Calcium-channel blockade in vascular smooth muscle results in vasodilatation and blood pressure reduction. In the kidney, experimental blockage of calcium-dependent mechanisms in animals and humans may result in inhibition of the vasoconstrictive and hypertrophic effects of angiotensin. The predominant effect of calcium-channel blockade in experimental animals, however, is the preferential vasodilatory action on the afferent arteriole. All calcium-channel blockers appear to dilate the afferent arteriole, but their effects on the efferent arteriole may vary (142).

The calcium-channel blocking agents differ with regard to their duration of action, activation of the sympathetic nervous system, and interactions with voltage-operated membrane channels; the potential impact of subclass differences among calcium-channel blockers has best been demonstrated by experimental kidney micropuncture studies in animal models. Afferent arteriolar vasodilatation is shared by calcium-channel blockers of different subclasses, resulting in potential impairment of renal autoregulation. As a result, as systemic pressure is reduced, the desired lowering of intraglomerular pressure may not occur unless efferent arteriolar resistance is also decreased (Table 55.5).

Decreased efferent tone has been shown in diabetic animal models treated with diltiazem or verapamil (143). Other studies have shown no effect of the dihydropyridine nifedipine on efferent arteriolar resistance (144). Additional renal effects, such

as changes in permeability of the glomerular basement membrane or histologic damage from diabetes, may also differ among subclasses of calcium-channel blockers.

These different renal effects are most relevant to the renal protective reduction in proteinuria, a surrogate marker of renal disease progression. Early studies revealed differences between the antiproteinuric effects of certain calcium-channel blockers (the nondihydropyridines verapamil and diltiazem) compared with the neutral or worsening effects of others (the dihydropyridine nifedipine), unrelated to the extent of blood pressure control (145). Hemodynamic disturbances in autoregulation, allowing direct transmission of systemic blood pressure to the glomerulus, would favor proteinuria, whereas a hemodynamic reduction in glomerular pressure or permeability or a reduction in glomerular hypertrophy (146) would minimize glomerular injury and proteinuria.

These complex actions account for conflicting effects on proteinuria and support the confirmations by recent clinical trials that nondihydropyridines reduce proteinuria and the dihydropyridines do not. The renal effects of nondihydropyridines such as diltiazem and verapamil more closely resemble those of ACE inhibitor therapy. A number of comparative trials in both type 1 and type 2 diabetic nephropathy have been reported.

Data on the use of calcium-channel blockers in patients with type 1 diabetes with incipient nephropathy are limited. The decrease in blood pressure and microalbuminuria with nifedipine was comparable to that with the ACE inhibitor perindopril over 12 months in a mixed population of nonhypertensive and hypertensive patients with type 1 and type 2 diabetes (145). A short-term randomized trial in normotensive microalbuminuric patients with type 1 diabetes reported a slight decline in systemic pressure with either nifedipine or captopril. Nonetheless, urinary albumin excretion rate increased 40% with nifedipine but decreased 40% with the ACE inhibitor. No significant changes in renal function occurred (146). In patients with type 1 diabetes with overt nephropathy, several agents, including nifedipine, nisoldipine, and isoldipine, failed to reduce proteinuria despite blood pressure reductions similar to those with ACE inhibitors (142). No studies have demonstrated a reduction in rate or loss of function in the long -term.

More trials in patients with type 2 diabetes have been reported. Both dihydropyridine and nondihydropyridine calcium-channel blockers may be useful in type 2 diabetic nephropathy. In several studies, nondihydropyridines and ACE inhibitors reduced the urinary albumin excretion to a similar extent. However, dihydropyridine calcium-channel blockers failed to reduce proteinuria levels in patients with type 2 diabetes and overt nephropathy.

In several studies, nondihydropyridines appear to be effective in patients with type 2 diabetes with overt nephropathy. Treatment with diltiazem resulted in a 30% reduction of proteinuria in nephrotic patients with type 2 diabetes with nephropathy in a 6-week crossover trial, similar to a group treated with lisinopril (147). The first long-term trial of calciumchannel blockers versus other antihypertensive therapies reported that nondihydropyridines slowed renal progression similarly to the ACE inhibitor and more than a β -blocker (148). Slowing of progression of renal disease correlated with reductions in proteinuria (Fig. 55.14).

A trial by Bakris et al. published in 1998 (149) indicated that the combination of the nondihydropyridine verapamil and the ACE inhibitor trandolapril had additive effects compared with either agent alone, despite similar levels of blood pressure reduction. Of note, one study (150) has addressed the issue of

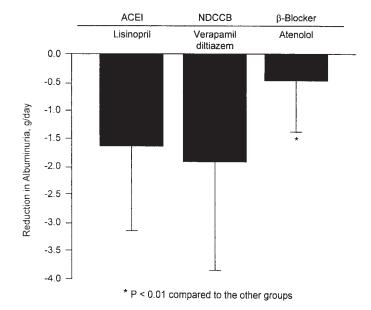

Figure 55.14. Similar sustained reduction (63 months) of albuminuria with the nondihydropyridine calcium-channel blockers (NDCCBs) verapamil and diltiazem and the angiotensin-converting enzyme inhibitor (ACEI) lisinopril in type 2 diabetic nephropathy. NDCCBs and the ACE inhibitor also had similar effects on slowing the decline in renal function. Despite similar blood pressure, the β -blocker atenolol was less effective. **P* < 0.01 compared with other groups. (Reprinted from Bakris GL, Copley JB, Vicknair N, et al. Calcium-channel blockers versus other antihypertensive therapies on progression of NIDDM associated nephropathy. *Kidney Int* 1996;50:1641–1650, with permission.)

underrepresentation of African Americans with type 2 diabetes in clinical trials, particularly because calcium-channel blockers may be more effective than ACE inhibitors for treating hypertension in African Americans (151). Over 6 months, proteinuria worsened by 50% in patients treated with isradipine compared with a 30% reduction in those treated with captopril; these changes were not related to changes in systemic hemodynamics or renal function. Caution is indicated when calcium-channel blockers are used in African Americans.

