose (carbon source) and ammonium sulfate (nitrogen source) required to support a yeast dry cell weight (DCW) of 100 g/liter, the following calculations may be used. For the amount of glucose (for cell growth): $(100 \text{ g of DCW/liter})(0.48 \text{ g of C/g of DCW}) / [(180 \text{ g of glucose/mol of glucose}) / (72 \text{ g of C/mol of glucose})] = 120 \text{ g of glucose/liter}$. However, since glucose is also an energy source for cell maintenance, the total amount of glucose required for both growth and maintenance is estimated as follows: cell yield = grams of DCW/gram of glucose consumed = 0.51 (17). Thus, for 100 g of DCW/liter, $100/0.51 = 196 \text{ g of glucose per liter}$. For the amount of nitrogen: $(100 \text{ g of DCW/liter})(0.075 \text{ g of N/g of DCW}) / \{ [132 \text{ g of } (NH_4)_2SO_4/\text{mol of } (NH_4)_2SO_4] / [28 \text{ g of N/mol of } (NH_4)_2SO_4] \} = 35.4 \text{ g of } (NH_4)_2SO_4 \text{ per liter}$.

Similar calculations are performed for the remaining elements of the microbe. If a growth factor required by the microbe is known (e.g., yeasts require biotin), it should be added. If the requirement for growth factors is unknown, a small amount of yeast extract (0.001 to 0.05%) may be added initially.

Care must be taken when using this approach to calculate the initial concentration of medium ingredients, since they may be growth inhibitory. For example, glucose at a concentration of 50 g/liter inhibits the growth of *Escherichia coli* and can be detrimental even at much lower concentrations. To circumvent this inhibition and achieve high cell densities, appropriate glucose feeding is usually employed. For example, a chemically defined medium used to produce recombinant human interferon- α_1 by *E. coli* is presented in Table 2 (19). As shown, glucose was present initially at a noninhibitory concentration of 30 g/liter. Subsequent glucose feeding was computer controlled, maintaining glucose below its inhibitory concentration throughout most (14 days) of the 16-day fermentation cycle.

By calculating the cell mass supported by each of the elements listed in the medium in Table 2 (such as carbon, nitrogen, phosphorus, sulfur, etc.), ammonium sulfate was identified as the growth-limiting nutrient. Based on the nitrogen level, 34 g of ammonium sulfate was calculated to support a maximum cell mass of 58 g of DCW per liter—the cell density achieved with the actual fermentation process.

In addition to the production of biologics, chemically defined media are proving to be profitable for producing secondary metabolites at manufacturing scale; a good example is the production of penicillin. Examples of chemically defined media that have proven to be economically successful for secondary metabolites are presented in Table 3 (8, 21).

When the chemically defined medium was compared with the initial, optimized complex medium for producing the secondary metabolite by *Streptomyces*, the chemically defined medium reduced the medium cost by 4.5-fold and increased the titer by 80% at the 800-liter scale.

TABLE 1 Typical elemental composition of microbes^a

Element	Composition (% of DCW) in:		
	Bacteria	Yeast	Fungi
Carbon	48	48	48
Nitrogen	12.5	7.5	6
Phosphorus	2.5	1.7	2.5
Sulfur	0.6	0.13	0.3
Potassium	2.8	2.5	1.4
Magnesium	0.3	0.3	0.2
Sodium	0.8	0.06	0.26
Calcium	0.56	0.2	0.75
Iron	0.11	0.26	0.15
Copper	0.02	0.006	
Manganese	0.006	0.004

46.3. COMPONENTS OF INDUSTRIAL FERMENTATION MEDIA

As noted above, most industrial fermentation media are complex formulations containing poorly defined ingredients. Often these ingredients contain multiple nutrients for the growth of fermentation microorganisms. However, for the purposes of medium development, a given ingredient is thought to provide primarily a single nutrient. For example, soy flour is used primarily to supply complex nitrogen or

protein for the growth of a microorganism. However, soy flour also contains substantial amounts of metabolizable carbohydrate and minerals. In the discussion below, the medium ingredients are classified according to their primary role in the fermentation process. On this basis, we can classify the fermentation raw materials in four broad nutrient categories: materials used primarily as sources of carbon, nitrogen, or minerals, and materials used for special purposes.

TABLE 3 Chemically defined media for representatives of actinomycetes and filamentous fungi

Medium component	Composition for production in:	
	<i>Streptomyces</i>	<i>Gliocladium</i>
(A) Medium		
Glucose	112.5 g/liter	
Sucrose		170.0 g/liter
(NH ₄) ₂ SO ₄	16.5 g/liter	8.9 g/liter
K ₂ HPO ₄	1.5 g/liter	1.73 g/liter
Monosodium glutamate	7.5 g/liter	66.4 g/liter
CaCl ₂	1.0 g/liter	
CaCO ₃		1.73 g/liter
MgSO ₄ ·7H ₂ O		1.12 g/liter
Biotin		0.17 g/liter
Salt solution (see part B)	20 ml/liter	2.6 ml/liter
P-2000	2 ml/liter	1.7 ml/liter
(B) Salt solution		
MgSO ₄ ·7H ₂ O	28.9 g/liter	
ZnSO ₄ ·7H ₂ O	0.5 g/liter	5.0 g/liter
CuSO ₄ ·5H ₂ O	0.05 g/liter	0.5 g/liter
FeSO ₄ ·7H ₂ O	0.5 g/liter	5.0 g/liter
MnSO ₄ ·H ₂ O	0.1 g/liter	1.0 g/liter
CoCl ₂ ·6H ₂ O	0.04 g/liter	0.4 g/liter

46.3.1. Carbon Sources

46.3.1.1. Carbohydrates

Glucose is the most frequently used carbohydrate in the fermentation industry. In the United States, it is derived from the corn-processing industry. Two types of products are in use, dextrose monohydrate and hydrolyzed corn syrups containing glucose at a level greater than 95% (called DE95 or dextrose equivalent of 95%). While dextrose monohydrate comes in the form of easy-to-handle crystalline material, it is more expensive. This material is used primarily in small-scale applications as in seed fermentors and when consistency is of the utmost importance. For the bulk of the glucose needs, such as for large-scale fermentations and for in-process feeding, the hydrolysate is the more economical material. If the fermentation microorganism is able to hydrolyze low-molecular-weight saccharides, less expensive corn syrups of various lower degrees of hydrolysis can be used. Industrial fermentation processes such as those for the production of penicillin can readily utilize hydrolysates with a dextrose equivalent as low as 20 (DE20). In fact, some processes give higher yields with these higher-molecular-weight saccharides than they do with pure glucose. The next level of complexity in these glucose-based carbohydrates comes in the form of various dextrans. These are primarily cornstarch products with just enough hydrolysis carried out to make them soluble in the fermentation medium. The dextrans, cornstarch, other starches (such as potato starch), and solid substrates in general are rarely used for in-process feeding. They are generally used as batched-in carbon sources for initial growth of the organism or as carbon sources that are gradually assimilated by the microorganism during the product synthesis phase. In the United States, the crudest and the cheapest source of complex carbohydrate is corn flour. This product is primarily starch but also contains about 5% protein. An important cost reduction strategy used by many fermentation companies is to use crude starch or corn flour in the batch along with the commercially available enzyme amylase. The amylase breaks down starch molecules to generate more readily utilizable carbohydrates. In many fermentation processes, the primary carbon source (the most readily utilizable, such as glucose) is metabolized rapidly during the growth phase and a secondary carbon source (such as oils) is utilized during production.

Sucrose is often used in fermentation processes. In its crystalline form, sucrose is available as table sugar of various degrees of refinement. The white crystalline sucrose is generally used in small-scale applications and in seed fermentors. However, it can also be used as a gradually utilized carbon source in some fermentations in which the organism has a limited ability for metabolizing sucrose. The use of disaccharides is often explored as alternate carbon sources for monosaccharides (such as glucose) when catabolite repression is encountered. The crudest form of sucrose comes as molasses, which contains anywhere from 3 to 10% protein. In some fermentations (for example, glutamic acid fermentation), this product gives excellent results as a combined carbon-nitrogen feed.

In the early days of penicillin fermentations, the carbon source of choice was lactose. This sugar is gradually metabolized by the penicillin-producing organism and hence can be batched into the medium from the beginning of the process. However, since the advent of controlled feeding of glucose, the importance of lactose in the fermentation industry has decreased. Lactose is available in granular

form for small-scale applications, and it is still used in some fermentations, especially in Europe, where it is more readily available than dextrose and corn syrups. The most economical source of lactose is derived from the cheese industry by-product cheese whey. This product is available in a spray-dried form and is an excellent source of protein and minerals besides being a source of lactose.

Other sugars that are used less frequently in the fermentation industry include maltose, mannitol, sorbitol, and xylose. All of these are generally used in their purified forms. A related carbon source for the fermentation industry is glycerol. It is useful in many processes as a gradually metabolized carbon source. Additionally, organic acids, such as acetic acid, may be used on rare occasions as combination pH control agents and carbon nutrients. Minoda (13) has reported on the potential uses of other unusual carbon sources for amino acid fermentations.

46.3.1.2. Oils

Various oils are widely used as carbon sources in the fermentation industry, especially in antibiotic fermentations. Oils can supply both the energy and the growth carbon needs of the organism. In many antibiotic fermentations, where the antibiotic backbone is synthesized from low-molecular-weight fatty acids, the oils make ideal carbon sources since they gradually supply these fatty acids during the fermentation process. The oils are used both as batched-in ingredients and as continuous feeds. In some fermentations, oils play an important auxiliary role even when they are not actively metabolized by the fermentation microorganism. The yield-enhancing effect of the oil when it is not metabolized is not well understood. However, oxygen diffusivity in oils is higher than in water, which may have a beneficial effect on oxygen transfer from bubbles. It is possible that the oil provides protection to cells from excessive shear forces or that it makes a key micronutrient from the complex medium more available to the microorganism in the form of micelles. In fermentations in which oils can be utilized as carbon feeds, they offer important benefits. First, the caloric content and the corresponding energy availability per unit volume of feed are appreciably higher for oils than for carbohydrates. One liter of vegetable oil has more than twice the utilizable energy as 1 liter of a 55% solution of glucose. This high energy density allows for lower feed rates and smaller feed vessels. Consequently, the fermentor volume management for long-cycle fermentations is easier with oil-fed fermentations than with sugar-fed fermentations. This enhanced management is true not only because less feed is introduced into the fermentor but also because the metabolism of oil does not produce as much water as the metabolism of sugars. The antifoaming property of the oils is also beneficial for most fermentation processes. Before the advent of synthetic defoamers, oils were used for foam control in many fermentation processes even when the carbon source of choice was a sugar. However, the oil added for foam control is metabolized by the organism, and continuous addition is required to control foam. The synthetic defoamers are more effective because they are not readily degraded by the fermenting microorganism and they are cost-effective. In special cases, when the presence of synthetic defoamer interferes with the downstream processing, oils are still used as defoamers. The antifoaming properties of several natural oils are reviewed by Vardar-Sukan (16).

The most important oil in the U.S. fermentation industry is soybean oil. It is abundant and relatively inexpensive. Other oils that are often used are lard oil, fish oil, and oils

of other plants such as corn, cottonseed, peanut, sunflower, and safflower. One specialty oil product that is synthetically made and has found application in the fermentation industry is methyl oleate. Methyl oleate is often used as a supplemental feed in conjunction with another feed such as soybean oil. The fatty acid contents of various oils vary according to their source, and there may be a theoretical basis for one type of oil to perform better than another type. However, the choice of oil in a given fermentation is generally determined empirically. The oil that is used in the shake flask fermentations during screening of the producing strains very often also gives better results in large-scale fermentations.

46.3.2. Sources of Organic Nitrogen or Protein

There are principally three classes of raw materials available to supply the organic nitrogen or protein requirement of a fermentation process: (i) those derived from agricultural products, (ii) those derived from brewery industry by-products, and (iii) those derived from meat and fish by-products. All of these products supply other important fermentation nutrients in addition to organic nitrogen.

46.3.2.1. Nitrogen Sources Derived from Agricultural Products

The sources derived from agricultural products are the workhorse ingredients of the fermentation industry. They include the products of commodities such as various grains and soybean. The soybean flours, meals, and grits head the list of applications in antibiotic fermentations. The popularity of the soy products is based on the fact that after the soy oil is extracted from the soybeans, the residue is about 50% protein, which is readily available for cell growth. In addition, soy flour, meals, and grits contain up to 30% utilizable carbohydrates. Most minerals required for microbial growth are also present in soy-based products. In many seed medium applications, where growth is the primary consideration, all that is required in the medium is soy flour along with salts such as magnesium sulfate and potassium phosphate. A product that is processed very similarly to soy flour is cottonseed flour. The protein in the cottonseed flour is less readily available and thus makes a good slow-releasing nitrogen source. Corn gluten meal is another readily available product that is suitable as a slow-releasing nitrogen source. Corn steep liquor, a by-product of the corn milling industry, was very extensively used in the early years of the antibiotic fermentation industry. In recent years, though, due to the variability in the product quality, the liquid form of corn steep liquor has fallen out of favor. Spray-dried corn steep liquor is now available and is used in many antibiotic fermentations because it is less variable. Other agricultural commodities used as nitrogen sources in the fermentation industry include peanut meal, linseed meal, wheat flour, barley meal, and rice meal. Plant or animal hydrolysates produced by the degrading action of enzymes, usually proteases, are widely used. Should a plant source be required, soybean hydrolysates can be used, or if an animal source is acceptable, then casein or whey protein hydrolysates may be used.

46.3.2.2. Nitrogen Sources Derived from Brewery Industry By-Products

The brewing industry is an important source of fermentation raw materials. The principal product is the yeast left over after beer fermentation. The suitability of the yeast by-product for a given fermentation depends upon the

method of drying. The yeast may be drum dried or spray dried. It is also sold as a paste produced by water evaporation in an industrial evaporator. All of these products have found applications in the fermentation industry as sources of nitrogen. However, the yeast is never used as the primary source of nitrogen. Instead, it is thought of as a nitrogen supplement with additional beneficial nutrients that are not available from grain-based nitrogen sources. Generally, these additional nutrients are organic phosphorus and unknown micronutrients. Brewery yeast is also refined into yeast extracts of different water solubilities, which are more expensive and used in smaller quantities. Yeast extract is often the single undefined component used in so-called semidefined fermentation media to provide micronutrients. The brewing and distilling industries supply two other by-products that are sometimes used in the fermentation industry: distillers' solubles, in the form of a concentrate or spray-dried powder, and leftover grains from the brewing process.

46.3.2.3. Nitrogen Sources Derived from Meat and Fish By-Products

Meat and fish products are very rich in protein. So are the by-products of these industries. The primary meat-based product is generically known as spray-dried lard water. This is a by-product of lard processing. The animal bones and tissues are boiled in water, sometimes in the presence of proteases, to free the fat. The resulting liquor is separated into fat and water layers. The water part is rich in proteins and peptides. This water, when spray dried, gives a product with a protein content of 80% or greater. The lard water can be obtained with different degrees of chemical or enzymatic hydrolysis. Hydrolyzed lard water products are sold as meat peptones under various brand names. A parallel line of products labeled fish meals and fish hydrolysates is derived from heat and enzymatic treatment of fish wastes. These products are generally about 70% protein.

46.3.3. Minerals

Minerals are used in fermentation media to serve many purposes, e.g., as major nutrients, as trace metal suppliers, as ionic strength-balancing agents, as precursors for secondary-metabolite synthesis, as buffering agents, as pH control agents, and as reactants to remove specific inhibitory nutrients from the medium. The nitrogen-containing salts (e.g., ammonium sulfate, ammonium nitrate, sodium nitrate, and potassium nitrate) can provide a substantial portion of the nitrogen requirement for cell growth when combined with organic nitrogen. When salts are used as nitrogen nutrients, their metabolism invariably results in pH changes in the medium. For example, when ammonium sulfate is utilized by the organism, the pH tends to fall, and when sodium nitrate is utilized, the pH tends to rise. Therefore, it is very important that adequate buffering or pH control be provided to counterbalance these pH effects. Ammonia used for pH control has the advantage of regulating pH while replenishing ammonium nitrogen used up from ammonium sulfate in the medium.

Another major nutrient supplied as inorganic salt is phosphorus in the form of phosphate salts. Phosphorus from soluble phosphate salts is more readily available to the organism than the phosphorus derived from organic nutrients such as yeast. As a result, it is possible to control the rate of growth by balancing organic phosphorus against inorganic phosphorus salts.

Although most organic nitrogen sources such as grain meals and yeast extracts contain many of the minerals

required for growth, the fermentation medium is often supplemented with salts that provide elements that are required in greater than trace quantities. For example, magnesium and potassium salts and the salts containing sulfate are generally included in the medium if they have not already been included for other purposes. Trace elements such as iron, zinc, manganese, copper, cobalt, and molybdenum are generally not included in fermentation media containing high concentrations of complex ingredients unless they serve specific purposes in metabolism. For example, if product synthesis is known to be carried out by an enzyme complex containing cobalt, this element will be included in the medium at a concentration of a few parts per million to ensure that it is not scarce. When a medium contains low concentrations of complex ingredients, it is important to include a trace element mixture in the fermentation medium.

In fermentations where the ionic strength has to be relatively high, sodium chloride or sodium sulfate is included in the medium. The insoluble salt calcium carbonate is added to prevent the fermentation pH from falling below 6.0. As the pH drops below 6, calcium carbonate dissolves in the medium, raising its pH. Phosphate salts are rarely used for buffering in fermentation media because the phosphorus balance has to be based on the metabolism rather than on the buffering needs. The soluble calcium salts such as calcium chloride and calcium acetate are often used to precipitate out soluble phosphate (in the form of calcium phosphate) from the media of fermentations in which product synthesis is strongly inhibited by phosphate. Minerals also serve as precursors in antibiotic fermentations. In penicillin and cephalosporin fermentations, sufficient sulfate salts have to be included in the medium to supply the sulfur required for the syntheses of these sulfur-containing antibiotics. Similarly, chloride salts must be included in the medium for vancomycin fermentation since the vancomycin molecule contains several chlorine atoms.

46.3.4. Specialty Chemicals

Several types of specialty chemicals are added to large-scale fermentation media. The most important of these chemicals are the defoamers. The defoamers reduce the interfacial surface tension between air and water to facilitate bubble coalescence. In the fermentation industry, silicone and polyol-based defoamers have largely replaced vegetable oils as defoamers. The advantages of the synthetic defoamers are that they are cost-effective and very slowly metabolized and do not have appreciable metabolic side effects. The two most popular defoamers in use in the fermentation industry are polypropylene glycol and silicone emulsion. The defoamers are generally batched with the starting medium. In many fermentations, however, it is necessary to supply defoamer throughout the fermentation cycle to control foam and to control air holdup. Emulsifiers used in fermentations (such as Tween and Span) play a role opposite to that of defoamers. They are added to stabilize small droplets of oily nutrients by increasing the surface tension between oil and water. The small droplets have a dramatically increased surface area and thus allow oily substrates to be more readily utilized by the fermentation organism. Metal-chelating agents such as EDTA are often included in fermentation media. The chelating agents have two diametrically opposed effects. On the one hand, they can tie up metal ions that are toxic to the microorganism. On the other hand, they can prevent the precipitation of a required trace metal by

forming a soluble complex. The availability of the metal to the fermenting microorganism depends upon whether the microorganism can effectively compete with the complexing agent for the required metal.

An important class of specialty products used in the fermentation industry is made up of various enzyme preparations. Crude preparations of enzymes such as amylase, protease, and cellulase are used to precondition the medium. Invariably, these enzymes are used at the mixing stage before medium sterilization. A partial breakdown of the starch of medium components such as corn flour can be achieved by the addition of amylase. The cellulase complex can be used to reduce the viscosity of a medium containing a high concentration of ingredients such as soy or cottonseed flour. Proteases can predigest the medium proteins before sterilization. Enzymatic pretreatment of a fermentation medium thus allows a crude and cheaper raw material to be substituted for a more refined and expensive raw material. Significant efforts are currently under way to investigate the pretreatment of cheaper raw materials to enable their economic fermentation to ethanol or other biofuels.

46.3.5. Sources of Information on Fermentation Raw Materials and Microbial Composition

The best source of information on a given class of fermentation raw material is the industry in which it is generated. Information about such things as the protein, fat, carbohydrate, and mineral contents of various raw materials is readily available from the supplier of the raw materials. However, this information is not necessarily generated for the use of the fermentation industry. It is generated for the benefit of the primary users, which in most cases are the animal feed and food industries. As a result, interpretation of the information for fermentation use is up to the fermentation scientist. For example, while the total nitrogen value of a grain-based product may be meaningful from the point of view of a weight gain calculation when the product is fed to a farm animal, it may not necessarily have the same meaning as the nitrogen available for the fermentation microorganism to grow on. For the same reason, the carbohydrate value provided by the manufacturer of one product may be higher than the value provided for a second product, and yet the second product could have more available carbon for a particular fermentation microorganism. The information provided by the manufacturer is a good approximation for the initial evaluation and for preliminary cost calculations. Actual fermentation experiments are necessary in all cases to justify a change of raw material. In recent years, some of the raw materials suppliers have taken it upon themselves to evaluate their products for various fermentation processes and publish the results in their own manuals or in scientific journals.

A list or database of fermentation raw materials is essential for the fermentation medium designer. Such a database should include medium composition (both molecular and elemental), but could also include such things as price, supplier, and availability. Useful lists of such data include the following.

- Miller and Churchill (12) lists many fermentation raw materials by their trade names along with their applications in various types of fermentation processes.
- Atkinson and Mavituna (1) is a useful source of data for a range of fermentation situations and has a list of compositions of fermentation medium components.

- Solomons (15), an older but classic practical fermentation guide, has a chapter on constituents of fermentation culture media.
- Kennedy and Reader (10) may have general applicability, although this paper describes only raw materials available in New Zealand.

Many such lists are prepared by the suppliers of fermentation media, such as the *Traders' Guide to Fermentation Media Formulation* (20). A similar information booklet relating to soy products, titled *Soy Protein Products in Fermentation*, is supplied by Cargill, Inc. (3). Knowledge of suppliers reveals trends in composition and availability and is particularly useful when it comes to using agricultural by-products for fermentation media.

In the case of some commodity products where there is intense price pressure on raw-material costs, or when the goal of the fermentation is to add value to an otherwise low-value by-product stream, the list of possible medium components is quite constricted. Usually this means incorporating agricultural products in the fermentation medium in a very crude state. Data on agricultural products are best found from the relevant trade organization or from food nutrition databases. Many countries maintain databases of food composition, including the United States, Denmark, Australia, and New Zealand, which profile the main agricultural products of the country concerned. These are usually conveniently Web searchable; see, for example, those provided by the U.S. Department of Agriculture (www.ars.usda.gov/Aboutus/docs.htm?docid=6300) and Plant and Food Research (www.crop.cri.nz/home/products-services/nutrition/foodcompdata/fcd-products/fcd-food-comp-tables.php). Another good source of data on agricultural by-products is the *Feed Industry Red Book* by Goihl and McEllhiney (6).

There are also compilations of media that can be useful for selecting a medium specific for a certain situation. Most of these compilations are laboratory media, rather than industrial fermentation media, and thus limited in use for scale-up. They do, however, provide a useful starting point. Examples of already specified media sources include *Handbook of Culture Media for Food Microbiology* (5), *Difco & BBL Manual: Manual of Microbiological Culture Media* (2), and *The Oxoid Manual of Culture Media, Ingredients and Other Laboratory Services* (14).

Most practitioners of fermentation medium design have favorite compositions for specific microorganisms, so soliciting colleagues for a suggested medium for a particular microorganism is often enlightening.

As discussed earlier in this chapter, the composition of the microorganism (molecular and elemental) is also important in medium design for the purpose of calculating potential biomass and product yield, via mass balance. For accurate data, it is best to measure the composition for the microorganism in question.

46.4. GENERAL CONSIDERATIONS FOR INDUSTRIAL (COMPLEX) MEDIUM DEVELOPMENT OR IMPROVEMENT

46.4.1. Rationale for Improving a Fermentation Medium

Designing an improved fermentation medium can be laborious, expensive, open-ended, and time-consuming, involving a large number of experiments. Consequently, it is important that the effort is justified and, most importantly,

that the target of the optimization is identified. The main reasons the fermentation industry designs improved fermentation media are to (i) improve product yield, (ii) decrease the cost of the medium, (iii) ease product separation, (iv) avoid the microbe making undesired by-products, (v) reduce waste treatment costs, and (vi) improve robustness (the ability of a medium to repeatedly perform well at large scale). It is very important at the start of a medium design campaign to clearly identify which of these reasons is the primary target of the effort.

In a typical industrial antibiotic fermentation, improving product yield always has a larger impact on the overall process cost than does simple medium cost reduction. Very often, yield improvement not only improves the economy of the fermentation process itself but also has beneficial effects on downstream processing. The product-to-impurity ratio increases as the fermentation yield increases, making the recovery process more efficient. In some mature fermentations, productivity improvement beyond a certain level is difficult to attain due to genetic limitations or the inability of the microorganism to tolerate increasingly higher concentration of the product. In such cases, fermentation raw-material cost reduction alone can be the major component of the overall cost reduction efforts. The value of the final product and the volume of the product produced are other important considerations. First, consider the final product value relative to the cost of the raw materials used. In the fermentation industry, the contribution of fermentation raw materials to the overall production cost may vary from as little as 5% (for example, the production of high-value biological agents such as interferon or the production of steroids) to as much as 50% (for example, the production of commodities such as ethanol). The scientist working on the former type of product has much greater flexibility in selecting raw materials, since the overall production cost is not appreciably increased by introduction of a relatively costly raw material. The goal here is to reduce the overall cost by increasing the fermentation yield. In the latter case, however, the incremental cost increase due to the introduction of a new raw material has to be more than compensated by the increase in yield and product quality. The agricultural commodity products and by-products from the brewery and corn wet-milling industries are the typical raw materials used in fermentation processes for low- and medium-value products such as organic acids and well-established antibiotics. On the other hand, exotic raw materials such as refined yeast extracts and exotic growth factors can be cost-effective in fermentation processes of high-value products such as biological peptides. The usage rate of a given raw material and the overall volume of the fermentation broth processed also have to be taken into account for medium development decisions. If an ingredient is used at a few parts per million, its unit cost does not significantly affect the overall process cost. If the volume of the fermentation broth is very large, however, the overall cost may still be significantly affected.

The availability of a given raw material in a given geographic location is another consideration. Should a specific material be shipped long distance, or should the medium formulation be changed so that a readily available material can be used in its place? This depends largely upon how sensitive the fermentation yield is to the type of material used. While a readily available raw material may give a somewhat reduced yield, in the long run it may be more cost-effective to standardize the medium with that material than to

depend upon a material that gives higher yield but may be subject to supply disruption. On the large scale, supply disruption is a crucial issue. Access to at least two suppliers of any particular component in the medium is recommended. This recommendation prevents a large disruption should one supplier suddenly no longer supply a given component or go out of business. In the case of some agricultural products, adverse weather can disturb supply. Agricultural products are also susceptible to price fluctuations. A rapid rise in cost of one component may mean its removal from the fermentation and substitution with another. One recent example of such price fluctuations was caused by the rapid rise in the use of biofuels, disturbing supply and prices of agricultural commodities. It is a useful exercise to rank each substrate on a price/kilogram of carbon and price/kilogram of nitrogen basis for comparison. In this way critical prices, where an alternative substrate becomes more cost-effective, can be identified and market prices tracked. A new component validation procedure ensures that new components can quickly be given an end-use test to confirm their performance and robustness.

Other factors to consider are whether the quality of the material will be adversely affected during long-distance shipping and/or prolonged storage. Raw materials such as yeast paste and corn steep liquor are not stable enough for prolonged storage. On the other hand, raw materials with low moisture content such as cottonseed meal, soy flour, and spray-dried yeast are reasonably stable over long periods of storage.

46.4.2. Nature of Fermentation Raw Materials

Most raw materials used in the fermentation industries are not designed for that use. They are generally designed to supply commodities for the food and feed industry. Thus, soy meals, cottonseed meals, and corn gluten meals are designed primarily as animal feed protein sources. Various yeast products are designed for both human food and animal feed applications. Corn syrups of different levels of hydrolysis are made for application in the food-processing industry. Since the fermentation industry is not the primary user of these raw materials, the industry does not have much control over their processing and the resulting quality from the point of view of their use in fermentation processes. Also, agricultural products are subject to variation due to growing seasons, soil conditions, and storage conditions. In short, raw-material variability is the rule rather than the exception. In medium design, then, it is necessary to use multiple sources of the same class of nutrient to reduce process variability. Thus, including two complex nitrogen sources in the medium formulation is more desirable than depending upon a single ingredient. It is also recommended that several lots of the same raw material be tested before settling on a given medium formulation. If the product yield varies excessively due to lot-to-lot variability, it is better to avoid that raw material in the medium formulation altogether. Crude complex raw materials are more likely to exhibit greater variability in composition compared to synthetic medium components.

At this point, it should be noted that water used to prepare fermentation medium is the major component of the medium. In large fermentation plants, this water is usually not distilled or deionized water, as may be the case in the laboratory. As a result, certain metal ions and organic components that come dissolved in the water as impurities become part of the fermentation medium. These

impurities and their concentrations may vary on a seasonal basis. In addition, the profile of inorganic and organic components that come with the water may vary when the municipal water treatment plant experiences upsets in its operations. Many fermentation plants use readily available water from adjacent water sources such as lakes, rivers, or deep wells with minimal pretreatment. These water sources are also subject to seasonal variability. Water quality is an important variable when fermentation processes are scaled up from the laboratory, where deionized or distilled water may be used. The water quality is also an important consideration when fermentations involving identical raw materials perform differently at differing physical plant locations. Most fermentation plants monitor the water quality only superficially, and it is seldom known which water quality parameters are important for a given fermentation process.

46.5. GENERAL GUIDELINES FOR FERMENTATION MEDIUM DEVELOPMENT

46.5.1. Seed Medium and Product Synthesis Medium

Generally, the purpose of the seed culture is to grow cells as fast as possible on the basis of predefined criteria such as dissolved-oxygen level, oxygen uptake rate, or centrifuged cell volume. This can be readily achieved by supplying the required nutrient for growth without regard to the product formation needs. When developing a medium for the production stage of a process, the selection of medium components and optimization of their concentrations in the medium are more involved. The objective is not only to develop cell mass but also to synthesize the product at the highest rate possible. The cell density attained, the growth rate during the cell growth, the fermentation time, and the subsequent maintenance metabolism are all important factors in maximizing product formation. The rate of cell growth often can be controlled by controlling the level of readily available nutrients such as glucose, amino acids, and soluble phosphate and by controlling the growth temperature. The slow-growth and maintenance metabolism during the product synthesis phase of the fermentation process is generally controlled by supplying additional nutrients slowly. This controlled nutrient feed is usually composed of glucose or vegetable oil. In some cases, ammonia or complex nitrogen sources are also supplied during this phase. Another way of controlling the slow-growth and maintenance phase of the fermentation process is to include in the medium a carbon (or nitrogen) source that is only gradually utilized by the organism. Often, carbohydrates such as lactose or starch are used for this purpose. The organism being cultivated must produce specific enzymes such as β -galactosidase or amylase to be able to utilize these carbon sources. Various oils are frequently added as the source of carbon that is gradually consumed by microorganisms exhibiting lipase activity. Coarse raw materials such as soybean grits and corn gluten meal are used to supply slow-releasing nitrogen. Enzymes such as cellulase and protease must be induced for the organism to utilize these coarse nitrogen sources. In addition to maintenance nutrients, some secondary-metabolite fermentations require the addition of precursor compounds. For example, the precursors phenylacetic acid and uracil are added to fermentations of the antibiotics penicillin and nikkomycin, respectively.

46.5.2. Using Laboratory Fermentation Medium as the Starting Point

Industrial fermentation organisms are generally highly mutated organisms that are developed in strain development laboratories over many years. The fermentation conditions under which these organisms have been selected must be taken into consideration during medium development work. If a strain has been selected with a laboratory fermentation medium that is based on cottonseed meal as the primary nitrogen source, it may not perform well in a medium based on corn steep liquor as the primary nitrogen source. This is not to say that more closely related medium ingredients such as soy flour and peanut meal may not give yield improvements. The relationship between the laboratory carbon source and the carbon source used in the large-scale fermentation is often not straightforward. Because in shake flask fermentations external pH control is not possible, a readily utilized carbon source such as glucose is very seldom used unless the medium is heavily buffered. Typically, a carbon source such as sucrose, lactose, dextrin, or starch is used to maintain the pH in a reasonable range. When these processes are scaled up, similar complex carbohydrates are initially used in a batch mode. As the process is developed further, however, they are often replaced with an external feed of a readily utilizable carbon source such as glucose, accompanied by pH control. A similar situation can also arise with regard to simple nitrogen sources. Although nitrates or amino acids have to be used in a laboratory fermentation medium for the purpose of pH balancing and slow nitrogen release, they can be replaced in large-scale fermentations with more readily available and cheaper materials such as ammonium sulfate or ammonia, with appropriate control mechanisms. The overall efficiency of nutrient utilization may also change when the fermentation process is scaled up to large fermentors, in which the agitation and aeration conditions are more intense than those in shake flasks. More often than not, the nutrient requirement increases when going from shake flasks to large fermentors.

46.5.3. Considerations of the Fermentation Medium as a Whole

A fermentation medium is typically prepared by dissolving or suspending various raw materials in water. Before the medium is inoculated with the desired microorganism, it is heat sterilized. The batch sterilization involves heating the medium to over 121°C for a period ranging from 30 to 60 min. Continuous sterilization is carried out by rapidly bringing up the temperature to 145 to 155°C and holding it at that temperature for 5 to 10 min. This heat sterilization of a mixture of ingredients in water has a profound effect on the resulting fermentation medium. A number of chemical and physical changes occur during sterilization. Insoluble ingredients such as grain flours and meals are partially solubilized. Macromolecules such as proteins and starch are partly degraded to more soluble and readily metabolizable lower-molecular-weight peptides and oligosaccharides. The inorganic components of the medium react among themselves and with organic components to give new compounds. For example, various metal ions complex with protein molecules to alter protein solubility, organic phosphorus compounds release phosphate into the medium, dissolved phosphorus is precipitated as insoluble metal phosphates, etc. In some cases, the heat sterilization generates toxic chemicals from relatively benign medium

ingredients. A well-known example of this toxicity is the Maillard reaction between reducing sugars and amino compounds to give growth-inhibiting amino sugars. To prevent this reaction, reducing sugars such as glucose are sterilized separately from the medium containing amino acids and ammonia. The two components of the medium are mixed after they are cooled to about 40°C. Since various medium components interact during sterilization, it is important to examine the effect of an ingredient being added or removed on the overall chemistry of the medium. The organism may not require calcium salt for growth or for product formation. However, calcium may play a critical role by precipitating out excess phosphate from the medium in the form of insoluble calcium phosphate and allowing a phosphate-regulated product to be synthesized. The elimination of soluble phosphate will also change the medium's buffering capacity. The pH of the medium during sterilization is important because the chemical reactions occurring in an aqueous medium are affected by pH. The pH can have an effect on both the rates of reactions and the equilibrium composition. For this reason, it is generally necessary to experiment with sterilization pH to optimize the performance of the medium under development. It is well known that by manipulating sterilization pH, one can increase or decrease protein solubilization from a medium containing insoluble protein sources such as grain flours and meals.

Sterilization heat damage to a medium can have a significant impact on fermentation medium performance. Unfortunately, heat input to a fermentation medium during sterilization can vary considerably on scale-up, depending on fermentor geometry. One way to quantitatively track the heat input as scale is varied is the use of the del factor (or Ro) calculation (18). Del factor can be used to track variations in heat input between sterilization batches, should a medium be unavoidably sensitive to such damage.

Some components of the medium may have an indirect effect even in the absence of heat sterilization. For example, seemingly inert oils and defoamers may create micelles in the broth that solubilize proteinaceous components and fats that may otherwise be unavailable for metabolism. Some surface-active agents have no metabolic effect but may have substantial effects on the oxygen transfer characteristics of the fermentation broth by changing the surface tension at the air-liquid interface. Many fermentation media containing complex proteins tend to foam heavily during sterilization, and addition of defoamer may be necessary even though the fermentation process itself does not require foam control chemicals. On rare occasions, the order of addition of various ingredients when the medium is prepared, the temperature at which the presterilized medium is prepared, and the length of time the medium is held before sterilization will affect the performance of the fermentation process.

Particle size can have a significant effect on fermentation medium performance. Large particles have a smaller surface area per unit volume than small particles, and this means that they may dissolve or get degraded at a slower rate during the fermentation, affecting fermentation kinetics. Calcium carbonate is particularly susceptible to this effect. Large particles also require a longer time to sterilize, meaning more heat damage to other components in the medium. Solid substrates also interfere with the common DCW cell mass assay, and one of the advantages of a synthetic medium is the ability to conduct meaningful DCW cell mass assays.

Regulatory preferences also play a part in fermentation medium design. Some companies may wish to avoid using all animal-derived products due to the potential

contamination by self-replicating proteins referred to as prions. Strong evidence supports prions' being responsible for causing bovine spongiform encephalopathy, a transmissible spongiform encephalopathy, in cattle. Other companies may accept the use of milk-based products, e.g., casein hydrolysate, or fish-derived products, e.g., fish meal.

When designing a fermentation medium, it is worthwhile doing an elemental mass balance, not only to see that sufficient components are present to achieve a desired yield but also to inspect the medium for overdosing. Too high a concentration of some minerals may be toxic. Copper is an example of a mineral of which it is easy to add too much. The exact amount that a microbe will tolerate can be strain specific. Corrosion of equipment may inadvertently add minerals to toxic levels. For this reason, copper pipes contacting the medium are to be avoided. Corrosion may also present an issue in the special case of growing marine microbes. Some marine microbes need high levels of sodium chloride in the fermentation medium, which can provide a significant corrosion challenge for stainless steel equipment.

Often forgotten in fermentation medium design is the fact that oxygen is a metabolic requirement and that carbon dioxide can dissolve in the medium and become inhibitory. While developing a medium at laboratory level, poor results may be due to poor oxygen transfer rather than the components in the medium. Another trap when developing a medium at small scale is the appearance of wall growth. This will invalidate results, as product formation (or lack thereof) in this wall growth is not representative of what will happen in a large-scale fermentor (where wall growth, if present at all, will be only a small fraction of the total fermentation volume). Wall growth on the small scale can be greatly reduced by adding a small amount of a growth dispersion agent for filamentous microorganisms, such as Junlon polyacrylic acid (7).

Because the fermentation medium after sterilization (and hence after the chemical and physical changes have taken place) is the real medium in which the organism of interest is to be grown, it is important to characterize the sterilized medium. Certain overall indices such as soluble nitrogen, reducing-sugar equivalent, and soluble phosphate are often used to characterize the sterilized fermentation medium. However, these indices give only a gross measure of the properties of the medium. Only by understanding the chemical and physical phenomena taking place in the medium during batching, sterilization, and the fermentation process itself can one truly master the art of fermentation medium development.

Last, it is important to ask, when are medium design efforts sufficient? Usually some form of medium design continues during the life of the product due to the introduction of new strains from a strain improvement program, the necessity of further yield improvements, or the replacement of components for some reason. The time to stop is when resources run out or when no changes seem to improve the best medium. It is important not to overinvest in medium design, and one tool useful in assessing this is to plot the number of media tested versus the maximum performance to date. Typically such a curve follows asymptotic behavior quite quickly (especially if statistical experimental design is used), which indicates visually when the point of diminishing returns is reached (11).

Fermentation medium design is both an art form and a logical science, and this is what makes it a challenge.

Scale-Up of Microbial Fermentation Process

XIAOMING YANG

47

47.1. INTRODUCTION

47.1.1. Scope

Microbial fermentation processes play a critical role in many important industrial applications. In various applications, fermentation processes are utilized to produce a final product, convert substrates, catalyze reactions, remediate environmentally toxic materials, or simply make mass biological materials. Process scale-up, in a broad sense, is a critical activity that enables a fermentation process achieved in research and development to operate at a commercially viable scale for manufacturing. A successful scale-up involves many aspects of successful preparation and planning beyond pure process scale-up technology. These include setting up clear goals and expectations, timelines and milestones, resources and organization, facility fit considerations, and quality and specifications. This chapter covers a broad scope of issues related to microbial fermentation process scale-up and describes specific steps to plan and execute a scale-up project.

47.1.2. Plan

The first step is to define the project goals, targets, facility, and timeline for completion. Common project goals and targets include the following parameters.

- Annual output of products (in grams or kilograms), based on an analysis of market demand and manufacturing capacity
- Productivity targets (such as grams/day, grams/liter/day, or lot/number of days, etc.), based on process capability and facility capability
- Yield per lot (grams or kilograms/lot), based on process capability, facility scale, and operational capability
- Process cycle time (days/lot), based on throughput, process, and operational constraints
- Cost targets (cost/gram, cost/lot, etc.), based on process capability, product price, market demand, and facility operating cost.

There may be other special targets as well. Ideally, one may have a strong desire to optimize all the targets for maximum benefit of a process. In reality, facility utilization and availability sometimes place a critical constraint on process scale-up planning. A firm may have to use an

existing facility that confines how a new process may be scaled up to fit into the facility. In this case, it may not be possible to optimize all of the above targets, and they have to be balanced and prioritized. Setup of the right objectives and targets is a cross-functional activity with business input and technology input.

With clear targets, the next step is to organize a team with all the necessary expertise. A detailed analysis of technical risks and challenges may lead to the appropriate level of resources and a realistic timeline. A project timeline with verifiable milestones is essential at the beginning of a project.

47.2. FERMENTATION PROCESS SCALE-UP

47.2.1. Cell Banking Strategy for Large-Scale Manufacturing

A commercial fermentation process requires a stable cell bank that ensures consistent and predictable production in the long term. A common cell bank strategy for large-scale production is to maintain a master cell bank (MCB), from which a working cell bank (WCB) is generated for routine production. This strategy allows the original source of genetically stable MCB to be preserved for an extensive period of time. Cell banks are usually stored in -70°C liquid nitrogen or a -80°C freezer.

The number of vials in the MCB and WCB depends on the frequency of production and the stability profile of the cell banks. It is common to have hundreds of vials for both cell banks. Many cell banks should be able to last for many years. The volume of each cell bank vial depends on the production inoculation needs. It is common to have 1 ml to tens of milliliters of cells in microbial cell banks.

The cell bank quality and stability need to be adequately tested and monitored. General tests of a cell bank include:

1. Cell recovery upon freeze and thaw: growth test
2. Contamination or purity tests: plating for colony morphology, genetic discrimination tests, phenotype tests, etc.
3. Real-time stability tests: time points for growth, genetic stability, and product expression stability
4. Production qualification: use of a small-scale production model process to check the cell bank's suitability for production
5. A comparability study of the MCB and WCB, recommended to ensure the WCB's performance

47.2.2. Seed Train Scale-Up Strategy

The purpose of a seed train is to propagate cells to a desired mass for inoculation into the production bioreactor. The traditional seed train includes thawing a vial and inoculating into shaker flasks for a certain number of stages with increasing flask sizes, and may include stainless steel reactors. The guiding principle for a seed train scale-up is to minimize the number of stages for the entire seed train, maintain robust growth, and finally prevent any negative impact of extended generations to productivity and product quality.

Typical studies of seed train scale-up may include:

1. *Vial thaw conditions.* This may include temperature and time between thaw and inoculation.
2. *Inoculation ratio.* It is always desirable to have fewer steps for the seed train for simplicity of operations. Therefore, a minimum inoculation ratio (vol%) needs to be defined at every step. For microbes, 0.1 to 5% is commonly used. However, overall process robustness needs to be demonstrated with the inoculation ratios.
3. *Seed train media.* Usually, seed train media are optimized to support growth, rather than product expression, in a batch mode. For operational simplicity, it is recommended to use a simple recipe for the seed train media.
4. *Genetic stability and production stability during the seed train process.* This requires studies with an extended duration, beyond that estimated to be required for generation at the production scale.

In practical operations, a manufacturing plant may carry a parallel seed train as a backup in case the main seed train fails, usually due to contamination. A typical seed train for fermentation is shown in Fig. 1.

47.2.3. Production Fermentation Scale-Up

The essence of scale-up of a fermentation process is to demonstrate fermentation production at large scale resulting in the same productivity and quality as that developed at small scale. One of the outcomes of a process scale-up is to finalize a detailed large-scale process description with settings of all operational parameters and their ranges at scale. The scaled-up fermentation has to be demonstrated with a certain number of runs for consistency and statistical significance. To achieve these goals, one may take the following steps.

1. Identify linear scale-up parameters.
 - a. *Temperature.* Temperature should be maintained the same at all scales. Temperatures of microbial processes range widely, mostly from 20 to 45°C. For large scale, consideration should be given to the mixing time, heat transfer rates, and control precision. Challenges

to meet temperature control requirements may be due to limited cooling capacity of a large bioreactor. To maintain temperature, a large-scale bioreactor needs to provide the same heat transfer rate (heat/volume/time) as the small-scale bioreactor does throughout the entire course of a process. Many high-cell-density cultures require extremely high heat removal rates. Good examples for various *Escherichia coli* and yeast fermentations can be found in the literature (1, 5).

- b. *pH.* pH provides an important cell physiological condition. It is to be maintained the same at large scale. Automated pH control needs to be tuned to provide an adequate control regimen for pH. This may be influenced by acid/base concentration and delivery system (pump, pressure, valves, etc.).
- c. *Pressure.* The pressure of a fermentation may remain the same across scales. It may be necessary to adjust the pressure set point from small scale to large scale by taking into account the higher hydrostatic pressure at large scale. Another factor for a potential adjustment arises when a small-scale process is developed at a location with a different elevation, and thus the atmospheric pressure is significantly different from that in the large-scale region. Pressure may also be adjusted as a strategy or tool to help improve gas transfer at larger scales, where a high agitation rate is difficult to reach.
- d. *Dissolved-oxygen (DO) level.* To keep the culture in the same respiration condition, the DO set point is kept consistent across scales. An automated DO control mechanism for a large-scale bioreactor needs to be defined. Commonly, DO is controlled in a cascade mode, in which agitation is increased based on culture oxygen demand and then airflow rate is increased or pure oxygen is introduced after the agitation reaches its maximum. In some cases, pressure may be increased to control DO.
- e. *Airflow rate.* Usually, the airflow rate is scaled up by a constant volumetric flow rate per fermentation broth volume. For a 1-liter fermentation with an airflow rate of 0.2 liter/min, this is 0.2 vvm. At the 100-liter scale, the flow rate would be 20 liter/min to maintain 0.2 vvm. To obtain an accurate airflow rate measurement at any scale, a mass flow device is needed. Due to pressure differences at various scales, the volumetric flow rate readings need to be calibrated via the mass flow measurement. In some cases, successful scale-up is conducted with superficial gas velocity (gas flow per unit cross-sectional area of reactor) kept constant. This approach addresses concerns of gas holdup due to the difference in geometry of fermentors at different scales.

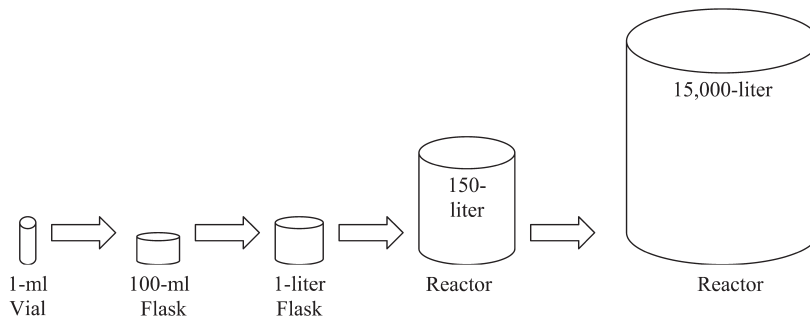

FIGURE 1 A typical microbial seed train.

- f. *Final fermentation volume and initial (starting) batch volume.* Usually, the ratio of the final fermentation volume versus the initial batch volume is kept constant in scale-up. The final fermentation volume is determined by the maximum working volume, usually about 70% of the total vessel volume, and with consideration of headspace needed to contain potential foaming and keeping the volume in a well-mixed region.
- g. *Nutrient concentrations.* Nutrient concentrations are maintained at large scale. The batch medium volume is scaled up proportionally. For fed-batch processes, nutrient feeding rates can be calculated based on the initial batch medium volume. For example, a feeding rate starts at 5 g/min at 2.5-liter batch volume in a small scale (5-liter) process. When scaling up to 10,000-liter fermentation, the feeding rate should start at 10,000 g/min at 5,000-liter batch volume. Evaporation may occur at any given scale. It needs to be accounted for in the design of nutrient feed rate and concentrations.
2. Identify nonlinear scale-up parameters.
- a. *Agitation.* This parameter is related to mixing time and oxygen transfer. It is described in detail in section 47.2.4.
- b. *Nonlinear feeding rates.* Often glucose and some nutrients are fed exponentially to match the cell growth profile. It is assumed that the exponential feeding of nutrient feed allows the nutrient concentration or uptake rate for each cell to be constant.
3. Perform fermentation preparation scale-up.
- a. *Media preparation.* At large scale, media preparation procedure, vessels, and conditions must be defined. Large-scale media preparation may be a challenge because of the delivery of large amounts of materials, the slow dissolution of ingredients, and the relatively longer hold time prior to sterilization and inoculation. Media solubility and stability should be studied prior to implementation. Sometimes media need to be filtered prior to use.
- Media sterilization methods include heat sterilization and filter sterilization. Generally, components that are sensitive to heat degradation are filter sterilized and components that are not sensitive to heat degradation are heat sterilized for large-scale fermentation. For filter sterilization it is important to consider absorption of critical trace nutrients of fermentation. A small-scale filtration model study is important to determine the impact.
- b. *Media hold.* Certain media will be made ahead of time and be fed during the fermentation process. One or more medium hold vessels and their conditions, such as temperature and mixing, need to be studied and defined.
- c. *Acid and base for pH control.* It is very important to plan ahead to identify the types of acid and base that are suitable for large-scale fermentation. Large-scale acid/base vessels are not always suitable for various types of acid and base used in small-scale studies since acid/base storage vessels have to meet corrosion requirements.
- d. *Medium and acid/base delivery systems.* Usually, automated valves and pressure or pump systems are used for the delivery of nutrient feeds, acid, and base. The control accuracy of the delivery system should match in proportion to the small-scale system to ensure process performance across scale. Sometimes the apparatus needs to be changed or retuned to fit a new process.

47.2.4. Bioreactor/Fermentor Scale-Up

In this section, we discuss specifically the scale-up of the bioreactor operational parameters such as agitation, airflow rate, and cooling capability based on small-scale data. These parameters determine a bioreactor's ability to provide a well-mixed nutrient environment, maintain DO for the organism, and keep a desired temperature for the culture.

To scale up a bioreactor, several criteria are used (2–4):

1. Constant agitation power input (power/volume)
2. Constant oxygen transfer coefficient (k_La) (h^{-1})
3. Constant mixing time (s)
4. Constant agitation impeller tip speed (m/s)
5. Constant heat transfer rate (heat/volume)
6. Constant gas volumetric flow rate (vvm)
7. Constant gas superficial velocity (m/s)

Criteria 1, 2, 5, and/or 6 are most common and successfully applied for large-scale microbial fermentation. Criteria 3, 4, and 7 are useful for special applications that are sensitive to mixing time, shear, and gas flooding, respectively. However, scale-up cannot be done while keeping all of these parameters constant at the same time due to the bioreactor's physical limitation. It is suggested to study and select appropriate scale-up parameters with a series of experiments from small scale to pilot scale.

A fermentor's agitation power input value (power consumption/volume) drives oxygen transfer and mixing time, so it is a simple and practical way to evaluate scale-up (3, 4).

$$P = N_{p0} \rho n^3 d_I^5 \quad (1)$$

or

$$N_{p0} = P / \rho n^3 d_I^5 \quad (2)$$

where P is power input ($\text{kg m}^2 \text{s}^{-2} = \text{W}$), N_{p0} is a dimensionless power number, n is agitation speed, ρ is density of the medium, and d_I is impeller diameter. The dimensionless power number can usually be obtained from standard impeller references and impeller vendors.

Scale-up of microbial fermentation is usually conducted by first assessing if adequate oxygen transfer rate (OTR) can be provided at a large scale. OTR is limited by maximum agitation speed, airflow rate, pressure, and pure oxygen supply.

$$\text{OTR} = k_La(C_0 - C) \quad (3)$$

where C_0 (mM) is the saturation concentration of oxygen in fermentation broth, influenced by the oxygen content in the inlet airflow and vessel pressure; C (mM) is the DO concentration of a culture at a given time; and k_La (h^{-1}) is the oxygen transfer coefficient, which is directly related to the fermentor's configuration, agitation speed, impeller design, and airflow rate. Therefore, k_La is a good indicator of a fermentor's oxygen transfer capability.

In general, OTRs decrease as fermentor scales increase. The maximum OTRs (in $\text{mM O}_2/\text{liter/h}$) are 300 for a bench fermentor, 100 to 150 for a pilot fermentor (>500-liter volume), and 50 to 100 for a large-scale fermentor (>10,000-liter volume) (6). The comparison of these OTR values can be used for scale-up considerations.

When using oxygen gas supplementation, C_0 is enhanced. Therefore, OTR can be proportionally increased according to equation 3. In industry, pure oxygen supplementation is a common approach to increase oxygen transfer capability at large scale.

High-density microbial processes usually generate a significant amount of heat. Cooling capacity is important at large-scale production since the ratio of jacket surface area

to volume decreases as processes scale up. Heat transfer rate (HTR) is a measure of the cooling capability of a fermentor.

$$\text{HTR} = hA(T - T_j) \quad (4)$$

where h is the heat transfer coefficient, related to the specific heat transfer efficiency of the jacket material and configuration; A is the vessel jacket area; T is the culture temperature; and T_j is the temperature of coolant inside the jacket.

As indicated by equation 4, low coolant temperature and large jacket area will improve heat transfer capability. To ensure a successful large-scale manufacturing process, HTR data must be collected during process optimization. The maximum heat transfer capacity of a large fermentor system must be evaluated along with the coolant system that supplies the jacket water.

47.2.5. Evaluation of Scale-Up Success

For a fermentation scale-up, the following parameters can be used to evaluate if the scale-up is a success.

1. *Product formation rate.* First of all, the final product titer or yield at large scale should equal that of small-scale

studies. In addition, product expression profiles during the course of the fermentation at different scales should trend similarly.

2. *Cell growth profile.* A successful scale-up results in a comparable growth profile between the large-scale fermentation and the small-scale fermentation. In addition, nutrient consumption rates, acid and base addition rates, and important metabolic profiles throughout the fermentation should be comparable.
3. *Operational aspects.* The success of a scale-up is also judged by how efficiently and effectively a new operation team at the receiving facility can execute the scaled-up process, including media preparation, media transfer, and process documents.
4. *Product quality.* Product quality should be examined to confirm a successful scale-up. This may require further purification of the product in order to assess its quality.

Table 1 provides an example of the parameters considered for the scale-up of a 15-liter fermentation to a 15,000-liter fermentation.

TABLE 1 An example of the parameters considered in fermentation scale-up

Parameters	Scale-up ratio	Initial fermentation weight (kg)	
		Small scale (15-liter)	Large scale (15,000-liter)
Start volume		6.8	5,000
Seed flasks			
No. of flasks		1	1
Flask volume (ml)		2,000	2,000
Per-flask medium volume (ml)		500	500
Per-flask inoculum volume (μl)		150	150
Inoculum %		0.03	0.03
Shaker speed (rpm)		275	275
pH		7	7
Temp (°C)		30	30
Time (h)		14	14
Optical density (OD) specification		0.7–1.2	0.7–1.2
Seed fermentation			
Start volume (liters)		— ^a	60
Inoculum volume (ml)		—	500
Inoculum %		—	1
Aeration rate (standard liters/min)		—	30
Pressure (psig)		—	5
DO set point (%)		—	>30
pH		—	7
Temp (°C)		—	30
Time (h)		—	6
OD specification		—	2.0–7.0
Additions			
For pH control		—	

(Continued on next page)

TABLE 1 (Continued)

Parameters	Scale-up ratio	Initial fermentation weight (kg)	
		Small scale (15-liter)	Large scale (15,000-liter)
Acid addition (expected) (g)		—	162
Base addition (expected) (g)		—	54
Production fermentation^b			
Start volume (liters) (after inoculation)		6.8	5,000
Condensate pickup during sterilization (kg)		0.5	0 ^c
Inoculum volume (liters)	1.0%	0.07	50.0
Agitation speed (rpm)	Constant k_{La}	350	125
Aeration rate (standard liters/min)	1 vvm	6.8	5,000
Pressure (psig)		12	10
DO set point (%)	Constant	>40	>40
pH	Constant	7.0	7.0
Temp (°C)	Constant	30.0	30.0
Additions			
	Density (g/ml)		
Glucose (kg)	1.26	0.09	178.13
Salt1 (kg)	1.10	0.20	382.98
Trace metals solution (kg)	1.00	0.02	29.69
Acid (expected) (kg)	1.00	0.24	457.20
Acid feed (prepared) (kg)	1.00	0.31	593.76
Base (expected) (kg)	1.00	0.13	255.32
Base (prepared) (kg)		0.22	415.63
Antifoam (expected) (kg)	1.00	0.01	24.34
Antifoam (prepared) (kg)		0.14	267.19

Feed 1 (prepared) (kg)		1.77	3,354.75
Feed 2 (expected) (kg)	1.14	2.48	4,696.65
Feed 2 (prepared) (kg)		2.77	5,248.85
Inducer (ml) (0.5 mg/ml)		12.5	23,750.4
Volume of components added		4.00	7,595.67
Final volume (expected) (liters)		10.80	12,595.67
Fermentation feed parameters			
Feed 1 exponential feeding parameters ^d			
Feed 1 density (kg/liter)		1.26	1.26
Start feed 1 (OD)	Constant	6 ± 1	6 ± 1
Initial feed (K1, g/liter/h)	Constant	10	10
Growth rate (K2, h ⁻¹)	Constant	0.4	0.4
Feed 2 feeding parameters			
Feed 2 density (kg/liter)	1.14		
Start feed 2 (OD)		29 ± 2.0	29 ± 2.0
Feed 2 rate	23.08 g/h/initial wt	156.7 g/h	115.4 kg/h

^a—, not applicable.^bAll parameters are scaled from initial fermentation weight.^cThe volume of "Condensate pickup during sterilization" can vary significantly in large-scale fermentors based on how the sterilization is carried out and the fermentor design. In some instances, this can be a negative number due to evaporation during sterilization.^dFeed 1 rate = $K1 \times \text{EXP}(K2 \times \text{time})$.

47.2.6. Product Intermediate Stability and Storage

Product generated during fermentation can be unstable. Studies are needed to define how long and under what conditions the fermentation product intermediate can be held in the broth before it is recovered or purified from the fermentation broth. This also depends largely on the form in which the product is produced, such as secreted, cytoplasmic, soluble, or insoluble. More vulnerable products are susceptible to degradation; therefore, less hold time is possible. It is very common that cooling down of a fermentor broth at the end of fermentation is required to slow down or stop product degradation. For large scale, it is also common to have a harvest hold tank available to allow efficient turnaround of the production fermentor.

47.2.7. Product Quality Considerations

It is not a surprise that scaling up a process may result in product quality differences. Large-scale fermentation may provide a different environment for microbial cells compared to small-scale fermentation. The differences are usually related to nonhomogeneous environments at large scale. At large scale, mixing time, gas distribution, nutrient concentration, and temperature distribution may not precisely match those at small scale. These conditions may affect product formation or transport in microbial cells. Therefore, it is prudent to adequately analyze product quality during process scale-up.

47.2.8. Waste Streams and Treatment

For a given process scale, process waste outputs and treatment requirements must be carefully calculated and considered as a part of a project plan and facility design. This is a requirement by environmental agencies. The waste output can be calculated based on material throughput at each step of the process as detailed in the process description. The required treatment of each waste stream should be evaluated according to regulations. In many cases, waste biological materials or organisms may present potential hazards to the environment; a waste collection tank and a treatment system including chemical or heat treatment often are required for large facilities.

47.3. RAW-MATERIAL SOURCING, HANDLING, AND CONTROL AT LARGE SCALE

For large-scale commercial production, one needs to consider and ensure that all the raw materials can be sourced reliably and with consistent quality. An important study for scale-up is to assess raw-material lot-to-lot variability. Fermentation processes often use raw materials that are less defined and tend to vary in nutrient content from lot to lot and from time to time. A quality or performance test plan for raw materials used in fermentation is highly recommended.

At large scale, large amounts of bulk raw materials are expected. Their transportation, delivery, handling, and storage are to be considered and planned prior to scale-up.

47.4. EQUIPMENT QUALIFICATION AND MODIFICATIONS

Scale-up projects often require implementation of new equipment or modification of existing equipment. This can be time-consuming and costly; however, it is essential. This activity may follow these steps to ensure a satisfactory outcome.

1. Define user requirements early.
2. Draft engineering drawings for functional review.
3. Monitor fabrication timeline.
4. Conduct factory acceptance testing before shipping to installation site.
5. Implement installation plan and wet testing.
6. Review documentation for completeness.

Equipment preparation is critical to ensure the overall success of scale-up.

47.5. SPECIAL CONSIDERATIONS FOR BIOPHARMACEUTICAL PROCESS SCALE-UP

In the biopharmaceutical industry, regulations are much more detailed and strictly enforced to ensure public safety and product efficacy. Therefore, special considerations are given during scale-up of a biological product fermentation. The following sections briefly describe a few major regulatory requirements applied to biological process scale-up.

47.5.1. Equipment Validation

Equipment validation is to document that equipment meets all predefined functionality criteria per process requirements with a high assurance. It is conducted in three stages: installation qualification, operational qualification, and performance qualification. Installation qualification documents how the equipment is fabricated and installed and whether the equipment meets the design specifications. Operational qualification documents satisfactory operational parameters per specification. It usually uses water instead of actual product for the testing. Performance qualification is an exercise that uses actual product to demonstrate performance as required. All the requirements need to be predefined and documented before any execution of operation and testing. In addition, a meaningful number of repeats have to be performed to validate the equipment.

47.5.2. Documentation

Unlike many other industries, the biopharmaceutical industry emphasizes documentation of detailed information about process, materials, analytical procedures, equipment, and staff training. For fermentation process scale-up, documentation may include process descriptions at small scale and large scale, material qualification and testing, analytical methods qualification, process intermediate stability, process hold steps, and scale-up production campaign summaries.

47.5.3. Process Validation

A unique requirement for commercial biopharmaceutical process scale-up is process validation. Process validation usually specifies a set of predefined criteria for each process step based on the purpose of the step, as well as for the final product quality. This is documented in a process validation plan or protocol. Three to five successful runs of the process need to be performed, and the results must meet all the predefined criteria. All important process parameters and product quality attributes of the validation runs will be discussed, analyzed, and then documented in a validation campaign report as a proof of process validation (see the guidelines of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use at www.ich.org).

47.5.4. Product Comparability

For pharmaceutical applications, product quality attributes must be comparable at all scales from development to

commercial. Biological product quality attributes include product purity, impurities such as aggregates, clipped product and oxidized product, process-related impurities such as process chemicals, and contaminants such as other microbes. For fermentation scale-up, samples are purified for product quality analysis. The product quality attributes must be analyzed and compared to those of the small-scale process in order to determine if product is comparable.

47.6. CONCLUSION

With the tremendous diversity of organisms and products in industrial fermentation, a precise and one-size-fits-all strategy for scale-up is not practical. However, the general principles of scale-up of microbial fermentation as described in this chapter are well established and widely practiced in industry with reasonable success. For each individual product and organism, there will always be a specific model weighted by critical parameters based on experimental knowledge.

Scale-up activity is complex, including cell biological factors, nutrient and metabolic factors, and processing-related factors. In addition, its success is highly dependent on product quality requirements and project emphasis. It is true that not all parameters and goals of a fermentation process are equal. Therefore, approaches and models in scale-up may vary due to project emphasis. The keys for scale-up are to achieve project goals, produce desired product with

acceptable quality and yield, and fully understand and control operational risks at large-scale manufacturing.

I thank Swapnil Bhargava, Mark Berge, and Henry Lin, who provided initial review and suggestions. Thomas Seewoester and Sam Guhan are appreciated for their time in critical review and valuable comments. Beth Junker gave me many good suggestions from the beginning of this chapter planning.

Cell Culture Bioreactors: Controls, Measurements, and Scale-Down Model

WAN-SEOP KIM

48

48.1. INTRODUCTION

Cell culture is an animal cell cultivation process to produce a protein of interest from genetically engineered cells in various culture vessels. Cells are cultivated under the optimized conditions for process parameters such as temperature, pH, and dissolved oxygen (DO). The protein of interest is produced into the extracellular culture media for the subsequent purification process step. A culture vessel can be a small (<100-ml) culture flask up to a large-scale (25,000-liter) vessel known as a bioreactor. In this chapter, types of bioreactors, bioreactor controls for process parameters, measurement of cell growth and metabolites, and a scale-down model using small- and pilot-scale culture vessels used in the biopharmaceutical industry are described.

48.2. TYPES OF BIOREACTORS

The term “bioreactor” is used for the cell culture vessel which cultivates animal cells to produce biological products, compared to a chemical reactor, which controls chemical reactions. The term “fermentor” is also often used, but it is more appropriate to describe the microbial (i.e., bacteria or yeast) fermentation vessel. The major types of bioreactors used for cell culture processes in the biopharmaceutical industry today are stirred and airlift bioreactors. Recently, disposable bioreactors have been utilized for their convenience. Each type of bioreactor can be used for batch, fed-batch, and continuous cultures. Table 1 provides an overview of each of the bioreactor types used for the cell culture process.

48.2.1. Stirred Bioreactor

The stirred bioreactor is the most widely used at the small (1- to 20-liter), pilot (50- to 1,000-liter), and large manufacturing (up to 25,000-liter) scales. There are no universal definitions of sizes for small, pilot, and large manufacturing scales. The stated scale ranges are representative scales that are generally used in the industry. The operation of the stirred bioreactor is relatively simple; cells and nutrient components are mixed by agitation and oxygen is supplied for aeration.

Most cell culture processes in industry today are developed with small- and pilot-scale stirred bioreactors. Because of the popularity of stirred bioreactors in process development and in-depth experience in the operation of large-scale stirred fermentors, most large manufacturing facilities

for cell culture processes use large-scale stirred bioreactors for commercial production runs.

The advantage of using the same type of bioreactor for small-scale through large-scale runs is that new cell culture processes can be more easily scaled up for commercial manufacturing. Also, large-scale manufacturing processes can be scaled down for investigation of cell growth, productivity, and quality-of-product issues in small-scale model systems.

A major concern with stirred bioreactors is the mechanical-shear effect on fragile cells caused by a high agitation rate. Especially in large-scale bioreactor runs, a proper agitation rate should be used to mix cells, nutrient components, and oxygen adequately without locally insufficient mixing. Use of low-shear impellers can reduce the shear damage of cells at a high agitation rate. In addition, recent developments in robust cell lines and new culture media containing a shear-protective agent will allow a higher agitation rate to be used to improve mixing of cells, nutrient components, and DO in the large-scale runs without damaging cells.

The second concern is microbial contamination by leaking at the mechanical agitator area. Since the agitator is a moving part that is operated with a motor external to the bioreactor, microbial contamination by leaking should be well prevented. The leaking can be avoided by using a double mechanical seal with a sterile barrier fluid such as clean steam condensate.

48.2.2. Airlift Bioreactor

The airlift bioreactor is the second choice of bioreactor for cell culture processes. The airlift system uses aeration from the bottom to mix cells and nutrient components instead of using an agitator as in the stirred bioreactor.

The advantages of the airlift bioreactor are that it does not produce mechanical-shear effects by the agitator and is a much more closed system, which results in a lower chance of contamination due to the lack of agitator moving parts. However, the airlift system needs a much higher aeration rate and pressure to avoid locally insufficient mixing within the whole bioreactor system.

Process development areas and pilot plants are typically equipped with small-scale stirred bioreactors. If large-scale airlift bioreactors are planned to be installed, small- and pilot-scale airlift bioreactors would be additionally required for new process development and scale-down support of large-scale manufacturing runs.

TABLE 1 Types of bioreactors

Type of bioreactor	Type of mixing	Use of bioreactor	Advantages and disadvantages
Stirred bioreactor	Agitation by impeller	Widely used in small-scale through large-scale (~25,000-liter) manufacturing	Well-known mixing technology Widely used at different scales High shear damage to cells—can be reduced by a low-shear impeller, robust cell line, or use of a shear-protective agent in the culture media Contamination due to agitator seal failure
Airlift bioreactor	Bottom airflow without agitation by impeller	Used much less than stirred bioreactors at manufacturing scale	No shear damage by agitation Closed system with no moving parts High aeration rate and pressure required Insufficient mixing may occur locally
Disposable bioreactor	Mostly rocking or shaking; magnetic agitation	Used for seed culture and small- and pilot-scale production runs	Ease of use and installation—no cleaning and sterilization required Closed system Currently available at up to 2,000-liter volume Low installation cost, but high operating cost

48.2.3. Disposable Bioreactor

A disposable bioreactor is another type of bioreactor that uses a sterilized disposable bag. The stirred bioreactor system using the disposable bag has recently become available in up to 2,000-liter volumes from Xcellerex (Marlborough, MA). The disposable bag is placed inside the vessel and the internal mixing of the bag is performed by a magnetic drive agitation. The pH, DO, and temperature controls of disposable bioreactors are similar to those of conventional stirred bioreactors.

Another disposable bioreactor called the Wave bioreactor is available from GE Healthcare (Piscataway, NJ). The mixing in the Wave bioreactor is typically performed by rocking or shaking the disposable bag on a stainless steel platform. The platform is used to hold and shake the bag and also to control temperature. Air and carbon dioxide gases are continuously supplied to the bag headspace to control the DO concentration and pH of the culture, respectively. The disposable bag is maintained as an inflated bag to create a large air-liquid interface for gas transfer.

The use of a disposable bag eliminates the requirement for bioreactor cleaning and sterilization procedures before and after runs, which creates much simpler product change-over procedures.

Since disposable bioreactors are available at scales of up to only about 2,000 liters, the disposable bioreactor is being used mostly as a seed bioreactor in large-scale manufacturing instead of the production bioreactor step. However, considering the advantages of disposable bags for convenience of use and the trend of higher productivity in recent cell culture process development, the use of the disposable bioreactor in pilot-scale production runs will significantly increase in the next 10 years.

48.3. BIOREACTOR CONTROL

Bioreactor setup and control of process parameters are the major factors in cell culture processes that consistently control cell growth and produce products according to their predefined quality attributes.

The control of process parameters and the associated concerns described below are based on the use of the most

widely used, stirred bioreactors. Table 2 provides an overview of the controls of process parameters and concerns. While the control of process parameters is described in detail, bioreactor setup (i.e., cleaning-in-place [CIP], leak test, and sterilization-in-place [SIP]), culture medium addition, and inoculation are only briefly described here because they are well-known, common processes.

48.3.1. Setup and Operation of Bioreactors

Bioreactor operation involves multiple steps of operations as follows.

1. Bioreactor setup
 - a. Preuse CIP, leak test, and preuse SIP
 - b. Standardization of pH and DO probes
2. Addition of culture medium and preparation of feed medium
3. Inoculation of seed cells and maintenance of control parameters: pH, DO, temperature, etc.
4. Sampling and culture maintenance with feeding and controlling probes
5. End of the run and postuse CIP

48.3.1.1. Setup, Media Addition, and Inoculation

CIP is a cleaning method for the internal area of bioreactors and pipes without disassembly to remove cell debris, culture media, remains of product, and impurities and residues of cleaning agents. Generally, it is automatically performed for the cleaning of pilot- and large-scale bioreactors before and after the runs.

A leak test is performed to ensure that the bioreactors maintain sterilized condition during the cultivation. Leakage is evaluated by measuring the pressure drop during a certain time interval after pressurization or by detecting helium gas leak after helium gas is supplied to the bioreactor.

SIP is a process to sterilize bioreactors by using steam prior to the addition of culture medium to cultivate cells of interest only. After the SIP is completed, culture medium is added into the bioreactor vessel by 0.2- and 0.1- μm -pore-size filtration. Prior to the filtration, the culture medium can be treated with a high-temperature, short-time sterilizer for viral inactivation. The temperature used is typically about 100°C for about 10 s. Temperature, agitation, aeration, and pH

TABLE 2 Controls of process parameters

Control parameter	Range of control	Method of control	Comments
Temperature	32–37°C in fixed or shift modes	Steam and cool system	Failure of gaskets and control valves if preventive maintenance is not adequate
pH	pH 6.8–7.6 in fixed or shift modes; pH 6.9–7.2 commonly used	CO ₂ gas and caustic chemical	The performance of pH probes should be verified with offline pH measurements A dead band can be considered if better pH control is needed, but it alters the control pH of culture if its range is wide
DO and aeration	DO 10–50% saturation; DO 25–40% commonly used	Overlaying air, sparging air, and pure oxygen gas	A proper strategy for the use of air-sparging rate and pure oxygen needs to be defined in high-oxygen-demanding cultures Internal bioreactor pressure and hydrostatic pressure should be considered for the standardization of the DO probes in pilot- and large-scale runs A foaming issue with a high sparging aeration rate
Agitation	Variable per scale	Agitation with Rushton, pitch-, or marine-type blades	Shear damage of cells by a high agitation rate Low agitation can reduce bulk mixing and affect pH, temperature, and dissolved gas control
Dissolved carbon dioxide	Less than 200 mm Hg; maximum of 150 mm Hg commonly used	Aeration and agitation	High dissolved carbon dioxide observed in large-scale runs; proper reduction of carbon dioxide is necessary

controls start after culture medium is added, and then cells from a seed culture are transferred to inoculate the culture medium for seed culture expansion or production runs.

48.3.2. Control of Process Parameters

48.3.2.1. pH

The control of pH is one of the most critical process controls during cell culture. It significantly affects cell growth, productivity, and quality of product, e.g., glycosylation (1, 3). The most common pH range in cell culture is 6.8 to 7.6, but typically the production process requires a narrower pH control range (6.9 to 7.2) for consistent quality and productivity. The control of pH is usually achieved by regulating CO₂ gas and base addition through a proportional-integral-derivative (PID) controller with feedback from the pH probe. Addition of CO₂ gas to the culture decreases the pH level of culture media, and base addition (e.g., sodium hydroxide) raises the pH.

While a small-scale bioreactor usually uses a single pH probe to maintain a target pH level for the entire culture duration, pilot- and large-scale manufacturing bioreactors typically utilize two pH probes to properly control the culture's pH level. One of the two pH probes is assigned as a control probe for the active control of culture pH, and the other probe serves as a backup probe. If the control pH probe shows continuous pH drifts or continuously significant differences compared to offline pH measurements, the control probe is replaced with the backup probe to ensure acceptable pH control.

During the cultivation of cells, the readings of two probes are monitored and compared with offline pH measurements made using a benchtop pH meter or a biochemical analyzer. If the pH difference between pH probe readings and offline pH measurements is out of the predetermined acceptable range, a 1-point pH correction is performed. A maximum pH difference of 0.1 is generally used to determine if the 1-point correction needs to be carried out.

The set point of pH can be controlled with or without a dead band. Due to the significant impact of pH on productivity and quality of product, the pH in a cell culture process should be tightly controlled. A dead band is not required or can be applied in a narrow range to control the pH at the target value. If pH perturbations are observed by adding excess CO₂ gas or base, the pH controller is not properly tuned or the agitation rate is not sufficient to mix the culture well. The pH control can be improved by widening the dead band or raising the agitation rate. However, widening of the dead band changes the actual control point of pH and may adversely affect productivity and quality of product. When a dead band for pH is applied to control pH at the beginning of culture, the pH is maintained at the upper limit of the pH set range with the dead band because aeration to a bioreactor increases the pH of culture by reducing dissolved carbon dioxide in the culture. So, CO₂ gas is mostly used to reduce and control the culture's pH. After cells start growing and produce lactate and carbon dioxide, the pH level drops and is maintained at the bottom limit of the pH set range with the dead band, primarily by use of base.

Different pH set points or pH shifts are often used during the cultivation of cells. The pH set point can be manually or automatically changed at a certain elapsed culture time. Alternatively, a dead band can be used instead of changing the pH set point if the set point needs to be shifted from high to low pH values.

48.3.2.2. DO and Aeration

DO concentration in the culture also significantly affects cell growth, productivity, and quality of product (8, 13, 20). A DO set point can be considered in the range of 20 to 50% air saturation. The most common DO set point is within 25 to 40% air saturation. Oxygen is supplied primarily by overlaying and sparging clean air from the top and bottom of the bioreactor. Additional pure oxygen or oxygen-enriched air is required to provide sufficient oxygen to the cells in high-density cell cultures.

Pilot- and large-scale manufacturing bioreactors typically use two DO probes to control the DO level at the set point. As described above for the use of two pH probes, one of the two DO probes is used to control the DO level in the culture and the other is to back up the control probe.

Standardization of the DO probes is usually performed by supplying nitrogen gas and clean air to the bioreactor. A DO probe in a small-scale bioreactor is usually standardized with clean air for the 100% level, without considering bioreactor pressure and hydrostatic pressure as is done for pilot- and large-scale bioreactor runs. The consideration of bioreactor and hydrostatic pressures during DO probe calibration allows for the maintenance of the DO concentration at the same level as small-scale bioreactors can maintain.

Air overlaying at the top of the culture medium replaces dissolved carbon dioxide in the culture with oxygen and also maintains the internal positive pressure of the bioreactor after completion of SIP. Air sparging from the bottom of the bioreactor also replaces dissolved carbon dioxide in the culture with oxygen, and is provided to the culture gradually or at a fixed rate until the end of the culture. The maximum aeration rate during the scale-up of culture is generally determined to maintain a constant volume of gas per volume of liquid per minute (vvm).

A gradual increase of the air-sparging rate, as the number of viable cells increases, efficiently provides oxygen to maintain the DO level at the set point. However, the gradual increase of the air-sparging rate itself at the peak time of the oxygen requirements may not provide sufficient oxygen to high-density cell cultures. When very high air-sparging rates are required, excess foaming could be observed. These issues can be addressed by sparging pure oxygen gas. A major disadvantage of a high fixed rate of air sparging at the early stage of the culture is that pH is increased by lowering dissolved carbon dioxide and then CO₂ gas is supplied, which results in pH fluctuations by both excess CO₂ gas and excess base. Foaming is also observed due to both excessively high aeration rate and CO₂ gas supply.

Therefore, the initial sparging aeration rate should be low at the beginning of culture to balance dissolved carbon dioxide concentration in the culture medium, and then the sparging aeration rate can be increased gradually or in stepwise fashion as required by cells to maintain a DO level at the set point. To avoid excessively high aeration rates, the maximum airflow rate can be set, and pure oxygen can be additionally supplemented if the aeration rate reaches a maximum set point and the DO set point cannot be achieved.

The use of antifoam negatively affects the oxygen transfer rate of the culture medium (12). Thus, in cases where antifoam is used, a higher oxygen concentration in air/oxygen gas and a lower DO set point (higher driving force) are required to transfer oxygen sufficiently to the cells. A high agitation rate improves the oxygen transfer rate and also minimizes the occurrence of local anaerobic conditions in the large-scale bioreactor. Due to shear damage of cells, a high agitation rate is not recommended, but recent trends including robust cell line development and use of shear-protective agents (15, 16) such as Pluronic F-68 allow the use of higher agitation rates for better mixing of oxygen and nutrient components.

48.3.2.3. Agitation

Agitation rate and impeller type should be well studied with small-scale and pilot-scale bioreactors at the process development stage so as to successfully scale up the cell culture process to the large-scale manufacturing runs (18).

Rushton impellers are often considered for microbial fermentation and not for cell culture processes due to their high shear impact on cells. Pitch-blade and marine-blade impellers are used for shear-sensitive cell culture to mix cells and nutrient components in axial and radial directions with lower shear rates. Recent robust cell line development allows for the use of any Rushton, pitch-, or marine-blade impellers, which are already installed in the bioreactor, to provide sufficient mixing of cells and nutrient components.

A low agitation rate may cause insufficient mixing of culture at the pilot- and large-scale manufacturing bioreactor runs, which results in locally uncontrolled pH, temperature, DO, dissolved carbon dioxide, and nutrient levels. A higher agitation rate improves mixing but generates a high shear rate that may damage cells.

After an agitation rate in small-scale process development is defined, scale-up of the agitation rate for pilot- and large-scale manufacturing bioreactors is determined by scale-up parameters: power per volume, volumetric oxygen transfer coefficient, tip speed, mixing time, etc. (18). Regardless of what scale-up parameter is used, the most important aspect of scale-up of the agitation rate is to achieve a similar metabolic condition of cells in culture at small scale through large-scale manufacturing runs. Measurement of metabolites during the culture is one of the most common ways to understand the metabolic condition of cells.

48.3.2.4. Dissolved Carbon Dioxide

Accumulation of high levels of dissolved carbon dioxide (>200 mm Hg) is one of the major concerns in large-scale cell culture because it is known to negatively affect cell growth, productivity, and quality of product (6, 17). In pilot- and large-scale runs, dissolved carbon dioxide levels of less than 150 mm Hg are generally maintained.

In culture medium containing bicarbonate, high concentrations of dissolved carbon dioxide can be reduced to the predetermined level (usually about 100 mm Hg) by gassing air from the top of the bioreactor. As the number of cells increases, production of carbon dioxide by cells increases and the dissolved carbon dioxide concentration can be elevated due to insufficient gas exchange in large-scale bioreactor runs. Increase of the agitation rate or air-sparging rate can reduce the level of dissolved carbon dioxide in the culture. It is not recommended to use very high air-sparging levels, which generate excess foaming and pH fluctuations by excess removal of dissolved carbon dioxide. During scale-up/scale-down of the cell culture process, the level of carbon dioxide is one of the indicators for proper agitation and aeration.

48.3.2.5. Temperature

It is also known that temperature significantly affects cell growth and product quality (11, 22). The temperature range of 36 to 37°C is used for the optimum growth of Chinese hamster ovary (CHO) cells and NS0 cells. Lower temperatures down to 32°C are often applied during the late stage of culture. A low temperature extends the duration of culture by maintaining higher viability of cells until the end of culture and also reduces enzymatic activities that negatively affect the quality of glycoproteins. The impact of temperature shift is dependent on the processes, cell lines, and products.

Temperature of culture is maintained by steam and cooling systems in pilot- and manufacturing-scale bioreactors. Small-scale bioreactors do not use steam, and the temperature is maintained with an electric heater or hot

TABLE 3 Cell growth and metabolite measurement

Parameter	Method of measurement	Comments
Cell growth: VCD and viability	Manual cell counting	Counting variation due to cell clumping—good mixing is needed
	Automatic cell counting	Selection of viable cells in the image with an automatic cell counter should be optimized
	Offline automatic cell counter	The optical light probe measures all cell mass including cell debris
	In situ optical light absorption probe	The RFI probe measures mass of viable cells only
Metabolites	In situ RFI probe	In situ probes for cell growth measurement cannot measure viability
	Offline biochemical analyzer	A biochemical analyzer is relatively reliable and widely used due to its convenience
	In situ probes	In situ probes are being tested widely for future use in cell culture processes and for PAT application
	In situ probe for carbon dioxide measurement	
	In situ near-infrared region probe	

jacket. It is necessary to equip an efficient cooling system to maintain low temperature for large-scale bioreactors and harvest tanks if the quality of product is affected during harvest duration. Steam gaskets should be well maintained to avoid temperature control excursions by their malfunction. SIP procedures and the use of steam for temperature control can damage the gaskets or generate residues that cause the gaskets to fail. The interval for preventive maintenance programs should be carefully determined to prevent failure of the gaskets.

48.4. MEASUREMENT OF CELL GROWTH AND METABOLITES

An overview of cell growth and metabolite measurements is presented in Table 3. Since changes in cell growth may alter productivity and quality of product, cell growth in cell culture processes is monitored daily or at predetermined intervals during the entire culture duration. Sampling at regular intervals is performed to measure viable cells and viability as well as metabolites such as glucose, lactate,

ammonia, and glutamine. In fed-batch cultures, viable cell density (VCD) is often used to determine feeding amount and other process parameter changes.

VCD is generally expressed as viable cell numbers per unit volume. A peak VCD is typically observed at the range of 5×10^6 to 12×10^6 cells/ml in commercial manufacturing runs. Viability is determined by dividing viable cells by total cells and is often used to determine harvest time since it indicates the metabolic status of cells and degree of debris that may affect the harvest step. Integral viable cell density (IVCD) and growth rate are also used to monitor cell growth. IVCD is the integral of VCD over time during the entire culture duration. The increase of IVCD may indicate increased product titer. Specific productivity is calculated by dividing product titer by the IVCD, which represents the product amount produced per cell. Growth rate of cells is the slope of cell density over time. Changes in the control of process parameters such as pH and temperature affect the cell growth rate, which can be observed by cell growth measurement. Representative cell growth (VCD and IVCD) and titer curves are shown in Fig. 1.

FIGURE 1 Representative cell growth (VCD and IVCD) and product titer profiles.

Metabolite levels are often used to calculate the amount of feeding in fed-batch processes and also to determine the shift time of process parameters such as pH and temperature. While glucose and glutamine are used as energy resources to produce cell mass, lactate and ammonia are produced as by-products from glucose and other nutrients and negatively affect cell growth and productivity (14). Generally, the by-products are more severely accumulated in fed-batch cultures with extended culture duration in large-scale bioreactors. When mixing is optimized, lactate level is typically increased as cells grow exponentially and then drops or remains constant during the stationary and death phases of culture. A continuous increase of lactate level is often observed until the end of culture when the process is improperly scaled up to the large-scale bioreactor runs. Considering that lactate production occurs owing to local anaerobic conditions, increasing agitation rate and/or air sparging helps to reduce the accumulation of lactate. Also, feeding medium composition and feeding strategy of the fed-batch culture should be optimized to reduce the lactate level. Maintaining glucose at a lower level will also help to reduce lactate accumulation. Representative glucose and lactate curves are shown in Fig. 2. Similar levels of by-products should be observed at small scale through large-scale manufacturing runs if the process is properly scaled up or down. Slightly higher lactate levels can be observed as the culture scale increases.

Since amino acid concentrations in culture media also affect cell growth, productivity, and quality of product, it may be necessary to measure amino acid levels in culture media to maintain cell growth and productivity consistently during the culture (5). Proper concentrations of amino acids can be maintained by feeding or further development of basal and feeding medium compositions.

48.4.1. VCD and Viability Measurement

The number of viable cells during the cultivation is measured by manual cell counting or automatic cell counters. The Vi-CELL™ cell viability analyzer from Beckman Coulter (Fullerton, CA) and the Cedex counter from Innovatis (Malvern, PA) are widely used for automatic cell counting.

A trypan blue exclusion method is generally used for both manual and automatic cell counting. The trypan blue

exclusion method is used to determine the numbers of viable and dead cells by counting white (viable) and blue (dead) cells. The trypan blue dye does not penetrate intact cell membranes of viable cells, which will remain white under a microscope. However, the trypan blue dye passes the damaged cell membranes of dead cells and stains the cytoplasm of dead cells in blue. Classical manual cell counting using a hemacytometer is still widely used in manufacturing runs, but recently mechanical, automatic cell counters have been more often applied to newly developed processes and current manufacturing processes. Due to varying operator techniques and cell clumping issues, count variations are often observed in manual cell counting. It is important to mix culture samples with a trypan blue dye sufficiently prior to cell counting in order to separate cells from the cell clumps and stain the individual cells with the dye. The automatic cell counter mechanically mixes cells with the trypan blue dye very well to separate and stain cells in the clumps. Cell numbers and viability in the automatic cell counter are affected by incorrectly counting debris and particles that meet predetermined photometric parameter ranges such as size, brightness, sharpness, and circularity of particle. The optimum range of each parameter in the automatic cell counter should be well determined to distinguish viable cells from dead cells and to avoid the counting of debris, which is mostly observed in low-viability cultures. Thus, the optimization of each parameter for each cell culture process and cell line should be performed prior to use in commercial runs. The default settings provided from the manufacturer can be the starting point for optimization. Considering convenience of use and reliability after the parameter settings are optimized, the automatic cell counter has recently become the first choice for cell counting in cell culture.

There are also in situ probes available for cell mass measurement. Total cell mass can be monitored by classical optical measurement using light absorption. It is widely used for microbial fermentation but not appropriate for cell culture because the probe does not distinguish between the viable cells and dead cells. Also, there is inaccuracy of measurement because the probe recognizes cell debris as cell mass, which is mostly observed in low-viability cell cultures. Another in situ probe, using a radio frequency

FIGURE 2 Representative glucose and lactate profiles.

impedance (RFI) method, is available for microbial fermentation and cell culture processes (4). However, this in situ probe can measure viable cell mass only. As with the classical optical measurement probe, the use of the RFI in situ probe should be limited due to lack of viability measurement.

48.4.2. Metabolite Measurement

Metabolites (glucose, glutamine, lactate, ammonia, etc.) are usually measured by sampling and analysis with offline biochemical analyzers during cell cultivation.

Biochemical analyzers are the first choice for the measurement of metabolites because of ease of use and reliability. The BioProfile® analyzer from Nova Biomedical (Waltham, MA) and YSI biochemistry analyzer from YSI Life Sciences (Yellow Springs, OH) are widely used for metabolite measurement. Most metabolites are simultaneously measured by analyzing one sample only. The combination of automatic sampling, measurement, and data collection provided by the biochemical analyzers supports the application of process analytical technology (PAT) to evaluate the impact of process changes (9, 10).

An in situ probe for carbon dioxide measurement by sensing a fluorescence signal is available for cell culture processes (19). An in situ probe, using absorbance of light in the near-infrared region (700 to 2,500 nm) of the electromagnetic spectrum, is also available to monitor metabolic conditions during cell culture in real time (2) and is widely applied to PAT projects by monitoring metabolites to control process parameters in a timely manner (21). Metabolites such as glucose, glutamine, lactate, ammonia, and amino acids can be monitored with an advantage of real-time measurements without sampling for in situ analysis of culture metabolites in order to maintain predetermined ranges of each metabolite in the fed-batch culture. The in situ probes will be widely used in the future due to the ease of real-time measurements and lack of sampling.

48.5. SCALE-DOWN MODEL

During the development of a new process, small- and pilot-scale runs generate data to develop future process control strategies in large-scale manufacturing runs by determining in-process control ranges and obtaining product quality information. The new cell culture process, developed in small-scale runs, is usually scaled up to the pilot plant scale prior to transferring the process to the large-scale manufacturing plant. The cost of a large-scale run is very high, so it is not feasible to test multiple process conditions in the large-scale bioreactors. Small- and pilot-scale bioreactors are used for new process development and troubleshooting for the large-scale runs. The processes should be scalable to make successful large-scale manufacturing runs. After the cell culture process is commercialized, it is often observed that the growth, productivity, and quality of product in the large-scale runs are inconsistent with those in small- and pilot-scale runs due to improper scale-up or process control issues in large-scale bioreactor runs. In order to solve unexpected issues in large-scale runs, a scale-down model to reproduce performance of the large-scale runs is required. After a scale-down model at small and pilot scales is developed and qualified by reproducing the performance of the large-tank runs in growth, productivity, and quality of product, the performance issues in

large-scale runs can be investigated by changing process parameters in the scale-down model. Also, these models are used to develop a design space for process parameters in a quality-by-design application to ensure predefined product quality (10).

48.5.1. Points of Consideration

There is no universal method to scale down the cell culture process. The type and scale of bioreactor and controls of the process parameters should be considered in designing the scale-down model. The typical parameters considered for scale-down models are as follows.

- Type of bioreactor and scale difference
- Process parameters: mixing by agitation, dissolved oxygen and carbon dioxide, aeration, and pH
- Metabolites: glucose, lactate, ammonia, and amino acids

The most reliable scale-down model for large-scale runs could be a pilot-scale model with the same type of bioreactors, because the difference between scales is minimized and because the design of the bioreactors is similar to produce consistent hydrodynamic mixing. In the process development area, culture scales of 1 to 15 liters are typically used for scale-down models to investigate issues in large-scale runs. The scale of the small-scale model can be shake flask or miniature-scale bioreactor scales of less than 10-ml culture volume as long as the small-scale runs reproduce the performance of large-scale runs (7).

Due to large differences in culture volume between scales, the mixing effect in the large-scale runs should be a primary consideration. Thus, the determination of an agitation rate for the small-scale model should be made primarily based on equal power per volume, volumetric oxygen transfer coefficient, shear rate, or mixing time (18). The details of the scale-up/scale-down parameters are not described here, but are covered in chapter 47 and in a reference indicated above (18). By testing different agitation rates, small- or pilot-scale runs may reproduce the large-scale runs by showing comparable growth, productivity, and quality of product. Once the agitation rate for the small-scale model is defined, the root cause of altered productivity or quality of product can be determined by changing agitation rates or by reproducing process control levels with the qualified scale-down model.

The control of process parameters in the large-scale bioreactor runs also needs to be reviewed and applied to the scale-down model to evaluate the impact of the different controls between different scales.

The level of dissolved carbon dioxide can be too high at the beginning of culture or build up during the cultivation of cells when gas exchange is insufficient in the large-scale runs. The high dissolved carbon dioxide level in the large-scale runs can be reproduced by reducing the sparging aeration rate, adding bicarbonate to the medium, or sparging CO₂ gas with the scale-down models.

Differences in the DO concentration between different scales can be observed, due to improper DO probe standardization by failure to consider bioreactor pressure or hydrostatic pressure in the large-scale bioreactors. The impact of the difference in oxygen concentration between different scales can be evaluated by changing a DO set point in the scale-down model. Excess DO fluctuation in large-scale runs with well-turned gas controllers would occur due to insufficient mixing of the culture. A small-scale run may reproduce DO fluctuations in the large-scale runs by changing the agitation rate.

The pH profile in large-scale runs may be different compared to small- and pilot plant-scale runs. Improperly tuned pH controllers may generate pH perturbation by supplying excess or insufficient base or CO₂ gas into the culture. A low agitation rate at the large scale also causes local pH perturbations. With the scale-down model in small and pilot scales, this pH perturbation may be reproduced by lowering the agitation rate to evaluate the impact of the local pH perturbation on the performance of the cell culture process. In the small-scale runs, offline pH measurements are generally consistent with online readings due to proper mixing and well-turned pH controllers. However, offline pH measurements often show significantly higher or lower pH values than online pH readings in the large-scale runs due to local pH perturbation by improper mixing. The impact of the pH difference could be evaluated using the scale-down model by widening a dead band or the pH 1-point correction range, or by setting different pH set points which are observed in the large-scale bioreactor runs.

The changes in productivity and quality of product between different scales are often indicated by metabolite profile changes. Major changes in the metabolite levels are observed with lactate and ammonia, which are considered as by-products of culture, in addition to the changes in glucose, glutamine, and amino acid concentrations. If metabolite profiles in the scale-down model are similar to the profiles observed in the large-scale runs, the scale-down model may represent the large-scale runs in order to investigate the root cause of productivity and quality issues in large-scale manufacturing runs by changing control parameters.

48.6. CONCLUSION

This chapter describes the types of bioreactors, bioreactor control for process parameters, measurements of cell growth and metabolites, and a scale-down model at the small scale through large-scale cell culture. The contents of this chapter could be used by cell culture scientists or engineers who work in process development or at pilot- or large-scale manufacturing areas for the installation and operation of cell culture bioreactors.

The types of bioreactors for cell culture processes are introduced to provide the advantages and disadvantages of each type. The proper control of process parameters such as pH, DO, agitation, and aeration is the most important consideration in the operation of bioreactors to consistently produce good cell growth, productivity, and quality of product. The points of consideration for the control of each parameter are described to explain how to maintain predefined set points for each parameter consistently from the small scale through large-scale cell culture runs. Also, offline and in situ probe measurement of process parameters, cell growth, and metabolites during the cultivation allows for these parameters to be monitored and maintained in predefined ranges. Process control with in situ probe measurement is widely applied to the PAT projects that were initiated by the FDA.

Upon scale-up to the large scale, processes often show “out-of-trend” results for productivity or quality of product. Small- or pilot-scale bioreactors are mostly used to investigate out-of-trend results. The pilot-scale runs are the most reliable for reproducing the performance of large-scale runs because of relatively comparable hydrodynamic mixing between scales. The scale-up parameters, such as equal power per volume, volumetric oxygen transfer coefficient,

shear rate, or mixing times, are also applied to determine the agitation rate for the scale-down model. The scale-down model should show comparable metabolite levels, cell growth, productivity, and quality of product to those observed at the large scale. The differences in the control of process parameters and metabolite levels between scales should be reviewed and applied to the scale-down model to investigate the impact on the large-scale runs. The scale-down model is also applied to the quality-by-design applications to develop a design space for process parameters to ensure predefined product quality. The PAT and quality-by-design guidance and application are further described in chapter 50 in this volume.

Continuous Culture

AN-PING ZENG AND JIBIN SUN

49

49.1. INTRODUCTION

Since the fundamental work of Monod (50), Novick and Szilard (53), and Herbert et al. (30) on the theory of continuous culture a half-century ago, the advantages and potential of this type of cultivation have been widely recognized. From an application point of view, these include high volumetric productivity, savings in labor and energy costs (e.g., inoculum preparation, reactor cleaning, and sterilization), uniform product quality, better automation and process control, and the use of more efficient and economical methods of medium preparation and downstream processing.

As a research tool, continuous culture provides well-defined cultivation conditions for genetic, biochemical, and physiological characterizations of cells (13, 26, 76, 81). It allows independent variation of growth parameters, enabling reliable kinetic studies of cell growth and metabolism for process optimization (27, 72). Competition and/or interaction of different species can be studied more easily in continuous mixed cultures than in batch cultures (26). Some phenomena, such as synchronized growth and oscillation, which are hardly observed in batch cultures, can be “trapped” and reproduced in continuous culture (7, 28, 45). The transition behavior of a continuous culture upon shift-up or shift-down of a variable is also a powerful tool to study the regulation of growth and metabolism (4, 6, 15, 32, 44). This kind of transient behavior can also be used for an improved medium design and optimization (22). In addition, continuous culture is also a useful means for selecting strains and/or subclones with improved growth characteristics and productivity (19, 46). On the other hand, mutation and instability of some producing strains due to the selection pressure in continuous culture is a major obstacle for the industrial application of this cultivation technique, particularly in the case of genetically modified cells (8, 38, 65, 75). Another obstacle is the difficulty in maintaining monoseptic conditions over a long period of operation at a large scale. Cell adhesion on the reactor wall and sensors is sometimes a problem, preventing long-term operation of a culture.

With the rapid development in ultrafast genome sequencing, functional genomics, and other “-omics” technologies, which can quantify cellular components at the system and molecular levels, continuous culture has received renewed interest in recent years. Unlike batch or fed-batch

culture—wherein environmental factors and cellular regulation and components submit to continuous change, and therefore the cellular state is an integrative outcome of all these cross-talking factors—continuous culture offers controllable and reproducible steady states wherein all cellular components remain unchanged for a long time. Combined with well-designed experiments, this provides a unique opportunity to elucidate the regulatory mechanism of cellular response to a single environmental or genetic perturbation. Microarray is among the most established tools to quantify the mRNA expression profile for this purpose. The reader is referred to the excellent review articles published recently (16, 21, 33). By applying the next-generation genome sequencing technology, one can identify the industrially or academically interesting mutations corresponding to adaptation or selection of the organisms or communities to the given environment. This knowledge can be used to engineer the organisms for further improvement of cellular properties—a strategy called “reverse metabolic engineering” or “evolutionary engineering” (3, 10, 16, 62).

The use of continuous culture received great interest in the 1960s for basic research in biology and cell physiology and led to a renaissance in the 1970s and early 1980s, mainly because of its potential industrial application for the production of single-cell protein, alcohols, solvents, and food-related products and for wastewater treatment. In today's biotechnological applications, continuous operation is fully established in wastewater treatment, production of some primary metabolites (e.g., ethanol and organic acids), and fermented foods and for some reactions catalyzed by enzymes. It is also used for the production of monoclonal antibodies and recombinant proteins by animal cell cultures. The major applications of continuous culture are, however, still found in fundamental studies and process optimization at laboratory scale. A number of new biological processes, such as animal cell cultures and microbial cultures with genetically modified cells, have been quantitatively studied with the help of continuous culture (5, 8, 23, 24, 29, 30, 43, 49, 52, 70, 72). Continuous culture has also been used for bioreactor characterization, control, and scale-up (12, 27, 72). Variations of the continuous culture (e.g., the auxostat) have been introduced and exploited (25, 48, 60, 61). These variations overcome some of the disadvantages associated with chemostat culture and open up new ways of continuous cultivation.

This chapter gives a brief introduction to the general concept and theory of different types of continuous culture. The design and operation of equipment and experiments are discussed from an application point of view. For more detailed treatment and special aspects of continuous culture, the reader is referred to several excellent textbooks and review articles (2, 13, 16, 21, 22, 26, 28, 39, 51, 56, 69, 75, 76).

49.2. GENERAL CONCEPT AND THEORY OF CONTINUOUS CULTURE

Depending on the control parameter and the operation mode, continuous culture can be classified into four general types (Fig. 1). A common feature of these cultures is that they consist of one or more culture vessels into which fresh medium or culture from a preceding vessel is continuously introduced at a rate, F , expressed in liters per hour, and that the culture volume, V , expressed in liters, is kept constant by continuous removal of the culture. The general concept and theory of these four types of continuous culture are described in more detail as follows.

49.2.1. Chemostat

The chemostat (Fig. 1A) is defined as a continuous culture system in which the feed rate is set externally and cell growth is limited by a selected nutrient. The second condition means that the specific growth rate, μ (hour^{-1}), of the organism is a function of a single growth-limiting nutrient. However, this definition may be relaxed to include continuous culture limited simultaneously by more than one nutrient component (26). Continuous cultures that are fed with an inhibitory nutrient or that form toxic products can be limited by growth inhibition under the condition of excess of all nutrients. Strictly speaking, they cannot be referred to as chemostat cultures.

A chemostat is usually started as a batch culture. Before a nutrient becomes limiting, the nutrient feed is started. Cells grow until the chosen nutrient becomes limiting. After this, cell growth is limited by the rate of addition of medium. The specific growth rate of a chemostat culture can be determined from a material balance for biomass: net increase in biomass = biomass in incoming medium + growth – output – death. In mathematical form this is

$$\frac{dX}{dt} = \frac{F}{V}X_0 + \mu X - \frac{F}{V}X - \alpha X \quad (1)$$

where dX/dt is the rate of accumulation of biomass per unit of time and per volume (g of dry cell weight [DCW] per h per liter); X_0 is the biomass concentration (g of DCW per liter) in the incoming medium; X is the biomass concentration (g of DCW per liter) in the bioreactor; and α is specific death rate of cells (h^{-1}). This expression can be simplified if one assumes that the chemostat is at a steady state, that there are no cells in the incoming medium, and that cell death is negligible. The assumption of steady state implies that there is no net accumulation of cells in the bioreactor, so the left-hand side of the equation is equal to zero. Furthermore, if the dilution rate, D , is introduced for F/V , equation 1 becomes

$$\mu X = DX \quad (2)$$

Hence

$$\mu = D \quad (3)$$

Thus, by maintaining a constant volume and changing the nutrient feed rate, one can precisely control the specific growth rate of a culture over a range up to the maximum specific growth rate (μ_{max}) and let the system come to a steady state. This is one of the most important properties

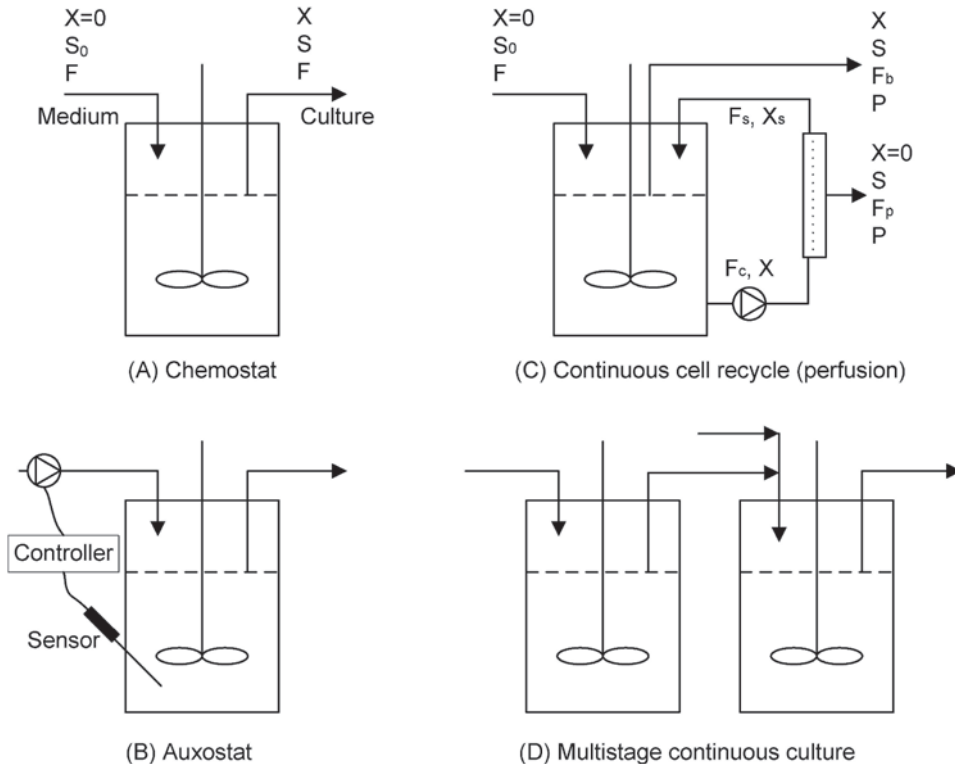

FIGURE 1 Schematic diagram of four types of continuous culture.

of a chemostat. Note that the following additional assumptions are made in the derivation of equations 1 to 3.

1. Cells are distributed randomly in the bioreactor; i.e., the cells do not adhere to each other or to the walls of the reactor, and the suspension is well mixed.
2. The population is nonsegregated and consists of physiologically identical cells.
3. The population density, X , is a continuous variable; i.e., the number of cells is sufficiently high and the size of each cell is sufficiently small for the discreteness of biomass to be ignored.
4. The volume occupied by the cells is negligible compared to the total volume of the culture.

Furthermore, assuming that as soon as medium enters the bioreactor it is instantly distributed uniformly throughout the culture, a material balance on the growth-limiting substrate can be formulated as net increase = input – output – substrate consumed by cells. For an infinitely small time interval, dt , this balance for the whole culture is

$$\frac{dS}{dt} = DS_0 - DS - q_s X \quad (4)$$

where S_0 is the concentration (g per liter) of substrate in feed, S is the concentration (g per liter) of substrate leaving the reactor, and q_s is the specific consumption rate of substrate (g per g of DCW per h). Equation 4 can also be written in terms of growth yield:

$$\frac{dS}{dt} = DS_0 - DS - \frac{\mu X}{Y_{x/s}^{\text{app}}} \quad (5)$$

where $Y_{x/s}^{\text{app}}$ is the apparent yield of biomass on substrate (g of DCW per g of substrate), which is defined as

$$Y_{x/s}^{\text{app}} = \frac{\mu}{q_s} \quad (6)$$

In general, both q_s and $Y_{x/s}^{\text{app}}$ are functions of μ and can also be affected by a number of other growth parameters, such as the nature of the limitation and the level of substrate concentration (79, 80). To illustrate the basic characteristics of a chemostat, $Y_{x/s}^{\text{app}}$ is assumed here to be constant.

Thus, under steady-state conditions, equation 5 reduces to

$$DS_0 - D\bar{S} - \frac{\mu\bar{X}}{Y_{x/s}^{\text{app}}} = 0 \quad (7)$$

where \bar{S} and \bar{X} denote steady-state values. For a chemostat in which growth inhibition by product formation and excess of other nutrients does not occur, the well-known Monod kinetic (50) may be used to describe the relationship between specific cell growth rate, μ , and the concentration of a limiting nutrient in culture:

$$\mu = \mu_{\text{max}} \frac{S}{S + K_s} \quad (8)$$

where μ_{max} is the maximal specific growth rate (h^{-1}) and K_s is a saturation constant corresponding to the substrate concentration at which the maximum specific growth rate is reduced by one-half. Substituting μ for D in equation 8, we obtain for a steady state

$$\bar{S} = K_s \frac{D}{\mu_{\text{max}} - D} \quad (9)$$

and from equations 3 and 7, the following expression for the steady-state biomass concentration is obtained:

$$\bar{X} = Y_{x/s}^{\text{app}} (S_0 - \bar{S}) = Y_{x/s}^{\text{app}} \left(S_0 - K_s \frac{D}{\mu_{\text{max}} - D} \right) \quad (10)$$

FIGURE 2 Steady-state values of biomass and growth-limiting substrate concentration in a chemostat according to equations 9 and 10. Parameters: $\mu_{\text{max}} = 1.0 \text{ h}^{-1}$; $K_s = 0.01 \text{ g/liter}$; $Y_{x/s}^{\text{app}} = 0.5 \text{ g/g}$.

The characteristics of a chemostat can be best viewed by examining the behavior of the governing equations derived above. Figure 2 shows plots of S and \bar{X} against dilution rate, D , with typical parameter values. The residual substrate concentration is only a function of the dilution rate. It increases slowly with D at low values but very rapidly as D approaches μ_{max} . The biomass concentration depends on the feed substrate concentration. At a given S_0 , biomass is almost constant at low values of D but rapidly declines at dilution rates close to μ_{max} .

49.2.2. Deviations from the Ideal Chemostat

The suitability of the simple chemostat theory has been demonstrated for a number of organisms, including bacteria, yeasts, and plant and animal cell cultures. In most cases, these cultures were carried out at very low feed concentrations of nutrient, in small-scale bioreactors, and/or in a relatively narrow range of dilution rate. Under these conditions, the assumptions made in the derivation of the above equations may be approximately fulfilled. Nevertheless, deviations from chemostat theory have been frequently observed. Figure 3 shows typical biomass profiles as a function of dilution rate in continuous culture that depart from chemostat behavior. The deviations may originate from interactions of cells with the equipment and reactor hydrodynamics, such as wall growth and imperfect mixing. Wall growth is caused by the adhesion of cells to glass and metal surfaces. As shown in Fig. 3A, wall growth can increase the steady-state biomass concentration and enable an operation to be carried out at dilution rates higher than the maximum specific growth rate (71). Brown et al. (11) studied the effect of imperfect mixing (stagnant zone) on the performance of a continuous culture (Fig. 3B). Depending on the relative size of the stagnant zone and the velocity of liquid exchange between the well-mixed zone(s) and the stagnant zone, the biomass concentration can be markedly reduced at a certain range of the dilution rate. Similarly, as in the case of wall growth, the operational dilution rate can be higher than μ_{max} . Simple chemostat theory assumes perfect mixing of medium; i.e., a drop of medium entering the vessel should instantly be distributed uniformly throughout the culture. Quantitatively, this means that the time constant required for mixing should be smaller

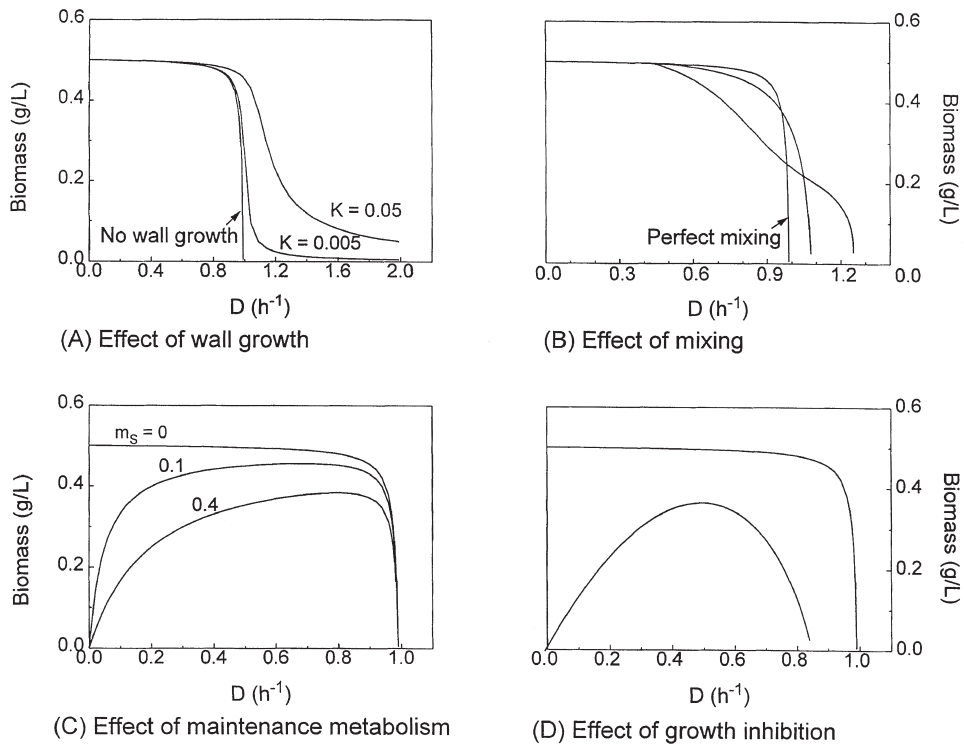

FIGURE 3 Typical profiles and reasons for continuous cultures deviating from chemostat behavior. The biomass curve of a corresponding chemostat culture (see Fig. 2) is also shown for comparison. (A) Effect of wall growth. K is the amount of growing biomass attached to the reactor surface per unit volume of culture. (B) Effect of imperfect mixing. (C) Effect of maintenance metabolism. m_s is the maintenance requirement for substrate ($g/g \cdot h$). (D) Effect of growth inhibition by product(s) and/or substrate.

than the time constants for mass transfer and bioreactions (83). In laboratory-scale reactors with a culture volume of a few liters, nearly perfect mixing can be obtained at proper agitation rates unless the reactor contains zones that screen the culture from the agitation or the culture becomes very viscous. In large-scale reactors, however, imperfect mixing is inevitably encountered.

The deviations observed in laboratory-scale reactors are quite often caused by biological effects. Among others, these include maintenance requirement (57), variations of growth yield due to metabolic overflow (67, 79, 80), growth inhibition by products and/or substrate (27, 78), and regulatory and segregating effects at low and high growth rates (4, 44). As shown in Fig. 3C and 3D, both the effects of maintenance metabolism and growth inhibition tend to decrease the steady-state biomass concentration, particularly at a low dilution rate. Under conditions of strong growth inhibition, the operation of a continuous culture may be only possible at dilution rates significantly lower than μ_{\max} . The factors mentioned above may be simultaneously involved in a culture system. In such a case, the relationship between the biomass concentration and the dilution rate will be more complicated.

49.2.3. Auxostat

An auxostat is a continuous culture in which a growth-dependent parameter is kept constant by adjusting the feeding rate of medium (Fig. 1B). The dilution rate and hence the specific growth rate of the culture adjust accordingly. The

choice of the feedback parameter for an auxostat is quite broad. It includes cell density (turbidity), pH, dissolved oxygen concentration, CO_2 in effluent gas, and concentrations of nutrients and products (25). Sometimes the term "nutristat" is also used to refer to auxostats using a nutrient concentration as the feedback growth parameter. Of the different kinds of auxostats, the turbidostat and the pH-auxostat have so far found the most applications (9, 25, 48, 60).

In a turbidostat, the biomass (cell density) is used as a control parameter. A sensor detecting the biomass density gives a signal to a pump to add more medium when the biomass density rises above a chosen level. By means of turbidostat control, therefore, the biomass density is set and the dilution rate adjusts itself to the steady-state value, in contrast to the chemostat, in which the dilution rate is fixed and the biomass concentration adjusts itself to the steady-state level. The governing equations of a turbidostat can be derived from the general equations 1, 5, and 8. Under steady-state conditions, we have

$$\bar{S} = S_0 - \frac{\bar{X}}{Y_{x/s}^{app}} \quad (11)$$

$$D = \mu_{\max} \frac{\bar{S}}{\bar{S} + K_s} \quad (12)$$

Here \bar{S} is linearly dependent on both \bar{X} and \bar{S}_0 , while D is a hyperbolic function of these two parameters. These relationships are illustrated in Fig. 4.

FIGURE 4 Steady-state limiting-nutrient concentration, \bar{S} , and dilution rate, D , as functions of biomass concentration in a turbidostat culture. Growth parameters are as given in the legend to Fig. 2.

In principle, turbidostat culture is suitable for the cultivation range in which the biomass concentration varies significantly with change in dilution rate, such as near the critical dilution rate (Fig. 4). This is of particular interest because operation near the maximum growth rate can be very unstable in a chemostat. The turbidostat also provides a means of maintaining cultures in a constant environment with excess of substrate. Since the growth rate is not fixed, the system will select for fast-growing organisms. Increase in the maximum growth rate will result from both selection of genetically different organisms (or mutants) and an adaptation of cellular metabolism. In the past, a photoelectric cell was the main sensor used to monitor cell density. This technique is limited to unicellular organisms and is difficult for long-term cultures, largely because of adhesion of organisms to the surface of the sensor. With the development of optical sensors based on laser or infrared light transmission/scattering, problems with long-term monitoring of biomass may be partly overcome.

In a pH-auxostat, the addition of fresh medium is coupled to pH control. As the pH drifts from a given set point, fresh medium is added to bring the pH back to the set point. The rate of addition of medium is determined by the buffering capacity and the concentration of nutrients in the medium. Buffering capacity is defined as the equivalents of titrant required to change the medium pH to the culture pH. The governing equation is the mass balance on the H^+ ion concentration, expressed as milliequivalents (meq) per liter, in the bioreactor (25):

$$\frac{dH^+}{dt} = D(H_F^+ - H^+) + \mu Xh - D(BC) \quad (13)$$

where H_F^+ is the H^+ ion concentration in feed (meq per liter), h is the acid production yield of cells (meq per g of biomass), and BC is the buffering capacity of medium (meq per liter).

By using fresh medium for pH control, the limiting nutrient level in the reactor can be manipulated by adjusting the buffering capacity and/or limiting nutrient concentration in the feed. For cultures producing high amounts of acid or alkali, the buffering capacity of the medium may not be sufficient. In this case, separate feeding lines for titrant and medium can be used (9). The concentration of nutrient determines the amount of ionic species produced and ions released during nutrient

uptake. Assuming that the difference between feed and bioreactor H^+ concentrations is very small, the following relationships can be obtained from equation 13 and substrate balance under steady state:

$$\bar{X} = \frac{BC}{h} \quad (14)$$

$$\bar{S} = S_0 - \frac{BC}{hY_{x/s}^{app}} \quad (15)$$

The specific growth rate achieved in a pH-auxostat is positively correlated with the concentration of the nutrient, S_0 , but inversely correlated with the buffering capacity, BC , in the feed medium. Roughly speaking, the specific growth rate achieved in a system with low buffering capacity can be about 10 times greater than with a well-buffered system (60). The biomass concentration is mainly determined by the buffering capacity of the medium.

The pH change of a culture is a good indication of cell growth and metabolic activity. However, the exact cause of pH change varies among organisms. It represents the summation of the production of different ionic species and ion release during nutrient uptake. The pH of a culture is normally reduced by the production of organic acids and by the uptake of ammonium. However, for microorganisms growing on protein- or amino acid-rich media, the pH will rise with growth because of the release of excess ammonia.

Generally speaking, auxostats have the following advantages over conventional chemostats. First, auxostats permit stable operation in the "high-gain" areas near the maximum growth rate. Second, they reach steady state more rapidly at high dilution rates than the open-loop chemostat. Third, population selection pressures in an auxostat lead to cultures that grow rapidly. Finally, it is possible to design a dual set point auxostat that controls two growth parameters (e.g., concentrations of two nutrients) simultaneously (25). This kind of dual set point auxostat permits control of nutrient concentration ratios with ease, which tends to be very difficult with a chemostat. On the other hand, the experimental setup and operation of an auxostat are somewhat complicated.

49.2.4. Continuous Culture with Cell Recycle (Perfusion)

Cell recycle is a useful means for increasing the concentrations of biomass and product in a continuous culture (5, 31, 41, 82). This system can be operated at a dilution rate higher than the maximum specific growth rate, leading to a much higher output of the reactor. Another property is that the dilution rate is almost independent of the growth rate. Recycle of biomass can also protect against shock loading with an inhibitory substrate, because the critical dilution rate is raised. It is particularly advantageous in the following cases: (i) the growth-limiting substrate is unavoidably dilute, for example, in the treatment of effluent; (ii) the substrate has a low solubility, such as when a gaseous substrate is used; (iii) the concentration of growth-limiting substrate has to be limited because of the formation of inhibitory product(s); (iv) product formation is not associated with growth; and (v) the product is unstable or may be degraded, e.g., by proteases in the culture with a long residence time.

Several methods can be used for the retention of biomass, such as filtration, sedimentation, centrifugation, and immobilization. Depending on the position of the separation device inside or outside of the reactor, the methods can be further divided into internal and external systems (56). The concentration of culture effluent outside of the reactor

by means of membrane filtration has so far found the most frequent application, except for the biological treatment of wastewater, in which the recycling of sludge after sedimentation has been used for a long time.

Figure 1C schematically shows a continuous culture with membrane cell recycle. The culture is circulated at an outflow rate F_c (liters per h) by a pump over a microfiltration membrane from which a cell-free filtrate is withdrawn at a rate of F_p (liters per h). In addition, a portion of the liquid culture containing biomass is withdrawn from the reactor at a bleed rate of F_b (liters per h).

Note that in a membrane bioreactor, the circulation rate of liquid culture, F_c , is normally much higher than the filtration rate, F_p , so that the concentration factor, $\alpha = X_s/X$, is very close to 1:

$$\alpha = \frac{X_s}{X} = \frac{F_c}{F_s} = \frac{F_c}{F_c - F_p} \approx 1 \quad (16)$$

Where X_s and F_s are the biomass concentration and flow rate at the outlet of the filtration module, respectively. Thus, the position of biomass withdrawal (bleed) does not affect the governing equations for the membrane bioreactor, which can be written as follows:

$$\frac{dX}{dt} = (\mu - B)X \quad (17)$$

$$\frac{dS}{dt} = D(S_0 - S) - q_s X = (B + f)(S_0 - S) - q_s X \quad (18)$$

where B is the bleed rate (h^{-1}), defined as $B = F_b/V = 1/\tau$; τ is the mean cell residence time (h); and f is the filtration rate, defined as $f = F_p/V$ (h^{-1}). The dilution rate, D , is the sum of rates of bleed and filtration. Assuming a constant apparent biomass yield (equation 6) and Monod kinetics (equation 8), the following steady-state solution of equations 17 and 18 is obtained:

$$\mu = B \quad (19)$$

$$\bar{S} = K_s \frac{B}{\mu_{\max} - B} \quad (20)$$

$$\bar{X} = \left(1 + \frac{f}{B}\right) Y_{x/s}^{\text{app}} \left(S_0 - K_s \frac{B}{\mu_{\max} - B}\right) \quad (21)$$

Thus, cell growth rate in a chemostat with cell recycle is determined by the bleed rate, B . From equation 17, it is obvious that in a system of total cell recycle ($B = 0$), the biomass would build up to reach a point where the cultivation becomes inoperable owing to high viscosity and difficulties in mixing and nutrient supply. Thus, a controlled bleed of biomass is necessary to maintain an active biomass. In some cases, cell death and lysis at high biomass concentration may be considerable so that total cell retention is possible. A comparison of equation 21 with equation 10 reveals that at a same growth rate, the chemostat culture with cell recycle can increase the biomass concentration of a simple chemostat by a factor of f/B . In practice, a value of f/B in the range 10 to 100 is feasible. The increase of final product concentration is normally much lower because of the reduction of productivity of cells at high concentrations.

49.2.5. Multistage Continuous Culture

The two-stage continuous culture system shown in Fig. 1D can extend the range of application of continuous culture. For example, the second stage may be used to extend the growth rate downward to zero, and the first stage may be used to achieve stable conditions with maximum growth rate, both of which conditions may be desired in certain cases but are impossible in the simple chemostat (56). The latter property is particularly useful when the substrate is

also a growth inhibitor. In the production of secondary metabolites and enzymes by continuous culture, the second stage may be used to provide a nongrowing situation in which product formation occurs. For products of foreign gene expression, the second stage can be used for induction of expression (70). Another useful application of the two-stage continuous culture is for reactor scale-down studies (12). The two-stage culture system can be extended to include more stages and more feeding streams with or without biomass recycle. For more information on these systems, the reader is referred to Pirt (56) and Moser (51).

49.3. EQUIPMENT SETUP AND DESIGN

49.3.1. General Setup of a Continuous Culture

Figure 5 shows a typical setup of a bench-scale reactor system for continuous cultivation. A continuous reactor system consists of at least three parts:

1. Reaction vessel, i.e., a bioreactor (at center) equipped with elements for aeration, mixing of liquid (medium) and solid (cells or insoluble substrate) phases, sampling, and control of temperature, pH, dissolved oxygen, foaming, and reaction volume. Equipment for online effluent gas measurement is also depicted in Fig. 5. Some of these control units may be omitted, depending on the type of fermentation.
2. Storage vessels for medium and solutions for control of pH and foam. They should be suitable for sterilization. Normally, the entire homogeneous, mixed medium is stored therein, containing the substrate as carbon and energy source (e.g., glucose) and other nutrients at given concentrations. More vessels are necessary if heat-sensitive components are used, because they need separate sterilization. Components may be mixed together before being fed into the reactor by a metering device (e.g., a pump) or may have separate connecting lines to the reactor.
3. Broth withdrawal and collection vessel (at right). The collection vessel is not mandatory but is useful for measuring the effluent rate of the culture and avoiding the release of organisms into the environment.

For some applications, such as selection of strains (or mutants), much simpler configurations of continuous culture can be used (39).

49.3.2. Equipment Selection and Design

Stafford (66) provides an excellent overview of potential problems and solutions concerning selection, design, and operation of individual equipment used in continuous culture. The following discussion is mainly based on Stafford and includes some updated information and the authors' experience with continuous culture. In addition, necessary equipment and its operation for continuous culture with cell recycle are addressed. As pointed out by Stafford (66), the type of fermentation may dictate the choice of equipment. Medium composition (chemically defined or complex) and organism morphology (filamentous or unicellular) set restrictions on the type of equipment that can be used. Therefore, the suggestions below serve only as a guideline and may need to be modified or even replaced according to the actual requirements.

49.3.2.1. Reactor

The scale of reactor is an important factor in selection of equipment and setup of a continuous culture. The con-

FIGURE 5 A typical setup of a bench-scale continuous-culture system. The feeding rate and the culture volume are controlled by a weight control unit.

sumption of medium and the need for other peripheral equipment are largely determined by the working volume of the reactor. For research purposes, a benchtop-scale reactor is convenient to operate. In addition, investment and space requirements are modest, and peristaltic pumps of adequate reliability are available. A benchtop reactor is easily dismantled for cleaning.

Small-scale culture vessels have some unique problems, however. When operated at volumes of less than 500 ml, sampling can significantly reduce the volume, affecting the dilution rate and leading to fluctuation of the system. Flow rates for obtaining low dilution rates can be very difficult to control, and feeding a complex medium at low flow rates can result in settling out of insoluble medium components in feed lines, causing plugging. It is often difficult to implement an online gas analysis owing to low back-pressure and low aeration rate. In addition, wall growth may represent a considerable fraction of the total population in a small vessel. For microbial cultures, a working volume of 1 to 5 liters (total volume of 2 to 7 liters) is in most cases appropriate. A lower working volume (e.g., 0.5 to 2 liters) may be desired for animal cell culture owing to the relatively high cost of medium. The alternative use of a reactor for batch or fed-batch cultures should also be considered.

Stirred-tank reactors are usually used in benchtop scale, although other reactor types, such as airlift and fluidized-bed reactors, are also available in small scale. The choice of a reactor type depends very much on the goal of the research. For small-scale stirred-tank reactors, there are also several variations in design, including flat-bottom and round-bottom vessels. The flat bottom eases handling on the bench and in the autoclave. On the other hand, round- or dished-bottom vessels ensure better mixing and are mostly used for culturing shear-sensitive cells. Jacketed reactors are also

available. The glass jacket gives better temperature control than the use of a heat exchanger inside the reactor. The jacketed reactor is more suitable for heat-sensitive cultures.

49.3.2.2. Nutrient Feed Reservoir and Auxiliaries

Nutrient reservoirs for continuous culture should have ports for feeding, addition and/or mixing of heat-labile nutrients and substrate, venting, and sparging of the medium (Fig. 5). The feed and sparging lines should be stainless steel tubes going to the bottom of the vessel. The venting line should be attached with a sterile filter. A magnetic stirring bar must be included to suspend any particulates and mix nutrients that are added after sterilization of the bulk medium. A separate sampling line is also useful for taking samples to determine the exact substrate concentration after refilling. A carboy or glass flask with a medium volume large enough for at least one steady state may be used as an intermediate reservoir. This can be calibrated by volume or placed on a weighing device so that the nutrient feed rate can be checked over several hours or days. It is also flexible enough for adjusting the nutrient concentration if different growth limitations are to be used.

Silicone rubber tubing or special gas-impermeable tubing should be used when tubing is required. It can be sterilized repeatedly, retains its resilience, and has excellent chemical resistance. The method of connecting tubing should be aseptic, fast, and reliable. One should be aware that the flow rate through a peristaltic pump is dependent on the resilience of the tubing. Because silicone rubber tubing loses its resilience with use, a long piece of tubing should be used so that the pump can be moved every other day to a new section. For extended operation, replacement of the tubing may be necessary.

The medium inlet line may be connected with a drip tube very close to the reactor. A drip tube provides a barrier

FIGURE 6 Diagram of a drip tube.

in the medium flow path and prevents microorganisms from growing into the feed line. It can be purchased from fermentor manufacturers or constructed as shown in Fig. 6. The drip tube may fail if pressure builds up in the reactor.

49.3.2.3. Broth Removal and Level Control

To achieve an accurate and constant control of the dilution rate, the working volume of the culture must be determined and controlled. The working volume of a culture is normally defined as the ungasged liquid volume. Two parameters can be used to control the ungasged liquid volume: gassed liquid level (assuming constant gas holdup) and weight of the reactor content. Because gassed volume is easier to control, it is widely used. However, constant gas holdup is difficult to achieve. Alternatively, weight control can be more accurate if properly installed, but it is much more expensive to implement on the bench scale of operation. The working volume

of the reactor system shown in Fig. 5 is kept constant by a weight control unit. The signal from the balance is used to control the pump for culture removal.

There are basically two ways of controlling gassed liquid level. The simplest method is to make use of the overpressure in the reactor from aeration. The effluent gas outlet can be placed at the broth surface. The effluent gas is directed into a waste reservoir that is vented aseptically to the atmosphere. When the culture volume increases above the effluent gas outlet, broth is forced out into the reservoir with the gas. Sometimes a pump is used to withdraw broth instead of using effluent gas. Both of these systems suffer from the problem that the cell concentration at the air/liquid interface can be quite different from that in the bulk liquid, especially if foam is formed. This can cause a nonrepresentative withdrawal of culture from the reactor.

Another method is to use a liquid level controller. Although this technique requires more equipment, it allows withdrawal of broth from below the liquid surface. A number of liquid level controllers are available. Most of them are based on a sensor within the vessel that makes physical contact with the culture fluid. Because the sensor is located within the reactor, failure of the probe will end the process. Depending on the type of sensor used, inaccuracies in volume can be caused by variations in agitation, aeration, foam generation, and wall growth. Ultrasonic level controllers are available that can be attached to the outside of a glass or steel vessel. They can be attached after autoclaving, and if a sensor malfunctions, it can be replaced without violating sterility.

Stafford (66) proposed the use of a redundant control scheme as shown in Fig. 7. In this system, a liquid level controller is backed up by the effluent gas system. The culture exit tube is located just below the liquid level, while the effluent gas exit is located just above the liquid

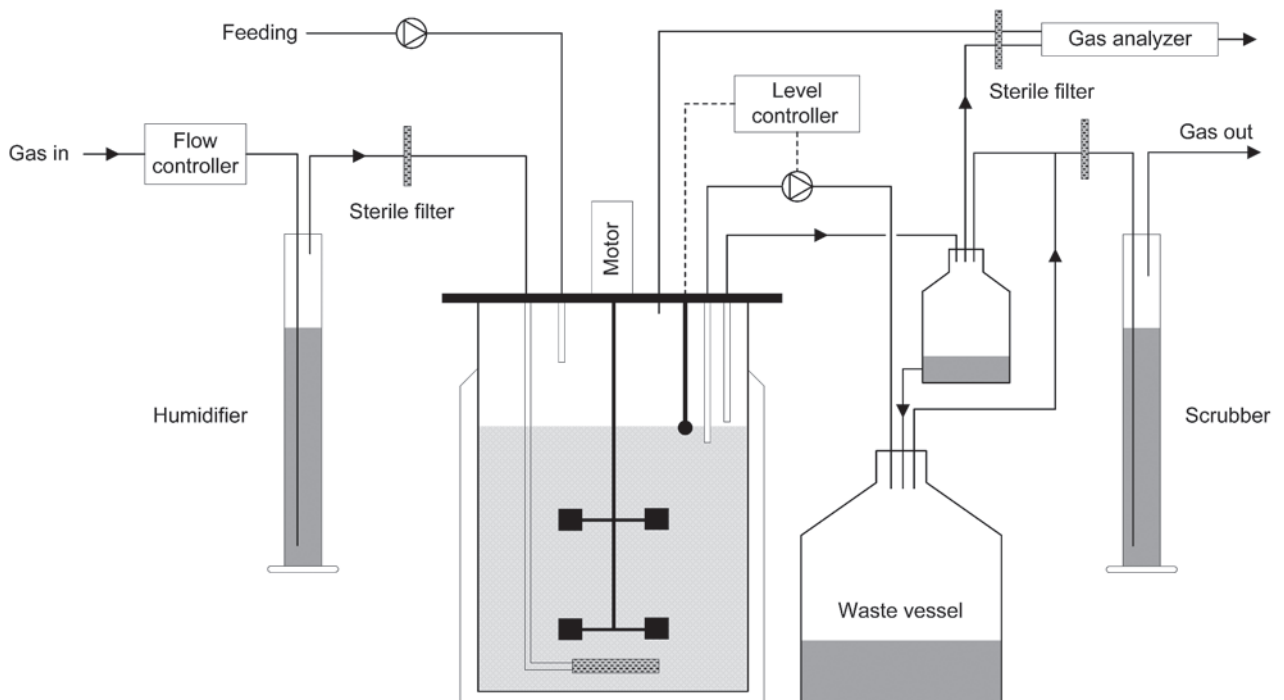

FIGURE 7 Control scheme for the reactor volume of a continuous culture that uses a liquid level controller backed up by an effluent gas system. (Modified from reference 66.)

level. If the level controller fails and remains in the "on" position, the waste broth pump cannot reduce the liquid level below the culture take-off line. If the level controller fails and remains in the "off" position, or the pump stops or the tubing becomes clogged, then the liquid level cannot rise above the effluent gas exit tubing. However, problems caused by the change of gas holdup and foam formation still cannot be fully eliminated. If an antifoam agent is added during operation, fluctuation in the liquid level may result. To avoid error in determining the dilution rate, the real ungasged liquid volume may need to be checked from time to time by a brief switch-off of aeration and agitation (in case of strong foaming), for example, after a steady state has been achieved. Nevertheless, this measure may lead to other negative influences on cellular metabolism owing to the shock of oxygen limitation.

A stable continuous culture requires accurate and reliable pumps. The pump heads and the pumping lines should be sterilizable. Most important, it should be capable of long-term aseptic operation. On the benchtop scale, peristaltic pumps meet these criteria. As fermentation scale increases, they become impractical. Silicone tubing should be replaced by piping. Generally, *in situ* steam sterilization is required for reactors greater than the 10-liter scale. Diaphragm pumps can be used that provide reliable, adjustable flow rates. These pumps have several advantages over centrifugal and gear pumps. First, they lack a mechanical seal. Over time, mechanical seals wear out and can be a source of contamination. Second, the pump head and the lines leading to and from the head can be sterilized by steam. Finally, the flow rate can be maintained over a wide range of pressure. This means that changes in the back-pressure of the vessel can be accomplished without substantially changing the pump flow rate.

49.3.2.4. Gas Inlet and Exit

An example of a gas supply and effluent system is shown in Fig. 7. Humidification of the gas prevents evaporation of medium from the vessel and improves the estimation of dilution rate if the culture effluent rate is measured in the outlet line. This may be significant when operating at a relatively high temperature (e.g., above 35°C), when using compressed air that is very dry, or when operating at dilution rates of less than 0.1 h^{-1} . Sterilization of the inlet

gas can be done by a membrane filter with proper pore size or a packed glass-wool filter. Two filters connected by a tee are recommended as a precaution, especially when using humidifiers. In the event that one filter becomes plugged, the other filter can be unclamped and used immediately. A regulated pressure of gas supply is important for safety. In case the gas exit becomes plugged, the gas pressure should be sufficiently low to prevent the vessel from exploding.

The effluent gas should be directed to an overflow reservoir (safety vessel). In this way, foam-out can be contained. The overflow reservoir is then connected to a graduated cylinder filled with 0.5% bleach. If an online gas measurement is desired, a bypass gas line from the reservoir can be used. The rest of the effluent gas is sparged through the liquid in the cylinder and vented through a sterilizing filter. The cylinder serves several functions. First, it gives a certain degree of back-pressure to the vessel, which is needed for effluent gas analyzers. It also facilitates sampling. Second, it provides a means to visually check whether the gas flow rate is high enough for the gas analyzer and if the reactor system is well sealed. Absence of bubbling may indicate loss of containment, which is of particular concern if pathogenic or recombinant organisms are being cultured. Finally, it acts as a scrubber to reduce unpleasant odors in the laboratory.

49.3.2.5. Cell Recycle

At laboratory scale, cell recycle is easily achieved by using a steam-sterilizable membrane microfiltration module. Figure 8 shows a simplified structure of such a module. It is composed of microporous membrane capillaries. The membrane is usually made of polypropylene or similar materials and is originally hydrophobic. After wetting with ethanol, it becomes hydrophilic. The capillaries normally have a diameter of about 8 mm and a pore diameter of about $0.2 \mu\text{m}$. Membrane modules with different diameters, pore sizes, and filtration areas are available.

An often observed problem of microfiltration is the decrease of filtration rate during operation. This is mainly caused by the formation of biofilms and adsorption of proteinaceous materials on the membrane surface (fouling) and/or loss of hydrophilicity. Factors affecting membrane fouling include concentrations and properties of cells, circulation rate, and properties of the broth and filtration rate. The use of antifoam may also significantly affect

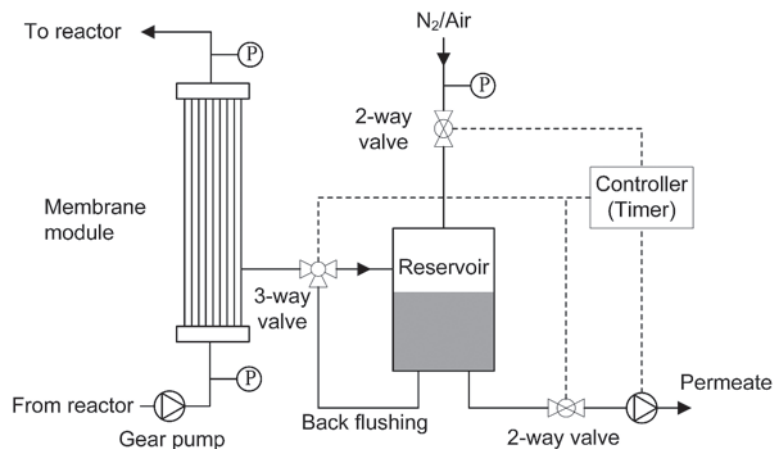

FIGURE 8 Schematic diagram of a back-flushing configuration for a cell recycle reactor with membrane microfiltration. The permeate in the reservoir is back-flushed through the membrane module by using pressurized nitrogen gas or air and controlled by a timer.

membrane performance. To reduce membrane fouling, a minimal broth circulation velocity of about 0.5 to 1 m/s should be maintained, normally by a gear pump. This may impose problems for shear-sensitive cells. The filtration module should also be periodically back-flushed with permeate. Such a back-flushing configuration is shown in Fig. 8 (82). A small permeate reservoir is used for the back-flushing. It is controlled by a computer system or by a timer. When back-flushed, the gas (N₂) line is opened and the permeate line and pump are switched off. The permeate is forced back into the membrane module through a back-flushing line. The back-flushing pressure (e.g., 10⁵ Pa) should not exceed the maximum operation pressure of the module given by the manufacturer (about 2 × 10⁵ to 3 × 10⁵ Pa for most modules). For long-term operation, the module may be back-washed daily with sterilized distilled water. A previous cleaning with a NaOH solution or wetting with ethanol may substantially recover the filtration performance of the module. Care should be taken to prevent NaOH and/or ethanol from running into the reactor. It is advisable to use two parallel filtration modules; while one module is being cleaned, the other remains in operation.

In recent years, ultrafiltration has been increasingly used for cell retention. An ultrafiltration module is made of a membrane with a pore size in the range of 0.1 to 0.01 μm. In addition to cells, macromolecules such as proteins and fats can also be retained. This can simplify the downstream processing in some cases. Present industrial applications of ultrafiltration include food and beverage processing; pharmaceutical production such as purification of monoclonal antibodies; and fractionation of plasma, whey, and egg proteins. In these applications, viruses and pathogens can be also retained and removed.

In mammalian cell cultures used for production of pharmaceuticals (e.g., factor XIII), an inclined sedimentation device with controlled vibration has been used in industrial scale. Hydroclone has also been examined for selective retention of mammalian cells.

49.4. EXPERIMENTAL DESIGN AND OPERATION

49.4.1. Experimental Design

In designing a continuous culture for long-term operation, one must be aware of the possibility of spontaneous mutations because of selective pressure. The rate of spontaneous mutation is estimated at about 1 in 10⁶ cell divisions (66). Sooner or later, cells with a competitive advantage will take over the original strain in the reactor. Thus, if one is interested in studying the physiology of a homogeneous cell population, the operation of a culture should not be too long in order to distinguish between metabolic responses of cells to changes in environmental conditions and genetic changes due to mutation. Some cultures form aggregates or exhibit strong wall growth after prolonged cultivation (e.g., after about 2 to 3 weeks for some *Enterobacter* strains) under metabolic stress (e.g., substrate excess, limitation by growth factors, product inhibition). For these kinds of culture, length of operation is also limited. Care should be taken when interpreting data obtained under conditions of aggregate formation and/or wall growth. If a long-term operation is planned, one should consider the necessity of replacing tubes (damage due to pumping and actions of acid and alkaline solutions) and filters for the incoming and effluent gases used during the process.

49.4.2. Medium Formulation

The basis for medium design is the nutritional requirement for cell growth and product synthesis. In addition to the identification of all components that are necessary for balanced growth or that may interfere with the kinetics of growth and product formation, one has also to establish the appropriate concentrations of the components in a continuous culture, especially if a certain kind of growth limitation is desired. As more and more genetically modified organisms are used for the production of high-value products, chemically defined media and tailored feeding are finding more applications. Considerations of stoichiometry and regulation of metabolism are important for these purposes (43).

The stability of medium formulation and interactions of nutrient components should be considered to avoid precipitation. Precipitation of medium components may be caused by high concentrations of metal ions (e.g., Fe, Ca, and Mg), high temperature during autoclaving, and high pH. This may result in the loss of metal ions and some other trace elements, impairing cell growth and product formation. To achieve a high cell density, the concentrations of metal ions and trace elements must be carefully controlled (or reduced). The use of chelating agents such as EDTA and citrate, particularly in combination, can effectively reduce precipitation. The proper selection of metal ions is also important, because the formation of insoluble salts, such as those associated with phosphate and magnesium, is often a problem.

49.4.3. Medium and Equipment Sterilization

The sterilization of a continuous-culture system is somewhat more complicated than that for a batch-culture system because of the necessity of having more and larger reservoirs for feed medium and acid and alkali solutions and the need to refill or replace them during the process (Fig. 5). Some components of the medium or the acid and alkali solutions may need to be sterilized separately. The lines connecting the various reservoirs and the waste broth vessel to the reactor can become sources of contamination and therefore should be sterilized and connected carefully. The connection should be done under aseptic conditions, e.g., on a clean bench if the reactor system is relatively small. For reactors larger than 5 liters, in situ sterilization may be necessary. This can be done with steam at 121°C, either indirectly through the double wall or by a heat exchanger inside the reactor, or directly by means of steam injection into the reactor. Steam injection is faster and easier but will cause an increase of medium volume by 10 to 15% owing to condensation. The piping lines for large reactors are normally sterilized in situ by using steam. Piping lines should be as short as possible, straight, and laid with a downward slope to ensure the outflow by gravity. T connections should be avoided if possible. To keep the danger of contamination to a minimum, all piping in the sterile stage of a reactor may need to be welded, with no detachable connections. This is very cost-intensive and is therefore only used for special processes (e.g., cell culture processes). In the practical operation of bioreactors, detachable connections are desired to achieve a high degree of flexibility. In this case, only flanges designed in accordance with sterilization requirements should be employed for all connections. The cross sections of piping should be neither reduced nor increased at the flange connection points to avoid accumulation of dirt. The two most popular flange systems are the so-called quick-connection clamping ring system and the screw-on

system (17). A common feature of these flanges is that a sterile connection is achieved by "O" rings. O rings are automatic sealing elements, the total sealing pressure of which increases with increasing pressure in the system.

49.4.4. Environmental Control

Temperature, pH, and dissolved oxygen (pO_2) measurement and control are similar in batch and continuous cultures. However, pH and pO_2 probes may present problems that are not usually encountered in short fermentations. Drifts in the pH and pO_2 probes can occur because of biofilm formation or adsorption of proteins and other materials on the tips of the probes. Whereas the pH probe can be roughly recalibrated by briefly changing the culture pH values and comparing with the offline measurements, this cannot be done with the oxygen probe. Whenever possible, polarographic oxygen probes should be used that have much better stability than galvanic probes after autoclaving, and the electronic zero feature can be used to zero them. For more detailed information on the environmental control of bioreactors, the reader is referred to Schügerl (63).

49.4.5. Start-Up

Continuous cultivation of microorganisms is started as a batch culture. It is normally switched to continuous culture during the exponential growth phase before substrate is completely consumed. The transition of a culture after the switch-over can display very different dynamic behaviors, depending on the nature of the culture and the reactor conditions at the time of switch-over (7, 18). Oscillatory transitions may occur as a result of sudden changes of environmental conditions, particularly during transition from substrate limitation to substrate excess (7, 18, 28, 45). If the culture is suddenly exposed to a very high concentration of toxic substrate, the oscillation may become so severe that cells are washed out. If a system can display multiplicity, the timing and operation mode of start-up of a continuous culture may also lead to different transition behaviors and different steady states (36, 77).

In most cases, the use of a half-strength medium for the initial batch growth can give a smooth transition from batch to continuous cultivation. Nutrient feed is started when the cell concentration is about half of that expected for steady state. In this way, the culture initially approaches a nutrient-limited fed batch after the switch-over. The specific growth rate declines as the cell concentration increases until the steady-state concentration is achieved. At this time, the level controller is turned on and the continuous fermentation begins.

49.4.6. Dynamic Behavior and Determination of Steady State

Steady state is defined as the condition of a continuous culture in which changes in the process parameters (e.g., concentrations of substrate, biomass, and product) and the physiological state of cells are no longer detectable. Normally, only the process parameters that can be measured either online or offline are used to judge if a culture has reached a steady state. In this case, as many process parameters as possible should be included. If product(s) is formed, particular attention should be given to the concentration of the product(s). The product usually reaches constant values later than the concentrations of biomass and substrate. The physiological state of cells reaches a steady state even more slowly, especially if long-term adaptations take place (55, 58).

In an ideal chemostat culture governed by Monod kinetics, the time required to achieve a steady state is about three to four times of volume replacement after a condition changes (56). The volume replacement time (residence

time) is given by $1/D$. In reality, a much longer time is often needed to achieve steady state, depending on the dynamic behavior of the culture and the magnitude of changes (30, 45, 58). Figure 9 gives some examples of transient behavior of a continuous culture after different step changes of substrate concentration in the feed medium at a constant dilution rate (77). In an extreme case, where the new feed concentration (y_0) increases subtly (from 0.334 to 0.335), the new steady state is reached after almost 40 residence times. The parameter change is visible only after about 24 residence times. On the other hand, if y_0 is increased by a large step, the new steady state is quickly reached after about nine residence times. Overshoot and underwing of

FIGURE 9 Transient behavior of a steady state after step changes in a continuous culture operated at a constant dilution rate. The culture is subjected to metabolic overflow and growth inhibition by substrate and products. The substrate concentration in the feed (y_0) is increased from (A) 0.334 to 0.550 (in dimensionless units), (B) 0.334 to 0.400, and (C) 0.334 to 0.335. The relative time is numerically equal to the number of reactor volume exchanges (residence times) (64).

biomass and product are observed in this culture system. More profound oscillatory transient behaviors are observed under certain conditions (6, 7, 22, 28, 45, 58).

In some culture systems, multiplicity of steady states can occur (1, 36, 45). Depending on the operation mode, two markedly different stable steady states can be obtained under the same cultivation conditions. Xiu et al. (77) presented a theoretical and mathematical analysis of multiplicity and instability of microorganisms in continuous culture and compared them with recent experimental results. Figure 10

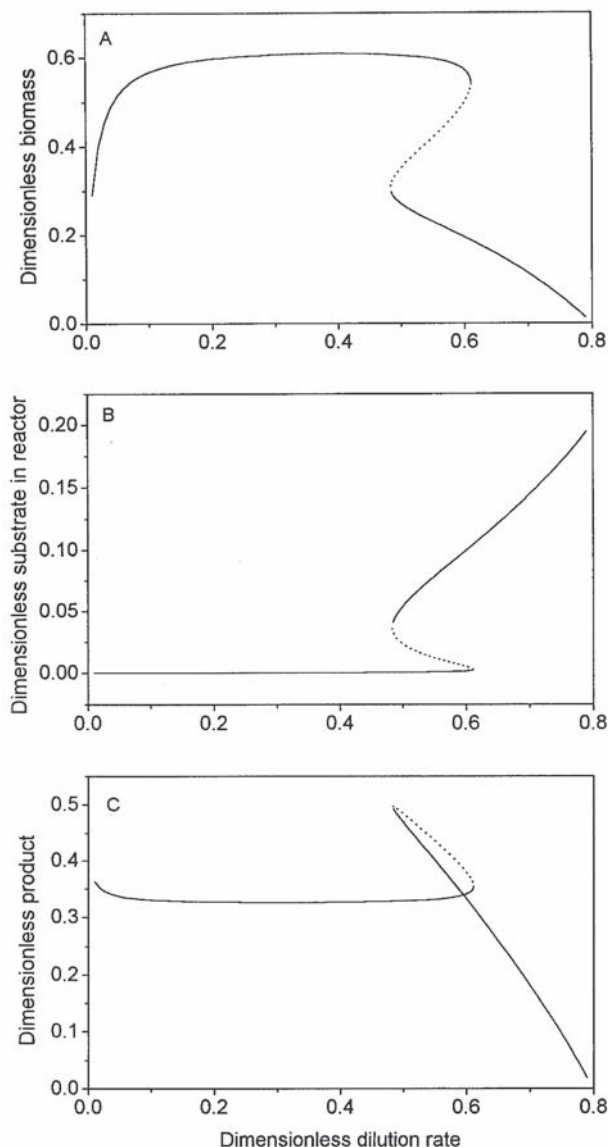

FIGURE 10 Steady-state concentrations of biomass (A), substrate in reactor (B), and product (C) in a continuous culture at a constant feed substrate concentration but varied dilution rates (dimensionless feed substrate concentration, $\gamma_0 = 0.2$). This culture is subject to metabolic overflow and growth inhibition by product. Multiple steady states are found in a given range of dilution rates. Depending on the operation mode, different steady states can be obtained under identical operation conditions (64).

depicts results for a culture operated at a constant feed substrate concentration. For cells grown on one substrate without limitation, the combined effects of product inhibition and enhanced formation rate of product under substrate excess appear to be the main reasons for the multiplicity and hysteresis phenomena so far experimentally observed. These combined effects can also lead to unusual dynamic behaviors, such as a prolonged time to reach a steady state, oscillatory transition from one steady state to another, and sustained oscillations (Fig. 9).

49.5. RECENT DEVELOPMENTS AND FUTURE TRENDS

Whereas the theory of continuous culture is well established, there have been several new developments in the use of this technology. In particular, recent developments in implementing continuous culture in microfluidics or microdevices are worth mentioning and briefly summarized below. With the maturation of microfabrication techniques, continuous culture in microfluidics is drawing increasing interest (35, 37, 40, 59, 64, 84, 85). Microfluidics deals with the behavior, precise control, and manipulation of fluids that are geometrically constrained to a small, typically submillimeter, scale. Microfluidic devices offer many unique properties, such as high surface-to-volume ratio, mass, and heat transfer rates, that are not accessible in conventional bioreactors. Combined with continuous culture, they can be used for a wide range of new applications. Their potential applications include (i) high-throughput screening of medium and parameter optimization; (ii) high-throughput screening of cell lines, drugs, and toxicity testing; (iii) investigation of cellular physiology, in particular at the single-cell level; (iv) controlled study of cellular differentiation and interactions; and (v) cell-based micro biosensors.

For example, fetal human hepatocytes and human hepatocarcinoma cells (Hep-G2) growing in a microchamber showed significantly higher production of albumin compared to standard cultivations in dishes. The higher production of albumin characterizes the higher activity of the cells and therefore the enhanced differentiation, which argues for close *in vivo* conditions (40). Reduction of the medium volume on top of the cells was considered one of the important reasons (73, 74). By running in perfusion mode, depletion of nutrients and oxygen and accumulation of waste products can be successfully prevented (40, 59). Moreover, continuous culture can be implemented in fully automated biosensor systems by continuous removal and analysis of perfusate. This type of biosensor is a cell-based assay chip wherein the cells act as a transducer that can be used, for example, for drug screenings. Shackman et al. (64) created a biosensor to study the response of Langerhans islet cells to step change of glucose. Various sensors for different cells have been built so far (37, 68). The extension of the throughput of biosensors can be realized by parallelization as arrays of different dimensions, e.g., 8 by 8, 10 by 10, or higher (34, 35, 42, 85). The patterning technologies for fabrication and the potential applications as biosensors are described in detail by Park and Shuler (54).

Microchambers can be integrated with other submicrometer elements such as fluid-handling devices and sensors, becoming sophisticated devices that integrate one or several laboratory functions on a single chip, often called "lab on a chip," or known as micro total analysis systems (μ TAS) when used for analysis purposes. A completed system would include cultivation, treatment, selection, lysis,

separation, analysis, etc. (20). Zhang et al. (84) presented a chip on which a chemostat culture was established for microbial cells with the capability of monitoring dissolved oxygen, pH, and optical density. Polydimethylsiloxane, used as a material for the fabrication of the chips, can offer the advantages of direct microscopic visibility of the culture and also biocompatibility. Polydimethylsiloxane is gas permeable and therefore very suitable for aerobic cultivation (14). The next challenge in the technology of on-chip cultivation systems is to adopt standardized interfaces. Not yet available is compatibility with labor equipment that would result in easy-to-use microdevices even for researchers who are not familiar with microfluidic technologies. Attempts are being made to overcome this issue by, for example, employing devices compatible with standard pipettes (47, 85).

As exemplified above by the combined use of continuous culture with microfluids, continuous culture may experience a renaissance again when combined with other enabling technologies or new concepts. With the development of more stable recombinant strains and cell lines and more reliable and accurate on-line measurement and control techniques, continuous culture will receive greater acceptance in the future, as a tool both for basic research and for industrial applications. In particular, its increased use in industrial biotechnology for bioconversion of biomass is expected. Bioconversion processes typically aim at large-scale production of chemicals and fuels from renewable biomass. A continuous operation of such processes is crucial to reduce the production cost. To realize the promise of the new concept, biorefinery continuous cascade or multistep processes are desired. Principles of operation and equipment setup and design for this type of continuous culture deserve further study.

We thank Benedikt Schöpke for providing information on continuous culture in microfluidics.

Advances in Sensor and Sampling Technologies in Fermentation and Mammalian Cell Culture

ADEYMA Y. ARROYO

50

50.1. INTRODUCTION: PROCESS ANALYTICAL TECHNOLOGY AND NEW SENSOR TECHNOLOGY

Significant progress has been made in the past 2 decades in understanding the impact of the cellular environment on culture physiology and its subsequent impact on productivity, product quality, and downstream processes. In September 2004, the Food and Drug Administration (FDA) published the *Guidance for Industry PAT—a Framework for Innovative Pharmaceutical Development, Manufacturing, and Quality Assurance* (20). In it, the FDA describes process analytical technology (PAT) as a mechanism to design, analyze, and control pharmaceutical manufacturing processes through the measurement of critical process parameters which affect critical quality attributes. The document notes that the term PAT includes “chemical, physical, microbiological, mathematical, and risk analysis conducted in an integrated manner” as a series of tools designed to increase process understanding while meeting regulatory requirements. Therefore, the PAT framework includes at-line and on-line sensing or analytical technologies that along with design of experiments (DOE), chemometrics, information technology, and multivariate analysis allow scientists and researchers to assess the quality of the product. Through the PAT initiative, the Office of Pharmaceutical Sciences at the FDA encourages a better understanding of the manufacturing process, identifying relationships between process parameters and reproducibility, culture performance, and product quality attributes. Although originally conceptualized for small-molecule manufacturing processes, it is increasingly being extended to biological processes, which are inherently more complex and generally less understood processes.

Since the publication of this guidance, and leading up to the time of this writing, research in this area has significantly increased. Industry and regulators have come together in conferences and meetings to invest in PAT, generating improvements in existing technologies and resulting in the evaluation and implementation of new tools for greater process understanding. Application of PAT tools across the industry also facilitates quality-by-design (QBD) efforts. QBD is a systematic approach to determining the critical quality attributes of a product. A QBD approach utilizes DOE to establish a design space or a process variability range within which the product attributes can vary

without affecting product quality. The ability to measure process data in real time using PAT tools, i.e., sensor technologies, data analysis, and process understanding, would enable manufacturing flexibility, efficiency, and, potentially, real-time release. This chapter reviews research on existing and new sampling and sensor technologies for monitoring fermentations and mammalian cell culture in the last decade. New technologies are discussed, as well as advances in existing technologies. Each one of these technologies contributes to enabling PAT and increased process understanding.

50.2. IMPLEMENTING A NEW SENSOR TECHNOLOGY

In order to understand the acceptability of any new measurement technology, it is important to consider both the accuracy and precision of a measurement. Measurement accuracy reflects how close a measurement is to the “true” value. For example, in the case of autosampling technologies, a researcher is typically introducing a new automated technology to replace an existing manual method. In this case, an accurate measurement is defined as one that gives values comparable to those obtained with the established measurement technology. Based on this, when an automated cell counting method is introduced to replace a manual method, it is important to understand how the cell density and viability measurements compare between the two methods. Understanding the comparability is important to allow useful comparison between old and new data. Without this understanding, a researcher can lose the value of many years of process development and/or manufacturing data. Further, the comparability data are a regulatory requirement if a new sample analysis technology is introduced into a commercial manufacturing process. Demonstrating comparability can be problematic, particularly if the newer technology is actually better at delivering measurements closer to the true value of the variable. In cases where there is an offset between the established and new measurements, it is important to characterize this offset and appropriate correlations so that data from the old and new measurements can be suitably compared.

Precision measures the ability of an analysis method to be reproducible. Understanding precision is part of evaluating any new sensor technology. Sensor reproducibility

may need to be measured over a wide range of conditions to understand the performance. Typical conditions studied are precision over time, with different sensors (including different vendor lot numbers), with different cell lines, at different cell densities and viabilities, using different media, and under various conditions of temperature, pH, and osmolality.

Satisfying the accuracy and precision requirements should be strongly considered when evaluating any new technology. Manufacturing and development considerations must be carefully evaluated and established early in the process. For manufacturing implementation, a regulatory strategy may be required near the beginning stages of the evaluation to ensure that the appropriate comparability data are gathered in a timely manner.

50.3. AUTOSAMPLING TECHNOLOGIES

Cell culture and bacterial processes continue to heavily rely on manual sample and off-line analyses for process monitoring. Manual sampling and analysis have several disadvantages, including risk of contaminating cultures, high labor costs, and lack of reproducibility. Given these issues, there has been increased interest in automated sample handling and analysis technologies in recent years. As mentioned above, the introduction of automated sample handling and analysis technologies requires demonstration that the automated technology provides results that are acceptable for the intended use.

50.4. CELL CULTURE PROCESS AUTOSAMPLING TECHNOLOGIES

In cell culture processes, a few technologies have been developed to automate sampling and analysis from bioreactors. The most explored technologies include BioProfile FLEX (Nova Biomedical, Waltham, MA) and the Automated Reactor Sampling (ARS) 800 (Groton Biosystems, Boxborough, MA) systems. Table 1 lists the process variables measured by the current systems.

50.4.1. BioProfile FLEX Autosampler

The BioProfile FLEX autosampler is an off-line cell culture monitoring technology that combines three off-line analyzers, namely, a nutrient metabolite analyzer, a cell counter, and an osmometer (14). The system has a pumping module and 10 reactor valve modules (RVM). The pumping module drives all fluid movement within the autosampler system via a syringe pump. Each RVM is designed to open only when the pressure gradient, determined by a built-in pressure sensor, is such that flow will be out of the bioreactor, thus serving to protect the sterility of the culture. The nutrient metabolite module analyzer provides gas, electrolyte, nutrient, and metabolite data. The cell counter measures viable and total cell counts, percent viability, and live cell diameter, while the osmometer measures osmolality. The autosampler is a modular system, with each module capable of working individually or in combination with others. If all modules are selected, a sample volume of about 1 ml is required with an analysis time of 7 to 7.5 min. This autosampler can be connected up to 10 bioreactors at the same time, with the flexibility of analyzing all or just selected bioreactors. The modular design and the single automation system allow for all process data to be collected under one system. Figure 1 shows the analyzer, module layout and general setup.

TABLE 1 Variables measured using autosampling technologies^a

Process variables	Analyte	Standard off-line analyzer
Gas, electrolytes ^b	pH	Nova BioProfile 400
	pO ₂	
	pCO ₂	
	Ammonium ion	
	Potassium ion	
Nutrient, metabolite	Sodium ion	Nova BioProfile 400
	Glucose	
	Lactate	
	Glutamine	
Cell density	Glutamate	Beckman Coulter Vi-Cell AS
	Viable cell density	
	Viability	
Osmometer	Live cell diameter	Advanced Instruments 3600
	Osmolality	

^aAdapted from reference 14.

^bNova FLEX can also measure calcium ion.

Comparability between the BioProfile FLEX and traditional off-line analyzers has been demonstrated (14). Results of the automated versus manual sampling method showed acceptable accuracy: 97 to 100% of the samples within 25% of each other and 81 to 100% of all samples within 10% of each other, with one exception, dissolved oxygen (DO) concentration. Oxygen levels measured as partial pressure (pO₂) can be highly variable, probably due to off-gassing and other phenomena during sampling handling. The data are based on runs with 13 cell lines and over 20 operators. The inter-instrument precision was also found to be acceptable, with most parameters showing minimum variability. However, there were some exceptions in the nutrient metabolite module when the concentrations tested were in the low end of the analytical range.

50.4.2. Groton Biosystems' ARS Systems

The ARS system from Groton Biosystems can sample from up to eight bioreactors and deliver the sample to up to four different analyzers. Remote valve interfaces (RVI) are used to sample from the bioreactors with no backflow into the reactor. The sample is pulled through the RVI into the sampling valve and then out to an analytical instrument. A cleaning procedure cleans all parts of the unit up to each RVI, including the sampling line to the analytical instrument. Unlike the modular design of the BioProfile FLEX, the Groton Biosystems ARS is an independent unit that requires software development to allow for communications between the sampling unit and each one of the analytical instruments, generally via object linking and embedding for process control protocols. The challenge of implementation relies heavily in the automation resources required for communications to the different analytical instruments and the automation support from each one of the vendors. Figure 2 shows the basic layout

FIGURE 1 Nova BioProfile FLEX system. (A) BioProfile FLEX unit (courtesy of John Balsavich, Nova Biomedical). (B) Internal modules (courtesy of John Balsavich, Nova Biomedical). (continued)

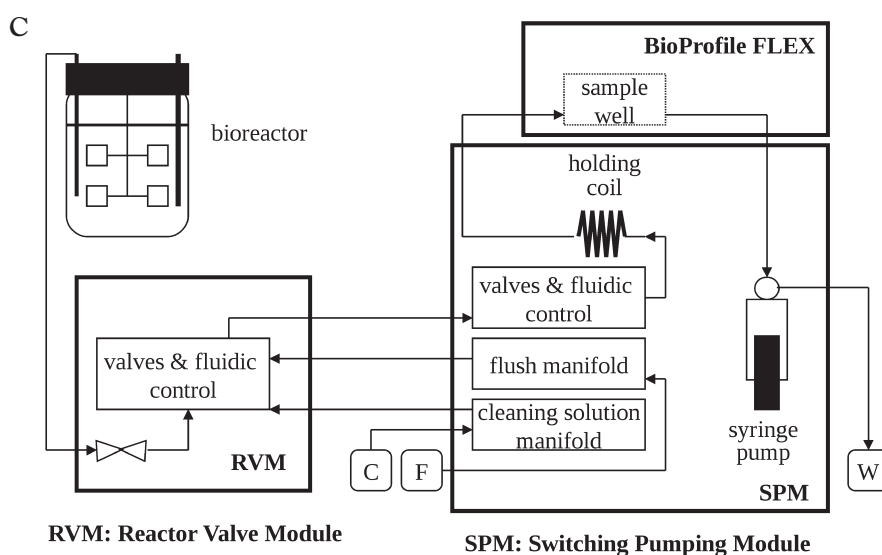

FIGURE 1 (continued) (C) Schematic of fluid flow paths through system. The sample flows from the bioreactor to the RVM to the switching pumping module (SPM) before reaching the BioProfile FLEX. Waste flows from the BioProfile FLEX to the SPM to waste container (W). Cleaning solution (C) and saline flush (F) flow from their respective containers to SPM manifolds to RVM fluidics, following the sample path through the system to the waste container. (Adapted from reference 14.).

of the system and a picture of the system connected to four bioreactors.

Several studies showed comparability between the manual and automated sampling methods (70, 83). Automated sampling showed pH results comparable with those of manual sampling, with 80% of the samples showing values within 0.05 pH unit and 100% within 0.1 pH unit. In the case of glucose, automated sampling values were within 25% of manual sampling values. All other metabolites showed results within 10% of those obtained with the manual sampling method. $p\text{CO}_2$ and $p\text{O}_2$ were variable, as in the BioProfile FLEX, probably due to similar off-gassing and sampling issues. Finally, automation and sampling and flow rate optimization were required for cell density and viability measurements (70). A different study showed successful interface with Nova BioProfile, Cedex, a fraction collector, and a high-performance liquid chromatography (HPLC) system for amino acid analysis (83).

50.5. BACTERIAL FERMENTATION AUTOSAMPLING TECHNOLOGIES

In bacterial fermentations, implementation of autosampling systems is challenging. High sample viscosity and cleaning requirements have to be overcome to ensure sample flow and sterility. Despite the challenges of automated sampling, there have been recent advances in automated sample analysis using robotics and a liquid handling system for sample management and analysis (V. Saucedo, unpublished data). This solution is generally customized, and it involves a partnership between users, researchers, and automation engineers to ensure that the design and implementation results in accurate measurements of the process variables. Several companies with expertise in custom liquid handling systems, automation, and robotics can be explored,

including Tecan Group Ltd. (Männedorf, Switzerland), Beckman Coulter, Inc. (Fullerton, CA), and Hamilton Company (Reno, NV).

50.6. FLOW INJECTION ANALYSIS

In addition to autosampling systems, another technology that can be used to deliver samples from bioreactors for analysis is flow injection analysis (FIA). The sample is taken using in situ filtration ceramic probes (Flownamics, Madison, WI) to a detection system based on amperometric, potentiometric, fluorescence, chemiluminescence, turbidity, or absorption measurements. The application of FIA to monitor cell culture processes has been described in the literature. Ammonia and glutamine were simultaneously monitored on-line in a hollow-fiber reactor containing hybridoma cells (71). Glucose and glutamine were monitored in serum-free hybridoma media using a split-stream FIA (52). One advantage of FIA systems is that the sensors employed do not have to be operated in a sterile manner and are therefore not subjected to the same stringent requirements as for in situ sensors. Although FIA techniques can be employed to measure a large number of cell culture components of interest, they have not been widely adopted due to concerns of introducing additional contamination risks, multiple detection systems, and calibration requirements. A review of this and spectroscopic methods (discussed next) can be found in the 2001 article by Schügerl (65).

50.7. IN SITU PROCESS MONITORING USING SPECTROSCOPY

Autosampling technologies can minimize the disadvantages associated with manual sampling. However, automated

FIGURE 2 Groton ARS System. (A) Schematic of the Groton ARS. Cleaning flow cleans all parts of the unit up to each RVI, including the sampling line to the analytical device. The sample is pulled through the RVI into the sampling valve and then out to an analytical instrument. Adapted from reference 70. (B) Picture of the ARS system connected to six bioreactors. (Courtesy of Daniel Abramzon, Genentech, Inc.)

methods continue to pose a sterility risk throughout multiple cycles of sampling and cleaning procedures. They also add complexity associated with the sampling software and hardware. In addition, the frequency of an at-line measurement (automated or not) can be low due to available volume and/or long analysis times. In situ sensors offer the advantages of maintaining the sterile envelope during culture, relatively simple hardware, measuring well-mixed samples, and high measurement frequency. In situ bioreactor sensor requirements include (i) ability to be sterilized, (ii) reliability and robustness, (iii) high specificity to the measured parameter, (iv) fast response time, and (v) minimal drift. In addition, the sensor must require minimal maintenance and must not increase the risk of contamination. Spectroscopic probes

are an established in situ technology in other industries, but they have not traditionally been used in bioreactor applications. One major challenge with these sensors is the complexity of the spectrum gathered in a bioreactor. Interpreting the spectra in a way that provides accurate, precise measurement of one or more variables is a complex challenge requiring chemometric tools to correlate spectra to a specific variable.

Spectroscopic methods have improved significantly in the last decade. Several companies have explored the use of near-infrared spectroscopy (NIRS), Raman spectroscopy, and mid-infrared spectroscopy (MIRS) for on-line bioreactor monitoring in bacterial fermentations and mammalian cell culture. Spectroscopy, particularly using

FIGURE 3 Regions of the spectra and their wavelengths.

NIR or MIR, is an attractive alternative for the measurement of cell culture components (including substrates, waste products, and essential and nonessential amino acids), cell concentration, and viability. Sample preparation is not required, and this technique can be used to measure a large number of parameters simultaneously.

50.7.1. NIRS

The IR region of the electromagnetic spectrum is composed of several sections: the MIR, the NIR, and the far IR, based on their proximity to the visible light (Fig. 3). NIRS is an optical method of gathering measurements between the visible and MIR regions of the electromagnetic spectrum (800 to 2,500 nm). The measurements are based on overtones of molecular vibrations. NIRS captures the contributions of all sample constituents, resulting in a complex spectrum with absorbance at multiple wavelengths. Data interpretation is thus dependent on multivariate data analysis (MVDA) and strong calibration methods (74).

In applications to cell culture processes or bacterial fermentations, a light source is introduced to the sample via a steam-sterilizable probe mounted using standard bioreactor ports. The resulting transmittance measurement can be correlated to individual analytes at various concentrations in a sample matrix. Chemometric methods are employed for data deconvolution and analysis. Initially the NIRS scans are trained using off-line measurements of cell counts, osmolality, metabolites, and amino acids or other cell culture or bacterial fermentation medium components. This training results in a calibration model that is then used to predict unknown spectral scans in independent bioreactor cultures.

A number of studies have been reported in the last decade using NIRS for bioprocess monitoring in cell cultures and bacterial fermentations. Some studies have been focused on investigating the tools required for interpreting the spectral information (74). Others have focused on real-time monitoring of specific analytes in animal cell culture or bacterial fermentations using in situ probes (3, 53, 61) or at-line analysis (49). In spite of this, NIRS is rarely applied in cell culture processes (even in a laboratory setting). This may be due to the fact that the spectroscopic measurements (position and intensity of spectrum) are sensitive to changes in process parameters such as pH, ionic strength, temperature, and the analytical ranges used when developing the models. Furthermore, depending on the application, multiple mathematical treatments may be required for different analytes in the same process. For example, the second derivative can be used to deconvolute overlapping peaks and resolve baseline drift, whereas the standard normal variant can be used to clean up noise or interference (3). In general, a robust application would

require a model based on a comprehensive design of experiments that incorporates the analyte ranges, process changes or excursions, and the appropriate mathematical treatments for each analyte.

Despite the challenges, the use of in situ sterilizable probes continues to be evaluated, as vendors have improved their design to withstand bioreactor operations. Several vendors are developing NIRS solutions, including Foss NIR Systems (Laurel, MD), which has a commercially available unit capable of connecting probes in up to nine bioreactors (nine channels). Successful implementation of these probes requires extensive testing, including probe design and integrity across multiple autoclaving or steam-in-place cycles, signal optimization (path length evaluation), bioreactor condition evaluations (aeration levels, fouling, temperature shifts, etc.), and the effect of sensor position in bioreactors of different scales. In addition, application of this promising technology for cell culture monitoring will require the establishment of robust calibration models that can be implemented routinely by nonexpert operators. Several studies using in situ probes are summarized in Table 2.

50.7.2. Raman Spectroscopy

Raman spectroscopy is a technique based on inelastic scattering. When a sample is illuminated by light, inelastic scattering is observed and a shift in energy (wavelength) can be detected. This energy shift is specific to a chemical bond, thus providing information about the sample chemistry or composition.

In the last several years, Raman spectroscopy has seen tremendous advances due to instrumentation and data analysis tool improvements. Applications of this technique to bioprocess monitoring have been limited. At-line or off-line monitoring using Raman spectroscopy has been explored in bacterial fermentations for the analysis of glucose, lactic acid, and optical density (69), and in fungal fermentations for the analysis of gibberellins, important agricultural products (51). Real-time or in situ monitoring has also been evaluated for carotenoid production in yeast cultures (6) and for glucose, acetate, formate, lactate, and phenylalanine in bacterial fermentations (43). As in the case of NIRS, robust mathematical algorithms and identification of the best "Raman shift" for a particular analyte are required.

The results of these studies suggest that Raman spectroscopy, though promising, is still evolving for bioprocess monitoring. Several aspects need to be evaluated or considered during the evaluation. These include attenuation of light scatter due to bubbles and high biomass, calibration models, probe window design, analyte concentration and variability (complex mixtures), and exposure time. Studies using in situ probes are summarized in Table 3.

TABLE 2 Summary of NIRS in situ probe monitoring applications

Type of culture	Analyte(s) monitored	Probes used	Model(s) used	Major findings and challenges	Reference
Mammalian cell culture					
CHO-K1	Glucose, lactate, glutamine, ammonia	In situ Foss NIR Systems probe Path length, 1.2 mm NIR range, 400–2,500 nm	2nd derivative, standard normal variant and combination of both	Large data sets were used to develop models for glucose, lactate, glutamine, and ammonia. The models were developed in a fed-batch bioprocess involving a temperature change.	3
CHO	Glucose, lactate	Seven in situ Bruker Matrix F FT-NIR system	PLS Multiplicative scatter correction	Multiplexing 5 to 6 probes in multiple bioreactors Sources of variance for multiple probes include spectrophotometer channels, probe construction variability, and mirror optical properties.	61
Bacterial fermentation					
<i>Vibrio cholerae</i>	Biomass, glucose, acetate	In situ Foss NIR Systems probe Path length, 0.5 mm NIR range, 400–2,500 nm	PLS	Control strategies improved using NIR data and electronic noses or chemical gas sensors Challenges include aeration disturbances, gas phase effects, probe fouling, and position of the probe within the reactor in relation to agitator and sparger.	53
<i>E. coli</i>	Biomass	In situ Foss NIR Systems probe Path length, 0.5 mm NIR range, 400–2,500 nm	PLS, 2nd derivative	At-line data were compared to on-line or in situ data. Temperature, agitation, aeration, and feeding affect the in situ results. Path length optimization was performed.	4

50.7.3. MIRS

The MIR range is the region past the NIR spectrum, between 2,500 and 25,000 nm (Fig. 3). There have been a number of studies exploring MIRS for fermentation monitoring. As in the case of NIRS, the spectra can provide specific information for different molecules and thus provide the possibility of real-time monitoring. One advantage of MIRS can be a higher selectivity and signal-to-noise ratio than with NIRS for some analytes. Comparisons between Fourier transform MIRS (FT-MIRS), NIRS, and FT-Raman spectroscopy in lactic fermentations showed FT-MIRS to be superior to the other spectroscopic methods in bacterial fermentations for at-line applications (69).

Multiple studies have been performed using MIRS for in situ monitoring and real-time analysis (15, 40, 41, 60). In all the studies, the most common probe used was the ReactIR 1000 (ASI Applied Systems, Millersville, MD). As with all other in situ applications, in situ monitoring results

are highly dependent on the design, performance, and reliability of the probe as well as the calibration models used for spectrum analysis. In situ MIRS studies are summarized in Table 4.

50.8. ADVANCES IN EXISTING SENSOR TECHNOLOGIES

Advances in traditional bioreactor sensor technologies are important. Some of these include glucose, biomass, and pH sensors.

50.8.1. Glucose

Glucose is an essential carbon and energy source in cell culture and bacterial fermentations. A real-time in situ glucose sensor would allow further exploration of feed control strategies coupled with optimization of growth and protein production. The implementation of an in situ glucose sensor

TABLE 3 Summary of Raman spectroscopy in situ probe monitoring applications^a

Type of culture	Analyte(s) monitored	Probe(s) used	Models constructed	Major findings and challenges	Reference
Bacterial fermentation, <i>E. coli</i>	Glucose, phenylalanine, acetate, formate, lactate	InPhotonics Raman probe	PLS, PCA, artificial neural networks	Light scattering from air bubbles and biomass needed correction. Errors in the physical model, instead of noise, limited the accuracy of the reading. Improved physical modeling and window materials with stable Raman spectrum can improve detection limits and sensitivity.	43
Yeast fermentation, <i>Phaffia rhodozyma</i>	Carotenoid	Process analyzer System 100 (Renishaw, Gloucestershire, United Kingdom) coupled to a 12.5-mm probe (EIC Laboratories, Inc., Norwood, MA)	PLS, PCR	Complicated multivariate techniques are not necessary when the target component has a strong signal, as in the case of carotenoids in this process.	6

has been challenging. Current measurements are based on off-line sample analysis using a metabolite analyzer or an HPLC. An in situ sensor would need to withstand sterilization and chemical cleaning (as needed, since sensors may be removed and cleaned if unable to withstand chemicals) and measure glucose concentrations in the presence of a variety of analytes over potentially long durations (up to 2 to 3 weeks for mammalian cell culture).

Current glucose sensing technologies in bioprocessing utilize the reaction of glucose oxidase (GOx) and oxygen. The reaction converts glucose to gluconic acid and hydrogen peroxide as shown in equation 1:

The search for an in situ sensor has been explored using this reaction. The approach has been to immobilize the enzyme in a matrix, membrane, or another surface where it is allowed to react with the process fluid. Glucose concentration can be correlated to oxygen consumption or hydrogen peroxide generation. In one study, a multilayered GOx-containing membrane was exposed to oxygen via on-line sampling (82). The generated hydrogen peroxide was measured amperometrically on a platinum working electrode as shown in equations 2 and 3, and the output of the sensor was converted to glucose concentration. In another study, an optical fiber biosensor was developed using a matrix for oxygen-sensitive complexes and GOx reaction (66). Oxygen consumption was determined by measuring the fluorescence lifetime of the complexes which are quenched by the oxygen.

Biosensors have also been used in several studies. Glucose binding protein labeled with a fluorescent probe can be used as a sensor by detecting the conformational change as a result of the glucose binding (23). Commercially available biosensors such as SIRE® (sensors based on injection of the recognition element) in conjunction with GOx have also been investigated (45). In this study, the glucose diffuses through a membrane and reacts with the GOx enzyme inside the SIRE® amperometric biosensor chamber.

In general, glucose measurements in cell culture processes and bacterial fermentations rely on off-line measurements. Commercial availability of an in situ probe will depend on sterilization capabilities, stability of the immobilized enzyme, activity without degradation, and other factors such as temperature and interference by other analytes over the course of the culture or fermentation. Spectroscopic methods discussed earlier may provide a solution before any of these approaches materialize into a reliable commercial sensor in a production environment.

50.8.2. Biomass

Biomass is traditionally measured by off-line methods. Systems like the Beckman Coulter Vi-Cell AS can be used to measure viable and total cell counts, percent viability, and cell size distribution in mammalian cell cultures. In bacterial fermentations, dry cell weight measurements are often used. All of these technologies require sampling and manual manipulations, which tend to be labor-intensive. In situ sensors for biomass measurement have been explored for a number of years. Some of the issues encountered include calibration, maintenance, or inability to measure very high optical densities, as in some bacterial fermentation cases (dynamic range limitation). However, on-line sensor

technology for biomass measurements has advanced in the last decade. Several sensing principles have been evaluated and further developed, including dielectric spectroscopy, optical density, IRS, and fluorescence.

50.8.2.1 Dielectric Spectroscopy

A review of the last 10 years of development shows that the main technologies used today are dielectric spectroscopy and optical methods (37). Dielectric spectroscopy measures the dielectric properties of a medium as a function of frequency. The use of dielectric spectroscopy as a tool to measure biomass has been clearly described (33). The biomass sensor produces an electrical field in the culture medium, resulting in charge separation or polarization. This polarization is the result of ion movement in the ionic culture fluid, with restriction across the intact cellular membrane. Each cell acts as a capacitor, and the charge separation is measured as capacitance. The capacitance of the cell suspension gives a measure of the extent of the field-induced polarization. A scanning frequency from 0.01 to 10 MHz is applied, and from the resulting β dispersion, it is possible to determine the permittivity due to media alone and media containing cells. The difference between these readings is related to the viable cell volume or concentration, provided the cell diameter does not change appreciably. The measurement is dependent on the integrity of the cell membrane. Thus, only viable cells are detected, and the capacitance signal can be correlated with viable cell count. Lysed cells or solid particles do not significantly affect the variation in capacitance.

There are several in situ dielectric spectroscopes available today. Aber Instruments (Aberystwyth, United Kingdom) biomass sensors have been documented in academic research (7, 16, 18, 38). A Fogale (Fogale Nanotech, Nimes, France) biomass system has also been evaluated in bacterial and yeast fermentations as well as mammalian cell cultures. Bacterial fermentation data showed good reproducibility in cultures with high conductivity and low cell concentration (5). In bacterial applications with sporulation, some challenges were observed, as cell structure changes during spore liberation and germination (63). In mammalian cell culture, monitoring and control (57) and viable cell number measurements (58) have been evaluated.

Implementation of dielectric spectroscopy sensors in a particular application will require testing, as their performance may be affected by the culture conditions (conductivity of the culture, stirring, and aeration conditions), probe geometry, or probe-to-probe variability, depending on the vendor and specific model (38). In any application, successful measurements can be used to calculate mean cell size and size distribution using off-line calibration methods (2), enable feedback control of feeds, automate batch refeed cultures commonly used for cell maintenance, and allow culture transfers based on on-line cell density targets.

50.8.2.2. Optical Sensors

Optical sensor systems are widely used in bioprocess monitoring (50). Optical density is the most common method for on-line biomass monitoring. The probes measure turbidity by either transmission or backscatter. Specific selection is dependent on the turbidity of the sample solution. There are multiple sensors on the market for mammalian cell culture and bacterial and yeast fermentations, and several of them have been evaluated in the literature (32, 79). These sensors are simple and do not require extensive calibration or mathematical models, although calibrations against an off-line analyzer may be required. However,

optical density measurements are affected by cell concentrations, cell morphology (dynamic range nonlinearity), and bioreactor conditions such as agitation rates and bubble sizes. A summary of the different sensors and applications is provided in Table 5.

50.8.2.3. In Situ Microscope

In the last decade, several studies have shown that cell number can also be measured using microscopy. An in situ microscope acquires images in a given sample volume during the fermentation process and performs cell counts. The system is essentially an in situ hemacytometer mounted on the bioreactor (Fig. 4). Comparisons between the hemacytometer hand counts, Cedex (biomass analyzer similar to the Vi-Cell AS), and an in situ microscope in mammalian cell cultures showed very good correlations (30). The system was also successfully tested in yeast fermentations, in which good correlations of cell density and viability were demonstrated (77). Additionally, it has been successful in measuring the level of colonization of fibroblasts on microcarrier surfaces during cultivation (62). The advantages of this technology include the ability to monitor cell morphology, cell density, and viability in real time without the need for reagents. Challenges for implementation include

the verification and/or development of image processing software for the specific applications (cell culture, yeast fermentation, etc.), cleaning and maintenance of the sampling window, sample zone optimization for a range of cell densities, and sampling zone consistency (reproducibility and accuracy testing).

FIGURE 4 Bioreactor with in situ dark-field microscopy probe (IDMP). Adapted from reference 77.

50.8.4. pH Sensors in Mammalian Cell Cultures

pH is a measure of hydrogen concentration in a solution. The pH value is calculated as minus the decimal logarithm of the hydrogen ion activity in an aqueous solution. Because of its algorithmic nature, a small change in pH units implies a large change in the concentration of hydrogen ions in the process medium. Mammalian cell cultures are significantly affected by changes in the pH of the culture. Very small variations, as small as 0.1 or 0.2 pH unit, can significantly affect culture growth and metabolism, in particular glucose consumption and lactate production (80). It is important to note that the pH set point and control strategy (e.g., dead band) are intimately linked to levels of dissolved carbon dioxide (dCO_2), base consumption for pH control, and, therefore, osmolality. These considerations make the accurate measurement of pH even more imperative.

Measuring and controlling pH are regularly performed during cell culture operations. Glass sensors have traditionally been used across the biotechnology industry for this measurement. This technology has been established for years and is generally reliable. A typical pH glass sensor design consists of a tube within a tube. The bottom of the inner tube has a bulb-shaped glass membrane of a specific pH. The inner glass tube body is filled with a buffer solution called inner reference electrolyte, containing Cl^- ions usually with a pH value of 7. The outer side of the glass tube body is filled with a KCl solution at a high concentration. A reference electrode is immersed in the inner reference electrolyte and equilibrates with the Cl^- ions in it. A reference electrode is also immersed in the outer reference electrolyte. The outer reference electrolyte is electrically in contact with the solution of interest via a reference junction. In essence, the pH probe is an electrochemical cell between the inner reference or measuring electrode and the outer reference electrode.

Some issues related to the use of pH probes for extended culture duration include drift and reduced sensitivity. To protect against on-line sensor drift, on-line pH measurements are usually compared to off-line analyzers or bench-scale meters to ensure that the correct value is maintained in the culture. Literature on these differences is limited, but disparity between on-line and off-line pH measurements has been reported (17). Comparisons between the standard glass sensor technology and an off-line analyzer and bench meter confirmed a downward drift in the on-line measurement. In this study, the phenomenon was clearly detected but a root cause was not identified. In searching for this root cause, an evaluation of the pH performance of different technologies in cell culture was performed (64). The results showed that glass technologies are the most accurate, but variability does exist across different vendors. This evaluation investigated the effect of process conditions (agitation and gassing) on pH measurements and the performance of different pH technologies in cell culture processes through several sterilization cycles. Technologies included glass, solid state, and optical. Further evaluation of the glass sensor technology showed that the main cause for drift in cell culture processes is the effect of steam sterilization on the glass membranes of the pH sensors (Saucedo, unpublished data).

50.8.5. dCO_2

dCO_2 concentrations are important to mammalian cell growth. High dCO_2 levels can inhibit cell growth, affect protein production, and result in product quality issues. dCO_2 is also an important process variable which can accu-

mulate to inhibitory levels at values of >120 to 150 mm Hg (21, 25, 34) and/or influence product quality at high cell density cultivations or scale-up due to inadequate CO_2 stripping. Generally, cell culture processes monitor dCO_2 using off-line analyzers such as the NovaFLEX and BioProfile, both from Nova Biomedical. This technology requires sampling and off-line analysis. On-line dCO_2 measurement would enable the implementation of control strategies for processes that require accurate measurements and close monitoring.

In situ probes have been developed since 1958 (67), and a number of evaluations have followed. Two of them are worth noting: the YSI 8500 (YSI Inc., Yellow Springs, OH) and the InPro 5000 (Mettler Toledo, Bedford, MA). The YSI 8500 is a fiber-optic dCO_2 sensor that has shown acceptable maintenance, response time, and sensitivity in cell culture processes (59). The InPro 5000 is a membrane-based probe for fermentation and cell culture applications. The CO_2 diffuses through the membrane, where a change in pH can be monitored by an electrode. Extensive evaluation in large-scale manufacturing of either probe was not available. Maintenance, probe-to-probe variability, and long-term performance may have to be evaluated for complete implementation of this measurement as well as control strategies. Until an in situ probe can be implemented, the use of the NovaFLEX autosampler system, discussed earlier, would allow for on-line data and enable control strategies to be implemented.

50.9. DISPOSABLE SENSORS

The need for disposable sensors has significantly increased in the last decade. A variety of companies have developed disposable bioreactors for bacterial fermentations and mammalian cell cultures, including GE Healthcare, Xcellerex, Thermo Scientific HyClone, and Applikon Biotechnology. In the same way, there has been a significant increase in the development of miniaturization and high-throughput technology for bioreactors. A number of companies have developed disposable-sensor technologies to provide sensing technology capabilities to these systems, including PreSens Precision Sensing GmbH (Regensburg, Germany), Polestar Technologies (Needham Heights, MA), Finesse Solutions (Santa Clara, CA), and Fluorometrix Corporation (Baltimore, MD). Disposable sensors have been developed and are currently available to measure pH, DO, dCO_2 , and, in some cases, dual variables, e.g., pH/DO. In these sensors, a fluorescent dye sensitive to the analyte of interest, e.g., pH, O_2 , or CO_2 , is immobilized in a matrix or patch. The patch can be mounted inside a microplate well or a miniature bioreactor (MBR), the bottom of a shake flask, or the end of fiber-optic cable, depending on the application (Fig. 5). A light-emitting diode (LED) source and a photodetector for light detection are required. The measurement is based on either fluorescence intensity or fluorescence decay.

Disposable sensors have been used in a number of bioreactor applications, including shake flasks, microplates, MBRs, and single-use bioreactors. Shake flasks are one of the most widely used tools for process development. However, sensor data have been challenging to obtain due to the large size of existing probes relative to the flask sizes. Outfitting shake flasks with patches has enabled on-line measurement and improved monitoring in these culture devices in a number of publications (27, 78). Quantification of DO in flasks was performed by immobilizing a thin-layer sensor, or spot with a 10-mm diameter and a thickness of

FIGURE 5 Disposable-sensor applications. (A) Shake flasks (adapted from reference 78); (B) microplates (adapted from reference 24).

less than 100 μm , at the bottom of the shake flasks (78). Oxygen mass transfer coefficients were compared in shake flask and stirred tank reactor *Escherichia coli* fermentations when using noninvasive sensors (27).

Sensor patches in microplate systems have also been evaluated using products from different manufacturers. Optical pH and DO were evaluated in microplates and mammalian cell culture using a high-throughput bioreactor system (24). Consistency and calibration across the different plates showed acceptable results. Dual-sensor capabilities have also been explored in microplates. This is of particular importance in microplate applications due to volume and surface area limitations. A dual-sensor application for pH and DO was evaluated in bacterial fermentations using a 24-well format, showing good reproducibility with measurements every 30 min (39). Dual sensors have also been used in MBRs. In one study, a 24-well plate MBR

system was assessed for *Saccharomyces cerevisiae*, *E. coli*, and *Pichia pastoris* cultivations (29). Each 10-ml MBR was equipped with optically isolated pH and DO fluorescence-emitting patches and sensors (PreSens-Precision Sensing GmbH). The results showed high interwell reproducibility for on-line temperature, pH, and DO. In a second study, the same system was assessed for cell culture applications using a Chinese hamster ovary (CHO) cell line from Genentech, Inc., also showing good results (8).

A few studies have also been published showing comparisons between optical disposable sensors and traditional electrochemical sensors. The results suggest that photobleaching control or optical sampling rate (how often the patch is excited) is important in establishing calibration and operation limits for a particular sensor (28, 46, 47). Additionally, depending on the vendor, software development may be required to allow for in-process calibrations and

TABLE 6 Disposable-sensor evaluations

Parameter	Company	Application	Reference(s)
pH	PreSens	Single-use bioreactors	46
	Fluorometrix	Microplates	24
DO	Fluorometrix	Shake flasks	27, 73
	PreSens	Shake flasks	78
		Microplates	24, 39

	Custom made for research	Perfusion bioreactors	22
Dual sensor applications: pH and O ₂	PreSens	Microplates	39
		MBRs	8, 29

integration to control platforms. In these studies, the data showed good agreement between electrochemical probes and optical sensors used for pH and DO measurements in 5-liter bioreactors and 250-liter single-use systems.

Disposable sensors provide a number of advantages, including high sensitivity (specific chemistry identified for a given application), ease of miniaturization, and, in some cases, noninvasiveness. However, several factors need to be considered for implementation, including signal variations as a result of photobleaching, light intensity variability, sensor positioning and orientation, potential irregularities in the patches, detector sensitivity, fluorescence of the sample, and software requirements. Various studies are summarized in Table 6.

50.10. PEPTIDE AND PROTEIN ANALYSIS MONITORING

In the last few years, there have been advances in other sensing technologies, in addition to sensors for the process variables discussed above, i.e., biomass, pH, DO, and dCO₂. At-line or on-line protein quantity and quality monitoring can provide significant advantages to process understanding. The current process usually requires sampling and analysis by the quality control department or protein analytical laboratories, depending on whether the sample is from manufacturing or development. Sample gathering, delivery, and assay completion can take hours to days. The implementation of rapid and accurate on-line or at-line analytical technologies for monitoring product quantity and quality during processing would improve large-scale manufacturing and process development. Having near-real-time data in large-scale manufacturing could enable control loops to optimize productivity and maintain the process within the design space or allowable process variability range. Implementation of high-throughput testing during process development would increase the ability to monitor a large number of conditions and establish the design space.

Several chromatographic methods have been used to monitor product concentration and product quality, including HPLC and mass spectrometry (31, 48, 65), among others. These technologies are generally well established and can be relatively easy to operate, given appropriate training. However, on-line implementation can be complex. Samples must be transferred from the reactor to the system regularly, and a cell removal device is required. Additionally, a strong program to support the maintenance requirements of these systems is very important to ensure column life and the

accuracy of the measurements. Most recently, the lab-on-a-chip (LOC) technology has become more attractive due to its high-throughput capabilities.

50.10.1. LOC

LOC generally refers to a device that allows the performance of one or multiple analyses on the microscale level. LOC sensors take advantage of microfluidic technology. Microfluidics refers to the control and manipulation of fluids in submilliliter scales where very small volumes, as low as picoliters, are required. The low volumes and small size of the device and system allow for samples to be analyzed faster and potentially at the point of sampling rather than in special laboratories. This can be of significant advantage for process monitoring in development laboratories, pilot plants, or manufacturing facilities. High-throughput applications of protein quality analyses in these environments can provide very valuable information about the process in almost real time.

The application of LOC technology to process monitoring, specifically protein quality, has become more popular in the last few years. The literature is limited, but a few studies have been presented or published on the analysis of protein quality in mammalian cell culture and fermentation products. The most common systems in the literature include the LabChip® 90 (Caliper Life Sciences, Hopkinton, MA) and the Agilent 2100 Bioanalyzer (Agilent Technologies, Palo Alto, CA).

The LabChip® 90 was used to perform a capillary electrophoresis-sodium dodecyl sulfate (CE-SDS) assay in high-throughput mode to monitor monoclonal antibody protein quality (11). Several assays were developed and optimized, including an assay to resolve nonglycosylated and glycosylated heavy chains and a glycan typing assay. The developed assays were much faster than the standard CE-SDS, with one of the assays taking 41 s for the microchip, versus 50 min for the standard assay. The LabChip® 90 has also been used in high-throughput mode to support *E. coli* process development (72). In this study, samples from 2-ml 96-well plates were purified using automated purification on a Tecan Genesis robot (Tecan, Research Triangle Park, NC). Purified samples were prepared, also by the Tecan Genesis robot, and processed by the LabChip® 90 system for protein quantification and identification. The fast sample handling and analysis enabled process optimization via a DOE approach. In the case of the Agilent 2100 Bioanalyzer, this technology has been evaluated to determine protein size (molecular weight distribution) and concentration in cell

TABLE 7 Multivariable analysis review

Method(s) used	Culture type	Application	Reference
PCA	Fed-batch cell culture	Fault detection and diagnosis of abnormal process conditions in pilot plant 2-liter bioreactors	26
PCA and AANN	Yeast fermentation	Fault detection by two different multivariate analysis methods: linear (PCA) and nonlinear (AANN)	68
PFA	Cell culture	Identification of threshold values of repressing metabolites (lactate, ammonia, osmolality, and carbon dioxide) in 5,000-liter bioreactors	81
PCA and PLS	Yeast fermentation	Use of seed quality information from manufacturing data to estimate final productivity	13

MVDA	Cell culture	Using MVDA as a root cause analysis tool for identifying scale-up differences and parameter interactions affecting process performance	36

culture samples (55). In this study, the Protein 200 LabChip assay kit using the Agilent 2100 Bioanalyzer was compared to the standard SDS-polyacrylamide gel electrophoresis tests. The results showed no statistical differences and a high level of reproducibility. Both technologies have the capability of providing protein quality information during production and look very promising as at-line protein quality monitoring technologies.

50.11. DATA TECHNOLOGY

Process understanding via data analysis has also become a powerful tool for bioprocess monitoring in the last decade. Companies are generally investing more in their data infrastructure and management to enhance their ability to capture the appropriate data and perform appropriate analysis. Several approaches have been evaluated in the literature, including hybrid modeling, multivariate modeling, and soft sensors. Table 7 summarizes a few studies since 1998 using different tools to evaluate data from cell culture and bacterial and yeast fermentation processes.

50.11.1. Hybrid Modeling

Hybrid modeling utilizes artificial intelligence, previous process knowledge, and reaction kinetics to predict fermentation process performance. Mass balance equations, process description, and available measurements are combined with neural networks to predict specific parameters. Implementation of these models can be challenging, as it requires appropriate data infrastructure and automation systems support, in addition to process experts. A few publications on fermentation applications are available. Some studies focus on comparisons between conventional models using mass balances and hybrid models utilizing artificial neural networks and process knowledge (19). Others discuss a process for the identification of hybrid models for bioprocesses (9). These studies illustrate significant challenges and testing required for implementation of this technology.

50.11.2. Multivariate Modeling

In an effort to increase process understanding, the biopharmaceutical industry is increasingly investing in multivariate analysis models that allow process optimization and contin-

uous process improvement. Applications in cell culture and bacterial fermentations are discussed in a number of articles reporting the use of different techniques to analyze multiple sets of measurements or variables (Table 7). Some of these techniques include principal-component analysis (PCA), auto-associated neural networks (AANN), partial least squares (PLS), principal-factor analysis (PFA), and MVDA. PCA has been used to detect abnormal process conditions in 2-liter cell culture bioreactors using both on-line and off-line data (26). In another evaluation, PCA was used to assess seed quality using data gathered from the manufacturing plant (13). These data were then used to evaluate the final productivity estimation of an antibiotic fermentation process. PCA and AANN techniques were used in yeast fermentations for the detection of faulty temperature sensors and plasmid instability (68). PFA multivariate analysis was used to identify inhibitory threshold values of specific metabolites to cell culture and protein quality in 5,000-liter bioreactors (81). The feasibility of using MVDA was evaluated for assessing scale-up performance and comparability of the cell culture manufacturing process (35). MVDA was also evaluated as a tool for root cause analysis in the identification of scale-up differences and parameter interactions affecting a cell culture process (36).

50.11.3. Soft Sensors

A soft sensor or software sensor can be described as the combination of hardware and software to derive variables that cannot be directly measured. The hardware is a sensor or a combination of sensors providing output about the process conditions in the bioreactor. The software is a series of algorithms or mathematical models correlating the hardware output to the unmeasurable variable of interest. Thus, the success of this sensor is highly dependent on the reliability of the on-line process variable measurements (hardware), the mathematical models (software) used, and, most importantly, the knowledge of the measurement and the process (12). An important factor in soft sensors' success is the use of artificial neural networks and recurrent neural networks, which combine information and recognize patterns to model and control dynamic systems (10).

Multiple software sensors have been explored in bioprocessing in the last few years, including biomass, acetate

formation, and specific growth rate. Recurrent neural networks were used in combination with feed rate, liquid volume, and DO to predict biomass concentration in yeast fermentations within 11% of the off-line value (10). Acetate formation from *E. coli* cultures was predicted using DO responses to feed transients (1), and glucose feed rate to enable sustained high specific growth rates was optimized in response to inferred glucose demand rate based on similar glucose/DO transients (84). Specific growth rate has also been predicted in a yeast fermentation using on-line DO concentration and mass balances (54). Growth rate was used in a control strategy to maximize protein production.

The use of soft sensors in practice has seen limited success. The complex data manipulation required makes it difficult to obtain a satisfactory measurement over a range of process conditions. In addition, noise and variability in traditional sensor measurements add to the complexity of designing a robust software algorithm. These challenges are important, but the reward is also potentially quite significant. The ability to obtain additional process information without implementing new sensor hardware continues to make soft sensors an attractive area for technology development. Rapid advances in computing technology can be expected to improve mathematical modeling capabilities and thus the robustness of soft sensors.

50.12. SENSORS IN DOWNSTREAM APPLICATIONS

The sensors discussed in this chapter allow for increased process understanding in upstream applications, i.e., cell culture and fermentation processes. New sensor technologies in downstream processing have also been explored in the last decade. As in the case of upstream sensors, downstream applications focus on data throughput and in situ sensors used in purification development and manufacturing operations.

There are several new technologies that have been explored and developed in the last decade. These technologies allow for high-throughput or on-the-floor testing of process variables such as endotoxin levels, total organic carbon concentrations, and at-line protein concentration measurements without dilutions. Protein quality using LOC technology, mentioned above, is also used to monitor product quality in downstream applications.

New developments in monitoring host cell protein clearance (HCP) in downstream processing are also important. In general, removal of CHO cell-derived proteins from the biopharmaceutical product is monitored using multiproduct immunoassays (42). However, these assays require intensive sample preparation and the use of robotics to facilitate high throughput. An example of a new technology involves the miniaturization of an affinity capture column to generate a sandwich-based immunoassay integrated into a compact disk microlaboratory for high-throughput HCP measurements (44). However, most of the newer technologies are for at-line measurements. On-line or in situ probes for downstream sensors have the same requirements as mentioned above, i.e., (i) ability to be sterilized (chemical sanitization only may apply to downstream sensors), (ii) reliability and robustness, (iii) high specificity to the measured parameter, (iv) fast response time, and (v) minimal drift. Extensive development and testing are required to achieve these requirements. Examples of downstream technologies are listed in Table 8.

50.13. IMPLEMENTATION OF A NEW PAT

Implementing PAT in development or manufacturing will require extensive testing to ensure acceptable performance and required comparability. Equally important to implementation is the infrastructure support required to manage the technology life cycle. Intensive vendor, instrument services, and automation support may be required to ensure reliability and robustness during testing and after imple-

TABLE 8 Examples of new technologies in downstream applications

Commercial name	Application ^a	Vendor information
Endosafe®-PTS™	Rapid, real-time endotoxin testing	Charles River Laboratories International, Inc., Wilmington, MA, http://www.criver.com
Sievers® 900 Portable TOC Analyzer	Portable TOC analyzer for at-line grab samples, or connected to an autosampler for high-volume applications	GE Analytical Instruments, Inc., Boulder, CO, http://www.geinstruments.com
NanoDrop™ (models 2000 and 2000c)	UV/Vis spectrophotometer for rapid quantification of protein samples without the need for dilution	NanoDrop, Wilmington, DE, http://www.nanodrop.com
NanoPhotometer™	UV/Vis spectrophotometer for rapid quantification of protein samples without the need for dilution	Implen, Inc., Calabasas, CA, http://www.implen.de
NanoVue™	UV/Vis spectrophotometer for rapid quantification of protein samples without the need for dilution	GE Healthcare Bio-Sciences AB, Uppsala, Sweden, http://www.gelifesciences.com
Gyrolab Bioaffy 200	Quantification of monoclonal IgG and HCP for the entire purification process from cell supernatant to purified product	Gyros AB, Uppsala, Sweden, http://www.gyros.com

^aAbbreviations: TOC, total organic carbon; Vis, visual; IgG, immunoglobulin G.

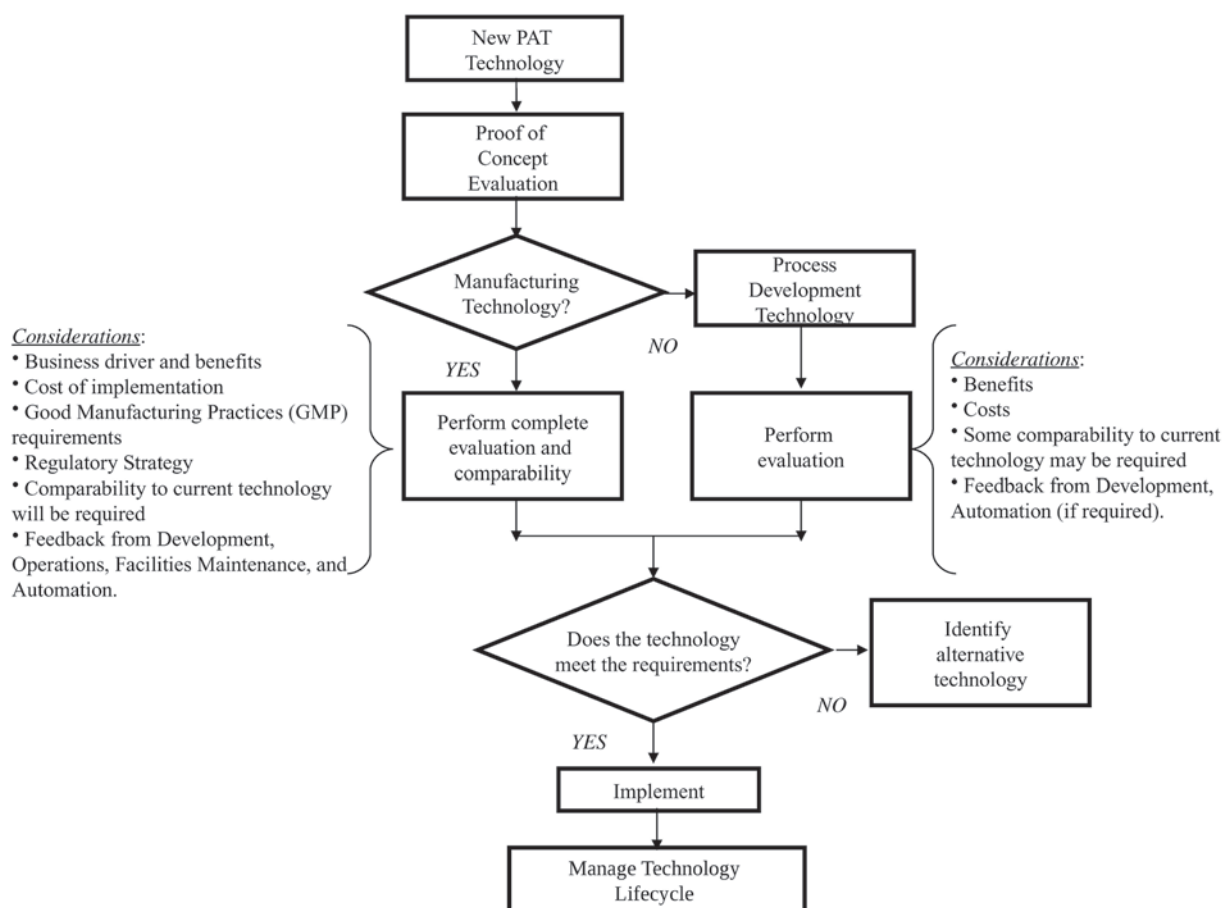

FIGURE 6 Potential steps required for the evaluation and implementation of a new PAT.

mentation. In addition, manufacturing implementation requires support from the regulatory organization within the company. Regulatory representatives can establish the strategy of implementation required for a particular technology early during development. Discussions with the FDA may be recommended in the technology development phase. This becomes more important if the implementation is complex or across multiple products, multiple sites, and multiple countries.

Depending on the evaluation challenges and the robustness of the technology, implementation of a new PAT may require several years. Ideally, technologies should be tested in development laboratories or pilot plants where data and knowledge can be gathered before implementation in a manufacturing environment. Figure 6 shows a potential path for the evaluation and implementation of a new PAT.

50.14. SUMMARY

It is clear from the literature that there have been tremendous efforts in the development and evaluation of new sensors and tools to enable PAT implementation in cell culture and fermentation processes. Universities, vendors, and companies are working together to advance sensor and sampling technology research and development and ensure process understanding and product quality. These advances have also been encouraged by the multiple QBD sessions

and workshops, increasingly common in conferences with pharmaceutical and biotechnology topics. This chapter covers some of the numerous technologies that have been developed or improved in the last decade.

Autosampling technologies that enable real-time data and potentially feedback control will become more common in processing facilities. Advances in in situ spectroscopic sensors could facilitate real-time monitoring of multiple analytes and process parameters. New developments in biomass and glucose sensing technologies could allow for feed optimization and maximum product yield. High-throughput product quality technologies such as LOC could allow real-time product quality monitoring during production. These technologies along with strong data analysis tools will ensure strong process understanding and allow for real-time release in the future.

I acknowledge Tina M. Larson, Robert Kiss, and Ashraf Amanullah, Genentech, Inc., South San Francisco, CA, for their review and helpful comments.

Bioreactor Automation

DAVID HOPKINS, MELISSA ST. AMAND,
AND JACK PRIOR

51

51.1. INTRODUCTION

Although successful growth of prokaryotic or eukaryotic cells in bioreactors can be achieved with little or no automation, increased monitoring and control of bioreactors can often improve process reliability, consistency, and understanding. The goal of bioreactor control is to manage the cells' environment and metabolism to maximize productivity and product quality. The complexity of an automation system will vary depending on a number of factors including process requirements, production costs, product value, quality requirements, regulatory constraints, and data acquisition requirements. This chapter introduces basic automation terminology and concepts as well as the rationale for implementing various levels of automation.

51.1.1. Brief History of Bioreactor Automation

Modern control theory was first applied to biotechnology in the 1970s (24) as developments in bioreactor sensor technology and increased availability of computer hardware in the years leading up to this era set the stage for more advanced bioreactor control implementations. Particularly useful were the commercial availability of the modern pH probe in 1945 (19, 23) and the membrane-covered dissolved oxygen (DO) probe in 1956 (7). Later, in 1964, Johnson et al. (13) introduced steam-sterilizable DO probes, which enabled practical use of the probes in bioreactors.

In the early 1970s, Humphrey and Nyiri demonstrated computer control of DO by varying agitation and airflow rates (20, 21). Other pioneers of bioreactor monitoring and computer control include Lim, Weigand, Zabriskie, N. S. Wang, Stephanopoulos, Cooney, H. Y. Wang, and D. I. C. Wang (8, 9, 18, 24, 29). An automated in-line sampling system which maintained sterility was introduced by Leisola and Kauppinen in 1978 (16). Later in the mid-1980s, new types of biosensors became commercially available for measuring components for glucose, amino acids, antibiotics, and macromolecules (14). Since the mid-1980s, the increased availability of low-cost computer and data storage hardware has significantly increased the amount of data collected for bioreactor processes, with data historians frequently being employed to facilitate archiving and retrieving data for analysis and troubleshooting.

51.1.2. Process Requirements

Before designing or purchasing an automation system, the full range of process operations and requirements must be

understood. Major operations associated with a given batch typically consist of equipment preparation and assembly, sterilization, inoculation, cell growth and production, and cleaning.

While these operations can often be performed manually for laboratory and smaller pilot-scale bioreactors (~500 liters or smaller), large-scale reactors require automation for most operations. For example, small-scale reactors can often be moved to cleaning/steaming areas or be sterilized with autoclaves, whereas larger bioreactors must be dealt with by cleaning in place (CIP) and sterilization in place (SIP). Larger bioreactors also pose a financial risk if a mistake or unusual event occurs that affects product quality or productivity. This often justifies additional automation to facilitate consistent operation. Some form of automation is typically used at all scales during inoculation, cell growth, and production in order to maintain proper culture conditions.

51.1.2.1. Automated Reactor Operations

Sterilization is required after reactor assembly and prior to inoculation. The sterilization process begins by heating the gas and vent filters with clean steam, followed by a vessel heat-up via a heated jacket and/or with steam injected directly into the reactor. Air in the bioreactor is eventually replaced with clean steam as the air exits through the vent and steam traps. The vessel is then pressurized to allow the temperature to rise to a minimum of 121°C, where it is held until a temperature- and time-based criterion is met. Steam is then shut off. While the steam condenses, a vacuum is prevented by the introduction of sterile air. The pressure is then slowly reduced from the sterilization pressure to the operating pressure. The bioreactor is also cooled by introducing water into the jacket, if present.

After sterilization and prior to inoculation, unstable or reactive media components may be added aseptically. In-situ sensors to detect variables such as cell density, DO, and pH may require standardization or adjustment prior to inoculation with the seed culture. During cell growth and production, additional transfers of nutrients, acid or base, and antifoam as well as periodic sampling may be necessary. For continuous or semibatch operations, harvest transfers for further downstream processing occur during the production phase. Care must be taken to ensure that the bioreactor remains sterile while adjoining lines are cleaned and sterilized.

Once production is complete, larger bioreactors are typically connected to a pump or a CIP skid that circulates cleaning solutions through spray-balls to clean the interior as well as each port. Valves must be manipulated as the vessel and each port are cleaned and rinsed. Temperature control may be active to maintain the desired cleaning solution temperature. Automation can be used to coordinate valve cycling on the bioreactor in conjunction with the cleaning equipment.

Sensors, control strategies, and automation systems capable of meeting these process requirements will be discussed in the following sections.

51.2. INSTRUMENTATION REQUIREMENTS

Bioreactor measurements can be categorized by the physical location of the sensor relative to the process they are measuring. "In-situ" or "in-line" sensors are exposed directly to the process fluid. "At-line" measurements are conducted on samples locally after they are aseptically withdrawn from the bioreactor in order to maximize accuracy or their timely utilization. Living cells in the noncontrolled sample environment may influence the sample itself. Dissolved gases can quickly change in concentration and, in the case of dissolved CO₂, can affect the pH of the sample. "Off-line" measurements are less time sensitive and are usually performed on aseptically stored supernatant within hours or days of sampling. Supernatant samples may be frozen or refrigerated to minimize continued biological or chemical reactions.

In a manufacturing setting, data from these three types of measurements—in-line, at-line, and off-line—may be obtained electronically or gathered manually by manufacturing or quality control personnel. Each type records data in separate systems, and provisions must be made for recombining these data electronically for review and analysis.

Desirable sensor traits include high precision and accuracy, signal linearity across the full operational range, minimal drift over time, insensitivity to other process conditions such as temperature, and robustness against failure for all process conditions. Sensors susceptible to drift must be verified by periodic at-line analysis of samples. The transmitter or automation system can then be adjusted as required. Measurements which are a function of temperature, such as conductivity and pH, require compensation if the batch temperature varies over time. This compensation may be incorporated into the sensor apparatus itself or into the automation system.

The materials of construction for the instrumentation must withstand the pressure and temperature requirements of sterilization and not leach material into the process. Typical materials acceptable for product contact include 316L stainless steel electropolished to an average roughness (R_a) of 10 to 20, ethylene propylene diene M-class rubber, Viton, silicone, Teflon, and glass.

Identifying advanced instruments that achieve these goals while monitoring cell density or metabolism can be more challenging than for sensors which directly measure physical and chemical properties. Bioreactors also have a limited number of ports for sensors. All sensors involve cost and risks that must be balanced with the operating benefit they provide.

51.2.1. Culture Conditions

Typical in-line measurements of reactor conditions include pH, DO, dissolved carbon dioxide, pressure, temperature, weight/level, foam level, and agitation speed.

51.2.1.1. pH

pH was one of the first in-line measurements of cell culture state and is a critical process control variable because cell growth, enzyme activity, and other biological processes are affected by pH (5, 14). Choosing a pH set point (SP) or trajectory for a particular process often involves striking a balance between the optimal pH for growth and that for protein production (26).

pH electrodes measure free H⁺ ions in the surrounding medium. In bioreactors, pH probes are typically inserted via a sterile connection port in the sidewall to allow direct contact with the culture medium. The pH probe should be placed in a well-mixed location and must be designed to withstand frequent sterilization and prolonged exposure to cell culture fluid (5, 26).

51.2.1.2. DO

Dissolved oxygen (DO) is a critical substrate during aerobic cell cultivation since cellular respiration requires oxygen. Gaseous O₂ is typically supplied to the culture medium by sparging air or oxygen into the reactor vessel. DO probes measure oxygen partial pressure (pO₂) in the culture medium rather than direct oxygen concentration. The probe should be located in a well-mixed region away from spargers or solids that may interfere with the measurement (26).

DO probes are typically galvanic or polarographic. Both types use an electrode system in which DO reacts with the cathode to produce an electrical current. Galvanic probes are generally preferred because they require less maintenance.

51.2.1.3. Dissolved Carbon Dioxide

Carbon dioxide partial pressure (pCO₂) is a measure of the dissolved CO₂ content of the culture medium. Carbon dioxide is often added to the headspace above the culture at small scale to maintain minimum pCO₂ levels. At large scale, reduced mass transfer rates can result in accumulation of pCO₂ in the medium as a result of cellular respiration. If not monitored and controlled, it can adversely affect cellular metabolism by lowering the cells' internal pH. Cell growth, product formation, and even glycosylation patterns have been shown to be negatively affected by high pCO₂ concentrations in culture medium (22).

Off-line blood-gas analyzers can be used to measure pCO₂. However, careful sample handling is necessary to ensure accurate readings. If the culture produces little acid, pCO₂ may be indirectly estimated based on pH (27). Recently, steam-sterilizable pCO₂ probes have been developed which operate as a modified pH electrode (22).

51.2.1.4. Pressure

Bioreactors are maintained at positive pressure to ensure aseptic operation. Bioreactor pressure also influences the partial pressure of dissolved gases. Higher vessel pressure increases the driving force for O₂ transfer and increases the capacity of the reactor to support higher cell densities. Conversely, higher pCO₂ pressures can have adverse effects on the culture. Diaphragm sensors are typically used to measure pressure (26).

51.2.1.5. Temperature

Living cells can be highly sensitive to temperature. As with pH, the optimal temperature for growth may differ from that for protein production. At temperatures exceeding the optimal range, cells will generally undergo thermal death. Insertable thermocouples, resistance thermometers, or thermistors are used to measure bioreactor temperature (26).

51.2.1.6. Volume

Level sensors based on conductivity, capacitance, or differential pressure measurements may be used to determine the bioreactor volume. Mass sensors such as load cells or scales may also be used, but require flexible connections between the bioreactor and the adjoining platform to perform correctly.

51.2.1.7. Foam

Foam formation can adversely affect a fermentation process by causing cell death and protein denaturation, and can also interfere with level measurements and exhaust filter operation. Various features of a bioreactor such as impeller blades and the position of additive inlet ports are designed to minimize foaming. Conductance and capacitance probes are typically used to monitor foam level.

51.2.1.8. Agitator Speed

Agitator speed influences several phenomena inside the reactor vessel and is thus important to monitor and control. Minimal agitation levels are required to ensure off-bottom mixing and sufficient mass transfer rate of gases to the culture. Conversely, high agitation rates can lead to shear damage to the cells and can induce foam formation. Agitation rate is typically measured by a frequency counter signal converted to rotations per minute and controlled via a variable frequency drive (VFD).

51.2.1.9. Nutrient Feed and Gas Flow

Gas flow is typically measured and controlled by mass flow controllers or volumetric rotameters. Liquid flow rate of feed or titrant solutions may be measured by source tank level, magnetic flow meters, or mass flow meters.

5.1.2.2. Cell Growth and Metabolism

Historically, various measurements at-line or off-line are used to monitor cell growth and metabolism of the cell culture. However, technology innovations are increasingly enabling the use of in-line measurements for bioreactor control.

51.2.2.1. OD (Turbidity)

Optical density (OD), or turbidity, measurements can be correlated with biomass concentrations. These measurements are typically performed off-line, but in-line OD sensors are also available. OD sensors rely on the transmittance, absorbance, and/or scatter of light. The wavelength of incident light, the angle of detection, interference from sample bubbling, and extraneous particulate matter are all important considerations for OD measurements (15, 17, 27). Cell viability and aggregation must be considered when translating OD measurements to cell concentrations.

51.2.2.2. Capacitance

Capacitance probes such as the ABER Biomass Monitor (ABER Instruments, Aberystwyth, United Kingdom) can determine viable cell density in-line. Capacitance measurements are similar in principle to trypan blue staining—in which only viable cells remain unstained due to intact membranes—with the plasma membrane of the cell acting as an insulator and preventing low-frequency electrical currents from charging the intracellular fluid. The resulting dielectric dispersion is proportional to cell radius and volume. Since only living cells have intact plasma membranes, many of the typical interferences such as lysed cells and media components are minimized with capacitance measurements (15).

51.2.2.3. NIR

Near-infrared spectroscopy (NIR) is another form of in-line biomass measurement. NIR is based on electromagnetic absorption between 700 and 2,500 nm, which has overtones and combination bands of the fundamental bending and stretching vibrations (11, 28). Weaker than mid-infrared, NIR enables direct sample analysis. NIR measurements are also possible at longer path lengths than traditional spectroscopic techniques, making it a suitable real-time method for biomass measurement (1, 28).

51.2.2.4. Exit Gas Composition

Measurements of exit gas composition and gas flow rates can be used to monitor the rate of cellular metabolism by enabling the calculation of oxygen uptake and carbon dioxide evolution rates. CO₂ in the gas phase is typically measured by infrared absorbance at <15 μm or by acoustic means. O₂ analysis is based on paramagnetic properties. Photoacoustic spectroscopy and magnetoacoustic technology are also used for CO₂ and O₂ analysis. Time delay and sample pretreatment issues must be addressed for these measurements (27). A centralized mass spectrometer can be used to monitor gas streams multiplexed from several reactors and can provide measurements of O₂, CO₂, and N₂ (6).

51.2.2.5. Redox Potential

Redox potential refers to the overall availability of electrons in the culture broth that result from reduced and oxidized forms of various media and culture components (2). Redox potential measurements are influenced by multiple factors, making interpretation of results difficult. However, redox measurements are useful when pO₂ sensor measurements become inaccurate (i.e., <10 mmol O₂/liter) (27). Redox potential is generally measured potentiometrically with electrodes that are similar in construction to pH electrodes (24).

51.3. CONTROL METHODS

This section describes various control objectives and methodologies for bioreactor operation.

51.3.1. Bioreactor Automation Design Goals

A bioreactor system has several levels of control, distinguished by their primary objectives as well as the frequency of execution. The system design should address each of the layers of control that are described in the following sections. Only safety, process control, and process optimization are necessary for most laboratory-scale bioreactor systems. Large-scale production facilities can benefit from the addition of procedural and plant floor control applications.

51.3.1.1. Personnel, Equipment, and Process Safety

Protection of personnel, equipment, and process should be considered during all phases of bioreactor design and operation. At the hardware specification phase, for example, the bioreactor pressure rating should be set above the associated utility supply pressures to prevent catastrophic bioreactor failure. A second layer of physical control is added by placing a rupture disk on the inner vessel and a pressure relief valve on the jacket of the vessel. This layer protects the bioreactor regardless of external component failures (e.g., pressure regulator).

Rupture disk sensors are monitored by the automation system in order to bring the bioreactor to a safe, nonenergized state in the event of a failure. Typical failure-state

adjustments include shutting valves to isolate the bioreactor from entering gases and fluids, and halting associated agitators and pumps. Operators must also be able to completely shut down a bioreactor with a main power switch (typical for small bioreactors) or emergency shutdown (“E-Stop”) switch (typical for large bioreactors).

Equipment can also be protected by direct feedback from a sensor. For example, a pressure switch placed directly after a positive displacement pump and wired to the pump motor controller can directly shut down the pump if the pressure exceeds the switch’s limit, thus protecting the pump and downstream equipment from damage. Note that these examples of physical and hard-wired protection are always active. They have a response time on the order of milliseconds and collectively provide the last line of defense against failures not handled by the automation system.

When protection is not required under all conditions, software automation is used to enable interlocks between sensors and energized equipment, such as motors and valves, at the appropriate time. An example of a bioreactor process interlock is the automatic closure of an addition valve when the titrant tank is empty, to avoid gas from the titrant tank flowing into the bioreactor. The interlock overrides the pH controller and prevents this condition from occurring, while activating an alarm to notify the operator of the abnormal condition. This interlock is enabled only when pH control is enabled and is not otherwise active. Software interlocks typically react on the order of tenths of seconds to seconds.

51.3.1.2. Basic Process Control

The purpose of a standard process controller is to maintain a process variable within a specified range, or as close to an SP as possible, by adjusting one or more process control devices. The frequency of adjustment is typically on the order of seconds to minutes. Process control algorithms are discussed in more detail in section 51.3.2.

51.3.1.3. Process Optimization

Control strategies can be implemented to optimize cell metabolism for cell growth, production, and/or product quality by periodically adjusting SPs of standard process controllers. The frequency of adjustment is typically on the order of seconds to days. The wide time scale is due to the fact that data used to compute the controller’s output may require evaluating several days of in-line and off-line data. This subject is discussed in more detail in section 51.3.3.

51.3.1.4. Phase and Recipe Automation

Bioreactor systems require procedural control of the sequences of process steps necessary to complete an operation. Each step requires some criteria to be met before the next can begin. Examples include completing a hold timer, reaching a target process value, receiving feedback that equipment is in the correct position, confirmation of successful communications between automation subsystems, or combinations thereof. Conditions are typically monitored on a once-per-second basis, with changes made to process controllers ranging from seconds to days. Procedural control includes phase, recipe, or unit batch control.

51.3.1.5. Plant Floor Management

Plant floor control involves the coordination and scheduling of several production systems within a manufacturing area. It has little to do with direct process control, but often

manages communication between higher-level corporate systems and process control systems. A typical scenario is for a production order to be issued by a corporate Enterprise Resource Planning system instructing the plant floor system to select the appropriate area recipe. Recipe parameters are selected and the area recipe is then started. As the area recipe is executed, equipment is selected and parameters are passed to each unit procedure, which is executed in a sequential, coordinated fashion. Key process data are collected from the selected equipment and related manufacturing computer systems as the area recipe is executed. Recipe steps can take anywhere from minutes to days to complete. These systems are typically known as manufacturing execution systems (MESs) or area batch control systems and are discussed further in section 51.4.

51.3.2. Process Control Algorithms

During process control, a process variable, termed the controlled variable (CV), is maintained at a desired SP. Most bioreactor automation uses a single-input, single-output controller, which consists of a sensor input, a controller, and a control device/actuator.

The controller calculates an output to send to the control device(s) based on the current and historical values obtained from the CV relative to the desired SP. The output of the controller is sent to one or more manipulated variables (MVs), or to another controller, which will cause physical changes in the process. These manipulations should cause the CV to approach the SP. During operation, disturbance variables are variables which affect the CV but cannot be controlled. They represent the natural fluctuation of the process. Figure 1 displays some of the more common attributes of an industrial-sized bioreactor. The CV, MV, and controller types corresponding to this figure are listed in Table 1.

Two key criteria for choosing the type of controller are the process sensitivity to fluctuations around the SP and whether the MV adjustments are to be performed periodically or continuously.

If the process is insensitive to some variance, and only periodic adjustments in the MV are desired, then basic on/off control is the controller of choice. If the CV must be precisely controlled or continuous adjustment to the MV is desired, then proportional-integral-derivative (PID) control is the controller of choice.

51.3.2.1. On/Off Control

On/off controllers are simple to understand and adjust. A control device, such as a pump, solenoid, or valve, is energized based on an on/off signal from a sensor or automation system. A digital sensor, such as a pressure switch, can directly drive equipment on/off. An analog sensor can be compared to a threshold value by an automation system to drive equipment on/off (e.g., “if level < 100 then open feed valve”).

The triggering events can be set to work in only one direction or both directions. For example, if the goal of an interlock is to place the equipment in a safe, nonenergized state when an unsafe condition is detected, it may not be desired to restart until an operator confirms that the unsafe condition has been addressed. A level controller, on the other hand, may open a feed valve when the level falls below a target value, and then close when the level reaches the target. Control can continue as the level rises and falls, as the actions to both open and close the valve are based on logically opposite conditions.

FIGURE 1 Typical bioreactor components.

A region of inactivity (deadband) can be introduced to avoid frequent switches between the on and off position and thereby reduce equipment wear. This region should be large enough to distinguish between a real process change and sensor noise. In the example shown in Fig. 2, the control equipment is energized when the CV falls below the lower action limit and remains on until the SP is reached. Once the SP is reached, the control equipment is de-energized and remains off until the process causes the CV to fall below the action limit again.

A common use of this type of controller is to maintain pH. Catabolism of carbohydrates produces acids that must be neutralized to maintain pH for optimal cell growth and production. The goal is to make these adjustments infrequently and minimize the reactor volume increase over the course of a

batch. This can be facilitated by using concentrated solutions, but care must be taken to ensure that mixing is sufficient to avoid local regions of extreme pH detrimental to culture health. Figure 3 shows a hypothetical example of a pH profile using this type of control. As the cell concentration increases exponentially over time, the rate at which the pH falls, and therefore the frequency of base additions, also increases.

Some cultures may require pH adjustment in both directions over the course of the culture due to changes in metabolism, dissolved CO₂ concentration, and cell density. Figure 4 shows how this controller can be modified for acid and base addition. As shown, the deadband region between the lower and upper action limits prevents overshoot from an acid or base addition from activating the other. The risk of overshoot is typically highest at the start of a run when the cell density is lowest.

For cultures where the cell density increases by several orders of magnitude, the frequency of addition may reach a point where the titrant is added constantly and pH cannot be maintained. This is known as controller saturation and can be corrected by adding adaptive features. In addition to

TABLE 1 Typical bioreactor control loops

CV	MV	Loop type
Vessel temperature	Heating/cooling	
Fluid flow	Cascaded PID	
Pressure	Exhaust flow	PID
pH	Acid/base pump	PID, on/off
pH	Headspace air/CO ₂ flow	PID
DO	Spurge air or O ₂ flow	PID, on/off
Dissolved CO ₂	Spurge N ₂ flow	PID, on/off
Foam	Antifoam pump	On/off
Gas inlet/outlet composition	Nutrient addition rate	PID
Agitator rpm	Agitator motor speed	PID
Level/weight	Nutrient/harvest	
Pump rates	PID	

FIGURE 2 On/off range control.

FIGURE 3 On/off pH range control.

turning a base addition pump on and off, the speed of the pump can be stepped up or down to extend the sensitivity and range of the controller. If the pH drops well below the lower action limit (see Fig. 5), a response limit can be set to double the pump speed, allowing the controller to return the pH to SP. If the reverse occurs and the demand for base drops so low that the smallest addition causes the pH to overshoot the SP, an overshoot limit can be set to reduce the pump speed by half. A delay is required to ensure that the speed is not adjusted repeatedly, and to allow both the controller and the process time to adjust to the new pump setting.

51.3.2.2. PID Controller

If the control equipment is continuously active, then PID controllers are typically used. These controllers respond to three components of the error measurement over time (see Fig. 6).

Although manufacturers of automation equipment vary the implementation of PID control, a typical form of the PID equation is:

$$\text{Output}_{SS} = \text{Output}_{SS} + K \left[\text{Error} + \left(\frac{1}{\tau_I} \right) \int \text{Error} dt + \tau_D \left(\frac{d \text{Error}}{dt} \right) \right] \quad (1)$$

where Output_{SS} is the steady-state output required to maintain SP; Error is $SP - CV$; K is the proportional control constant; τ_I is the integral control constant; $\int \text{Error} dt$ is the integral of error with respect to time; and $d \text{Error}/dt$ is the derivative of Error with respect to time (i.e., $\Delta \text{Error}/\Delta \text{time}$).

If the CV is maintained at the SP, all three error terms equal zero and the output equals the steady-state value, Output_{SS} . As process demands change, or as sporadic disturbances occur, the error becomes nonzero and the various terms come into play. The proportional (P) term, $K * \text{Error}$, adjusts for temporary disturbances but cannot completely return the process to SP if a step change in the process occurs. When the process or SP changes, $\text{Output} = \text{Output}_{SS} + K * \text{Error}$. If $CV = SP$, the error is zero, but Output_{SS} no longer represents the output required to maintain SP. Therefore, as shown in Fig. 7, the process will settle into a new steady state with a constant offset from SP if only proportional control is used.

The integral (I) term, $K * (1/\tau_I) \int \text{Error} dt$, accumulates error over time and will continue to increase in magnitude while error persists. The integral term will therefore

FIGURE 4 On/off control with deadband.

FIGURE 5 Adaptive on/off control.

compensate for the offset problem seen with proportional-only control. If the integral constant τ_I is too large, excessive oscillation around the SP can occur, as shown in Fig. 7.

The derivative (D) term, $K * \tau_D (d \text{Error}/dt)$, is seldom necessary, but can be useful for countering rapid disturbance changes more quickly than with proportional and integral control alone. This reduces SP overshoot and allows the controller to reach SP more quickly, as shown in Fig. 7. The disadvantage of derivative control is that noise in the CV is magnified and can translate into erratic control. To avoid this issue, one can simply use PI control, or smooth the derivative error data using various methods before calculating the derivative term.

Most modern automation systems have a built-in auto-tune feature to determine appropriate K , τ_I , and τ_D parameters. If this feature is not available, Seborg et al. (25) reviews several methods for PID parameter estimation and provides a good introduction to control theory and advanced PID controller issues.

It is particularly important to test bioreactor PID controller performance throughout the full process range to ensure that the controller can maintain SP without excessive oscillations and does not become unstable at any point in the process. The output required to maintain steady state can change exponentially over the course of a batch, and some cases may require more than one set of PID parameters to correctly control during periods of low as well as high demand. Figure 8 shows that PID parameter set 1 is used initially and switched to set 2 when the high output limit is reached. If the demand slows and the output drops, set 1 is reinstated when the low output limit is reached. The range between low and high output limits acts as a buffer zone to ensure that the PID controller is not constantly disrupted by changes between PID parameter sets 1 and 2.

Another common issue is that a control device with the capability to deliver the output required to maintain control over the full process range may not have the precise response needed to control smoothly during periods of low demand. This can result in near on/off control of the MV, resulting in large oscillations of the CV. In this case, the output range may be split between small-scale and large-scale control equipment, each with its own PID controller, to provide precise control throughout the full range of the process. Figure 9 illustrates how control is passed between the two separate PID controllers in split range PID control, using the output of the currently active controller to determine when control should be switched to the other controller. The buffer range between the low and high output limits prevents frequent

FIGURE 6 PID measurements.

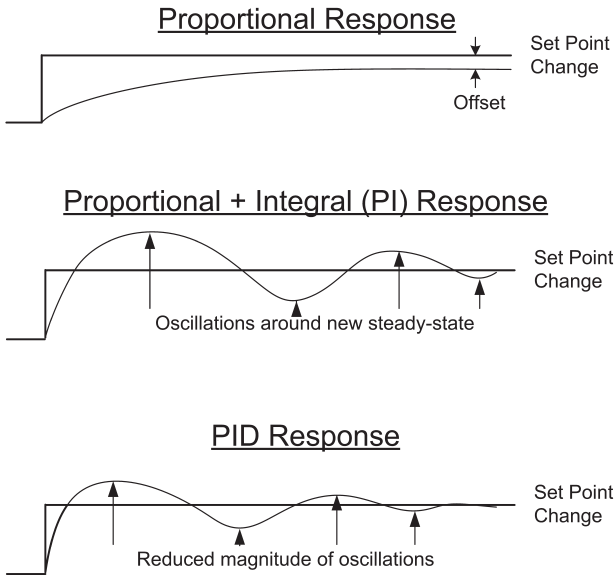

FIGURE 7 PID term contributions.

switching between the high- and low-range controllers. The integral term of the inactive PID controller must also be reset before control is passed to it to ensure a smooth transfer.

51.3.2.3. Cascade Control

Cascade control connects an outer (master) controller to an inner (slave) controller by passing the output from the master to the SP of the slave. This is useful when the physical control of one subsystem has a direct impact on another. Bioreactor temperature control is typically performed by circulating a fluid through a jacket that surrounds the side and bottom of the vessel (see Fig. 1). The jacket fluid is heated or cooled as necessary, which in turn transfers heat to or from the vessel. The jacket controller is set to cascade mode to allow its SP to be fed remotely by the vessel temperature controller's output. The jacket temperature controller is said to be a slave to the master vessel temperature controller. It is not important for a slave controller to actually achieve its SP, but simply to respond in the correct direction to changes in the SP. For this reason, slave PID controllers can operate successfully using proportional-only control.

51.3.2.4. Split Range Output

A split range output takes a single analog controller value and separates it into two separate values that can be used to drive two individual control devices. To continue with the temperature control example, the jacket

FIGURE 9 Split range PID control.

FIGURE 8 Adaptive PID control.

controller output requires a single output value to drive both heating and cooling actions. Typical controllers range from 0 to 100%, with the control equipment at rest at 0%. In contrast, a jacket temperature controller is at rest at 50%, which allows 50 to 100% output to be translated to 0–100% heating and 50 to 0% output to be translated to 0–100% cooling (see Fig. 10). Note that the controller responds equally in magnitude to positive and negative error. Therefore, the MVs should respond similarly for the controller to have a balanced effect on the process.

In our example, 0% PID output corresponds to full cooling and should transfer an equal but opposite amount as that delivered by a PID output of 100%, which corresponds to full heating. A deadband can be implemented to provide a buffer zone where no output is active, in order to reduce oscillations and equipment wear by preventing small variations near the SP from causing a counter-response as the temperature crosses the SP.

51.3.2.5. TPO

When a controller with an analog output is used, such as a PID controller, and the MV is digital, such as an open/close valve or an on/off pump, then a time proportional output (TPO) must be used to convert the PID percent output to a digital signal that is active for a proportional fraction of the specified cycle time.

For example, if the cycle time is 10 s and the controller output is 10%, then the valve is opened for 1 s and closed for 9 s. The calculation is repeated at the end of each cycle. The TPO scan interval is the time period at which the valve position is determined. Therefore, the total time a valve can be open is a multiple of the scan interval. The ratio of the scan interval over the cycle time determines the resolution of the TPO. If the cycle time is 10 s and the scan interval is 1 s, then only controller output changes in multiples of 10% will cause an actual change to the time a valve is open. The scan interval should be set short enough to prevent controller overshoot during the most responsive portion of the process, but not shorter than the time it takes for the valve to physically open.

FIGURE 10 Split range output.

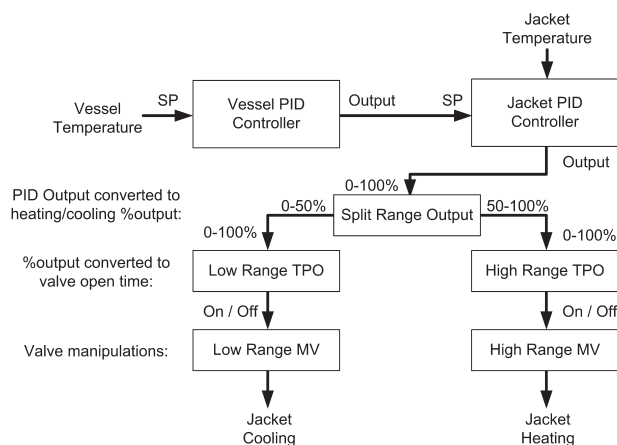

FIGURE 11 Temperature control example.

Figure 11 summarizes how these control elements are integrated in our temperature control example. The vessel PID controller output is transferred to the jacket PID SP. The jacket PID output is split between heating and cooling values, which are in turn converted to valve open/close signals with the TPO modules.

51.3.3. Process Optimization

Process optimization involves monitoring cell growth and metabolic state and making appropriate changes in the SPs of the process control loops discussed in the previous section to maximize production. Often off-line, at-line, and in-line data must be combined and evaluated, with adjustments performed manually. In some cases, the process changes too quickly for this to be a viable option, and inferences from the available data are made to make adjustments automatically (3, 4, 10, 18).

51.3.3.1. Process Monitoring

Section 51.2 lists several sensors that are available for bioreactors. Widely used measurements include pH, DO, temperature, pressure, agitation rate, overlay and sparge gas flows, titrant addition volume, and substrate addition volume. Good-quality sensors which measure inlet and outlet gas composition, cell density, foam detection, redox potential, and $p\text{CO}_2$ are also available, but are not as prevalent and not necessary to properly control cell growth and production in all bioreactor processes.

Several methods can be used to assess data quality from these in-line sensors before process conditions are calculated and used for feedback control. Dual sensors for pH, DO, and temperature are often installed to provide redundancy. In this case, the average value is used for control and the difference between the two values is monitored. If the difference becomes large, an alarm is issued so a sample can be taken to determine which sensor is correct. The correct sensor is then selected, rather than the average value, for subsequent control.

Some smart sensors run their own diagnostics and can alert the automation system of failure. Noise from fluctuations in the bioreactor, sensor signal, transmitter circuitry, and analog-to-digital conversion are typically dampened with simple averaging or filter functions within the transmitter or the control system. Excessive filtering should be avoided as it introduces delays between the observed value and the actual event when real disturbances occur.

At-line and off-line data are available infrequently, which can slow the process considerably. Biochemical assays of product, media components, cell quantities, and various metabolite concentrations are often somewhat inaccurate. It is important to standardize these instruments often and to perform repeated, randomized sample analysis so that an unbiased average value can be determined. Also, comparison of direct measurements to values estimated from other measurements can detect outliers, which can then be rejected.

It can be difficult to completely capture these data reconciliation steps within an automation system's programming, and thus these steps are typically performed by experienced manufacturing and process support staff. If at-line and off-line data are used for automatic process optimization, alarm limits should be put in place to alert the staff of unusual values or unusual new process control SPs. The alarm should also prevent the process optimization system from making process changes until the problem is corrected.

Key parameters for process optimization often include cell density, growth rate, oxygen uptake rate, carbon dioxide evolution rate, base or nutrient demand, and by-product formation.

51.3.3.2. Batch Optimization

Simple batch processes basically allow a freshly inoculated culture to grow while maintaining culture conditions. Optimization of the culture is therefore limited to choosing the time to terminate the batch and to making adjustments to SPs based on culture age, cell density, or changes in metabolism. Although infrequent additions of titrants and limiting nutrients may occur, batch processes tend to optimize production by making controller adjustments as expected milestones are reached, rather than implementing regulatory controls. A simple example is a temperature SP change to induce production of a protein by a recombinant organism once a target cell mass is achieved. This shifts the bulk of the cell's machinery from cell growth to protein production. Other common adjustments required during batch processes are related to equipment limitations and are discussed in section 51.3.3.5, as they are common to all modes of operation.

51.3.3.3. Fed-Batch Optimization

The goal of fed-batch and semicontinuous feeding strategies is to extend cell growth and production by controlling the state of cell metabolism. An example of a fed-batch process includes using a defined medium to stoichiometrically match the elemental content of the cell and ensure that inhibitory concentrations of feed components are not reached during late stages of the culture. The initial medium contains all nutrients required for the entire batch with the exception of the key substrate. The concentrated substrate solution is fed to maintain the proper concentration in the bioreactor. Maintaining the concentration also ensures that the cell metabolic state remains stable. A desired metabolic state has a corresponding yield of cell mass on substrate, for which the appropriate feed rate can be calculated using equation 2, based on current estimates or measurements of cell density, growth rate, and bioreactor volume.

$$\text{Feed rate} = \frac{\mu XV}{(YS_0)} \quad (2)$$

where feed rate is the substrate flow rate (liters/hour), μ is the current growth rate (1/hour), X is the current cell

density (grams/liter), V is the current bioreactor volume (liters), Y is the yield of cells on substrate (grams of cells/gram of substrate), and S_0 is the feed solution substrate concentration (grams/liter).

In some processes, ammonia can be used both for pH control and as a nitrogen source. To maintain a stoichiometric ratio of carbon to nitrogen (C/N), the total batch substrate volume required to maintain the desired molar C/N ratio is calculated throughout the batch by multiplying the total volume of ammonia fed as a result of pH control by a conversion constant after each addition and directing the substrate addition controller to add substrate until the new target total batch substrate volume is reached. An advantage of this approach is that total batch volumes are used to calculate additions, rather than multiple instantaneous calculations, which accumulate error over time.

51.3.3.4. Semicontinuous Optimization

Semicontinuous processes begin with a batch growth stage, followed by a continuous feed and harvest stage. This strategy can provide nearly continuous, high-product-concentration material and therefore is the most efficient use of a bioreactor. The choice between fed-batch and semicontinuous feeding strategies is often dependent on productivity, product stability, and the selected downstream process.

Chemostats feed media with all components in excess except for a single limiting substrate while withdrawing culture broth to maintain a constant bioreactor volume. The feed rate is chosen to optimize product concentration and quality, cell density, growth rate, and by-product concentrations, which all become constant as the process approaches steady state.

Perfusion processes feed media at a fixed rate, with all components in excess of that required for the cell mass in the bioreactor. Cells either are returned to the bioreactor after separation from the harvest stream, or are retained within the bioreactor. Changes in cell density can be compensated for by modifying the feed flow rate to ensure that sufficient nutrient concentrations are maintained. Process control adjustments of semicontinuous processes are minimal, with the majority of changes occurring in the transition between growth and continuous harvest modes.

51.3.3.5. Equipment Constraint Management

Bioreactor heat and mass transfer limitations often constrain the optimization of high-cell-density processes. The oxygen mass transfer requirements and metabolic heat load are proportional to the product of growth rate and cell density (μX). Viscosity, which increases with cell density, also has an adverse effect on mass and heat transfer.

To maintain temperature, the bioreactor design must provide sufficient jacket surface area and cooling systems capable of dropping the jacket temperature as low as needed. If the physical design of the bioreactor cannot control temperature, then the substrate flow rate can be reduced to maintain temperature. This will cause the growth rate to be reduced, thus preventing the temperature from rising to a point where the cell death rate increases rapidly. Cultures are typically terminated in a controlled fashion prior to reaching this physical limitation.

To maintain DO throughout the full range of demand, mass transfer from sparged gas can be managed by automatically switching the control strategy between agitation,

sparge gas flow, sparge gas O_2 composition, and pressure as the maximum desired output of each controller is successively reached.

Agitation reduces bubble size and thus increases surface area, while also improving mixing within the bioreactor. Agitation is often the first controller to be used for DO control. Agitation also increases shear and is therefore limited to low rotations per minute (rpm) values for shear-sensitive insect and mammalian cells.

Spurge flow rate can be increased to provide a higher liquid-gas interface area to allow more oxygen to be transferred. Increasing O_2 composition of the sparged gas increases the driving force from the gas to the liquid. For bacterial fermentations, the process typically involves increasing airflow first and then increasing the O_2 sparge gas concentration by supplementing the air with pure oxygen, preferably using separate sparger lines (Fig. 1). Increasing spurge flow rates eventually becomes ineffective as the agitator is "flooded" with gas and cannot mix the liquid and gas as efficiently. Agitator power consumption will decrease as this occurs. Cells sensitive to gas-liquid interfaces are sparged with pure O_2 to minimize the flow rate of sparged gas.

Cultures with very high O_2 demand may also require the pressure of the bioreactor to be increased, which causes the concentration of all dissolved gases to increase. This step is not performed for cells sensitive to high pCO_2 .

Finally, if the DO controller cannot maintain SP, either the substrate feed can be slowed or the temperature can be reduced to decrease growth rate.

51.4. AUTOMATION SYSTEMS

A variety of commercial automation packages are available to provide the various levels of control discussed in section 51.3. Some common examples of automation hardware and software are discussed in this section.

51.4.1. Sensor Signal Processing

In-line sensors typically send millivolt (mV), milliamp (mA), or optical signals to an associated transmitter which converts the signal to a current, a voltage, or a numeric value, which is then communicated to the automation system. The raw signal is amplified and sometimes filtered to stabilize the output. Common transmitter output voltage ranges are 0 to 10 V direct current (VDC), 1 to 5 VDC, and 0 to 1 VDC. Common transmitter output currents include 0 to 20 mA and 4 to 20 mA. Digital transmission of numeric values by "smart devices" via ethernet or other protocols is increasingly replacing analog transmission.

The transmitter often has a display and the ability to calibrate the signal so that the displayed engineering units and output signal range match actual process conditions. The transmitter may also provide other signal conditioning functions, such as compensation for temperature effects or signal linearization. The transmitter may exist in a stand-alone device, as a card that slides into a personal computer or rack system, or as a module that can be mounted in a panel (see Fig. 12).

51.4.2. Analog and Digital Signal Conversion

Sensor signals and transmitter outputs can also be connected to microprocessor-based control systems such as programmable logic controllers (PLCs), supervisory control and data acquisition (SCADA) systems, and distributed control systems (DCSs).

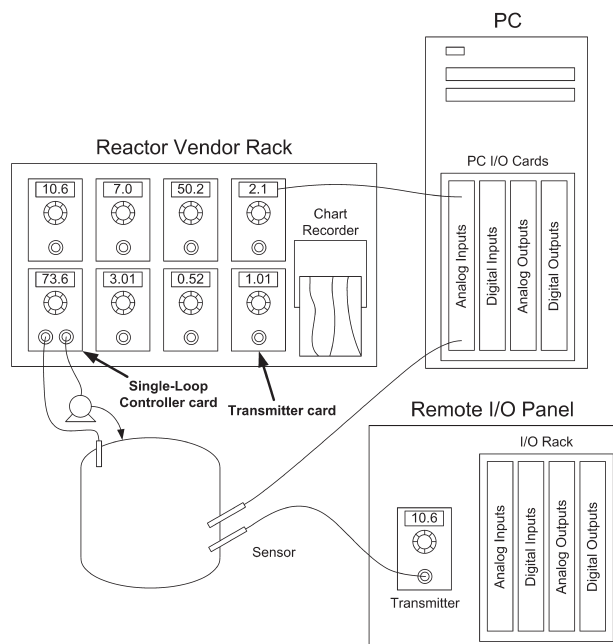

FIGURE 12 Automation I/O hardware examples.

SCADA systems are software applications installed on standard computers or servers that allow data to be transferred between various input and output devices as well as other computer-based process data systems. One form of interfacing is to use input/output (I/O) cards inserted directly into the SCADA computer. These cards convert analog and digital sensor input signals to numeric values stored in the SCADA database. Similarly, numeric values within the SCADA database can be converted to analog and digital output signals which cause a response in the control equipment. SCADA vendors supply software drivers specific to the I/O cards used, to allow the SCADA system to pass data between the SCADA database and the I/O cards.

PLC and DCS systems have their own proprietary remote I/O racks where I/O cards are installed and connected to sensors and control equipment. These systems also provide I/O cards for common equipment. For example, resistance temperature detector cards take thermocouple inputs directly and convert them to temperature without the need for intermediate transmitters. 24-VDC output cards are used to drive solenoids directly. The remote I/O racks are connected to PLCs, or a DCS equivalent, via proprietary digital communication networks (Fig. 13).

Smart devices are microprocessor controlled and provide their own signal conversion. They may contain other functions such as self-calibration, sensor fault diagnosis, and digital communication with control systems via standard protocols such as Foundation Fieldbus, Profibus, HART, RS-232, and RS-485.

The analog and digital signals are eventually converted to numeric values which are stored in the control system's memory. These numeric values are no longer subject to signal interference and can be precisely used for further calculations or communicated to other microprocessor-based systems. The precision of the conversion is determined by the number of bits used by the converter, which must be adequate for the application.

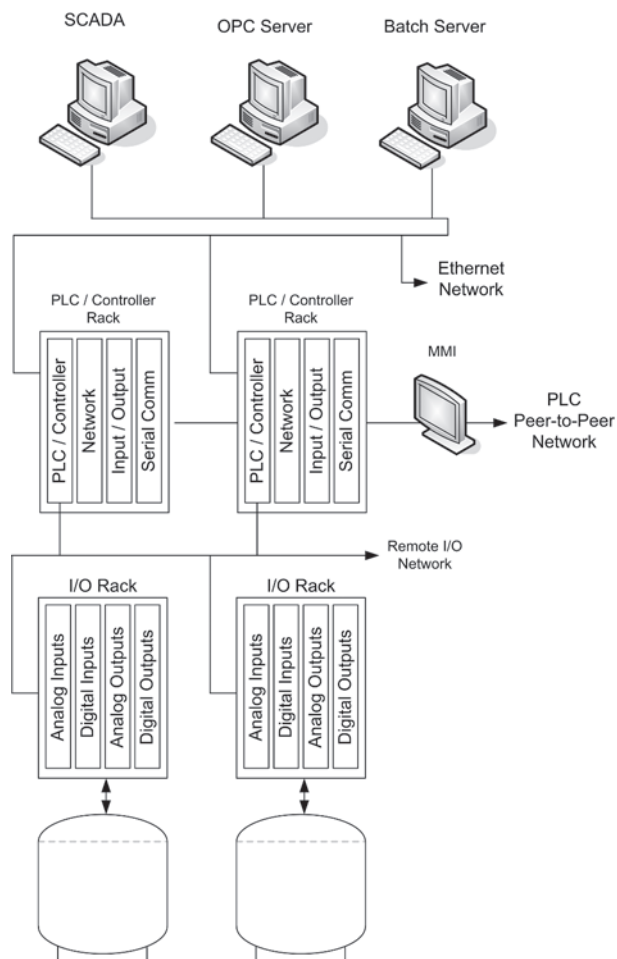

FIGURE 13 PLC/SCADA network examples.

51.4.3. Actuation

Bioreactor control primarily involves the manipulation of gas and liquid flows. On/off flow control is achieved with a variety of valves. Solenoids are driven by 24-VDC or 120-VAC signals and are used for non-process contact applications. Example uses include process gases and jacket heating/cooling temperature control. Solenoids are also used to allow air pressure actuation (typically at 90 to 110 psig) of diaphragm valves, which are designed for aseptic process-contact applications such as culture, titrant, and media transfers. Diaphragm valves are spring-loaded to position the valve in the fail-safe condition. When actuated, the valve moves to the opposite position. For the most part, the fail-safe condition is the closed position, but bioreactors will often have a gas supply valve, such as sparge air, and a vent valve which fail to the open position so the culture has a chance of survival during a short power outage.

Flow rate control is performed with a pump or a flow control valve. Peristaltic pumps are low-flow-range positive-displacement pumps that can be operated aseptically. They respond linearly to a control system's output signal and are relatively inexpensive. Examples of positive-displacement pumps capable of larger flow rates include stainless steel rotary lobe and centrifugal pumps. Rotary lobe pumps cause less cell shear and are therefore useful for cell culture transfers. Centrifugal pumps are less expensive and can be used for non-cell contact applications such as bioreactor clean-

ing procedures. Metering (or dosing) pumps and valves are also available which very precisely control rotations per minute and position, respectively, by digitally positioning toothed gears. Metering pumps are used for short, precise volume additions.

Flow control valves require the source vessel to be pressurized at a roughly constant pressure above the destination vessel. The control system's output signal drives a current-to-pressure (I/P) device which converts 4–20 mA to 3–15 psig air pressure. The increasing air pressure positions the diaphragm from the spring-closed, fail-safe position to the fully actuated, open position. Flow control valves are susceptible to some hysteresis as the mechanism wears and loosens.

Agitation rate is controlled by a VFD. The control system output is converted to increasing frequencies within coils in three-phase motors which rotate the agitator. VFDs are often microprocessor-driven devices which may store fault codes and display power usage. VFDs often fault when asked to rotate the motor at less than 5 to 10% of full speed, as power requirements increase quickly in this range. VFDs are also used to drive pumps requiring variable flow rates.

51.4.4. PLC/SCADA Systems

As discussed, SCADA systems use I/O software drivers to communicate to internal I/O cards or external equipment such as PLCs or smart devices. Current I/O values are stored in the SCADA database. Various function blocks are available to manipulate the data, provide control logic, and send output values to control equipment. There is often an option to write custom code in a proprietary macro language, or in common programming languages such as Visual Basic or C. These custom code options provide additional flexibility that can be useful for process optimization control.

Operator interface screens can be quickly developed using templates which connect to SCADA database values. Templates can include simple value display, value entry, shapes that can change size according to process or calculated values, buttons that run code or select options, and alarm displays. Function block templates may also be available which display all block parameters and settings for a particular instance of a function block. These screens allow the user to visualize and control the process. In addition to operator-initiated actions, the SCADA system is capable of making requests of the operator, such as alarm or prompt acknowledgments which may be required before the automation system takes further action.

SCADA systems also provide a means for storing the data of interest and communicating with other computer-based data systems such as data historians, relational databases, batch control systems, and MES systems. For larger distributed systems, a main SCADA server will communicate with various I/O sources, execute function block logic, and update the SCADA database, while remote SCADA workstations will simply provide operator interface functionality. This allows the SCADA server to focus on communication and control and not be disrupted by operator actions.

PLCs are robust microprocessor-based systems designed specifically for process control. PLCs have no user interface and communicate with I/O equipment on isolated networks via vendor-specific protocols. They are programmed in various low-level languages, which allow them to provide control responses on the order of milliseconds. PLCs can communicate with each other and with man-machine interfaces (MMIs) over a peer-to-peer network (see Fig. 13). MMIs contain basic screen templates,

similar to those described earlier for SCADA systems, which are connected directly to PLC memory locations. Keypad or touch-screen selections on the MMI change PLC memory values, which the PLC then acts on. MMIs have no control capabilities, nor do they store or process data in any way. They are simply PLC interfaces.

SCADA servers are not as robust or as efficient as PLCs. Combining the SCADA with PLCs is a more expensive option than using SCADA alone, but provides a solid automation platform which is preferred for large-scale industrial bioreactors where automation failures can have a large financial impact. PLC design should include all information necessary for direct process control so if the SCADA system should become unavailable, control can continue without interruption. SCADA design should focus on providing a view of the process to the operator and handling all operator and external data system requests. In this way, a SCADA system can provide a single interface point for a large production area.

PLCs are connected to the SCADA server via a separate network, typically an ethernet connection (see Fig. 13). PLCs therefore improve data integrity and communication speed by segregating I/O, PLC/MMI, and SCADA traffic among three different networks. SCADA servers may also contain two network cards so that the PLC-SCADA network can be separated from SCADA communication with other computers. Separating communications in this way and splitting functionality between MMIs, PLCs, and SCADA results in an efficient, robust automation system.

51.4.5. Batch Control Systems

Batch control systems provide recipe-based sequential process control and are specifically based on the ISA S88 standard (12). These systems are useful for large production facilities where the equipment is frequently reassigned to produce various products. They are not as useful for pilot plants where the process is still under development and frequent changes are made.

51.4.6. DCS

DCSs (distributed control systems) essentially combine the functionality of PLC, SCADA, and batch systems under one umbrella. DCS systems are designed for larger production facilities and are not often used for benchtop or pilot-scale bioreactor systems.

51.4.7. MES

MESs (manufacturing execution systems) integrate all plant floor activities and provide an electronic record for each batch of material produced. In practice, the scope of MESs can vary widely. At one extreme, the MES simply records electronically what was once written manually on a paper batch record. These are known as paper-on-glass systems. At the other extreme, the MES fully integrates the batch record with the automation system and all the business systems that drive or support plant floor activities. Such business systems can include those which schedule operations, purchase and track raw materials, verify personnel training documentation, track equipment maintenance, schedule instrument calibration, provide electronic copies of Standard Operating Procedures (SOPs), and provide bioreactor sample assay results. The MES also tracks the status of all plant floor equipment and in-process materials. With all of this information, quality checks can be performed before the process is allowed to proceed, thereby reducing errors and waste. Building these quality checks into a

validated system also minimizes the amount of review required. Only exceptions, such as observations recorded by the operator and significant process alarms and events recorded by the MES and automation systems, need to be reviewed. All data are available electronically, minimizing batch record review time and reducing batch release time.

The key to choosing the proper balance of MES complexity versus risk reduction is to perform a risk evaluation. Reviewing quality records that resulted in lost bioreactor batches and conducting a formal risk analysis with engineering, manufacturing, and quality departments will help identify the highest-priority problem areas. The MES design can then focus on eliminating the major issues. Organizations must also balance the long-term benefits associated with a given design with the investment and potential time delays associated with starting up and validating a complex system.

Purification and Characterization of Proteins

ULRICH STRYCH AND RICHARD C. WILLSON

52

52.1. BACKGROUND

This chapter provides an introduction to the fascinating, useful, and sometimes dreaded world of protein purification and characterization. It is intended to provide an introduction to the most commonly used laboratory-scale methods, along with pointers to detailed references for further reading.

The goals of purification vary with the intended use of the purified protein. The amount of protein needed can range from micrograms for microsequencing or the raising of antiserum, through milligrams for activity characterization or structural studies, to kilograms or even tons for pharmaceutical products. Purity is determined by the general level of other protein contaminants, but also by the absence of contaminants of special interest, which can include endotoxins, highly antigenic proteins, viruses, high levels of salts, and competing enzymes or biological activities. With glycosylated proteins, in particular, the presence of various glycoforms of the protein might also negatively affect certain applications.

Protein purification can generally be divided into five broad stages, which do not all need to occur sequentially: (i) preparation of the source, (ii) gathering of all available information about the protein's properties, (iii) development of an assay, (iv) primary isolation, and (v) final purification (Fig. 1). Each of these steps can often be made easier, or even avoided, by effectively searching the literature. Only rarely is the protein of interest unrelated to any that have previously been purified. Hints and tricks from previous work can greatly simplify development of a novel purification strategy; it sometimes may even be possible to "purify by phone" if a previously isolated protein will serve the intended purpose and can be obtained in sufficient quantities.

52.2. PREPARATION OF THE SOURCE

Preparation begins with selection of the raw material (or the system) from which the protein will be isolated. The source is here assumed to be microbial or a cultured metazoan cell line, although transgenic animals and plants may well be of interest for future applications.

It is important to start with ample quantities of target protein in the raw material. Overall purification yields (defined as the ratio of the amount of target protein finally

purified to the amount of the target protein in the raw material) for optimized pharmaceutical protein processes often exceed 80%, but the first few exploratory purifications of a poorly characterized target expressed at low levels may achieve levels closer to 1%, or even less. It is thus prudent to start with an abundant amount (at least 10 to 20 times as much as needed) of protein in the raw material; a common mistake is to start with raw material that already contains less target protein than eventually desired either because purification yields were unexpectedly low or the measurement of the original concentration in the presence of a large excess of host cell proteins was inaccurate.

Abundant supplies are also desirable to permit greater evaluation of alternative purification strategies and will allow each step to be optimized for a greater degree of purification, at the expense of yield.

Protein supplies can be increased by increasing the cultivation volume, by increasing the cell density (e.g., by computer-controlled fermentation with pH control, enhanced oxygen transfer, and regulated feeding of substrate), or by producing more of the desired protein per cell (8). Expression levels can be increased by screening for high-producing cell lines; by cloning and overexpression; by use of nonmetabolizable antibiotics to better maintain selection pressures (e.g., switching away from ampicillin, which is degraded by resistant cells); by use of tightly regulated, strong promoters such as T7 (*Escherichia coli*, pET-System [91]) or NICE (*Lactococcus*, nisin-controlled expression [60]); and often by expression at lower temperatures, as low as 10°C for *E. coli* (74).

In addition to its quantity, the *quality* of the raw material is also subject to optimization. Improvements can include elimination of key contaminants (e.g., proteases, competing enzymatic activities, and serum components), optimization of posttranslational processes, maximization of extracellular secretion or correct folding, and the genetic addition of purification tags such as polyhistidines or glutathione-S-transferase, as discussed below.

In some cases it will be impossible to express and purify a particular protein in a living system, because the protein either has a toxic effect on the cells or it is too rapidly degraded by enzymes of the host cell. Here cell-free translation systems can alleviate the problem by providing all the necessary components for the transcription and translation of a given gene in a premixed cocktail of nucleotides, amino

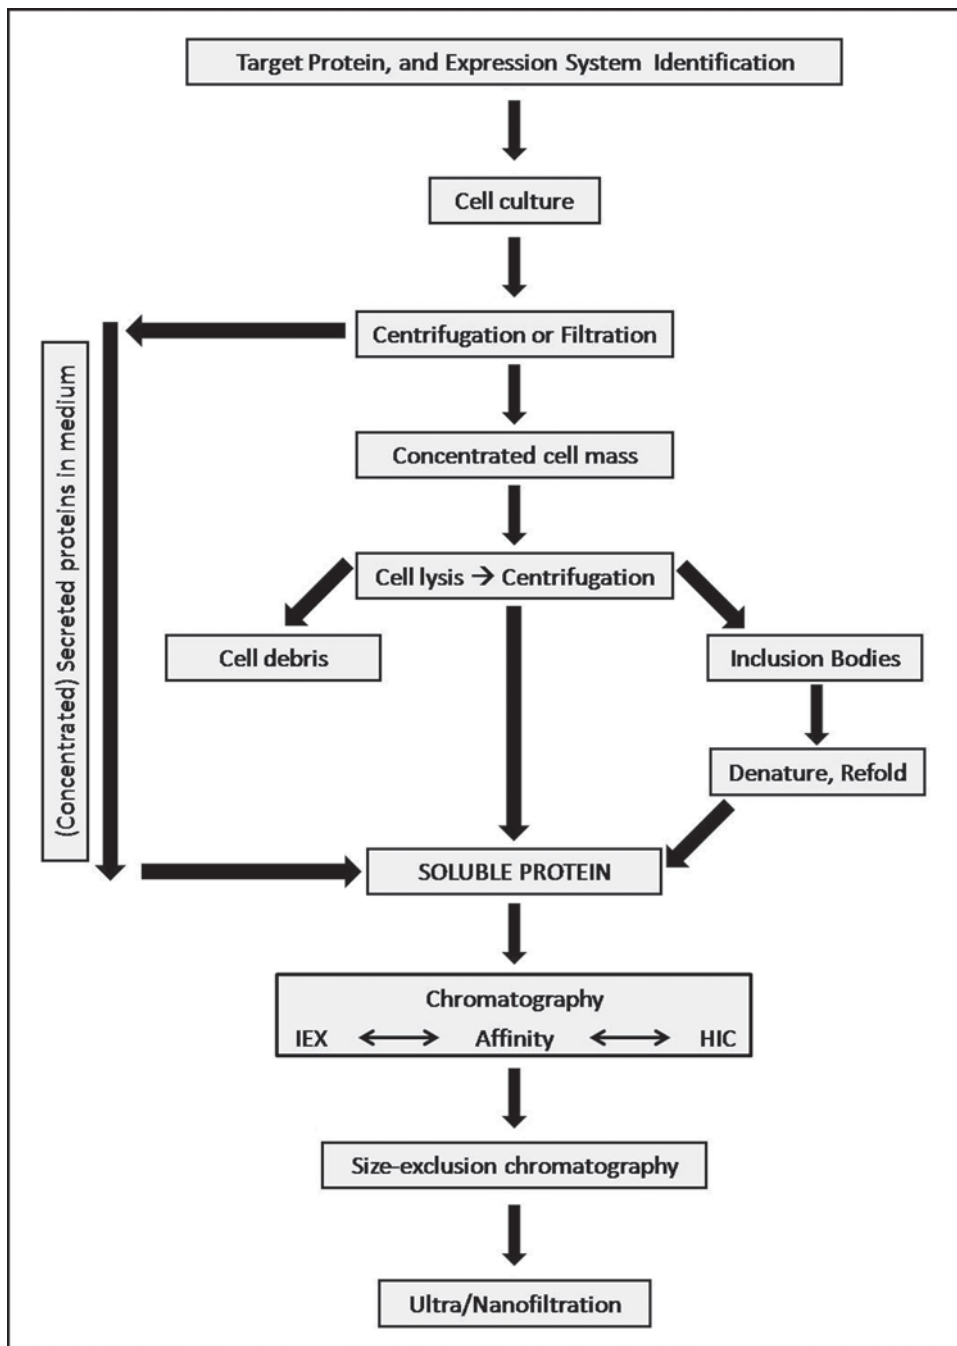

FIGURE 1 Overview of a typical protein purification protocol. After being expressed in the host, the protein of interest will be found in the supernatant or will remain inside the cells, either soluble or as inclusion bodies. HIC, hydrophobic interaction chromatography; IEX, ion-exchange chromatography.

acids (natural and/or unnatural), tRNAs, enzymes, and ribosomes (83). Three in vitro translation systems are most commonly used: *E. coli* lysates (53), wheat germ extracts (57), and rabbit reticulocytes (18). Expressing proteins in cell-free systems does come at high expense and traditionally was a matter of last resort if in vivo systems had failed, but this approach is becoming increasingly popular. Novel cell-free expression systems allow the rapid screening of large numbers of different proteins (100), can incorporate

nonnatural amino acids (38) and introduce disulfide bonds (37), and, overall, have reached a stage where their industrial application appears to be imminent (93).

Recombinant proteins are still most commonly expressed in the enterobacterium *E. coli*. While the bias towards this system might be partly historical (it was one of the first bacteria described in the late 19th century), its ability to grow rapidly on inexpensive nutrients, both aerobically and anaerobically, is an advantage over other

bacterial strains in the laboratory environment. It is the best understood microbial system, with the widest array of genomic and proteomic tools available for its manipulation. *E. coli* strains have been genomically optimized to encode fewer nucleases and proteases, and/or to possess additional genes for the expression of, for instance, highly processive bacteriophage polymerases (91) or rare tRNAs (20). Last but not least, pathogenicity factors present in some wild-type *E. coli* isolates have been removed from laboratory strains.

In recent years an autoinduction medium originally developed by Studier (90) and now distributed by EMD Chemicals has gained an increased following in the protein expression community. The system employs the common *lacUV* promoter-controlled T7 polymerase-dependent bacterial strains and plasmids, but after growing uninduced to a high cell density and metabolizing all carbon sources but lactose, the cells then spontaneously *autoinduce* high-level protein expression, without the need to add a costly synthetic inducer such as IPTG (isopropyl- β -D-thiogalactopyranoside). Not only does this constitute an economic advantage, but the well-defined and optimized medium also increases cell density and target protein yield.

As noted above, some genes are not expressed well in *E. coli*; in particular, eukaryotic genes whose products require posttranslational modifications are better expressed in alternative systems. These include insect cells that are infected with genetically engineered baculovirus particles, yeasts such as *Saccharomyces* sp. and *Pichia pastoris* (13, 70), and other fungi (62) that have found application as hosts for the industrial-scale production of recombinant proteins. Because of their fastidious nature, mammalian cell lines were not historically the first choice for protein production, but as mammalian expression systems and cell culture technology have improved, they have become more and more competitive. There also is increasing scientific and medical interest in complex and/or glycosylated proteins (notably antibodies) best produced in mammalian cells (48). Nevertheless, establishing and maintaining a stable mammalian cell line expressing recombinant proteins remains a technically challenging, lengthy, and quite costly endeavor. In one remarkable improvement of this process, transient transfection or transient gene expression (3), large amounts of relatively inexpensive plasmid DNA are transfected into eukaryotic cells, rapidly but temporarily turning transfected cells into protein production engines. Although the recombinant genetic material is lost from the culture after mitosis, by using optimized vectors and improved transfection protocols and by coexpressing helper proteins, cell densities obtained through transient transfection/transient gene expression can be equivalent to those obtained with stable cell lines (2). So, just as with the above-mentioned *E. coli* systems, these protein production hosts are constantly being optimized in order to yield larger quantities of the target protein at lower cost (21, 98).

52.3. KNOWLEDGE OF THE PROTEIN'S PROPERTIES

It is essential to collect as much information on the protein as possible. Knowledge of almost any characteristic of the protein may find application in the development of a purification process. Much of this information can be obtained using publicly available Internet resources such as Entrez (<http://www.ncbi.nlm.nih.gov/sites/gquery>) or ExPASy

(<http://www.expasy.ch/>). The properties of interest are summarized as follows.

- Source: cell type, expression level, intra/extracellular location, folding state, presence of proteases/glycosidases
- Tolerance of: endogenous proteases, temperature range, pH range, ionic strength, hydrophobic surfaces, cofactor or metal ion loss; freeze-thaw stability (for storage, during and after purification)
- Aggregation tendencies
- Size: molecular weight, amino acid sequence, multimeric state (monomer or homo/heteromultimer), hydrodynamic radius
- Charge: isoelectric point, titration curve, electrophoretic mobility
- Binding partners: substrates and cofactors (and analogs), screening-derived binding agents (antibodies, peptides, aptamers), metal affinity; binding to any of these in immobilized forms for affinity chromatography; stabilizing effects of binding partners

52.4. ASSAY

While a method to monitor the presence of the target protein during the purification protocol is essential, an assay for the desired activity of the protein is also highly desirable. General assays for use in purification must be convenient and rapid; precision is less important. Typical methods include colorimetric assays (Bradford Assay [10]), UV spectrophotometry, visible absorbance of proteins with some cofactors, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), immunological assays (enzyme-linked immunosorbent assay, dot-blot), gel-shift assays, and enzyme activity assays, as well as biosensor testing of fractions (SPR, Biacore, etc.; see below). While in principle these assays have not changed much over the last few decades, improved instrumentation and increased availability of prepackaged chemical detection systems (kits) have made these assays faster and more reproducible and have significantly reduced the amount of sample that has to be sacrificed.

52.5. RECOVERY AND INITIAL ISOLATION

Recovery and initial isolation steps separate the product from the majority of the water in the cultivation medium and from the majority of the host cell components. Recovery of both extracellular and intracellular proteins thus usually begins with the separation of the soluble culture medium from the insoluble cell pellet by centrifugation or filtration.

52.5.1. Concentration

The secretion of the target protein into the extracellular medium is generally desirable, but is rare with *E. coli*. It may require genetic signals to be placed on the target protein, or manipulations of the complex cell secretion machinery. Secreted proteins are naturally separated from most contaminating proteins (i.e., the cell), making purification easier, but requiring concentration of the target protein from a large volume of cell-free culture medium. This concentration step can be achieved by ultrafiltration or adsorption on chromatographic media. Ultrafiltration can be carried out at small scale in centrifugally driven cells, or at larger scale in stirred cells or tangential-flow units (59, 97). Adsorption can employ any of the chemistries noted below, although expensive and/or delicate adsorbents (e.g., immobilized

antibodies) are normally only used for initial capture on the small scale, or for highly unstable proteins. An increasingly popular approach at larger scale is direct protein capture in fluidized beds of dense adsorbent particles from culture media and cell lysates, thus reducing the number of early processing steps.

52.5.2. Cell Lysis

Total lysis of cells is required for the liberation of cytoplasmic proteins. Microbial lysis often employs chemical agents such as chloroform, toluene, SDS, or EDTA. In addition, freeze-thaw cycling and mechanical stress will also aid in this crucial first step of the purification. Enzymes such as lysozyme or nuclease (e.g., Benzonase™) are used to degrade the cell wall (especially of gram-negative organisms) and reduce the viscosity caused by nucleic acids.

Chemical, enzymatic, and freeze-thaw methods are often less than completely effective and may best be used on smaller scales. Mechanical methods include sonication (for small scale), grinding, glass bead mills, the French press, and the Manton-Gaulin homogenizer. Each of these methods affects proteins as well as cells and requires optimization for the optimum recovery of the target protein, but each can give reliable, satisfactory results. The French press in particular is a standard tool for lysis of some tens of grams of wet cell paste by repeatedly forcing cells through a small orifice at high pressure (10,000 to 40,000 lb/in²). Primary isolation yields may benefit from cooling, or from the addition of protease or glycosidase inhibitors. These measures can be particularly valuable with cell lysis using mechanical methods, which tend to heat samples.

Periplasmic proteins can be selectively liberated by osmotic shock, which ruptures only the outer membrane by sudden transfer from hyper- to hypotonic medium. Successful performance and scale-up of this operation can be tricky and may benefit from measurement of release of enzyme activities known to be cytoplasmic (e.g., β -galactosidase) or periplasmic (e.g., alkaline phosphatase).

Cell lysates are unattractive substances, rich in degradative activities, sticky lipids, and viscous nucleic acids along with thousands of protein contaminants. Soluble proteins are often recovered from cell lysates by using precipitation or (less commonly) liquid partitioning, as these methods are tolerant of viscosity, particulates, and fouling. Ribosomes and nucleic acids can first be precipitated with streptomycin, protamine, spermine, or polyethyleneimine (22). The desired protein is often concentrated and partially purified by precipitation with ammonium sulfate or polyethylene glycol (80, 92). The stepwise addition of optimized levels of precipitant can be used for the controlled precipitation of first some contaminants and then, using a higher concentration, the desired protein. Additional contaminants remain in the final supernatant. Exact results depend on the rate of precipitant addition, temperature, mixing, and aging for precipitate formation, but these are generally robust laboratory-scale methods from which partially purified proteins can be recovered at high yields.

52.5.3. Refolding Proteins from Inclusion Bodies

Recombinant proteins expressed in *E. coli* often misfold to form dense, insoluble aggregates of inactive protein (19). Depending on the overall protein concentration, these aggregations might be immediately obvious in the form of visible protein inclusion bodies in the cell, or they can be detected by SDS-PAGE of the soluble and insoluble fractions of a cell lysate. Generally, protein in these inclusion

bodies is inactive and not useful for any kind of enzymatic, mechanistic, or structural investigation. Thus researchers aspire to minimize the formation of inclusion bodies through, for instance, systematic site-directed mutagenesis of the protein sequence, the coexpression of chaperones (folding helper proteins), or the reduction of the temperature at the time of expression, or they undertake to refold the protein to its native conformation (96). Although misfolded, inactive protein in the form of inclusion bodies usually is not directly useful, proteins in inclusion bodies can be harvested rather easily by centrifugation at purities exceeding 70%, and can often be renatured to their native tertiary structure. While there are alternative methods under development (16), the first step in this process is commonly the solubilization of the inclusion bodies in strong chaotropic solutions such as 6 M urea or guanidine hydrochloride (65). After this rapid and reliable first step, the dissolved, denatured protein is then allowed to slowly renature to its native conformation by successively removing the denaturant through dialysis, dilution, or chromatographic separation. In the renaturation step, unimolecular refolding processes must compete with multimolecular reaggregation reactions, so immobilized or highly dilute protein molecules must be used. The development of a process that quantitatively recovers the target protein in its native form can be challenging and is always unpredictable. In many cases, though, a low refolding yield is acceptable because the protein is abundantly available from inclusion bodies in the first place. Thus, large-scale purification protocols for inclusion bodies of commercially attractive proteins, such as human epidermal growth factor (82) or thrombolytic agents (28), are still employed.

Several rules of thumb for refolding have emerged (27, 66):

1. Small, disulfide-free, single-peptide-chain proteins are easiest to refold, but proteins of all types have been refolded.
2. Refold at low protein concentrations.
3. If possible, immobilize the refolding protein by adsorption to prevent multimolecular reactions which promote reaggregation.
4. Control redox potential (through dithiothreitol and β -mercaptoethanol addition) and regulate oxygenation.
5. Add additives such as arginine, polyethylene glycol, or cyclodextrins to suppress aggregation during protein refolding (56, 94).
6. Reduce denaturant concentration in multiple small steps as opposed to one single drastic reduction step.
7. Allow up to 2 to 10 days for refolding.
8. Recycle any reaggregated protein back to the refolding process.

52.6. PROTEIN PURIFICATION

Chromatography is the most common method of preparing highly purified, active proteins (54). Most forms of chromatography involve selective adsorption of proteins on the surface of porous particles, through interactions that can primarily be classified as ion-exchange, hydrophobic, and affinity. Chromatographic operations are also classified as low-pressure, medium-pressure (including GE Healthcare's popular ÄKTA), and high-pressure (high-pressure liquid chromatography [HPLC]), depending on the pressure used to force liquid through the packed bed of adsorbent particles (Table 1). In general, high pressures imply higher costs but also finer adsorbent particles and better resolving power.

TABLE 1 Types of liquid chromatography

Feature	Low-pressure	Medium-pressure	High-pressure (HPLC)
Particle size	40–150 μm	10–75 μm	2–15 μm
Flow driver	Gravity, peristaltic	Piston or syringe	Positive displacement
Run time	40–1,000 min	15–60 min	0.5–30 min
Apparatus cost	Low	Medium–high	High
Resolving power	Lowest	Intermediate	Highest
Particulate tolerance	Low	Very low	Lowest

Samples loaded onto high- and medium-pressure columns must be rigorously free of particulates.

In addition to the adsorbent matrix, an apparatus for chromatography includes a column into which the particles are packed (glass, plastic, or steel, depending on operating pressure), a pump or height differential to drive liquid flow, some method for introducing the sample into the flow before the column (a switching valve, or manual pipetting onto the top of the packed bed), and a fraction collector that deposits the emerging, fractionated proteins into different vessels. Possible enhancements include UV and visual absorbance detectors for monitoring the emergence of the various proteins from the column, a conductivity monitor for tracking changes in salt concentration used to elute proteins from the column (especially in ion-exchange chromatography), and a computer for control and evaluation of the results. Large-scale operations frequently use step changes in elution conditions, and valves to direct individual fractions to separate vessels.

Not all adsorptive separations involve particles in a column (71). Particles can be used for batch adsorption by gently mixing them into a solution containing proteins to be captured or by suspending dense particles in upflowing liquid in a fluidized bed. The resolution obtained in this manner is low, but the method is tolerant of fouling and fine particulates and can easily be applied to large volumes of solution. Nonparticulate supports, notably membranes, are available in many of the surface chemistries discussed below. These yield rapid adsorption and desorption kinetics, albeit at reduced capacities which may be balanced by rapid cycling (9, 77).

There are a variety of excellent references for the methodological details of chromatographic separation of proteins (see below); the present discussion will address general characteristics, along with some guidelines for method development.

52.6.1. Ion-Exchange Chromatography

Ion-exchange chromatography (1) is the most common high-resolution method for preparative separation of proteins and is used in most protocols (Table 2). It will be discussed in particular detail because of its importance, and also to illustrate the general issues involved in the development of chromatographic separations. Adsorbents with fixed positive charges (immobilized amines, e.g., DEAE, quaternary methylammonium) are called anion exchangers and are employed at pH values above the isoelectric point of the protein to be adsorbed so that the protein's net charge will be of opposite sign to that of the adsorbent. Matrices bearing negative charges (carboxylates and sulfonates, e.g., carboxymethyl and sulfo-propyl) are called cation exchangers and are used at lower pH values. In practice, the protein of interest is usually adsorbed rather than passed through the column, as higher resolution and some degree of concentration can be achieved. Ion-exchange adsorption depends strongly on the ionic strength (I), equal to half the sum of the concentrations of all ions present, each multiplied by the square of the ion's charge. For 1 M NaCl, $I = 1$ M; for 1 M $(\text{NH}_4)_2\text{SO}_4$, $I = 3$ M. Initial trials might employ ionic strengths of 10 to 100 mM for loading and a gradient increasing to 1 M for elution.

The combinations of pH and matrix type (anion or cation exchange) at which the protein will be adsorbed can be predicted with some confidence from its isoelectric point (pI), although the detailed distribution of charges on the protein's surface plays a role (72), as do nonspecific interactions with the adsorbent backbone. If the pI is not known, it can sometimes be measured through isoelectric focusing (IEF) electrophoresis, or estimated from the sequence using services widely available online, for instance at the ExPASy Proteomics Server (<http://www.expasy.ch/>). Otherwise, a sample containing the protein is loaded (at low ionic strength) on an anion-exchange column at the lowest pH at which it is known to be stable, or on a cation-exchange

TABLE 2 Modes of adsorptive chromatography

Feature	Ion-exchange	Hydrophobic	Metal chelate	Biospecific
Adsorbent	Carboxyl, amine, sulfonate	Propyl, butyl, phenyl	Chelator, loaded with Cu^{2+} , Ni^{2+} , Zn^{2+}	Antibody, cofactor, receptor
Selectivity	Moderate–high	Moderate–high	Moderate–high	High–very high
Capacity	High	High	Moderate–high	Moderate–high
Matrix cost	Low	Low	Moderate	High
Elution	High salt, pH	Low salt	pH, imidazole	pH, chaotrope
Initial salt	Low	High	Indifferent	Often indifferent

column at its highest stable pH. The column is then washed with 2 to 3 volumes of the starting buffer, or until the initial peak of nonbinding protein has fallen to baseline. Most proteins will be retained on the column and can be eluted with a gradient of increasing salt concentration up to 1 to 2 M applied over a volume 5 to 10 times that of the column packing volume. Failure to quantitatively bind all protein can be due to overloading of the column (5 to 10 mg of total protein per ml of column packing is a conservative starting point); high loading ionic strength; failure to regenerate the column sufficiently at low ionic strength after the previous elution (this can require more than 5 column volumes of low-salt buffer and is ideally verified using a conductivity monitor); instability of the protein while adsorbed (this can improve at lower temperatures, or with slightly increased loading ionic strengths); or instability at too extreme a loading pH.

Optimization of the method involves increasing the fraction of the protein recovered in active form, the purity of the recovered material, and the rate at which purified protein is isolated (through loading of larger samples or shorter separation times). Steps to optimize process development often include loading under less permissive conditions (higher salt, pH closer to neutrality) to cause more contaminants to wash through unadsorbed; higher operating temperatures; faster liquid flow rates (to the limits specified by the adsorbent manufacturer); and testing of shorter gradients or gradients tailored to be shallow only near the ionic strength at which the protein of interest is eluted.

52.6.2. Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) (35) exploits the presence of exposed hydrophobic groups on the surfaces of proteins, which can interact with immobilized nonpolar moieties such as short alkyl chains and phenyl rings (i.e., immobilized propane and benzene). Adsorption is promoted by high ionic strength, and elution often employs a salt gradient of decreasing concentration. As burial of nonpolar groups is a major contributor to protein stability, there is reason for concern that exposure to hydrophobic surfaces may be denaturing. Many very-hydrophobic polymer surfaces are in fact rapidly coated with denatured protein, making this a major constraint on the selection of support materials for chromatographic matrices. Isolated hydrophobic groups sparsely immobilized on polar supports such as polysaccharides and acrylates, however, are not nearly as denaturing as bulk materials, and recoveries of many proteins from optimized hydrophobic separations can approach 100%. The cost and capacity of HIC matrices are attractive, as is the method's tolerance of high salt concentrations, which can allow immediate processing of proteins eluted in high salt from a previous ion-exchange

chromatography or ammonium sulfate precipitation step. HIC is widely used in industrial processes and is probably underutilized in academic laboratories.

52.6.3. Affinity Chromatography

The remaining adsorptive techniques are affinity methods, which exploit selective interactions characteristic of biological systems. The normal biological functions of many proteins depend on their ability to associate with substrates, cofactors, etc., and proteins often will bind selectively to immobilized forms of these partners. Alternatively, an affinity agent such as an antibody can be used to selectively capture the protein of interest. Finally, it has become increasingly popular to append DNA encoding a "purification handle" protein with affinity for an available ligand to the gene encoding a recombinant protein of interest. The resulting fusion protein can then be purified by its affinity for this ligand. The purification tag sequence can often be removed posttranslationally by proteolysis using site-specific proteases, or left in place for many applications. In one particular system, intein and a chitin binding tag are fused to the protein of interest. The recombinant protein is then adsorbed to a chitin column, and intein-mediated self-cleavage of the tag occurs upon addition of thiols (e.g., dithiothreitol), releasing the tag-free protein into the eluate (14). Typical purification handles are listed in Table 3.

The most commonly used type of affinity chromatography is probably immobilized-metal affinity chromatography, or IMAC. It exploits the affinity of certain chelated metal ions (e.g., Ni^{2+} and Zn^{2+}) for the amino acid side chains of cysteine and especially histidine. Elution is achieved by pH gradient or the addition of competitive metal-chelating compounds such as imidazole. IMAC adsorbent matrices are relatively inexpensive and robust, and selectivity can be high. The method is also tolerant of variations in ionic strength.

Biospecific affinity chromatography describes separations based on molecular recognition interactions normally found in nature, such as antibody/antigen, enzyme/cofactor, and hormone/receptor affinity (89). Many widely applicable premade affinity matrices (at least 50 types) are commercially available. Among the most popular affinity methods are Cibacron Blue dye affinity for purification of enzymes binding ATP or NAD(P)(H), to which this textile dye bears a coincidental structural resemblance, and chromatography on protein A of *Staphylococcus aureus* for purification of antibodies (32, 43, 50). There are also many "activated" matrices on the market that have been chemically derivatized for facile coupling of affinity ligands through surface amines and carbohydrate groups.

The selectivity of affinity separations can be enormously high. This advantage is somewhat balanced in certain cases

TABLE 3 Affinity chromatography using protein tags

Protein tag	Affinity medium	Eluent	Reference(s)
Polyhistidine	(Cu^{2+} , Ni^{2+} , Zn^{2+})-charged agarose	Imidazole	4, 45
Glutathione-S-transferase	Glutathione agarose	Glutathione (reduced)	86
Maltose binding protein	Dextrin agarose	Maltose	75
Strep(II)-peptide	StrepTactin agarose	Desthiobiotin	79
F_c (antibody constant region)	Protein A/G	Citric acid, glycine (pH \leq 3)	5, 26
Intein-chitin binding domain	Chitin	Thiols	14

by the cost and delay of obtaining and coupling suitable ligands. Also, the harsh conditions that may be required for elution of the bound protein can damage both target protein and affinity column. An active area of development in purification technology is the screening of large numbers of potential ligands, including phage-displayed peptides, aptamers, and small organic molecules, for use as improved affinity separation ligands (76).

From a commercial aspect, it appears that the purification of antibodies is attracting particularly strong interest. Human immunoglobulin (polyclonal immunoglobulin G [IgG]) for the treatment of immune deficiencies is prepared from human plasma through cold ethanol precipitation and purified from contaminating molecules such as IgM by anion-exchange chromatography (44). In addition to IgG, there are currently 23 other antibody-based drugs on the market (49), and an expansion of this arsenal is likely. These therapeutic monoclonal antibodies are produced recombinantly in large (>10,000-liter) Chinese hamster or mouse cell cultures. After the monoclonal antibodies are separated from the host cells by centrifugation and filtration, most remaining contaminants (>98%) are removed by protein A affinity chromatography (103). Commonly, one or more additional chromatography steps, such as ion-exchange chromatography, are then employed to generate the final product. A crucial element in all pharmaceutical purification protocols is the removal of viral particles. Virus inactivation is achieved by heat, nanofiltration (64), or UV light treatment (78). Historically, lipid-enveloped viruses (e.g., human immunodeficiency virus and hepatitis type C virus) have also been removed from therapeutic protein preparations by solvent/detergent treatment (31).

52.6.4. Size-Exclusion Chromatography

Size-exclusion chromatography (SEC; also known as gel filtration or molecular sieve chromatography) differs from the absorptive methods in that protein interactions with the chromatographic matrix are not exploited, but minimized (34). SEC media display pores of varying sizes, and differential access to these pores is the basis of separation. Large molecules run faster, as they enter fewer pores and flow through an effectively smaller volume. All molecules above a certain size run together, “excluded,” as they enter very few pores. Small molecules below the “included” size limit run together, exploring nearly all pores. Useful resolving power is confined to a range of hydrodynamic radii (not molecular weights) between the effective sizes of the largest and smallest pores; matrices of differing average pore size are used to purify proteins of different sizes. The inclusion and exclusion limits of a given matrix are given by the manufacturer. It is important to remember that larger molecules run faster (the opposite of a sieve or filter) and that separation is on the basis of molecular radius, not molecular weight. This implies that an elongated protein runs more rapidly than a compact globular protein of the same molecular weight, and both run much more slowly than a high-aspect-ratio nucleic acid or random coil carbohydrate of the same molecular weight as the proteins.

SEC has relatively low sample capacity, and the packing and sample loading of long, narrow SEC columns is more demanding than preparation of relatively squat columns of adsorptive media. It is well worth testing the quality of a newly packed SEC column using a tracer such as acetone or blue dextran. SEC is a gentle, nondenaturing method, and in contrast to most methods is capable of removing aggregated forms from nearly pure protein samples. An SEC column can be “calibrated” by running a set of proteins

differing in molecular weight, but all of similar shape (in usual practice, all globular). The retention times will ideally give a linear dependence on the logarithm of the molecular weight of the protein (deviations often indicate interactions with the matrix, which can be suppressed by adding salts or traces of organic solvents to the running buffer). The retention time of the unknown protein indicates its largest dimension. This information is especially valuable if it can be compared with the molecular weight obtained through (denaturing) SDS-PAGE, as large differences in the results of the two methods can often be the first sign of aggregation or multimerization.

52.6.5. Field-Flow Fractionation

Field-flow fractionation is a means to separate complex mixtures of proteins (and particles) based upon their difference in the diffusion coefficient, which itself is determined by their hydrodynamic size (36). In this method, proteins are separated in a field-flow fractionation channel in lieu of a chromatographic column, so no specific adsorbents such as gel matrixes are required. In addition, proteins can be analyzed under physiological conditions. Today, field-flow fractionation is often coupled with further, more sensitive analytical methods such as mass spectrometry (MS) or capillary isoelectric focusing (73).

52.6.6. High-Throughput Protein Purification

The recent improvements in DNA sequencing have given rise to an exponential increase in the amount of information on genomes and transcriptomes from all kingdoms. So-called “next-generation sequencing” platforms generate gigabytes of nucleic acid information per day, and the technology is advancing rapidly. Many of these nucleic acid sequences may in silico appear to encode promising new protein products, but unless they are actually translated and the protein is purified and characterized, no final decision on the real value of any individual protein can be made. Traditional protein purification methods often constitute the bottleneck in this process, delaying the discovery of potential new protein products and the advancement of biological understanding.

In an effort to address this problem, in recent years more and more automated protein purification platforms have entered the marketplace. The inherent diversity of protein molecules makes the parallel processing of a mixed batch very challenging, if not impossible. This problem is circumvented by the (genetic) addition of tags such as polyhistidine or protein A to all proteins of interest. The resulting pool of proteins can then be purified by a single type of affinity chromatography (e.g., IMAC or IgG affinity) using, for instance, magnetic particles. Using a microtiter plate format, for example, 96 individual recombinant *E. coli* colonies each expressing a different open reading frame can be grown in parallel and chemically lysed. The crude extract is purified in a mobile solid-phase approach using paramagnetic affinity particles. During the purification, the bead-bound protein of interest can easily be separated from the nonmagnetic proteins of the host cell by applying a magnetic field. The field can be removed for washes and elutions. Eventually the protein of interest can be eluted from the beads. Robotic pipetting systems such as Qiagen’s BioSprint or Beckman Coulter’s Biomek® make this parallel and exploratory approach even more reliable and rapidly yield purified proteins.

Other instruments such as BioRad’s Profinia™ protein purification system employ the same principal approach

of purifying tagged proteins by affinity chromatography on a somewhat larger scale. The purification process is automated and monitored by UV absorption, and the protein of interest is automatically separated from the background. While these systems do not allow the parallel processing of more than a few proteins at a time, they yield much larger quantities of the target protein than the microtiter plate purification described above.

Probably the most commonly found instruments in the protein purification laboratory and increasingly also in large-scale protein purification facilities are GE Healthcare's ÄKTA™ automated liquid chromatography systems. These devices use the same chromatographic media as in standard chromatography, but can conduct automatic screening for optimized purification conditions, provide better buffer control, and allow the combination of multiple purification steps into one automated purification protocol. While this family of instruments comprises platforms for purification from bench to industrial scale, the relatively high initial investment may make them cost-prohibitive for smaller laboratories.

52.6.7. Industrial-Scale Protein Purification

While the above-mentioned methods are all generally applicable to large, industrial-scale purification processes, the focus in these protocols is slightly shifted. For instance, scaling up the initial steps of a protein isolation protocol from an Erlenmeyer flask to a fermentor requires a much stronger emphasis on highly efficient protein concentration methods that can process volumes of 10,000 to 300,000 liters. Thus, these large volumes are almost always concentrated by various cell-centrifugation and filtration processes before any kind of chromatographic purification is undertaken (for some examples of industrial-scale protein purifications see references 45, 50, 54, and 85).

Given the inherently diverse nature of proteins—every protein purification protocol is probably to some extent unique, and often requires the specific adaptation of a particular set of methods—a few general rules for protein purification can be summarized as follows.

1. Tailor the process to the intended purpose. Do not over-purify, and focus on the contaminants that matter in the planned application.
2. Establish a convenient assay.
3. Select the right source of raw material, and use sufficient amounts.
4. Work quickly, or in the cold, or both.
5. Eliminate proteases early through host selection, separation, or inhibition.
6. Identify stable intermediate storage forms.
7. Avoid freeze-thaw cycles.
8. Use columns of appropriate capacity.
9. Build on previous work.

52.7. PRODUCT CHARACTERIZATION

Complete characterization of the purified product involves study of the idiosyncratic activities of each protein, which are beyond the scope of this chapter. There are also, however, general structural properties that are subject to determination by generic methods (13, 16, 26).

52.7.1. Electrophoresis

Probably the most common method of protein characterization is SDS-PAGE, which gives the molecular weight(s) of the peptide chain(s) of the protein as well as

a good indication of the purity of the sample (33). SDS converts nearly all protein into regular rodlike forms of constant charge per unit mass, so that electrophoretic mobility is independent of amino acid composition. The polyacrylamide gel serves to suppress mixing induced by temperature gradients arising from the heating associated with current flow, which would reduce resolution. SDS-PAGE can use commercial precast gels, or gels can be cast at the time of use. Related electrophoretic methods include IEF (39, 40), for measuring isoelectric point; native gel electrophoresis, in which proteins are not denatured with SDS; and two-dimensional gel electrophoresis (12, 47), in which IEF separation by charge is combined with orthogonal separation by mass using SDS-PAGE. Native electrophoresis and IEF also show promise as preparative methods (30, 81).

Capillary electrophoresis is conducted in tubing (or chip microchannels, e.g., the popular Agilent Bioanalyzer) of very small diameter (<100 μm) using high voltages (e.g., 30 kV). Capillary electrophoresis can achieve very high resolution in analytical separations, requiring only a few minutes (33).

52.7.2. Peptide Sequencing

The classic Edman degradation (25), albeit in an automated way, is still being used to identify the N-terminal amino acid residues of peptides (87). Most workers will choose to have this procedure performed by a specialist core facility. This sequence information can be used to confirm the identity of the protein; to establish the degree of removal of N-terminal methionines, purification handles, or secretion leader peptides; and to detect exoproteolytic degradation. Protein sequencing depends on sequential, stepwise removal of N-terminal amino acids in the form of labeled derivatives that are separated by HPLC and identified by their characteristic retention times. Blocked N termini are not uncommon and require removal of the blockage, isolation and sequencing of internal peptides, or use of MS sequencing as discussed below. Many applications of protein sequencing are now being replaced by MS (88).

52.7.3. Tryptic Mapping

Tryptic mapping, in which small peptides derived from a protein by endoprotease (e.g., trypsin) action are separated by high-resolution reverse-phase HPLC or MS, allows sensitive detection of variations in protein (especially pharmaceutical) preparations (51, 84). Individual peptides can be subjected to sequencing as described above (e.g., avoiding problems with blocked N termini) or, more commonly nowadays, MS to confirm the identity of a given peptide, to develop information for DNA probe development, or even to establish the entire sequence of the protein, often with the aid of peptide fragment databases, which are increasingly derived from genome sequences.

52.7.4. Analytical Ultracentrifugation

In protein purification, analytical ultracentrifugation is a powerful tool for understanding protein association in solution under physiological conditions (6). This technique, which requires considerable investment in equipment and training, allows measurement of a variety of properties of a protein sample, including solution molecular weight, self-association, interaction with other molecules, and sample homogeneity. In principle, samples are analyzed either by sedimentation velocity, a hydrodynamic method,

or sedimentation equilibrium analysis, a thermodynamic method (46). Sedimentation velocity, a high-speed centrifugation method, is used to determine the mass of a sample, detect aggregates, verify the homogeneity of a sample, and allow some estimation of the shape of protein molecules. Sedimentation equilibrium, a low-speed centrifugation method, is also used to measure protein molecular masses in solution, but is most suitable to determine the stoichiometry between different proteins, for instance, between a receptor and its ligand. With modern instruments, samples can now be analyzed in real time using either absorbance, interference, or fluorescence (17).

52.7.5. Spectroscopy

Circular dichroism gives an indication of the fraction of the polypeptide that is composed of specific secondary structural features, such as α -helix and β -sheet. Raman spectroscopy has been used (less widely) for similar purposes and especially for characterizing metal-containing protein cofactors (41, 58).

52.7.6. Dynamic Light Scattering

Small particles such as globular proteins move in solution in a random pattern described as Brownian motion. In dynamic light scattering (DLS), a laser light of a known wavelength is directed at a protein solution and the shift in light frequency caused by the particles in the solution is measured by a fast photon counter (7). The shift in frequency is inversely proportional to the hydrodynamic or Stokes radius of the protein. Since DLS only provides an averaged value for the whole solution, the sample under investigation has to be pure and cannot contain heterogeneous mixtures of different proteins. The advantages of DLS are that it is nondestructive, and it can be performed in solution, in real time. This provides for immediate results (as opposed to, for instance, lengthy analytical centrifugations) and allows the direct monitoring of protein binding events when two defined samples are mixed in the DLS reaction cuvette.

52.7.7. Biosensors

Biosensor devices such as GE Healthcare's BIAcore, NeoSensors' IASys instrument, and Sensata's Spreeta sensor, are now widely used for detecting and characterizing intermolecular interactions. These devices allow the label-free, continuous detection of proteins, cells, or nucleic acids present in a narrow region adjacent to a gold-coated detector surface that is permanently targeted by a laser light. After the molecules of interest (the *ligands*) have been chemically immobilized on the sensor, their putative binding partners (the *analytes*) can be passed over the sensor. The chemistries involved are derived from those of affinity chromatography and are now generally well characterized by the instrument manufacturers. For a signal to be produced, a meaningful amount of mass must be captured by the interaction.

For example, in studying the interaction of an antibody with a small hapten or antigen, it would be better to immobilize the hapten, i.e. make it the ligand, and capture the much larger antibody, as capturing the hapten might not produce a useful signal. The binding of the analyte to the ligand changes the refractive index of the surface, proportional to the molecular weight of the analyte, thus allowing the determination of the concentration of the analyte. Because of their sensitivity, low material consumption, and convenience, these devices are very useful for tracking the desired protein in the course of purification.

They have an equally important role in characterizing the purified protein, helping to identify specific binding pairs such as antibodies and antigens or receptors and their agonists or antagonists (for an excellent, topical review on current applications, see reference 23). Since all binding events are detected in real time, complex kinetic studies are often conducted using surface plasmon resonance instruments. It is necessary, however, to guard against the often severe effects of mass transfer limitations (15). This becomes an issue when the transfer of the analyte from the bulk solution to the sensor surface is slower than its actual binding to the ligand, resulting in a shortage of analyte at the sensor surface. These and other errors (rebinding, avidity effects of multivalency, e.g., with antibodies) have been reduced as users have become more familiar with these devices.

52.7.8. Analysis of Glycosylation

Analysis of glycosylation is an actively developing field, in particular because the comprehensive study of all glycoproteins in an organism (*glycomics*) has recently attracted heightened interest. The characterization of glycoproteins, however, remains quite challenging. Many eukaryotic (and a few prokaryotic) proteins contain sugars, which are sometimes essential to the protein's function. For instance, we now know that glycosylated proteins are involved in a wide variety of crucial molecular recognition events. Available methods include stains and blots for detection of glycosylation, deglycosylating enzymes, sugar-specific lectins for blotting and separations (42), and nuclear magnetic resonance and MS methods of characterizing individual side chains (61, 102).

52.7.9. Mass Spectrometry

With the tremendous growth in the field of proteomics, MS has blossomed in recent years into an indispensable tool for the identification of complex protein samples, with market growth driving continuing advances in instrumentation and methods of sample introduction (24, 52). While a family of related MS techniques exists, the present discussion will introduce the uses of MS as a class of methods, all of which are driven by the ability to determine the mass of proteins and peptides with remarkable precision, of the order of a few hydrogen atoms in a typical protein. The technique, therefore, can detect and characterize almost any important modification or variation in a protein's covalent structure. These include posttranslational modifications, such as glycosylation, N-terminal methionine addition or removal, methionine oxidation, proteolytic trimming, and many sequence mutations and deamidation events. Because these modifications are detected without being specifically looked for, MS is an excellent way to characterize any newly purified protein.

As mentioned above, in the era of proteomics (and post-proteomics) MS has advanced into new applications. These include protein sequencing, on-line coupling to HPLC and capillary electrophoresis, and identification of "hits" from combinatorial libraries. A new application driven by the availability of genome sequences and cDNA libraries is the identification of unknown proteins separated by electrophoresis or HPLC from a diseased tissue, or a cell line exposed to an agent thought to alter expression of one or more genes. MS determination of the molecular weight of a protein showing interesting behavior (or, if digestion can be done, of one or more peptides derived from the protein)

gives mass values that can then be searched against the (large) database of all proteins/peptides encoded by that genome or cDNA bank. This type of search can often be successful and in many cases will avoid the need to purify the protein in question at all.

52.7.10. Calorimetry

Calorimetry is a label-free method that is unique in that it allows the direct measurements of thermodynamic binding constants, reaction stoichiometry, enthalpy (ΔH), and entropy (ΔS) during a protein-protein interaction. Isothermal titration calorimetry (ITC) (69) is the most quantitative means available for directly measuring the thermodynamic properties of a protein-protein interaction. An ITC instrument measures the heat evolved on association of a ligand with its binding partner. A typical ITC instrument thus contains two reaction chambers, a sample and a reference cell, whose temperatures are monitored continuously. Any tiny change in temperature between sample and reference cell is compensated by a heating device in the ITC instrument. The power necessary to perform this compensation provides a measurable value that can be used to infer the reaction kinetics.

In differential scanning calorimetry (11), a protein is heated at a constant rate. When the protein becomes thermally denatured there is a measurable heat change. The instrument thus reports the enthalpy (ΔH) of unfolding due to heat denaturation. A characteristic reporting value from a differential scanning calorimetry experiment is the *thermal transition midpoint* (T_m), where 50% of the biomolecules are unfolded. The more stabilizing the intra- and intermolecular forces within a given protein molecule, the higher the T_m .

52.7.11. Protein Structure Determination

The ultimate way to characterize and understand a protein and its interactions with its substrate, cofactors, or other proteins is through nuclear magnetic resonance (NMR) spectroscopy and X-ray crystallography. NMR (63, 68, 99) is a particularly powerful tool in understanding the dynamic interaction of proteins with ligands in solution (101). This nondestructive method was originally limited to small molecules but, in certain cases, has been adapted to analyze molecules as large as 900 kDa (29, 95). While NMR can be used at many stages of the protein characterization process, it has a found a distinctly strong role in screening potential protein ligands during the drug discovery process (67).

X-ray crystallography has long had the reputation of being an inherently slow process that is more of an art than a scientific method. However, in recent years remarkable advances in this technology have been achieved. This is probably most evident by the increase of protein structures deposited in the Protein Database (55). Nearly every step of X-ray crystallography can now be automated. Robots perform the parallel expression and purification of proteins. Each protein is then screened for crystal formation in a sparse matrix approach using approximately 100 conditions of various buffers, precipitants, and additives. Once again, robots perform the pipetting steps, and cameras screen the reaction compartments for crystallization products. However, even with these recent advances, most X-ray structures still require time-consuming hands-on optimization of the crystallization conditions and interpretation of the diffraction patterns. Realistically, as shown by a 2007

survey of structural genomics centers worldwide (55), still only a small fraction (13%) of all soluble proteins can be crystallized right away.

Subject Index

- A**
A54145, genetic engineering of, 391–410
 cloning in, 391–395
 combinatorial biosynthesis in, 399–406
 expression systems for, 396–399
 gene clusters in, 394, 396
 novel products in, 399–406
Abacavir, production of, 486–487
Aber Instruments biomass sensors, 708
Abiotic elicitors, 207
Abyssomicin C, 15
Accessory enzymes and proteins, 502–503
Acetic acid
 as inhibitor, in ethanol production, 616
 production of, 591–593
Acetohydroxy acid synthase, in valine production, 596
Acetyl coenzyme A
 in amorpha-4,11-diene synthesis, 365–375
 in isoprenoid production, 599–601
Acetyl xylan esterase, 501–502
O-Acetylserine sulfhydrylases, in amino acid production, 596
Achromobacter obae, ACL racemase of, 449
Achromobacter xylosoxydans, in hydroxy-nicotinic acid production, 482
Acid pretreatment, of lignocellulose feedstock, 622
Acidobacteria, isolation of, in diffusion chamber, 6
Acidophiles, enzymes of
 assays for, 54–55
 host-vector systems for, 53
 sampling of, 45
Acidovorax, enzymes of, 443
Acidovorax facilis, nitrilases of, in 1,5-dimethyl-2-piperidone production, 482
ACL hydrolase, functions of, 449
ACL racemase, functions of, 449
Acrylamide, production of
 biocatalysis in, 481–482
 nitrile hydratase in, 441–442
Acrylonitrile, in acrylamide production, 481–482
Actinobacteria
 in cellulose degradation, 566
 microbial trap isolation of, 10
 selective isolation of, 13–27
 colony selection in, 17–18
 incubation of, 17
 integrated procedures for, 20–21
 media for, 17–19
 samples for, 13, 15–16
 taxa recognition in, 19–20
 suborders of, 14
Actinomyces, in cellulose degradation, 566
Actinomycetes
 gene cloning in, 352
 isolation of, in microbial trap, 10
 miniaturized fermentation of, 110–114
Activated charcoal, in plant cell culture, 199
Activity screening, for cellulose-degrading enzymes, 573–574
Actuation, in automated bioreactors, 728–729
Acyases, in chiral amino acid production, 483–485
Acylation, in hydrolase activity, 513–517
N-Acyyl-D-amino acid amidohydrolase, functions of, 449
N-Acyyl-D-amino acid racemase, functions of, 449
Adaptability, genetic, in robustness, 606
ADE1 gene, of nonconventional yeasts, in heterologous product expression, 303
ADH genes, of nonconventional yeasts, in heterologous product expression, 305
Adipic acid, production of, 598
Adiponitrile, in cyanoveramide production, 482
Adsorptive chromatography, for protein purification, 734–738
Aeration
 for mammalian cell culture, 678–679
 for plant cell culture, 201–202
 for solid-phase fermentation, 120
Aerobic fermentation, solid-phase, *see* Solid-phase fermentation
Affinity chromatography
 for mammalian cell culture, 180–181
 for protein purification, 736–737
Agar, in plant cell culture, 199
Agar diffusion assay, for antibiotics, 67–68
Agar plug method, for secondary metabolites, 74
Agarose-based resins, in mammalian cell culture, 181
Aggregation, of enzymes, in nonaqueous transformations, 511
Agilent 2100 Bioanalyzer, for peptides and proteins, 712–713
Agitation, *see* Mixing
Aglycone exchange, 357–358
Agrobacterium
 N-carbamoyl-D-amino acid decarbamoylase of, 447
 genetic engineering of, 321
Agrobacterium radiobacter
 haloalcohol dehydrogenase of, 529–530
 halohydrin dehalogenase of, 488
Agrobacterium tumefaciens, in plant cell transformation, 208
Airflow, for fermentation, 670
Airlift bioreactors
 for insect cell culture, 215–216
 for mammalian cell culture, 676
AKTA protein-purification system, 738
L-Ala-L-Gln dipeptide, production of, 445–446
Alanine, production of, 595–596
L-Alanine, production of, 141
alcA promoter, in heterologous protein expression, 151
Alcohol(s)
 in beverages, fermentation improvement for, 610–612
 enantioselective resolution of, 513–514
Alcohol oxidase gene, in heterologous protein expression, 148–149
Alcohol oxidoreductase, of extremophiles, screens for, 57
Aldol condensations, *Candida antarctica* lipase B in, 526–527
Aldoxime dehydratase, in nitrile synthesis, 443
Algal culture, 577–590
 algal types for, 577–580
 benefits of, 577
 biomass measurement from, 585
 carbon dioxide provision for, 582
 from culture collections, 580–581
 gas-liquid transfer in, 582
 harvesting of, 580
 hydrodynamics of, 582

- Algal culture (*continued*)
 kinetics of, 585–587
 laboratory systems for, 583
 large-scale systems for, 583–585
 light requirements for, 581–582
 lipid formation in, 587–589
 maintenance of, 581
 maximizing fixation and product formation in, 587–589
 medium for, 582–583
 monoculture preparation for, 580–581
 from natural habitats, 580–581
 nutrients for, 582–583
 physiologic conditions for, 583
 potential products from, 577
 productivity measurement in, 585–587
 resources for, 577–581
 species selection for, 577
 variables in, 581
- Alicyclobacillus acidocalderius*,
 endo-mannanases of, 499
- Alkaline D-peptidase, functions of, 449
- Alkaline lysis method, for *Clostridium*
 DNA extraction, 241
- Alkaline phosphatase
 in mammalian cell genetic engineering, 341
 promiscuity of, 531–533
- Alkalophiles, enzymes of
 assays for, 54–55
 host-vector systems for, 53
- Alkene monooxygenase, for terminal
 epoxide production, 483
- Allelic exchange, in myxobacteria,
 265–268
- Altman approach, for alanine production,
 595–596
- Alzheimer's disease, drugs for, 488
- Ambruticin, novel analogs of, 433–436
- amdS* gene, of filamentous fungi, in
 heterologous product expression,
 320–321
- Amidase, in chiral amino acid production,
 484–485
- Amines
 enantioselective resolution of, 513–515
 enzymes modified with, in nonaqueous
 transformations, 511
- Amino acid(s), *see also individual amino acids*
 production of, 449
 aromatic, 597–599
 chiral, 483–485
Escherichia coli in, 595–596
 in mammalian cell culture, 681
 robustness improvement for, 612–613
 unnatural, 596
- D-Amino acid amidase, functions of, 449
- D-Amino acid dehydrogenase, production
 of, 447–448
- 7-Aminocephalosporanic acid, production
 of, 485
- 7-Aminodesacetoxycephalosporanic acid,
 production of, 485
- Aminoglycoside-3-phosphotransferase,
 of nonconventional yeasts, in
 heterologous product expression, 304
- 12-Aminolauric acid, synthesis of,
 ω -laurolactam hydrolase in, 443
- 6-Aminopenicillanic acid, production of, 485
- D-Aminopeptidase, functions of, 449
- Ammonia, formation of, in mammalian
 cell culture, 681
- Ammonia fiber explosion pretreatment, of
 lignocellulose feedstock, 622–623
- Ammonia recycle percolation
 pretreatment, of lignocellulose
 feedstock, 622–623
- Ammonium salts, in fermentation media,
 663–664
- Amorpha-4,11-diene, 364–379
 biosynthesis of, 364–365
 incorporation into *Escherichia coli*,
 365–366
 increased production of, 372–374
 oxidation of, 373, 375
 pathway optimization for, 367–372
 production of, 142
- Amorpha-4,11-diene oxidase, 373, 375
- Amorphadiene synthase, 371–372
- Amorpha-4,11-diene synthase, 365–367
- Amoxicillin, production of, 485
- Ampicillin, production of, 485
- Amplification by ligation, for cellulose-
 degrading enzymes, 571–572
- Amplified-rDNA restriction analysis, for
 taxonomy, 35
- Amycolatopsis*, selective isolation of, 19, 21
- Amycolatopsis orientalis* subsp. *lurida*,
 racemase of, in chiral amino acid
 production, 484
- Amylase(s), 503–505
 of extremophiles, 55
 production of, 489–490
- α -Amylases, 503–504
- β -Amylases, 504
- Amyloglucosidase (glucoamylase), 504
- Anaerobic bacteria, in cellulose
 degradation, 566
- Anaerobic fermentation, solid-phase,
see Solid-phase fermentation
- Anaerocellum thermophilum*, in cellulose
 degradation, 565–566
- Analog signal conversion, for automated
 bioreactors, 728–729
- Analytical ultracentrifugation, for protein
 characterization, 738–739
- Angucyclines, 349
- Animal(s), cellulose degradation in, 565
- Animal cell culture, *see* Continuous
 culture; Insect cell culture;
 Mammalian cell culture
- Anion-exchange chromatography, for
 mammalian cell culture, 180
- Antibiotics, *see also specific antibiotics*
 in actinobacteria selection, 17, 18
 glycosylated, 347–363
 production of, in solid-phase
 fermentation, 121–123
 screening for, 62–72
 algorithm for, 65, 69
 assay development and validation
 in, 64–65
 assay types in, 65–68
 cell-free vs. cell-based, 63
 effectiveness of, 62
 evaluating hits in, 69–70
 goals of, 62
 novel elements of, 63–64
 sample selection for, 68–69
 strain selection for, 68–69
 strategies for, 62–63
 target identification in, 64
- Antibodies, monoclonal, production
 of, mammalian cell culture for,
see Mammalian cell culture
- Anticancer agents, from *Clostridium*, 249, 253
- Antimalarial drugs, artemisinin, 141, 142,
 364–379
- Antisense assays, for antibiotics, 65–68
- Antisense RNA technology, for
Clostridium, 248–249
- Antiviral drugs, production of, 486–487
- AOX1 gene, in heterologous product
 expression, 148–149, 305
- Apoptosis, prevention of, in mammalian
 cell lines, 165
- Apramycin, as selectable marker, 264
- Aquasant biomass sensors, 709
- Arabidopsis thaliana*, arabinofuranosidases
 of, 500
- α -L-Arabinofuranosidase, 500–501
- Arabinogalactan galactanohydrolase, 501
- Aranciamycin, 348, 355, 358
- Archaea
 enzymes of, 55
 taxonomy of, 30, 33–34
- Arginine, production of, 231–232
- Artemisinin
 need for, 364
 precursor of (amorpha-4,11-diene),
 364–379
 biosynthesis of, 364–365
 incorporation into *Escherichia coli*,
 365–366
 increased production of, 372–374
 oxidation of, 373, 375
 pathway optimization for, 367–372
 production of, 600–601
 production of, 141, 142
- Arthrobacter*
 haloalcohol dehydrogenase of, 530
 xylanase of, 490
- Artificial chromosomal expression system
 (ACE), in mammalian cell
 culture, 161
- Arxila adenivorans*, heterologous protein
 expression in, 307
- Aryl-alcohol oxidase, in biomass
 degradation, 503
- Ascospiroketals, 81
- Aspartame, production of, 483
- Aspartokinase, in lysine production, 228
- Aspergillus*
 in heterologous protein expression,
 149–152, 305
 in monoclonal antibody production, 157
 secondary metabolites of, 73–75, 80–81
- Aspergillus aculeatus*, pectinase of, 490
- Aspergillus awamori*, in heterologous protein
 expression, 150–151
- Aspergillus kawachii*, arabinofuranosidases
 of, 500
- Aspergillus nidulans*
 glucuronidase of, 501
 in heterologous protein expression, 150–152
- Aspergillus niger*
 in citric acid production, 121
 feruloyl esterase of, 501
 genetic engineering of, 318
 β -D-glucosidases of, 497
 in heterologous protein expression, 150–152
 mannanases of, 499
 miniaturized fermentation of, 108
 pectinase of, 490
 secondary metabolites of, 89
 xylanase of, 490
- Aspergillus ochraceus*, secondary metabolites
 of, 81, 83, 85
- Aspergillus oryzae*
 acylases of, in chiral amino acid
 production, 484
 genetic engineering of, 318

- in heterologous protein expression, 150
in solid-phase fermentation, 117–118, 120
- Aspergillus terreus*, in solid-phase fermentation, 122
- Aspinolides, 83
- Aspyrone, 83
- Asymmetric synthesis, biocatalysis in, 483
- Atorvastatin, production of, 487–488
- ATP efficiency, in lysine production, 229
- Aurofurasin, 80
- Auto-associated neural networks, 713
- Autographa californica* multiple nucleopolyhedrosis virus, in insect cell culture, 212, 217–218
- Autoinducible gene expression systems, *Escherichia coli*, 545
- Automation, of bioreactors, 719–730
control methods for, 721–727
design goals of, 721–722
history of, 719
instrumentation for, 720–721
process requirements for, 719–720
systems for, 727–730
- Autonomous plasmids, nonconventional yeasts, 307
- Autonomous replication sequences, in heterologous protein expression, 303, 307
- Autosampling, 653–655, 701–703
- Autoselection, in *Saccharomyces cerevisiae* engineering, 288, 289
- Auxins, in plant cell culture, 198–199
- Auxostats
for cellulolytic bacteria culture, 652
for continuous culture, 688–689
- Auxotrophic markers
for amorpho-4,11-diene pathway, 369–371
in nonconventional yeasts, 303
- Auxotrophs, for heterologous protein expression, 150
- Avermectins, production of, 527–528
- Avicelase (cellulohydroxylase), 496
- Avilamycins, 347–348, 353–354
- Azafenidine, production of, 482
- B**
- Baby hamster kidney fibroblast cells, for cell culture, 163
- Baccatin, in paclitaxel production, 487
- Bacillus*
mutant screening of, 106
subtilisin of, 513
xylanases of, 56
- Bacillus cereus*
 β -amylase of, 504
enzymes of, 449
- Bacillus lentus*, in detergent enzyme production, 610
- Bacillus licheniformis*
amylase of, 490
in detergent enzyme production, 610
xyloglucan endo-transglycosylases of, 499
- Bacillus megaterium*
enzymes of, in amorpho-4,11-diene production, 375
glucose dehydrogenase of, in omapatrilat production, 488
- Bacillus subtilis*
arabinofuranosidases of, 500
in detergent enzyme production, 610
enzymes of, 446
galactosidase of, 501
lipase of, 475–476
- Bacillus thermoproteolyticus*, thermolysin of, in aspartame production, 483
- Bacteria, taxonomy of, 30, 33–34
- Bacterial artificial chromosomes, in daptomycin gene cloning, 391–395, 399–402
- Bacterial surface technique, for enzyme screening, 467
- Bacteriological Code, 30–31
- Bacteriophages, *Clostridium*, 240, 242
- Bacteroides fragilis*, galactosidase of, 501
- Bacto-tip method, for separation of cellulose-degrading bacteria, 567–568
- Baculovirus, synthesis of, in insect cell culture systems, 217–219
- Baeyer-Villiger monooxygenases, 530–531
- Baeyer-Villiger reactions, *Candida antarctica* lipase B in, 526–527
- Base pretreatment, of lignocellulose feedstock, 622–623
- Basidiomycetes*, in cellulose degradation, 566
- Batch bioreactors
automated, 726, 729
for cellulolytic bacteria culture, 647–652
ethanol production, 629
for insect cell culture, 216–217
for recombinant products, 137–139
repetitive, 649–650
- BE2100 biomass sensor, 709
- Beckman-Coulter Vi-Cell AS system, for biomass measurement, 708
- Beer industry
by-products of, in fermentation media, 663
robustness improvement for, 610–612
- Benthic algae, 580
- Benzethonium chloride, in actinobacteria sample treatment, 16
- Berberine, 206
- Beta-carotene, production of, 599
- Beta-lactams, production of, 414–421, 485
- Beverage industry, fermented, robustness improvement for, 610–612
- B-factor iterative test, for directed evolution, 473, 475–476
- BIAcore instrument, for protein characterization, 739
- Binding assays, for mammalian cell culture, 186
- Biocatalysis, 480–494; *see also* Enzyme(s)
advantages of, 480, 550
in asymmetric synthesis, 483
in biomass conversion, 495–508
in bioprocess development,
see Bioprocess development
catalytic mechanisms in, 495
challenges of, 549–550
vs. chemical catalysis, 480
in chemical industry, 480–483
enantioselective, 444–445
in enantioselective synthesis, 483
Escherichia coli enzymes for, 539–548
in food industry, 489–491
in nonaqueous transformations, 509–523
in paper and pulp industry, 489–491
in pharmaceutical industry, 483–489
in racemic resolution, 482–483
regioselective, 481–482
in textile industry, 489–491
- Biocontrol agents, solid-phase fermentation for, 124
- Bioenergy, biomass sources for, *see* Biomass
- Bioethanol production, *see* Ethanol production
- Biofilms, formed by cellulolytic organisms, 634–643
biofilm characteristics and, 634
Clostridium thermocellum, 637–642
dynamics of, 637
equilibrium in, 636–637
in nature, 634–635
study tools for, 635–637
- Biofuel production
algal culture in, 577–590
cellulolytic bacteria in, 634–656
from lignocellulosics, 621–633
microbial communities in, 565–576
cell separation and manipulation of, 567–569
cellulose utilization quantification and, 566
cultivation methods for, 566–567
culture-independent enzyme discovery and, 569–574
DNA extraction from, 569–570
DNA screening methods for, 570–574
flow cytometry of, 568
in man-made environments, 566
in nature, 565–566
- Biological robustness, 605
- Biologics License Application, 187
- Biomass, *see also* Cellulose; Lignocellulose
algal, 577–590
biofuel production from
lignocellulose, 621–633
microbial communities for, 565–576
composition of, 621
enzymes converting, 495–508
accessory, 502–503
amylases, 503–505
cellulases, 496–497
classification of, 495
hemicellulases, 497–502, 505
multienzyme systems for, 505
protein engineering of, 505
ethanol production from, 613–616, 621–633
measurement of, 107
recycling of, 652
sensors for, 708
- Biopharmaceuticals, mammalian cell culture for, *see* Mammalian cell culture
- Bioprocess development, 549–562; *see also* Insect cell culture; Mammalian cell culture; Plant cell culture
advantages of, 550
assessment in, 553
biology of, 550–551
challenges of, 549–550
diffusion limitations in, 557–558
downstream processing in, 560
engineering principles of, 551–552
examples of, 559–560
ideal reaction conditions in, 560
media for, 557
membrane bioreactors for, 554–556
metabolomics of, 550–551
microbial robustness in, 605–620
microreactors for, 553–554
minibioreactors for, 553–554
miniplants for, 554
modeling in, 552–553
optimization of, 557–559
procedures for, 551–553
product removal in, 558–559
robustness aids in, 609–610
separation technologies for, 556–557
simulation in, 552–553
techniques for, 553–557

- BioProfile analyzer, 682
 BioProfile carbon dioxide sensor, 710
 BioProfile FLEX autosampler, 701–703
 Bioreactors
 airlift
 for insect cell culture, 215–216
 for mammalian cell culture, 676
 for algae, 583–585
 automation of, 719–730
 control methods for, 721–727
 design goals of, 721–722
 history of, 719
 instrumentation for, 720–721
 process requirements for, 719–720
 systems for, 727–730
 batch
 automated, 726, 729
 for cellulolytic bacteria culture, 647–652
 for ethanol production, 629
 for insect cell culture, 216–217
 for recombinant products, 137–139
 repetitive, 649–650
 BIOSTAT Qplus, 647–652
 cell growth in, 680–682
 for cellulolytic bacteria culture, 647–652
 continuous, 551–552
 for continuous culture, 690–694
 continuous-cascade, for ethanol production, 630
 control of, 677–680
 cylindrical, 583, 584
 disposable-bag, for mammalian cell culture, 169, 677
 fed-batch
 automated, 726–727
 for ethanol production, 629–630
 for insect cell culture, 216–217
 for mammalian cell culture, 169
 for recombinant products, 137–139
 for fermentation, 671–672
 for filamentous fungi, 326
 flat plate, 583, 584
 fluidized-bed, for solid-phase fermentation, 127
 for insect cell culture, 215–216
 for mammalian cell culture, 168–171, 676–684
 membrane, 554–556
 miniature, 114, 553–554
 operation of, 677–678
 packed-bed
 for insect cell culture, 216
 for solid-phase fermentation, 126–127
 photobioreactors, 583–585
 for plant cell culture, 203–204
 plug flow, 551–552
 product removal from, 558–559
 for recombinant products, 136–141
 rotary drum, for solid-phase fermentation, 127
 scale-down of, 682–683
 scale-up of, 671–672
 semicontinuous, automated, 727
 semicontinuous-cascade, for ethanol production, 630
 setup of, 677–678
 for solid-phase fermentation, 126–127
 stirred-tank, 551–552
 for continuous culture, 691
 for insect cell culture, 215–217
 for mammalian cell culture, 676
 suspended solids in, 649
 tray, for solid-phase fermentation, 126
 tubular, 583, 584
 types of, 551–552
 wave, for insect cell culture, 216
 Bioremediation, microbial isolation for, 6–7
 Biosensors, *see* Sensors
 BIOSTAT Qplus bioreactor, 647–652
 Biotic elicitors, 207
 Biotin, production of, 660
 Biotransformation
 for glycosylated products, 355–356
 nonaqueous, 509–523
 BiP protein, in heterologous protein expression, 149
 Bisnaphthalene, 81
 Blast tool, for genotyping, 34
 Bld proteins, in beta-lactam regulation, 418–419, 422
 BLIP protein, 411
 Blue-green algae (cyanobacteria), 578
 BMS-186318 antiviral drug, production of, 487
 Boron oxidation, Baeyer-Villiger monoxygenase and, 531
 Brasilicardin, 350
 Brewery industry
 by-products of, in fermentation media, 663
 robustness improvement for, 610–612
 Broth removal, for continuous culture, 692–693
 BT65 cell growth sensor, 709
 Bubble column, for bioprocesses, 559
 Buffers
 for mammalian cell culture products, 183
 for nonaqueous systems, 511–512
 in plant cell culture, 199
Burkholderia caryophylli, hydrolase of, 532
Burkholderia gladioli, esterase of, 475
 C
 Cadaverine, production of, 230
 8-Cadinene hydroxylase, 375
 Calcium phosphate, in mammalian cell genetic engineering, 332
 Calcium salts, in fermentation media, 664
 Callus culture, of plant cells, 203
 Calorimetry, for protein characterization, 740
Candida, heterologous protein expression in, 304
Candida albicans, heterologous protein expression in, 304
Candida antarctica
 lipase B of (CALB), promiscuity of, 526–527
 lipase of, 488, 513, 514
Candida cylindracea, in lobucavir production, 487
Candida rugosa, lipase of, 514
 Capacitance, measurement of, 721
N-Carbamoyl-D-amino acid decarbamoylase, in *p*-hydroxy-D-phenylglycine production, 447
 Carbohydrate(s), *see also* Glucose; Starch
 in fermentation media, 662
 Carbohydrate-binding modules, 325, 502–503
 Carbon, in fermentation media, 662–663
 Carbon dioxide
 in algal culture, 582, 587
 in bioreactor automation, 720
 in continuous culture, 695
 as inhibitor
 in ethanol production, 615
 in fermentation, 668
 in mammalian cell culture, 679
 in mammalian cell culture, 169–170, 679, 682
 measurement of
 in mammalian cell culture, 169–170
 in recombinant product production, 139–141
 in solid-phase fermentation, 120
 sensors for, 710
 in solid-phase fermentation, 125
 Carbon dioxide auxostat, for cellulolytic bacteria culture, 652
 Carbon sources, in plant cell culture, 197–198
 Carbonic anhydrase, algal culture and, 587
 Carboxymethyl cellulase, of extremophiles, 55
 Carcinomuconic acid, in adipic acid production, 598
 Carotenoids, production of, 600
carQSR promoter, in myxobacteria, 268–269
 Cascade control, in automated bioreactors, 725
 Catalysis, *see* Biocatalysis
 Catalytic promiscuity, 525–527
 Catapulting method, laser, for separation of cellulose-degrading bacteria, 567
 Catechol dioxygenase
 of extremophiles, 57–58
 in oxygen transfer rate measurement, 100
 Cation-exchange chromatography, for mammalian cell culture, 180, 182
 CAZy database, for enzymes, 495
 CcaR protein, in beta-lactam regulation, 418, 421
 CdcAB toxin-antitoxin system, for *Escherichia coli* enzyme production, 541–542
 Cefaclor, production of, 485
 Cefadroxil, production of, 485
 Cell bank, for fermentation, 669
 Cell counting
 in algal culture, 585
 in mammalian cell culture, 681–682
 Cell culture
 Escherichia coli, 132–142
 fungal, 145–156
 insect, 212–222
 mammalian, *see* Mammalian cell culture
 miniaturization of, 99–116
 plant, 196–211
 Cell cycle, control of, in mammalian cell lines, 165
 Cell density, in automated bioreactors, 723–724
 Cell density at infection, in insect cell culture, 218–219
 Cell growth, in scale-up, 672
 Cell lysis, in protein purification, 734
 Cell pools, in mammalian cell genetic engineering, 335
 Cell recycle, in continuous culture, 689–690, 693–694
 Cell separation technology, for cellulose-degrading bacteria, 567–568
 Cell sorting, for separation of cellulose-degrading bacteria, 568
 Cell wall
 of nonconventional yeasts, proteins of, in heterologous protein expression, 311
 plant, substances degrading, *see* Biomass, enzymes converting

- Cell Xpress, in mammalian cell line selection, 164
- Cell-based screening, for antibiotics, 62–72
algorithm for, 65, 69
assays for, 64–68
vs. cell-free assays, 63
evaluating hits in, 69–70
novel elements of, 63–64
sample selection for, 68–69
strain selection for, 68–69
target identification in, 64
- Cello robotic system, for mammalian cell screening, 335
- Cellobiase (β -D-glucosidase), 497
- Cellobiohydrolases, 496
- Cellobiose dehydrogenase
in biomass degradation, 503
of extremophiles, 56–57
- Cellobiose phosphorylase, 497
- Cellobiose phosphorylase (cellobiose phosphorylase), 497
- Cellulases, 505
in ethanol production, 624–626
of extremophiles, 55, 57
production of, 490–491
types of, 496–497
- Cellulolytic microorganisms, 566
culture of, 644–656
controlled, 645, 647–652
media for, 644–645
monitoring of, 652–656
surface microbiology of, 634–643
- Cellulomonas fimi*
endo-mannanases of, 499
 β -xylosidase of, 498
- Cellulose
in biomass feedstocks, 622
degradation of
assessment of, 566, 567–569
in biofilms, 634–643
cultivation methods for, 566–567
enzymes for, 55, 569–574; *see also*
Cellulases
man-made environments for, 566
microorganisms for, 566, 634–656
in nature, 565–566
pretreatment effects on, 623
- Cellulose 1,4- β -cellobiosidase (cellobiohydrolase), 496
- Cellulose C, analysis of, 653, 656
- Cellvibrio mixtus*
glucuronidase of, 501
mannanases of, 499
- Centrifugal pumps, in automated bioreactors, 729
- Centrifugation
of actinobacteria samples, 15
in mammalian cell culture, 180, 181
in miniaturized fermentation, 106–107
in protein characterization, 738–739
- Cephalalexin, production of, 485
- Cepharmycin C, production of, 412, 414–417, 422
- Ceramic hydroxyapatite chromatography, for mammalian cell culture, 182
- Cervimycins, 349
- Chaetoglobosins, 81, 84
- Chaperones, in heterologous protein expression
Escherichia coli, 279
nonconventional yeasts, 311
- Chelating agents, in fermentation media, 664
- Chemical(s), specialty, in fermentation media, 664
- Chemical degradation, of mammalian cell culture products, 183–184
- Chemical epigenetic approach, to silent biosynthetic pathways, 89, 91
- Chemical industry
algal culture for, 577–590
biocatalysis in, 480–483
Escherichia coli products for, 591–604
- Chemical transfection, in mammalian cell genetic engineering, 332
- Chemically defined media, 659–660
- Chemoselectivity, of hydrolases, 515–517
- Chemostats
in cellulolytic bacteria culture, 652
in continuous culture, 686–688
- Chemotactic method, for actinobacteria sample treatment, 16
- Chemotaxonomic properties, for taxonomy, 36–37
- Chinese hamster ovary cells, in cell culture, 162, 164–166, 170
- Chloramphenicol acetyltransferase, in mammalian cell genetic engineering, 341
- Chlorheximide gluconate, in actinobacteria sample treatment, 16
- Chlorides, in fermentation media, 664
- Chloroform, in DNA extraction, from extremozymes, 45–46
- Chloroperoxidase, in nonaqueous transformations, 519
- Chlorophyll, in algal culture, 581–582
- Chlorophyta, culture of, 578
- Chromatin remodeling, in mammalian cell culture, 161
- Chromatography
for amorpho-4,11-diene pathway, 367–368, 373
for cellulolytic bacteria culture monitoring, 653, 656
for enzyme screening, 467, 626
for ethanologen screening, 627–629
for mammalian cell culture, 180, 182, 185–186
for peptides and proteins, 712
for protein purification, 734–738
for robustness improvement, 607
for secondary metabolites, 75
- Chromosomal engineering, for recombinant products, *Escherichia coli*, 280–283
- Chromosomal integration, *Saccharomyces cerevisiae*, 290–297
- Chryseobacterium proteolyticum*, protein glutaminase of, 232
- Chymotrypsin
covalent modification of, 511
in nonaqueous transformations, 513
- Cip protein, in biomass degradation, 503
- Citric acid, production of, in solid-phase fermentation, 121
- Citrulline, production of, 231–232
- Cladosporium cladosporioides*, secondary metabolites of, 89
- ClaR protein, in beta-lactam regulation, 418, 421–422
- Classification, in taxonomy, 28
- Clavaminic synthase, 417–418
- Clavaminic acid, 416
- Clavams, *see Streptomyces clavuligerus*
- Clavulanic acid, production of, 412, 414–417
- Cleaning-in-place, for bioreactors, 677
- ClonePix, for mammalian cell screening, 164, 336
- Cloning
of cellulose-degrading enzyme genes, 572–573
of *Clostridium*, 242
filamentous fungi, 319–320
of lipopeptide genes, 391–395
in mammalian cell genetic engineering, 335
- Clostridium*, 238–261
antisense RNA technology for, 248–249
bacteriophages of, 240, 242
classification of, 238
cloning of, 242
DNA isolation in, 240–242
in ethanol production, 627
gene inactivation in, 246–248
gene isolation in, 242–243
genome sequencing of, 249–253
heterologous protein expression in, 249
homologous protein expression in, 249
host vector systems of, 243–245
IS elements of, 240
molecular typing of, 254
mutagenesis in, 245–246
overview of, 238
physiology of, 238–239
plasmids of, 239–240
products of, for human disease, 249, 254
transposons of, 240, 245–246
- Clostridium acetobutylicum*
antisense RNA technology for, 248
DNA isolation in, 241
gene inactivation in, 246–247
genome sequencing of, 249–250
host vector systems of, 243, 244
mutagenesis in, 245
- Clostridium asparagiforme*, genome sequencing of, 250
- Clostridium baratii*, DNA isolation in, 241
- Clostridium bartlettii*, genome sequencing of, 250
- Clostridium beijerinckii*
gene inactivation in, 246
genome sequencing of, 250
- Clostridium boltea*
genome sequencing of, 250
transposons of, 240
- Clostridium botulinum*
bacteriophages of, 240
DNA isolation in, 241
gene isolation in, 242
genome sequencing of, 250
host vector systems of, 244
physiology of, 239
plasmids of, 239–240
- Clostridium butyricum*
DNA isolation in, 241
genome sequencing of, 251
host vector systems of, 244
mutagenesis in, 245
- Clostridium carboxidivorans*, genome sequencing of, 251
- Clostridium cellatum*, genome sequencing of, 251
- Clostridium cellulolyticum*
antisense RNA technology for, 248
biofilm formation by, 635
endo-1,4- β -D-glucanases of, 496
genome sequencing of, 251
- Clostridium cellulovorans*
accessory substances of, 503
genome sequencing of, 251

- Clostridium difficile*
bacteriophages of, 240
DNA isolation in, 241–242
gene inactivation in, 246
genome sequencing of, 249, 251
host vector systems of, 243, 244
transposons of, 240
- Clostridium hathewayi*, genome sequencing of, 251
- Clostridium hiranonis*, genome sequencing of, 251
- Clostridium hylemonae*, genome sequencing of, 251
- Clostridium innocuum*, genome sequencing of, 252
- Clostridium kluyveri*, genome sequencing of, 249, 252
- Clostridium leptum*, genome sequencing of, 252
- Clostridium ljungdahlii*, genome sequencing of, 252
- Clostridium methylpentosum*, genome sequencing of, 252
- Clostridium nexile*, genome sequencing of, 252
- Clostridium novyi*
bacteriophages of, 240
genome sequencing of, 249, 252
products of, for human disease, 249
- Clostridium orbiscindens*, genome sequencing of, 252
- Clostridium papyrosolvens*, genome sequencing of, 252
- Clostridium pasteurianum*, genome sequencing of, 252
- Clostridium perfringens*
bacteriophages of, 240, 242
DNA isolation in, 241–242
gene inactivation in, 246, 247
genome sequencing of, 249, 252
host vector systems of, 243, 244
mutagenesis in, 246
plasmids of, 239–240
transposons of, 240
- Clostridium phytofermentans*, genome sequencing of, 252
- Clostridium ramosum*, genome sequencing of, 252
- Clostridium scindens*, genome sequencing of, 253
- Clostridium septicum*
DNA isolation in, 241
gene inactivation in, 246, 247
- Clostridium sordellii*, products of, for human disease, 249
- Clostridium spiroforme*, genome sequencing of, 253
- Clostridium sporogenes*
genome sequencing of, 253
host vector systems in, 244
- Clostridium sticklandii*, genome sequencing of, 253
- Clostridium symbiosum*
genome sequencing of, 253
transposons of, 240
- Clostridium tetani*
genome sequencing of, 249, 253
physiology of, 239
plasmids of, 239
- Clostridium thermoaceticum*, genome sequencing of, 249
- Clostridium thermocellum*
arabinofuranosidases of, 500
biofilm formation by
cell organization in, 640
experimental system for, 637–640
form-function relationship in, 641–642
in nature, 634–635
study tools for, 635–637
in cellulose degradation, 566
culture of
controlled, 645, 647–652
media for, 644–645
monitoring of, 652–656
endo-1,4- β -D-glucanases of, 496
in ethanol production, 615
genome sequencing of, 253
heterologous protein expression in, 249
mutagenesis in, 245
- Clostridium tyrobutyricum*, gene inactivation in, 246
- ClosTron vectors, 247–248
- CMCase (endo-1,4- β -D-glucanase), 496–497, 624
- Cobalt-catalyzed sulfite oxidation method, for oxygen transfer rate, 100
- Coculture techniques, for secondary metabolites, 81–82
- Codon optimization, in heterologous product expression
filamentous fungi, 323
nonconventional yeasts, 310
- Coelichelin, 84, 86, 88
- Cofactor engineering, of enzymes, 461–462
- Cofactor-dependent enzymes, promiscuity of, 530–531
- Cold capture antibody secretion assay, for mammalian cell screening, 336
- Cold temperatures, organisms tolerating, 44, 53–54
- Colloidal chitin-mineral agar, for actinobacteria, 17
- Colony pickers, for mammalian cell screening, 336
- Colony selection, actinobacteria, 17–18
- Column photobioreactors, for algal culture, 583, 584
- Colyophilization, of enzymes, 510
- Combinatorial active-site saturation test, for directed evolution, 472–473, 476–477
- Combinatorial biosynthesis, 527–528
- Comparability, of products, 674–675
- Compendial raw materials, for mammalian cell culture, 188
- Computation-guided approaches, to mutagenesis, 453–465, 474
- Confocal laser scanning micrograph, of *Clostridium thermocellum*, 641–642
- Confocal Raman spectroscopy, for separation of cellulose-degrading bacteria, 567
- Conjugal transfer, for DNA transfer, in *Clostridium*, 242–243
- Conjugation, of myxobacteria, 263
- Consensus approach, for enzyme design, 458
- Constitutive promoters, in mammalian cell genetic engineering, 340–341
- Contaminated environments, microbial isolation in, 6–7
- Continuous bioreactors, for cellulolytic bacteria culture, 647–650
- Continuous centrifugation, in mammalian cell culture, 181
- Continuous culture, 685–699
auxostats in, 688–689
with cell recycle, 689–690, 693–694
chemostats in, 686–688
environmental control in, 695
equipment for, 690–694
experimental design for, 694–696
history of, 685–686
of insect cells, 216–217
media for, 694–695
multistage, 690
setup for, 695
small-scale, 691
steady state in, 695–696
sterilization in, 694–695
theory of, 686–690
two-stage, 690
- Continuous-cascade fermentation, for ethanol production, 630
- Continuous-flow system, for *Clostridium thermocellum* culture, 637–642
- Contract manufacturing organizations, for mammalian cell culture, 189–190
- Control
of automated bioreactors, 721–727
of bioreactors, 677–680
of cell cycle, in mammalian cell lines, 165
of cellulolytic microorganism culture, 645, 647–652
of continuous culture, 692–693
of foam, 662–664
of solid-phase fermentation, 124–126
- Controlled variables, in automated bioreactors, 722–724
- Conversion, rate of, in bioprocesses, 558–559
- Cooling, in large-scale fermentation, 671–672
- CopyControl Fosmid Library Production kit, 47–48
- Corn byproducts, in fermentation media, 662–663
- Corn steep liquor, in fermentation media, 663
- Corn syrup
high-fructose, production of, 560
hydrolyzed, in fermentation media, 662
- Cornstarch, in fermentation media, 662
- Corrosion, of fermentation equipment, 668
- Corynebacteria
characteristics of, 225
DNA array analysis of, 226, 228
genomes of, 225
heterologous proteins of, 232
metabolomics of, 228
proteomics of, 228
reduced genome of, 226–227
reengineering of, 230–232
strain improvement strategies for, 228–230
strain reconstruction for, 230–232
transposon mutagenesis in, 225–226
- Corynebacterium*, haloalcohol dehydrogenase of, 529
- Corynebacterium ammoniagenes*, in uridine 5'-diphosphogalactose production, 489
- Corynebacterium efficiens*
genome of, 225
in glutamic acid production, 612
transposon mutagenesis in, 226
- Corynebacterium glutamicum*
DNA arrays of, 226, 228

- genome of, 225
 in glutamic acid production, 142, 612–613
 heterologous proteins of, 232
 metabolomics of, 228
 proteomics of, 228
 reduced genome of, 226–227
 strain improvement strategies for, 228–230
 strain reconstruction for, 231–232
 transposon mutagenesis in, 225–226
Corynebacterium jeikeium, genome of, 225
 Cosmid libraries
 for A54145, 394
 for cellulose-degrading enzymes, 572
 for daptomycin, 391–394
 for extremozymes, 48–50
 for glycosylated products, 351–352
 Costs, of mammalian cell culture, 189–190
 Cotranslational translation, 311
 Cottonseed flour, in fermentation media, 663
 Counterselection, in *Saccharomyces cerevisiae* engineering, 288
 Covalent modification, of enzymes, in nonaqueous transformations, 511
 C7p, in beta-lactam regulation, 418
 Crabtree effect, in mammalian cell culture, 167
 Cre recombinase, of nonconventional yeasts, in heterologous product expression, 304–305
creA promoter, in heterologous protein expression, 151
 Cre/*loxP* excision system, for corynebacteria, 226–227
 Critical quality attributes, of mammalian cell culture products, 185
 Cross-linking, of enzymes, in nonaqueous transformations, 511
 Crosswise catalytic promiscuity, 531–533
 Cryopreservation, of algae, 581
 Crystal(s), cross-linked, of enzymes, in nonaqueous transformations, 511
 Crystallization, in bioprocesses, 559
 Crystallography, for protein characterization, 740
 Culture(s)
 algal/microbial, 577–590
 cell, *see* Cell culture
 cellulolytic microorganisms, 644–656
 continuous, *see* Continuous culture
 extinction, for cellulose-degrading bacteria, 569
 extraction of, 74–75
 plant cell, 196–211
 of secondary metabolites, 74–75, 80–86, 91
 seed, 666
 Culture collections, in taxonomy, 29–30
Cupriavidus, enzymes of, 443
 Cyanoaddition, hydroxynitrile lyases in, 517–518
 Cyanobacteria, culture of, 578
 Cyanohydrins, synthesis of, hydroxynitrile lyases in, 443–444, 517–518
 α -Cyano-3-phenoxybenzyl alcohol, cyanoaddition to, 518
 2-Cyanopyrazine, in 5-hydroxypyrazine-2-carboxylic acid production, 488
 3-Cyanopyridine, in niacinamide production, 482
 5-Cyanovaleramide, production of, 482
 Cyclodextrins, production of, 556–557
 Cycloheximide, of nonconventional yeasts, in heterologous product expression, 304
 Cylindrical systems, for algal culture, 583, 584
 Cysteine, in unnatural amino acid production, 596
 Cytochrome P450 enzymes, in amorpho-4,11-diene production, 373, 375
 Cytokinins, in plant cell culture, 198–199
 Cytoplasmic streaming test, for plant cell viability, 205
 Cytosporones, 81, 84
D
Daldinia, secondary metabolites of, 73
 Daldinins, 81, 84
 Dankasterones, 81, 84
 Daptomycin, genetic engineering of, 391–410
 cloning in, 391–395
 combinatorial biosynthesis in, 399–406
 expression systems for, 396–399
 gene clusters in, 394, 396
 novel products in, 399–406
 Data mining, for cellulose-degrading enzymes, 570–571
 Databases, for fermentation media, 664–665
 1-Deactylbaccatin II, in paclitaxel production, 487
 Deamidation, of mammalian cell culture products, 183–184
 Defoamers, in fermentation media, 662–664
 Degradation
 of biomass, 503
 of cellulose, *see* Cellulases; Cellulose, degradation of
 of mammalian cell culture products, 183–184
 Degussa process, for chiral amino acid production, 484–485
 3-Dehydroquinase synthase, in shikimic acid production, 597
 Delivery modes, for mammalian cell culture products, 184
 Denaturation, of enzymes, 550
 6-Deoxyerythronolide B
 analogs of, 383–384, 387–388
 production of, 382–383, 385–387
 3-Deoxy-heptulosonate-7-phosphate, in shikimic acid production, 597–598
 Deoxysugars, in antibiotic production, 351–355
 Deoxyxylulose-5-phosphate, in amorpho-4,11-diene synthesis, 365–367, 370
 Depth filtration, in mammalian cell culture, 181
 Dereplication, 35, 69–70
 Derivative, in automated bioreactor control, 724
 Design of experiments, in process analytical technology, 700
 Detergents, enzyme additives to, 480, 609–610
 Dextrins, in fermentation media, 662
 Dextrose monohydrate, in fermentation media, 662
 DIACHAR program, for media design, 18–19
meso-Diaminopimelate dehydrogenase, in D-amino acid dehydrogenase production, 447–448
 Diammonium 2,2'-azino-di-(3-ethylbenzylthiazoline sulfonate), for oxygen transfer rate measurement, 100
Diatrype, secondary metabolites of, 89
 Dibenzothiophene monooxygenase, direct evolution of, 474
 2,3-Dichlorophenoxyacetic acid, in plant cell culture, 198–199
 Dideoxynucleotide chain termination sequencing, for cellulose-degrading enzymes, 571
 Dielectric spectroscopy, for process monitoring, 708–710
 Differential assays, for antibiotics, 67
 Diffusion chamber method, 3–7
 chip variation of, 7–9
 Diffusion limitation, in bioprocesses, 557–558
 Digital signal conversion, for automated bioreactors, 728–729
 Dihydrodipicolinate synthase, in lysine production, 228
 Dihydrofolate reductase genes, in mammalian cell culture, 160–161, 334–335
 2,3-Dihydroxy-2,3-dihydrobenzoic acid (2,3-*trans*-CHD), production of, 599
 Diltiazem, production of, 488
 Dimethylallyl diphosphate, in amorpho-4,11-diene synthesis, 365–367, 371
 1,5-Dimethyl-2-piperidone, production of, 482
 Dinophyta, culture of, 578
 Dipeptides, screening for, 445–446
 Direct solubilization, of enzymes, 511
 Directed evolution, of enzymes, 466–479
 B-factor iterative test for, 473, 475–476
 in bioprocess development, 550
 combinatorial active-site saturation test for, 472–473, 476–477
 comparative studies of, 474–477
 computation-guided approaches to, 474
 disadvantages of, 454–455
 enantioselectivity enhancement in, 476–477
 error-prone PCR for, 468–469, 475
 for fine-tuning, 446–449
 in galactosidase transformation, 475
 rational design and, 453–465
 recombinant gene mutagenesis for, 473–474
 saturation mutagenesis for, 469–473, 475
 screening for, 466–468
 selection methods for, 466–468
 stability and, 457–458
 thermostability increasing in, 475–476
 Direct-inlet mass spectrometry, for secondary metabolites, 75
 Disk-stack desludging centrifugation, in mammalian cell culture, 180
 Dispersion and differential centrifugation technique, for actinobacteria samples, 15
 Display techniques, for enzyme screening, 467
 Disposable sensors, 710–712
 Disposable-bag bioreactors, for mammalian cell culture, 169, 677
 Dissolved carbon dioxide, *see* Carbon dioxide
 Dissolved oxygen, *see* Oxygen

- Distillation, in bioprocesses, 556
 Distributed control systems, for automated bioreactors, 728, 729
- DNA
Clostridium, isolation of, 241–242
 extraction of
 from cellulose-degrading enzymes, 569–570
 from extremozymes, 45–47
 introduction of
 in mammalian cell genetic engineering, 332–333
 to *Streptomyces clavuligerus*, 413
 measurement of, for mammalian cell screening, 336
 plasmid, production of, 141
 synthetic, in heterologous protein expression, 310
 transfer of
 in *Clostridium*, 242–243
 in myxobacteria, 262–264
- DNA arrays, corynebacteria, 226, 228
 DNA fingerprinting, for taxonomy, 35
 DNA replication, antibiotic assays based on, 66
 DNA shuffling, in directed evolution, 473–475
 DNA-DNA hybridization, for taxonomy, 35
 DNA-DNA relatedness, in taxonomy, 29, 32–35
 Documentation, of fermentation process, 674
 Dosage, for mammalian cell culture products, 183
 Downstream processing
 in bioprocess development, 560
 in mammalian cell culture, 179–183
 sensors in, 714
 Drained fresh weight, in plant cell culture, 204
 Drip tube, for continuous culture, 692
 Droplet-based strategies, for enzyme screening, 467
 Drug(s), *see also specific drugs, e.g.*, Antibiotics
 enantiomers of, production of, 483–489
 Drug resistance, markers for, in nonconventional yeasts, 303–304
 Dry weight, in plant cell culture, 204
 D-stat, for cellulolytic bacteria culture, 652
 Dupont, chemical production by, 482
 Dutomycin, 349
 Dynamic kinetic resolution, of racemic mixtures, 515
 Dynamic light scattering, for protein characterization, 739
- E**
 Ecdysteroid hormones, in mammalian cell genetic engineering, 340–341
 Ecl5 intron, in *Escherichia coli* chromosomal engineering, 282–283
 Effective reactions, in bioprocesses, 560
 EF-Tu inhibitors, in antibiotic assays, 68
 Electrocompetent cells, preparation of, 308–309
 Electrophoresis
 for *Clostridium*, 239
 for mammalian cell culture, 185–186
 for protein characterization, 738
 for taxonomy, 35
 Electroporation, for DNA transfer
 in *Clostridium*, 242
 in mammalian cell genetic engineering, 333
 to myxobacteria, 263
 in nonconventional yeasts, 308–309
 Electrostatic interactions, in enzyme function, 456
 Elicitation, in plant cell culture, 207
 Embryogenesis, somatic, in plant cell culture, 208
Emericella, secondary metabolites of, 81, 85
 Emericellamide, 81, 85
Empedobacter brevis, enzymes of, 445
 Emulsifiers, in fermentation media, 664
 Emulsions, of enzymes, in nonaqueous transformations, 511
 Enantioselective catalysis, 444–445
 in chemical industry, 483
 hydrolases in, 513–515
 Enantioselectivity, of enzymes, 458
 enhancing, 476–477
 screening for, 467–468
 Encapsulation, of algae, 581
endA gene, *Escherichia coli*, 279–280
 Endo-1,5- α -arabinanase, 500–501
 Endogalactanase, 501
 Endo-1,4- β -D-glucanases, 496–497, 624
 Endoglucanases, of extremophiles, 55, 57
 Endo- β -mannanase, 499
 Endoplasmic reticulum, proteins of, in heterologous protein expression, 311
 Endo-polygalacturonases, 500
 Endosafe-PTS sensor, 714
 Endoxylanases, 57, 498
 Energy
 biofuels for, *see* Biofuel production
 biomass sources for, *see* Biomass
 Energy landscape, in catalysis, 455–457
 Enhancers, in mammalian cell genetic engineering, 331–332
 Enrichment culture technique, for enzyme screening, 441–444
Enterobacter, secondary metabolites of, 82
 Enzyme(s), *see also specific enzymes*
 active-site de novo design of, 461–462
 in biocatalysis, 480–494
 in chemical industry, 480–483
 in food industry, 489–491
 in paper and pulp industry, 489–491
 in pharmaceutical industry, 483–489
 in textile industry, 489–491
 in biomass conversion, 495–508, 624–626
 in bioprocesses, 549–562, 609–610
 in cell lysis, 734
 cellulose-degrading, screening for, 569–574
 classification of, 495
 cofactors of, 461–462
 commercial sources of, 624–626
 costs of, 626
 in detergent industry, 609–610
 discovery of, tools for, 441–452
 engineering of
 computational approaches to, 453–465, 474
 directed evolution in, 446–449, 453–465, 466–479
 of *Escherichia coli*, 539–548
 in ethanol production, 624–626
 from extreme environments,
 see Extremozymes
 in fermentation media, 664
 in lignocellulose hydrolysis, 624–626
 metal-binding sites of, 461
 new functions of, 449
 in nonaqueous transformations, 509–523
 promiscuity of, 524–538
 robustness of, 605
 screening for, 441–449
 in solid-phase fermentation, 120–121
 stability of, 550
 Enzyme-linked immunosorbent assay, for mammalian cell screening, 335
 Epigenetic approach, to silent biosynthetic pathways, 89, 91
 Epi-isozizaene, 88
 Epirubicin, 358
 Episomal systems, for mammalian cell genetic engineering, 337
 Epothilones, production of, 384–385, 388
 bacterial host for, 428–429
 genetic tools for, 429–430
 modulation of, 432–433
 novel analogs of, 430–432
 Epoxidation, *Candida antarctica* lipase B in, 526–527
 Epoxides, terminal, production of, 483
 Equipment, *see also* Bioreactors
 for bioreactor automation, 721–722
 for continuous culture, 690–694
 for fermentation, at large scale, 674
 Erdman degradation, for protein characterization, 738
 Ergot alkaloids, production of, 122
 Error, in automated bioreactor control, 724
 Error-prone PCR, in direct evolution, 468–469, 475
 Erythromycin, analogs of, 387–388
Escherichia coli, 595–596
 in amino acid production, 595–599
 in artemisinin precursor production, 364–379, 600–601
 DNA transfer from, to *Mycococcus xanthus*, 262
 enzymes of, 539–548
 in detergent formulations, 610
 high-cell-density fermentation for, 545
 host cell selection for, 540–541
 inducible gene expression systems for, 544–545
 overview of, 539–540
 vectors for, 541–544
 in ethanol production, 615, 627
 expression host for, 278–283
 expression vectors for, 273–278
 genotypes of, 279–280
 hydrolase of, 532
 in isoprenoid production, 599–601
 in lipopeptide production, 393–394, 399–401
 in (R)-mandelic acid production, 482–483
 in methionine production, 230
 in monoclonal antibody production, 157
 mutant screening of, 106
 nitrilases of, 444
 in organic acid production, 591–595
 penicillin amidase of, 513
 in polyketide production, 385–388
 proteins of, purification of, 731–733
 recombinant products from, 132–144
 bioreactors for, 137–141
 chromosomal engineering for, 280–283
 enzymes, 539–548
 genotypes suitable for, 279–280
 growth in, 136–137
 instrumentation for, 133–134
 limitations on, 274–275, 277
 localization of, 277–278
 medium for, 134–136
 nonprotein, 141–142
 process for, 132
 protein fusion technology for, 278

- protein misfolding and, 278
 recovery of, 141
 seed culture for, 134
 starter culture for, 136
 strain improvement for, 273–286
 replication of, 542
 secondary metabolites of, 88
 strain improvement of, 273–286, 540
 in uridine 5'-diphosphogalactose
 production, 489
 wild-type, limitations of, 273
- Eschsholtzia*, cell culture of, 207
- Esterases
Burkholderia gladioli, 475
 extremophiles, 57
- Esterification, 559–560
- Ethanol production
 enzymes for, 57, 624–626
 ethanol tolerance in, 615
 ethanologen screening in, 626–629
 feedstock selection for, 621
 fermentation methods for, 629–630
 hydrolysis in, 624–626
 from lignocellulose, 621–633
 microorganisms in, 626–629
 pretreatment methods for, 621–624
 for robustness improvement, 613–616
 in solid-phase fermentation, 121
- Ethanologens, testing of, 626–629
- Ethyl lactate, production of, 593
- Ethylacetate/dichloromethane/methanol
 method, for secondary metabolite
 extraction, 74
- Euglenophyta, culture of, 579
- European Medicines Evaluation Agency,
 Good Manufacturing Practice
 requirements of, 187–190
- Evans blue staining test, for plant cell
 viability, 205
- Evernimomycins, 347–348
- Evolution
 directed, *see* Directed evolution
 genetic adaptability in, 606
- Excipients
 for enzymes, in nonaqueous
 transformations, 510
 for mammalian cell culture products, 184
- Excision, of corynebacteria genome
 regions, 226–227
- Excision elements, in nonconventional
 yeasts, 304–305
- Exit gas composition, measurement of, 721
- Exo-1,4- β -glucanase (cellobiohydrolase),
 496, 624
- Exo- β -glucanases, 498–499
- Exometabolomics, 73
- Exo-polygalacturonases, 500
- Exo-polygalacturonidase, 500
- Exo-polygalacturonosidase, 500
- Exotoxin, *Pseudomonas aeruginosa*, 132,
 140–141
- Expansin, 502
- Exporters, in lysine production, 229
- Expression augmenting sequence elements
 (EASE), in mammalian cell
 culture, 161
- Expression systems, for heterologous
 proteins, 145–156
- Extinction cultures, for cellulose-degrading
 bacteria, 569
- Extraction
 of cellulose-degrading enzymes, 569–570
 of *Clostridium* DNA, 241
 of cultures, 74–75
- DNA
 from cellulose-degrading enzymes,
 569–570
 from extremozymes, 45–47
 of secondary metabolites, 74–75
- Extremozymes, 43–61
 activity screens for, 57–58
 DNA extraction from, 45–47
 host-vector systems for, 51–53
 library construction for, 47–51
 lignocellulose-degrading, 55–57
 sampling for, 43–45
 types of, 53–55
- Extrolites, *see also* Secondary metabolites
 definition of, 73
- EzTaxon tool, for genotyping, 34
- F**
- FabF, inhibitors of, 68
- FabH, inhibitors of, 68
- FabI, in antibiotic assay, 66
- Farnesyl diphosphate synthase, in
 amorpha-4,11-diene synthesis,
 365–367, 371
- Farnesyl pyrophosphate, in isoprenoid
 production, 600
- Fatty acid(s)
 in fermentation media, 662–663
 of lipopeptides, 406
 in taxonomy, 37
- Fatty acid biosynthesis proteins, in amorpha-
 4,11-diene production, 373–374
- Feasibility study, of assays, 65
- Fed-batch bioreactors
 automated, 726–727
 for ethanol production, 629–630
 for insect cell culture, 216–217
 for mammalian cell culture, 169
 for recombinant products, 137–139
- Feed(s), for mammalian cell culture, 167–168
- Feeding rates, for fermentation, 671
- Fermentation
 alcoholic, for beverages, 610–612
 batch, 629
 cellulolytic microorganisms in, 644–656
 continuous-cascade, 630
 in ethanol production, 629–630
 fed-batch, 629–630
 high-cell-density *Escherichia coli*, 545
 media for, 659–668
 chemically defined, 659–660
 components of, 661–665
 guidelines for, 666–668
 information sources for, 664–665
 rationale for improving, 665–666
 miniaturization of, 99–116
 scale-up of, 669–675
 bioreactors for, 671–672
 cell banking strategy for, 669
 documentation in, 674
 equipment qualification and
 modifications in, 674
 equipment validation in, 674
 evaluation in, 672–673
 intermediate stability and storage
 considerations in, 674
 plan for, 669
 process validation in, 674
 product comparability in, 674–675
 product quality in, 674
 raw materials in, 674
 at same productivity as small-scale,
 670–671
- sampling technologies for, 700–718
 seed train for, 670
 waste streams in, 674
 semicontinuous-cascade, 630
 sensors for, *see* Sensors
 solid-phase, 117–131
- Fermentors, for solid-phase fermentation,
 126–127
- Feruloyl esterase, 501–502
- Fibrobacter intestinalis*, biofilm formation
 by, 635
- Fibrobacter succinogenes*, biofilm formation
 by, 634–635
- Field-flow fractionation, for protein
 purification, 737
- Filamentous fungi
 genetic engineering of, 149–152, 318–329
 evaluation of, 326
 example of, 325
 gene silencing in, 324
 gene targeting in, 323–324
 genome mining and, 318
 metabolic pathways in, 319
 overexpression in, 322–323
 screening in, 321–322, 324–325
 selection markers for, 319–321
 strain improvement in, 322–326
 transformation in, 321
 secondary metabolites of, 318
- Fill and finish step, for mammalian cell
 culture products, 184–185
- Filtration
 in continuous culture, 693–694
 in mammalian cell culture, 180–183
 in miniaturized fermentation, 106–107
- Fine chemicals
 algal culture for, 577–590
 production of, *Escherichia coli* in,
 591–604
- Firefly luciferase, in mammalian cell
 genetic engineering, 341
- Firmicutes*, in cellulose degradation, 566
- Fish by-products, in fermentation media, 663
- Flat-plate bioreactors, for algal culture,
 583, 584
- Flaviolin, 88
- FLD1* gene, in heterologous product
 expression, 148–149, 305
- Flour, in fermentation media, 662
- Flow analysis, of metabolites, 609
- Flow cells, for *Clostridium thermocellum*
 culture, 637–642
- Flow cytometry, for separation of cellulose-
 degrading bacteria, 568
- Flow injection analysis, 703
- Flow rate
 in automated bioreactors, 728–729
 in bioreactor automation, 727
- Fluid filtration, in mammalian cell
 culture, 180
- Fluidized-bed bioreactors, for solid-phase
 fermentation, 127
- Fluorescein diacetate test, for plant cell
 viability, 205
- Fluorescence-activated cell sorting
 in enzyme screening, 467–468
 in mammalian cell line selection, 164
- Fluorescent stain, for mammalian cell
 screening, 335–336
- 5'-Fluoroorotic acid, in heterologous
 product expression
 filamentous fungi, 320
 nonconventional yeasts, 303
- Fluxomics, for robustness improvement, 609

- Hydrophilic interaction chromatography,
 for mammalian cell culture, 180
- Hydrophobic effect, in enzyme function,
 456–457
- Hydrophobic interaction chromatography,
 for protein purification, 736
- Hydrothermal systems, sampling of, 44
- p*-Hydroxy-D-phenylglycine, production of,
 447, 485
- 3-Hydroxyglutaronitrile, nitrilase action
 on, 444–445
- 4-Hydroxy-3-methoxycinnamoyl-sugar
 hydrolase (feruloyl esterase), 501–502
- 5-Hydroxymethylfurfural, as inhibitor, in
 ethanol production, 614–615
- 3-Hydroxy-3-methylglutaryl-CoA
 reductase, in amorpho-4,11-diene
 synthesis, 365–367, 369, 373
- 3-Hydroxy-3-methylglutaryl-CoA synthase,
 in amorpho-4,11-diene synthesis,
 365–369, 373
- 6-Hydroxynicotinic acid, production of, 482
- Hydroxynitrile lyases
 in cyanohydrin synthesis, 443–444
 in nonaqueous transformations, 517–518
- (S)-6-Hydroxynorleucine, in omapatrilat
 production, 488
- (R)-2-Hydroxy-2-phenylacetic acid
 (mandelic acid), production of,
 482–483
- 5-Hydroxypyrazine-2-carboxylic acid,
 production of, 488
- 17 β -Hydroxysteroid dehydrogenase,
 cofactor engineering of, 461
- Hygromycin, as selectable marker, in
 myxobacteria, 263–264
- Hygromycin phosphotransferase, of non-
 conventional yeasts, in heterolo-
 gous product expression, 304
- Hypersecretion, in filamentous fungi, 325
- Hyperthermophiles
 definition of, 53
 enzymes of, host-vector systems for, 52–53
- Hyphenated diode array detector, for
 secondary metabolites, 75
- Hypocrea jecorina*
 accessory substances of, 503
 arabinofuranosidases of, 500
 cellobiohydrolases of, 496
 endo-1,4- β -D-glucanases of, 496–497
 endo-mannanases of, 499
 galactosidase of, 501
 β -D-glucosidases of, 497
 xylanases of, 498
 xyloglucan endo-transglycosylases of, 499
 xylosidases of, 498

 sion, nonconventional yeast, 304
- Immobilization, of enzymes, in nonaqueous
 transformations, 509–510
- Immobilized-metal affinity chromatog-
 raphy, for protein purification,
 736–737

- Impellers, for mammalian cell culture, 679
 Inactivation, of viruses, in mammalian cell culture, 182
 Inclusion bodies, misfolded proteins in, 734
 Incorporating Synthetic Oligonucleotides via Gene Reassembly, 474
 Incubation
 of actinobacteria, 17
 in diffusion chamber, 4–5
 of insect cells, 214
 of secondary metabolites, 74
 Indoleacetic acid, in plant cell culture, 198–199
 Indolebutyric acid, in plant cell culture, 198–199
 Inducible gene expression systems, *Escherichia coli*, 544–545
 Inducible promoters, in mammalian cell genetic engineering, 340–341
 Industrial processes
 algal culture, 577–590
 amino acid production, 595–599
 artemisinin, 141, 142, 364–379, 600–601
 automated bioreactors for, 719–740
 biocatalytic, 549–562
 cell culture, 676–684
 chemical, 480–483
 clavams, 411–425
 continuous culture, 685–699
 enzyme use in, 480–494
 ethanol production, 621–633
 fermentation
 media for, 659–668
 microbial, 669–675
 sampling technologies for, 700–718
 food, 489–491
 insect cell culture, 215–217
 isoprenoid production, 599–601
 mammalian cell culture, 157–178, 179–195, 700–718
 nonaqueous biotransformations, 509–523
 organic acid production, 591–595
 pharmaceutical, 157–178, 179–195, 483–489
 plant cell culture, 196–211
 protein purification for, 731–742
 pulp and paper, 489–491
 robustness improvement in, 605–620
 solid-phase fermentation, 117–131
 textile, 489–491
 In-gel ligation, in polyketide production, 380–381
 In situ microscope, for biomass measurement, 709
 In situ probe, for cell viability measurement, 681–682
 In situ process monitoring, 703–707
 In situ product removal, in bioprocesses, 558–559
 Inoculation
 in miniaturized fermentation, 105–106, 108–110
 in recombinant product production, 136, 137
 in solid-phase fermentation, 124
 Inosine 5'-monophosphate, selective phosphorylation of, 448–449
 Inosine monophosphate dehydrogenase, of nonconventional yeasts, in heterologous product expression, 304
 InPro 8100 biomass sensor, 709
 InPro 5000 carbon dioxide sensor, 710
 Insect(s), cellulose degradation in, 565
 Insect cell culture, 212–222
 for baculovirus synthesis, 217–219
 cell growth in, 212–217
 cell lines for, 212–213
 continuous, *see* Continuous culture
 historical review of, 212
 large-scale, 215–217
 media for, 213–214
 monitoring of, 219
 product recovery in, 219
 small-scale, 214–215
 Insect resistance, plant cell transformation for, 209
 Insulin, production of, 148
 Integral viable cell density, in mammalian cell culture, 680
 Integrated cell sorter, for separation of cellulose-degrading bacteria, 568
 Integrated expression, nonconventional yeasts, 305–307
 Integrative plasmids
 myxobacteria, 268
 Saccharomyces cerevisiae, 291, 293
 Interferon alpha, production of, 148, 660
 Interleukin-6, production of, 152
 International Code of Nomenclature of Bacteria, 30–31
 International Code of Nomenclature of Prokaryotes, 31
 International Committee for Systematics of Prokaryotes, 31
International Journal of Systematic and Evolutionary Microbiology, 32
 Introns
 for gene inactivation, 247–248
 for mammalian cell genetic engineering, 332
 Iodide, in plant cell culture, 197
 Ion exchange chromatography
 for mammalian cell culture, 180
 for protein purification, 735–736
 Ionic liquid pretreatment, of lignocellulose feedstock, 624
 Iron
 in mammalian cell culture, 167
 in plant cell culture, 197
 IS elements, *Clostridium*, 240
 Isoamylase, 504
 Isolates, in taxonomy, 29–30
 Isolation, 3–12
 of algal samples, 580–581
 diffusion chamber method, 3–7
 ichip variation method, 7–9
 media for
 for actinobacteria, 17–19
 for diffusion chamber, 6–7
 microbial trap for, 9–10
 selective, 13–27
 Isopentyl diphosphate, in amorpha-4,11-diene synthesis, 365, 370
 Isopentyl pyrophosphate, in isoprenoid production, 599–601
 Isoprenoids, production of, 599–601
 Isopropyl myristate, production of, 556
 Isopropylmalate dehydrogenase, engineering of, 459
 Iterative gene targeting, in heterologous product expression, 293, 296
 Iterative saturation mutagenesis, for directed evolution, 472–473
 IUBMB Enzyme Nomenclature and Classification, 495
 K
 Kanamycin
 derivatives of, 358
 in heterologous product expression, nonconventional yeast, 304
 as selectable marker, in myxobacteria, 263–264
 Kar2 protein, nonconventional yeasts, 311
 Keio collection, of knockout strains, 280
 Kemp elimination, in enzyme design, 462
 2-Keto-3-deoxy-phosphogalactonate aldolase, in shikimic acid production, 598
 2-Keto-6-hydroxyhexanoic acid, in omapatrilat production, 488
 Kinetics
 of algal culture, 585–587
 of cellulose utilization, 644
 Kinetin, in plant cell culture, 199
 Kits
 for directed evolution, 469
 for DNA extraction
 from *Clostridium*, 241
 from extremozymes, 46
Kluyveromyces, heterologous protein expression in, 303
Kluyveromyces lactis, heterologous protein expression in, 305, 307, 311
 Koji process, 117
 L
 Lab-on-a-chip (LOC) analysis, for peptides and proteins, 712–713
lac genes, in heterologous product expression *Escherichia coli*, 544–545
 nonconventional yeasts, 305, 309–310
lac operator, for myxobacteria, 269
 Laccases
 in biomass degradation, 503
 of extremophiles, 57
 Lactamases, in abacavir production, 486–487
 Lactate, formation of, in mammalian cell culture, 681
 Lactate dehydrogenase, cofactor engineering of, 461
 Lactic acid, production of, 593–594
 Lactose, in fermentation media, 662
 Lambda phage vectors
 for cellulose-degrading enzymes, 572
 for extremozyme libraries, 50–51
 Laminarinase, 498–499
 Landomycins, 348, 354–355, 358
 Lard water, in fermentation media, 663
 Laser manipulation, for separation of cellulose-degrading bacteria, 567
 ω -Lauro lactam hydrolase, in 12-aminolauric acid synthesis, 443
 Leak test, for bioreactors, 677
 LEAP system, for mammalian cell screening, 336
 Leaves, for plant cell culture, 202
LEU2 gene, of nonconventional yeasts, in heterologous product expression, 303, 304
 Level control
 in cellulosytic bacteria culture, 649
 in continuous culture, 692–693
Libertella, secondary metabolites of, 81, 85
 Libertellenones, 81, 85
 Libraries, *see also* Cosmid libraries

 - (R)-Mandelic acid, production of, 482–483
 - Mandelonitrile, nitrilase action on, 444–445
 - Manganese peroxidase, 56
 - Manihot esculenta*, hydroxynitrile lyase of, 517
 - Manipulated variables, in automated bioreactors, 722
 - Mannan(s), enzymes degrading, 499
 - Mannan mannanohydrolases, 499
 - Mannanases, 499
 - Mannheimia succiniciproducens*, in succinic acid production, 142, 594
 - Mannitol
 - in fermentation media, 662
 - in plant cell culture, 199
 - β -Mannosidase, 499
 - Manufacturing execution systems, distributed control systems, 729–730
 - Marine environment, actinobacteria isolation from, 13–27
 - Marine sediments, microbial isolation in diffusion chamber method for, 6
 - ichip method for, 8–9
 - Marine-blade impellers, for mammalian cell culture, 679
 - mariner* insertions, in myxobacteria, 264–265, 429
 - Marker genes, *Saccharomyces cerevisiae*, 288–289
 - Markovnikov additions, in hydrolase reactions, 517
 - Mass spectrometry
 - for amorpho-4,11-diene pathway, 367–368, 373
 - for cellulolytic bacteria culture monitoring, 652–653
 - for mammalian cell culture, 185–186
 - for peptides and proteins, 712
 - for protein characterization, 739–740
 - for robustness improvement, 607
 - for secondary metabolites, 75
 - Mass transfer, in algal culture, 582
 - Master cell bank, for fermentation, 669
 - Matrix attachment regions, in mammalian cell culture, 161
 - MAX cell mass sensor, 709
 - MDM medium, for cellulolytic bacteria culture, 645–647
 - Meat by-products, in fermentation media, 663
 - Mechanical manipulation, for separation of cellulose-degrading bacteria, 567
 - Media
 - for algal culture, 582–583
 - animal component-free, 166
 - for bioprocesses, 557
 - for cellulolytic bacteria, 644–645
 - chemically defined, 659–660
 - for continuous culture, 694–695
 - for fermentation, 659–668
 - chemically defined, 659–660
 - components of, 661–665

- Media (*continued*)
 guidelines for, 666–668
 information sources for, 664–665
 laboratory formulation, 667
 for product synthesis, 666
 rationale for improving, 665–666
 in scale-up, 671
 for hydrolase reactions, 515–517

 357–359
- pBAD promoter, in heterologous product
 expression, *Escherichia coli*, 544–545
- PCR (polymerase chain reaction)
 for algal biomass measurement, 585
 for cellulose-degrading enzymes, 570
 for *Clostridium*, 241
 for cosmid library screening, 352
 error-prone, in direct evolution,
 468–469, 475
 filamentous fungi DNA isolation for,
 321–322
 for taxonomy, 35
- Pectate lyases, 500
- Pectin lyases, 500
- Pectinases, 490, 500
- Penicillin(s), 80
- Penicillin amidase, in nonaqueous
 transformations, 513
- Penicillin G amidase, in beta-lactam
 production, 485
- Penicillium*, secondary metabolites of,
 73–75, 80
- Penicillium chrysogenum*, genetic
 engineering of, 318
- Penicillium patulum*, methylsilylic acid
 synthase of, 381–382
- (S)-2-Pentanol, production of, 488
- Peptide(s), sensors for, 712–713
- Peptide sequencing, for protein
 characterization, 738
- Peptidoglycan, in taxonomy, 36
- PER.C6 cells, in cell culture, 163
- Perfusion systems, for mammalian cell
 culture, 169
- Periplasm, *Escherichia coli* proteins in, 277–278
- Peroxidases
 in biomass degradation, 503
 of extremophiles, 57
 in nonaqueous transformations, 518–519
- Peroxyflavins, Baeyer-Villiger
 monooxygenase and, 530–531
- Personnel, for bioreactor automation,
 721–722
- Perylenequinones, 89
- Pestalone, 85
- Pestalotia*, secondary metabolites of, 81
- pH
 for algal culture, 583
 for automated bioreactors, 723
 for bioreactor automation, 720
 for cellulolytic bacteria culture, 648
 for continuous culture, 689, 695
 for fermentation, 667, 670, 671
 miniaturized, 107
 solid-phase, 125
 for mammalian cell culture, 170, 678, 710
 for nonaqueous systems, 511–512
 for plant cell culture, 198
 sensors for, 710–712
- pH auxostat, for cellulolytic bacteria
 culture, 652
- Phage(s)
 of *Myxococcus xanthus*, 262–263
 polyvalent, for actinobacteria isolation, 16
- Phage display technique, for enzyme
 screening, 467
- Phanerochaete chrysosporium*
 enzymes of, 57
 xyloglucan endo-transglycosylases of, 499
- Phase and recipe automation, 722
- Phenalinolactone, 350, 352, 355
- Phenol, in actinobacteria sample
 treatment, 16
- Phenol oxidase, 56
- Phenol/chloroform method, for DNA
 extraction, from extremozymes,
 45–46
- Phenosafranin staining test, for plant cell
 viability, 206
- Phenotype characterization, for taxonomy,
 35–37
- Phenotypic variation, robustness and,
 605–606
- (S)-*m*-Phenoxybenzaldehyde cyanohydrin,
 production of, 483
- Phenyl acetone monooxygenase,
 promiscuity of, 530–531
- Phenylacetaldehyde cyanohydrins, nitrilase
 action on, 444–445
- Phenylalanine, production of, 613
- D-Phenylglycine, production of, 485
- 1-Phenyl-2-propanol, production of, 556
- Phoenicine, 80
- Phomopsis asparagi*, secondary metabolites
 of, 81
- Phosphate, in plant cell culture, 197
- Phosphoenolpyruvate, in amino acid
 production, 597–598
- Phosphoenolpyruvate carboxykinase, in
 lysine production, 228
- Phospholipase A₁, production of, 152
- Phosphomevalonate kinase, in amorpha-
 4,11-diene synthesis, 365–367
- Phosphonate monoester hydrolase,
 promiscuity of, 532
- Phosphopantetheinylation, in polyketide
 production, 385
- Phosphorus, in fermentation media, 663
- Phosphorylation, of nucleotides, 448–449
- Photobioreactors, for algae, 583–585
- Photosynthesis, in algal culture, 581–582
- Phylogenetic species concept, 28–29
- Physiologic properties, for taxonomy, 36
- Phytagar, in plant cell culture, 199
- Phytoalexins, 207
- Phytoene, production of, 599
- Phytohormones, in plant cell culture,
 198–199
- Phytosterols, biotransformation of,
 488–489
- Pichia pastoris*
 in heterologous protein expression,
 148–149, 305, 307–312
 in monoclonal antibody production, 158
- Pichia stipitis*
 in ethanol production, 627
 in heterologous protein expression, 305
- Picrophilus*, enzymes of, 55
- Pilot study, of assays, 65, 69
- Pilot-scale model, for mammalian cell
 culture, 682–683
- Piromyces equi*, feruloyl esterase of, 501
- Pitch-blade impellers, for mammalian cell
 culture, 679
- PKS gene clusters
 in filamentous fungi, 318
 in myxobacteria, 426–428, 433–434
 silent biosynthetic pathways and, 79, 86

 sterile explants for, 202–203
 strain improvement in, 207
 suspension, 203
 temperature for, 201
 transformation in, 208–209
- Plaque assay, for insect cell culture, 218
- Plasmid(s)
 autonomous, 307
Clostridium, 239–240
Escherichia coli, 368–369, 371, 541–544
 in lipopeptide production, 393
 myxobacteria, 268
 nonconventional yeasts, 307
Saccharomyces cerevisiae, 287–290
Streptomyces clavuligerus, 413
- Plasmid DNA, production of, 141
- Plasmodium* infections, artemisinin for, 141,
 142, 364–379
- Plastics, toxicants leaching from, in minia-
 turized fermentation, 103–104
- Platform technologies, in mammalian cell
 culture, 180
- Plug flow bioreactors, 551–552
- PMAI gene, of nonconventional yeasts, in
 heterologous product expression, 305
- Polishing chromatography, for mammalian
 cell culture, 182
- Polyadenylation, in mammalian cell
 genetic engineering, 331
- Polycation-mediated DNA uptake,
 in mammalian cell genetic
 engineering, 332–333
- Polyethylene glycol, enzymes
 modified with, in nonaqueous
 transformations, 511
- Polygalacturonase, 500

- Polygalacturonan hydrolases, 500
 Polygalacturonan lyases, 500, 505
 Poly-3-hydroxybutyrate, production of, 230
 Polyketide(s), production of
 in *Escherichia coli*, 385–388
 in *Streptomyces coelicolor*, 380–385
 Polyketide synthases, promiscuity and, 527–528
 Polyketomycin, 348, 352, 355
 Polylactic acid, production of, 593
 Polyol oxidases, of extremophiles, 58
 Polyphasic approach, to taxonomy, 29, 32
 Polypropylene, toxicants leaching from, in miniaturized fermentation, 103–104
 Polypropylene glycol, in fermentation media, 664
 Polysialic acid, long-chain, production of, 141
 Polysorbate 80, for mammalian cell culture products, 184
 Polystyrene, toxicants leaching from, in miniaturized fermentation, 103–104
 Polyvalent phage method, for actinobacteria isolation, 16
 Pond, for algal culture, 583–585
 Porcine pancreas lipase, 513
Porphyromonas gingivalis, biofilm formation by, 636
 Positivity rate, of assays, 65
 Posttranslational translation, 311
 Potassium, in fermentation media, 664
 Precipitation, in protein purification, 734
 Preformulation, of mammalian cell culture products, 183–184
 Prenyl pyrophosphate, in amorpho-4,11-diene synthesis, 365–367
 Pressure
 for bioreactor automation, 720
 for fermentation, 670
 Pretreatment
 in fermentation, 664
 of lignocellulose, 621–624
 Principal-factor analysis, 713
 Principal-component analysis, 713
 Prions, in fermentation media, 668
 Process analytical technology, 700, 714–715
 Process control, for automated bioreactors, 722
 Product formation rate, in scale-up, 672
 Product promiscuity, 524–525
 Product quality, in scale-up, 672
 Productivity
 of algal culture, 578, 580, 585–587
 of mammalian cell culture, 680–682
 Profina protein-purification system, 737–738
 Programmable logic controllers, for automated bioreactors, 728–729
 Prokaryotes, taxonomy of, *see* Taxonomy
 Proliferation theory, of biofilm formation, 637
 Promiscuity, enzyme, 524–538
 in alkaline phosphatase superfamily, 531–533
 catalytic, 525–527
 in cofactor-dependency, 530–531
 crosswise catalytic, 531–533
 definition of, 524
 examples of, 524–526
 in hydrolases, 526–527
 mutagenesis for, 533
 nucleophile, 528–530
 product, 524–525
 in secondary metabolism, 527–528
 substrate, 524, 527–528
 Promoters
 in heterologous protein expression
 Aspergillus, 150–151
 Escherichia coli, 274, 277
 filamentous fungi, 323
 nonconventional yeasts, 305
 Saccharomyces cerevisiae, 147, 288, 290
 in mammalian cell genetic engineering, 331, 340–341
 Proportional-integral-derivative control, for automated bioreactors, 724
 Proteases
 deficiency of, in filamentous fungi strains, 324–325
 as detergent additives, 610
 engineering of, 459
 in ethanol production, 625
 in fermentation media, 664
 in heterologous protein expression, 279
 in nonaqueous transformations, 513–517
 chemoselectivity of, 515–517
 commercial availability of, 513
 for enantioselective resolution of racemic chemicals, 513–515
 regioselectivity of, 515–517
 Protein(s), *see also* specific proteins
 characterization of, 738–740
 in fermentation media, 663
 heterologous, *see* Heterologous protein expression
 properties of, 733
 purification of
 assays for, 733
 cell lysis in, 734
 characterization after, 738–740
 concentration step in, 733–734
 high-throughput, 737–738
 industrial-scale, 738
 methods for, 734–738
 properties and, 733
 recovery in, 733–734
 source preparation in, 731–733
 stages of, 731
 sensors for, 712–713
 Protein A affinity chromatography, for mammalian cell culture, 180–181
 Protein disulfide isomerase, in heterologous protein expression, 149, 311
 Protein folding, in heterologous protein expression, 149
 Proteomics
 amorpho-4,11-diene production, 372–373
 corynebacteria, 228
 for robustness improvement, 607
 Protoplast-mediated transformation, of filamentous fungi, 321
 Prototrophic method, in *Saccharomyces cerevisiae* engineering, 288, 289
Prunus amygdalus, hydroxynitrile lyase of, 517
 Prymnesiophyta (Haptophyta), 579
Pseudoalteromonas haloplanktis, enzymes of, 55
Pseudomonas
 lipase of, 487, 513
 secondary metabolites of, 88
Pseudomonas aeruginosa
 exotoxin of, 132, 140–141
 hydrolase of, 532
 secondary metabolites of, 82
Pseudomonas cepacia, in lobucavir production, 487
Pseudomonas chlororaphis
 in enzyme screening, 442
 nitrilases of, 482
 nitrile hydratase of, 482
Pseudomonas fluorescens, secondary metabolites of, 90
Pseudomonas pseudoalcaligenes, in malic acid production, 483
Pseudomonas putida
 biofilm formation by, 636–637
 growth of, 100
Pseudomonas solanacearium, in abacavir production, 486–487
 Psychrophiles, enzymes of
 assays for, 53–54
 sampling of, 44
 Pullulanase, 504
 Pulsed-field gel electrophoresis
 for *Clostridium*, 239
 for taxonomy, 35
 Pumps
 in automated bioreactors, 728–729
 for continuous culture, 693
 Purification, in mammalian cell culture, 180–183
 Pyocyanin, 82, 85
pyr genes, of filamentous fungi, in heterologous product expression, 320–321
Pyrococcus abyssi, enzymes of, 52–53
Pyrococcus furiosus, galactosidase of, 501
 Pyrosequencing, for cellulose-degrading enzymes, 571–572
 Pyruvate
 in alanine production, 595–596
 in carotenoid production, 600
 in isoprenoid production, 599–601
 Pyruvate carboxylase, in lysine production, 228
 Pyruvic acid, production of, 593
Q
 Quality
 critical, of mammalian cell culture products, 185
 of fermentation products, 672, 674
 of mammalian cell culture products, 171
 Quality-by-design, in process analytical technology, 700
 QuikChange protocol, for directed evolution, 469–470
 Quinic acid, production of, 597–598
 Quinones, respiratory, in taxonomy, 37
 Quorum sensing, in *Escherichia coli* engineering, 545
R
 Racemic resolution
 in biocatalysis, 482–483
 in nonaqueous transformations, 513–515
 RACHITT (random chimeragenesis on transient templates) method, in direct evolution, 474
 Radiofrequency impedance method, for cell viability measurement, 681–682
 Raffinose-histidine agar, for *Streptomyces*, 18–19
 RAISE (random insertional-deletional strand exchange) mutagenesis, 474
 Raman spectroscopy, for process monitoring, 705, 707

- Random chimeragenesis on transient templates (RACHITT) method, in direct evolution, 474
- Random insertional-deletional strand exchange mutagenesis, 474
- Random insertion/deletion (RID) method, for direct evolution, 474
- Random mutagenesis, in enzyme engineering, 458–459
- Random segment deletion, in corynebacteria, 226
- Random strand transfer recombination, in direct evolution, 474
- Rapamycin-dependent gene expression system, 340
- Rational and semirational design, of enzymes
 cofactor engineering and, 461–462
 consensus approach to, 458
 cost effectiveness of, 454–455
 energy aspect of, 455–456
 enzyme grafting in, 460–461
 of enzymes, 453–465
 free energy and, 456–457
 libraries for, 459
 screening and, 453–454
 selectivity engineering and, 458–461
 single-variant, 459–460
 stability engineering and, 457–458
 substrate docking in, 460
- Raw materials
 for fermentation, 659–668
 availability of, 665–666
 vs. chemically defined media, 659–660
 guidelines for, 666–668
 information sources for, 664–665
 at large scale, 674
 nature of, 666
 rationale for improving, 665–666
 types of, 661–665
 for mammalian cell culture, 188
- RDP-II database, for genotyping, 34
- Reaction media, for bioprocesses, 557
- recdA* gene, *Escherichia coli*, 280
- Recombinant products
 from bacterial cultivation, 132–144;
 see also *Escherichia coli*, recombinant products from
 bioreactors for, 136–141
 growth in, 136–137
 instrumentation for, 133–134
 medium for, 134–136
 nonprotein, 141–142
 process for, 132
 recovery of, 141
 seed culture for, 134
 starter culture for, 136
 heterologous, 145–156
 filamentous fungi for, 149–152
Pichia pastoris for, 148–149
Saccharomyces cerevisiae for, 146–148, 287–301
 system selection for, 145
 mammalian cell culture for, see Mammalian cell culture
 mutagenesis methods for, 473–474
- Recombineering, for recombinant products, *Escherichia coli*, 280–283
- Recycling
 of biomass, 652
 cell, in continuous culture, 689–690, 693–694
- Red algae (Rhodophyta), 579
- REDIRECT system, for gene disruption, in *Streptomyces clavuligerus*, 413–414, 419
- Red-mediated recombination, in *Escherichia coli*, 280–282
- Redox potential, measurement of, 721
- Refolding, of proteins, 734
- Regeneration, in plant cell culture, 201, 207–208
- Regioselective catalysis, 481–482, 515–517
- Regulations, in media design, 667–668
- Release testing, in mammalian cell culture, 188–189
- Repetitive batch culture, of cellulolytic bacteria, 649–650
- Replication, of *Escherichia coli*, 273–275, 542
- Replicative plasmids, myxobacteria, 268
- Reporter assays, for antibiotics, 65, 66
- Reporter genes
 for mammalian cell genetic engineering, 341
 nonconventional yeasts, 305
- Resequencing, for robustness improvement, 606–609
- Resins, enzymes supported on, 509–510
- Respiratory chain, in lysine production, 229
- Respiratory quinones, in taxonomy, 37
- Restriction enzyme analysis, for taxonomy, 35
- Retroaldol reaction, in enzyme design, 462
- Retroviral vectors, in mammalian cell genetic engineering, 337–340
- Reverse micelles, enzymes modified with, in nonaqueous transformations, 511
- Reverse termination sequencing, for cellulose-degrading enzymes, 571–572
- Reversion assays, for antibiotics, 68
- Rheoswitch, for mammalian cell genetic engineering, 341
- Rhizobium leguminosarum*, hydrolase of, 532
- Rhizopus oligosporus*, in solid-phase fermentation, 120
- Rhodococcus*
 in abacavir production, 486–487
 enzymes of, 443
 nitrile hydratase of, 481–482
- Rhodococcus coprophilus*, selective isolation of, 15
- Rhodococcus rhodochrous*
 in enzyme screening, 441–442
 nitrile hydratase of, 482
- Rhodococcus ruber*, oxidoreductase of, 518
- Rhodophyta, 579
- Ribotyping method, for taxonomy, 35
- Ribozyme display technique, for enzyme screening, 467
- Rice
 fermentation of, 126
 transgenic, 209
- RID (random insertion/deletion) method, for direct evolution, 474
- RNA gene knockdown tools, 324
- Robustness, microbial, 605–620
 in amino acid production, 612–613
 biological, 605–606
 in cellulosic ethanol production, 613–616
 characteristics of, 605
 definition of, 605
 enzyme processing aids for, 609–610
 in fermented beverage industry, 610–612
 genetic adaptability in, 606
 redundancy and, 606
 systems biology tools for, 606–609
 in xanthan production, 613
- ROSETTA software, for enzyme design, 458
- Rotary drum bioreactors, for solid-phase fermentation, 127
- Rotary pumps, in automated bioreactors, 729
- Routine serial subculturing, of algae, 581
- rRNA methods, for genotyping, 33–34
- Rubisco carbon dioxide-fixing enzyme, 587
- Rubrofusarin, 80
- Rumen bacteria, biofilm formation by, 634–636
- Ruminococcus albus*, biofilm formation by, 634–635
- Ruminococcus flavivaciens*, biofilm formation by, 635
- Rushton impellers, for mammalian cell culture, 679
- S
- Saccharomycins, 347, 349, 352, 354, 358
- Saccharomyces cerevisiae*
 in amorpho-4,11-diene synthesis, 365
 in ethanol production, 613–616, 627
 in fermented beverage production, 611–612
 in heterologous protein expression, 146–148, 287–301
 chromosomal integration in, 290–297
 factors affecting, 297
 plasmid vectors in, 287–290, 292
- Saccharothrix espanaensis*, in saccharomycin production, 347, 349
- Safety, for bioreactor automation, 721–722
- SAGE (serial analysis of gene expression), for robustness improvement, 607
- Salinispora*, secondary metabolites of, 73
- Salinispora tropica*, antibiotic derived from, 15
- Salinity, for algal culture, 583
- Salinosporamide A, 15
- Salt activation, of enzymes, in nonaqueous transformations, 510
- Salt-loving organisms, see Halophiles
- Sampling
 of actinobacteria, 13, 15–16
 automated, 701–703
 of cellulolytic bacteria culture, 653–655
 of extremozymes, 43–45
 sensors for, see Sensors
- Sandwich covers, sealing, 101–102
- Sanger sequencing, for cellulose-degrading enzymes, 571–572
- Saquayamycin Z, 348, 354–355, 358
- Saturation mutagenesis
 in enzyme engineering, 458–459, 469–473, 475
 iterative, for directed evolution, 472–473
- Scaffold/matrix associated region (S/MAR) elements, for mammalian cell genetic engineering, 332
- Scale-down, of mammalian cell culture, 682–683
- Scale-up
 of algal culture, 583–585
 automated bioreactors for, 719–740
 of biocatalytic processes, 549–562
 of cell culture, 676–684
 of continuous culture, 685–699
 of ethanol production, 621–633
 of fermentation, see Fermentation,
 scale-up of
 of insect cell culture, 215–217
 of mammalian cell culture, 700–718
 protein purification for, 731–742

- ScaR protein, in beta-lactam regulation, 418
- Scenario analysis, of bioprocess, 553
- Schizophyllum commune*, feruloyl esterase of, 501–502
- Screening
 of actinomycetes, 110–114
 of anti-infective compounds, 62–72
 of enzymes, 441–449
 cellulose-degrading, 569–574
 in directed evolution, 466–468
 rational design and, 453–454
 of ethanologens, 627–629
 of extremozymes, 43–61
 of filamentous fungi strains, 321–322, 324–325
 in mammalian cell genetic engineering, 335–336
 of mammalian cell lines, 163–164
 miniaturized fermentation for, 104–106
- Sealing tapes, for miniaturized fermentation, 100–101
- Seawater
 in algal culture, 583
 sampling of, for extremozymes, 45
- Secondary metabolites, *see also specific products*
 characterization of, 75
 chemically defined media for, 659–660
 enzyme promiscuity and, 527–528
Escherichia coli, 364–379, 385–388
 extraction of, 74
 filamentous fungi, 318
 glycosylation of, 347–363
 identification of, 28–42, 75
 isolation of
 new approaches to, 3–12
 selective, 13–27
 myxobacteria, 426–437
 novel, 73–77
 in plant cell culture, 206–207
 production of, 74
 screening of
 for anti-infective compounds, 62–72
 in extreme environments, 43–61
 separation of, 75
 from silent biosynthetic pathways, 78–95
 in solid-phase fermentation, 121–123
Streptomyces clavuligerus, 411–425
Streptomyces coelicolor, 380–385
 taxonomy of, 73–74
- Secretion assays, for mammalian cell screening, 336
- Sediments, microbial isolation from
 actinobacteria, 13–27
 freshwater, 6
 marine, 6, 8–9
- Seed(s), for plant cell culture, 202
- Seed culture, for recombinant products, 134
- Seed medium, for fermentation, 666
- Seed train, for fermentation, 670
- Selectable markers
 in heterologous protein expression, 303–304
 in mammalian cell culture, 333–334
 myxobacteria, 263–264
- Selection markers, filamentous fungi, 319–321
- Selection systems, for enzymes, in directed evolution, 466–468
- Selective isolation, of actinobacteria, 13–27
 colony selection in, 17–18
 incubation of, 17
 integrated procedures for, 20–21
 media for, 17–19
 samples for, 13, 15–16
 taxa recognition in, 19–20
- Selectivity engineering, of enzymes, 458–461
 grafting in, 460–461
 libraries for, 459
 single-variant design in, 459–460
 substrate docking for, 460
 targeted random mutagenesis for, 458–459
- Selenium, in mammalian cell culture, 167
- Self-cloning, filamentous fungi, 319–320
- Self-heating plant material, microbial isolation from, 16
- Semicontinuous automated bioreactors, optimization of, 727
- Semicontinuous-cascade fermentation, for ethanol production, 630
- Semirational design, *see* Rational and semirational design
- Sensitivity analysis, of bioprocess, 553
- Sensors
 for automated bioreactors, 727
 for autosampling, 701–703
 for biomass, 708
 for bioreactor automation, 720
 for carbon dioxide, 710
 data technology for, 713–714
 for dielectric spectroscopy, 708
 disposable, 710–712
 for downstream applications, 714
 for flow injection analysis, 703
 glass, 710
 for glucose, 706, 708
 history of, 700
 implementing new technology, 700–701
 for new process analytical technology implementation, 714–715
 optical, 708–709, 711–712
 for peptide and protein, 712–713
 for pH, 710
 for protein characterization, 739
 for safety, in automated bioreactors, 721–722
 signal processing for, 727
 soft, 713–714
 for spectroscopy, 703–707
- Separation
 in bioprocesses, 556–557
 of cellulose-degrading bacteria, 567–568
 of secondary metabolites, 75
- Sequencing
 genome, 37, 249–253
 next-generation, 571–572
 pyrosequencing, 571–572
 reverse termination, 571–572
 for robustness improvement, 606–609
 Sanger, 571–572
- Serial analysis of gene expression (SAGE), for robustness improvement, 607
- Serial subculturing, of algae, 581
- Serine, production of, 229–230
- Serine hydrolase, *Candida antarctica* lipase B as, 526–527
- Serine hydroxymethyltransferase, in serine production, 229–230
- Set point, in automated bioreactor control, 724
- Shake flask culture
 for ethanol production, 627–629
 of insect cells, 214–215
 of plant cells, 201–202
 sensors for, 710–711
- Shear denaturation, 550
- Shikimic acid, production of, 597–598
- Shikonin, 206, 207
- Short-chain dehydrogenase/reductase family, 529–530
- Sievers 900 Portable TOC Analyzer, 714
- SIGEX approach, to enzyme screening, 445
- Silencing, gene, in filamentous fungi, 324
- Silent biosynthetic pathways, secondary metabolites from, 78–95
 background of, 78–79
 chemical epigenetic approach to, 89, 91
 coculture techniques for, 81–82
 culture manipulation and, 80–86, 91
 genomic technologies for, 86–89, 91
 genomisotopic method for, 89–91
 heterologous expression of, 86, 88
 hybrid approaches to, 89–92
 phenotype malleability and, 80
- Silicon, in algal culture, 582
- Silicones, in fermentation media, 664
- SimCell bioreactors, 171
- Simocyclinone, 348, 354–355
- Single-use technologies, in mammalian cell culture, 189
- Single-variant design, in enzyme engineering, 459–460
- SIRE glucose sensor, 708
- Size-exclusion chromatography
 for mammalian cell culture, 180
 for protein purification, 737
- Small insert expression libraries, for extremozymes, 50–51
- S/MAR (scaffold/matrix associated regions), for mammalian cell genetic engineering, 332
- Sodium chloride, in fermentation media, 664
- Soft(ware) sensors, 713–714
- Soil
 microbial isolation from
 actinobacteria, 13–27
 diffusion method for, 6–7
 microbial trap method for, 10
 sampling of, for extremozymes, 43–45
- Solanum lycopersicum*, mannases of, 499
- Solenoids, in automated bioreactors, 728–729
- Solid-medium activity screening, for cellulose-degrading enzymes, 573
- Solid-phase fermentation, 117–131
 advantages of, 118
 biocontrol agent production in, 124
 in bioreactors, 126–127
 carbon dioxide in, 120
 characteristics of, 117–118
 disadvantages of, 118
 enzyme production in, 120–121
 food products in, 117, 123–124
 history of, 117
 liquid-phase, 117–118, 122–123
 microbial growth in, 118–120
 mixed-phase, 117–118, 122–123
 moisture content in, 119–120
 monitoring of, 125
 oxygen in, 120
 process control in, 124–126
 secondary metabolite production in, 121–123
 vs. submerged fermentation, 118
 substrate in, 117–118, 120
 temperature in, 119
 water activity in, 119–120
- Solubilization, of enzymes, in nonaqueous transformations, 511
- Solvation effects, in enzyme function, 456–457

- Somatic embryogenesis, in plant cell culture, 208
- Sorangium cellulosum*
DNA transfer into, 263
heterologous gene expression in, 268–269
mutagenesis of, 264, 266
in natural product formation, 426–429, 431, 433–436
secondary metabolites of, 88
- Sorbitol
in fermentation media, 662
in plant cell culture, 199
- Sorghum bicolor*, hydroxynitrile lyase of, 517
- Southern analysis, filamentous fungi DNA isolation for, 322
- Soybean(s)
in fermentation media, 663
transgenic, 209
- Soybean oil, in fermentation media, 662–663
- Sp2/0 lymphoid cell line, for cell culture, 162–163
- Species concept, for taxonomy, 28–30
- Specificity productivity (Qp), in mammalian cell culture, 159, 161, 163–164
- Spectrophotometry, for mammalian cell culture, 185–186
- Spectroscopy
for process monitoring, 703–710
for protein characterization, 739
- Sphaeropsidales*, secondary metabolites of, 80–81
- Sphingomonas*, enzymes of, 443
- Spinner flask culture, of insect cells, 214–215
- Spiroisnaphthalene, 81
- Split range output, for automated bioreactors, 725
- Spodoptera frugiperda*, insect cell lines from, 212–213, 215, 218
- Sporotrichum thermophile*, feruloyl esterase of, 501
- Spreeta sensor, for protein characterization, 739
- Stability
of mammalian cell culture products, 183–184
of product, in fermentation, 674
- Stability engineering, of enzymes, 457–458
- Stabilizing and antirepressor elements (STAR), for mammalian cell genetic engineering, 332
- Stable expression, in mammalian cell culture, 160–161
- Staggered extension process, in directed evolution, 473–474
- STAR (stabilizing and antirepressor elements), for mammalian cell genetic engineering, 332
- Starch
in algae, 578–579
amylase action on, 503–505
in biomass feedstocks, 622
in fermentation media, 662
- Starch-binding domain, in filamentous fungi, 325
- Starch-casein-nitrate agar, for actinobacteria, 17
- Starter culture, for recombinant products, 136
- Statins, production of, 487–488
- Steaming-in-place, for bioreactors, 677
- Stepwise discriminant analysis, for media selection, 19
- Sterile explants, for plant cell culture, 202–203
- Sterile facilities, for plant cell culture, 200–201
- Sterilization
in automated operations, 719–720
of continuous culture media and equipment, 694–695
of media, 134–136, 667
- Steroids, biotransformation of, 488–489
- Stevenson's basal media, supplemented, for *Amycolatopsis*, 19
- Stigmatella aurantiaca*
DNA transfer into, 263–264
media for, 269
mutagenesis of, 266
- Stimulating and anti-repressor (STAR) elements, in mammalian cell culture, 161
- Stirred-tank bioreactors, 551–552
for continuous culture, 691
for insect cell culture, 215–217
for mammalian cell culture, 676
- Storage, of product, in fermentation, 674
- Strains
in antibiotic screening, 68–69
improvement of
corynebacteria, 228–230
Corynebacterium glutamicum, 612–613
filamentous fungi, 322–326
plant cell culture, 207
reconstruction of, corynebacteria, 230–232
- Streptomyces*, for lipopeptide production, 393–394
- Streptomyces coelicolor*, for polyketide production, 380–382
in taxonomy, 29–30
- Stratagene GenMorph kit, for directed evolution, 469
- Streptococcus coelicolor*, accessory substances of, 503
- Streptomyces*
chemically defined media for, 661
in phenalinolactone production, 350
secondary metabolites of, 73, 81, 88
selective isolation of, 18–19
- Streptomyces albidoflavus*, selective isolation of, 18–19
- Streptomyces ambofaciens*, in lipopeptide production, 393, 397
- Streptomyces antibioticus*, in simocyclinone production, 349
- Streptomyces argillaceus*, in glycosylation, 358
- Streptomyces aureofaciens*, in lipomycin production, 349–350
- Streptomyces avermitilis*, in avermectin production, 527–528
- Streptomyces clavuligerus*, genetic engineering of, 411–425
for beta-lactam production, 414–421
biological features of, 412
genetic features of, 413–414
secondary metabolites of, 411–425
- Streptomyces coelicolor*
in polyketide production, 380–385
secondary metabolites of, 84, 86, 88
- Streptomyces cyanogenus*
in glycosylation, 358
in landomycin production, 349
- Streptomyces diastatochromogenes*, in polyketomycin production, 349
- Streptomyces echinatus*, in aranciamycin production, 349
- Streptomyces fradiae*
in aranciamycin production, 358
in glycosylation, 358
in lipopeptide production, 393–395, 397–399, 403, 406
in urdamycin production, 349
- Streptomyces globisporus*, in landomycin production, 349
- Streptomyces griseus*, in streptomycin production, 142
- Streptomyces lividans*, in lipopeptide production, 393–394, 397
- Streptomyces mobaraensis*, transglutaminase of, 491
- Streptomyces nodosus*, in BMS-186318 production, 487
- Streptomyces noursei*, heterologous protein expression in, 304
- Streptomyces roseosporus*, in lipopeptide production, 391–395, 397–399, 403, 406
- Streptomyces viridochromogenes*, in avilamycin production, 347
- Streptomycin, production of, 142
- Streptosporangiaceae*, selective isolation of, 16, 20–21
- Streptoverticillium mobaraense*, transglutaminase of, 232
- Subculture
of algae, 581
in diffusion chamber, 6
of plant cells, 203
- Substrate, for lignocellulose hydrolysis, 624
- Substrate docking, for enzyme engineering, 460
- Substrate promiscuity, 524, 527–528
- Subtilisins
from corynebacteria, 232
covalent modification of, 511
in nonaqueous transformations, 513, 514
- Succinic acid, production of, 142
corynebacteria in, 230
Escherichia coli in, 594–595
- Sucrose
in fermentation media, 662
in lactic acid production, 593–594
in mammalian cell culture products, 184
in plant cell culture, 197–198, 204–205
- Sugars
in acetic acid production, 592–593
enzymes degrading, screens for, 57
for industrial fermentation, 230
in lactic acid production, 593–594
- Suicide substrate method, for filamentous fungi screening, 325
- Sulfite oxidation method, for oxygen transfer rate, 100
- Sulfite resistance, in nonconventional yeast, 304
- Sulfolobus*, enzymes of, 52
- Sulfoxidation, Baeyer-Villiger monooxygenase and, 531
- “Supertertiary”/quaternary structure, of enzymes, 495
- Supervisory control and data acquisition systems, for automated bioreactors, 728–729
- Surface tension, in miniaturized fermentation, 99
- Surfactants
enzymes modified with, in nonaqueous transformations, 511
for mammalian cell culture products, 184

- Suspension culture
 of cellulolytic bacteria, 649
 of mammalian cells, 169
 of plant cells, 203
- Swollenin, 502
- Synchronization, of cultures, in miniaturized fermentation, 105–106
- Systems biology, in microbial robustness, 606–609; *see also* Robustness, microbial
- T**
- T7A1 promoter, in myxobacteria, 269
- Takamine process, 117
- Tapes, sealing, for miniaturized fermentation, 100–101
- Target reversion assays, for antibiotics, 68
- Targeted random mutagenesis, in enzyme engineering, 458–459
- Target-inhibitors, in antibiotic assays, 68
- Taxol, 207, 487
- Taxonomy, 28–42
 chemotaxonomic properties for, 36–37
 culture collections and, 29–30
 current practices and procedures for, 32–37
 description of, 28
 domains in, 30
 genotype characterization in, 32–35
 higher ranks in, 29
 importance of, 28
 information resources for, 37–38
 morphological properties for, 36
 nomenclature rules for, 30–32
 phenotype characterization in, 35–37
 physiologic properties for, 36
 publications of names for, 31–32
 in secondary metabolite screening, 73–74
 species concept and, 28–30
 type strains in, 29–30
 whole genome sequencing in, 37
- TDH3 gene, of nonconventional yeasts, in heterologous product expression, 305
- Teichoic acids, in taxonomy, 36
- Temperature
 for algal culture, 583
 for bioprocesses, 549–550
 for bioreactor automation, 720, 727
 for cellulolytic bacteria culture, 647–648
 for continuous culture, 695
 extremes of, organisms tolerating
 psychrophiles, 44, 53–54
 thermophiles, 44, 51–53
 for fermentation, 670
 for mammalian cell culture, 170–171, 679–680
 for plant cell culture, 201
 for solid-phase fermentation, 119, 125
- Terminal epoxides, production of, 483
- Terminators
 in *Escherichia coli* engineering, 543
 in *Saccharomyces cerevisiae* engineering, 290
- Terpenoids, production of, 599–601
- Test tubes, fermentation in, 114
- Tet-inducible systems, for mammalian cell genetic engineering, 340
- Tetracenomycin, 358
- tetR-tetA* regulator, for myxobacteria, 269
- Thallion Pharmaceuticals, Inc., secondary metabolite scanning method of, 86
- Thermoacidophiles, enzymes of
 host-vector systems for, 52
 lignocellulose-degrading, 55–57
- Thermoanaerobacter*, genome sequencing of, 253
- Thermococcus kodakaraensis*, enzymes of, 53
- Thermolysin, in aspartame production, 483
- Thermomonospora fusca*, enzymes of, 57
- Thermomyces lanuginosus*, xylanase of, 490
- Thermophiles, enzymes of
 assays for, 53
 host-vector systems for, 51–53
 sampling of, 44
- Thermoplasma acidophilum*, enzymes of, 55
- Thermostability, of enzymes, 457–458
- Thermotoga maritima*
 galactosidase of, 501
 glucuronidase of, 501
- Thermus thermophilus*, enzymes of, 51–52
- Thin-layer chromatography, for secondary metabolite detection, 73, 75
- Thioredoxin, cofactor engineering of, 461
- Threonine, production of, 596
- Time point of infection, in insect cell culture, 218–219
- Time proportional output control, for automated bioreactors, 725–726
- Titration rate, for cellulolytic bacteria culture monitoring, 653
- Tolyocladium cylindrosporum*, secondary metabolites of, 75
- Totipotency, 207–208
- Toxicants, in miniaturized fermentation, 103–104
- Trace elements, in plant cell culture, 197
- Trametes versicolor*, enzymes of, 57
- Transcription
 in heterologous protein expression, 147–148
 regulation of, in *Escherichia coli*, 542–543
 termination of
 in *Escherichia coli* engineering, 543
 in *Saccharomyces cerevisiae* engineering, 290
- Transcriptomics
 amorpho-4,11-diene production, 372–374
 corynebacteria, 226, 228
 for robustness, 607
- Transformation
 for glycosylated products, 355–356
 in heterologous protein expression, 150–152, 303
 nonaqueous, 509–523
 in plant cell culture, 208–209
 of yeast, 287
- Transglutaminases, 491
- Transient expression, in mammalian cell culture, 161, 336–337
- Transition state analogs, in substrate docking, 460
- Translation
 in heterologous protein expression, 147–148
 regulation of, in *Escherichia coli* engineering, 543
Saccharomyces cerevisiae, 297
- Translocation, types of, 311
- Transposons
Clostridium, 240, 245–246
 corynebacteria, 225–226
 myxobacteria, 264
- Trap, microbial, 9–10
- Tray bioreactors, for solid-phase fermentation, 126
- Trehalose, in mammalian cell culture products, 184
- Tributyryn assay, for enzyme screening, 467
- Trichoderma reesei*
 enzymes derived from, 624
 genetic engineering of, 318
- Trichoplusia ni*, insect cell lines from, 212–213, 215, 218
- Trichosporon*, in naproxen production, 487
- Trioleins, production of, 557
- Triose phosphate dehydrogenase, of nonconventional yeasts, in heterologous product expression, 305
- Triphenyltetrazolium chloride test, for plant cell viability, 205–206
- Triticum aestivum*, xylanase inhibitors of, 498
- tRNA 16S, for genotyping, 34
- TRP1 gene, in heterologous product expression, nonconventional yeasts, 303
- trpC* promoter, in heterologous protein expression, 150
- Trypan blue exclusion method, for cell viability, 681
- Trypsin, engineering of, 459
- Tryptic mapping, for protein characterization, 738
- Tubular bioreactors, for algal culture, 583, 584
- Tunicamycin, 411
- Tunnel structure, of cellobiohydrolases, 496
- Turbidity, measurement of, 721
- Turbidostats, in continuous culture, 688–689
- Turbulence, in miniaturized fermentation, 102–103
- Tylosin derivatives, 358
- U**
- Ubiquitous chromatin opening elements (UCOE), for mammalian cell genetic engineering, 332
- Ultra performance liquid chromatography, for secondary metabolites, 75
- Ultracentrifugation, for protein characterization, 738–739
- UltraClean MegaPrep kit, for DNA extraction, from extremozymes, 46
- Ultrafiltration
 for bioprocesses, 556
 for continuous culture, 694
 for mammalian cell culture, 180
- Ultraviolet spectra, for secondary metabolite detection, 75
- Umami taste, products for, 448–449
- Unfolded protein response, 149
- URA3 gene, in heterologous product expression
 nonconventional yeasts, 303, 304
Saccharomyces cerevisiae, 293, 296
- Urdamycins, 348, 354–355, 358, 359
- Uridine 5'-diphosphogalactose, production of, 489
- V**
- Validation
 of assays, 65
 of fermentation equipment and process, 674
 in mammalian cell culture, 186–188
- Valine, production of, 596
- Valves, in automated bioreactors, 728–729

- van der Waals forces, in enzyme function, 456
 Vanillin, production of, 141
 Variable frequency drive, for agitation control, 729
- Vectors
Clostridium, 243–245
 filamentous fungi, 319–322
 for heterologous protein expression
Aspergillus, 150–151
Escherichia coli, 273–278, 541–544
 glycosylated products, 351–352
 of nonconventional yeasts, 303–304
Pichia pastoris, 148–149
Saccharomyces cerevisiae, 146–147, 287–290, 292
 for mammalian cell culture, 160, 330–332, 337–340
 for polyketide production, 380–382
- Vegetable oils, in fermentation media, 662–663
- Verrucomicrobia*, isolation of, in diffusion chamber, 6
- Verrucospora maris*, antibiotic derived from, 15
- Versatile peroxidase, in biomass degradation, 503
- Viability assays, for plant cell culture, 205–206
- Viable cell density, in mammalian cell culture, 680–681
- ViCELL cell viability analyzer, 681–682
- Viral vectors, for mammalian cell genetic engineering, 337
- Viruses, removal of, in mammalian cell culture, 181–183
- Viscosity, problems with, 559
- Vitamins
 in algal culture, 582
 in cellulolytic bacteria culture, 645–646
 in plant cell culture, 198
- Vitreoscilla*, heterologous protein expression in, 310
- Volume
 for bioreactor automation, 721
 for fermentation, 671
- W
 Wall growth, in fermentation, 668
 Waste streams and treatment, in fermentation, 674
- Water
 actinobacteria isolation from, 13–27
 in algal culture, 582–583
 contaminated, microbial isolation in, 6–7
 control of, in nonaqueous systems, 511
 in fermentation media, 666
 sampling of, for extremozymes, 43–45
 in solid-phase fermentation, 125
- Water activity, in solid-phase fermentation, 119–120
- Wave bioreactor, for insect cell culture, 216
- Weight measurement, in plant cell culture, 204
- Well-closure systems, in miniaturized fermentation, 100–102
- Wet fresh weight, in plant cell culture, 204
- Whey, in fermentation media, 662
- Wine industry, robustness improvement for, 610–612
- Wood rot fungi, oxidases of, in ethanol production, 625
- Working cell bank, for fermentation, 669
- X
 Xanthan, production of, 613
 Xanthine dehydrogenase, in heterologous protein expression, 152
Xanthomonas axonopodis, hydrolase of, 532
Xanthomonas campestris, in xanthan production, 613
- X-ray crystallography, for protein characterization, 740
- Xylanases
 in ethanol production, 624–626
 of extremophiles, 56
 production of, 490
- Xyloglucan endo-transglycosylase, 499–500
- Xyloglucan hydrolase, 499–500
- Xylose
 enzymes degrading, 55–56
 in fermentation media, 662
 fermentation of, 230
 β -Xylosidase, 498
- Y
Yarrowia lipolytica, heterologous protein expression in, 307
- Yeast(s), *see also specific yeasts, e.g., Saccharomyces cerevisiae*
 brewery, in fermentation media, 663
 for fermented beverage industry, robustness improvement for, 610–612
 nonconventional, *see Nonconventional yeasts*
 transformation of, 287
- Yeast centromeric plasmids, 287–288
- Yeast episomal plasmids, 287
- Yeast extract, in plant cell culture, 199
- Yeast integrative plasmids, 287
- Yeast replicating plasmids, 287
- Yeast surface technique, for enzyme screening, 467
- YFG1 gene, of *Saccharomyces cerevisiae*, in heterologous product expression, 291, 293, 294
- YSD culture media, in insect cells, 214
- YSI 8500 carbon dioxide sensor, 710
- Z
 Zap Express, for extremozyme libraries, 50–51
- Zeatin, in plant cell culture, 199
- Zeaxanthin, production of, 599
- Zeocin, of nonconventional yeasts, in heterologous product expression, 304
- Zeolite, enzymes supported on, 509–510
- Zymomonas*
 in alcoholic beverage production, 611
 in ethanol production, 627
- Zymotis bioreactor, 126–127