The safety of calcium-channel blockers in diabetic patients has been widely debated. In 1995, a meta-analysis indicated that short-acting dihydropyridine calcium-channel blockers might be harmful, particularly in patients with hypertension and diabetes, by increasing the rate of myocardial infarction (152). At the premature termination of the ABCD trial, increased cardiovascular morbidity and rates of myocardial infarction in hypertensive patients with type 2 diabetes treated with nisoldipine relative to those in patients treated with enalapril were reported (40). The FACET study also was terminated owing to reported increases in cardiovascular events in a group of patients with type 2 diabetes treated with a dihydropyridine calcium-channel blocker (54). In contrast, the Syst-Eur Trial reported reduced cardiovascular events with the long-acting calcium-channel blocker nitrendipine (153), and the HOT trial reported an association of felodipine with a reduction in cardiovascular events (38). Although the cardiovascular risk is of concern, the above trials have not established the degree of this risk associated with calcium-channel blockers, which remains uncertain (154). Slow-acting formulations of calcium-channel antagonists may be safer (140). No changes in the recommended use of calcium-channel blockers has yet emerged from these trials (142).

Role of Diet in Slowing Progression of Diabetic Nephropathy

Diet clearly has a role in nephropathy by improving glycemic control. Moreover, as weight loss contributes to improved glycemic control, the value of the diet cannot be overstated. In addition, dietary changes can improve blood pressure regulation by reducing sodium intake and possibly be resulting in a more balanced diet. The role of other specific diets in preventing progression is more controversial. In particular, a low-protein diet has been advocated as being of particular importance in slowing progression of diabetic nephropathy. Animal and human studies have shown that the institution of a low-protein diet slowed the progression of both diabetic and nondiabetic kidney disease (155-157). The rationale is that increased protein intake leads to an increased GFR and increased glomerular hydrostatic pressure. Reducing this pressure (as ACE inhibitors do) by reducing protein in the diet should be protective for the kidney. Although studies in humans have been apparently successful, however, in practice it is quite difficult for a patient to stay on a low-protein diet. The recommendations at this time are for patients not to eat less than 0.6 g of protein per kilogram daily to avoid malnutrition. In general, less than 0.8 g/kg daily is considered a low-protein diet. At this time we recommend reviewing a patient's diet with a nutritional expert, and if the diet is quite high in protein, to suggest reducing the protein content. Possibly a low-protein diet should be used only by patients for whom other interventions cannot be done or are inadequate.

MANAGEMENT OF END-STAGE RENAL DISEASE

The above-discussed treatments represent the evolution of management of diabetic nephropathy over the past few years; however, eventual progression to ESRD may still be expected in many patients with type 1 or type 2 diabetes. Despite recent advances from clinical trials outlined above, in the United States diabetes has risen from a common cause of new cases of ESRD to being the largest single cause (Fig. 55.15). In the United States, the increase in incidence of ESRD due to diabetes continues to exceed all other

	Hypoglycemia	More GI complaints
		Orthostatic hypotensio

TABLE 55.6. Comparison of Dialysis Options for the

major causes. The high incidence of ESRD due to diabetes extends globally (Fig. 55.16).

gastrointestinal

The ESRD population is growing by 10% per year. Summary statistics from the 1999 United States Renal Data Systems (USRDS) report show 84,076 diabetics receiving dialysis and 18,350 with transplants at year-end 1997, comprising 33% of the total Medicare ESRD population. More than 33,000 diabetic patients, or nearly 42% of all new patients, initiated treatment under the Medicare program that year (2,158).

The incidence rates of reported therapy for ESRD have risen from 48 to 124 per million population over the past reported decade. About one half of the patients are older than 64 years of age, and only 2% are younger than 20. Much of the increase is due to older type 2 diabetic patients, so that the mean age of diabetic patients with ESRD is now over 60. About two thirds have type 2 diabetes.

ESRD in patients with diabetes reflects the demographics of diabetes itself (159). About 70% of diabetic patients with ESRD are white and 30% are black. The predominant cause is type 1 diabetes in whites and type 2 diabetes in blacks (160).

Dialysis options for the diabetic patient receiving dialysis are shown in Table 55.6. In the United States, patients with diabetes are somewhat more likely than those without diabetes to be managed with chronic hemodialysis and less likely to have a functioning transplant. Whatever the modality, the treatment of patients with diabetes is considerably more costly than that of patients without diabetes: Compared with an average of \$42,853 spent annually for all patients, the cost for each patient with diabetes was greater by more than \$8,000 regardless of modality. The number of hospital admissions is one-fifth higher, and the number of days hospitalized is one-fourth greater than for patients without diabetes (2).

TABLE 55.7	End-Stage Renal Disease Problems for the
	Patient with Diabetes

Problem	Evaluation
Vascular access	Preservation of vasculature and early assessment for native fistula

Visual impairment	Ophthalmology evaluation
Foot ulcers	Podiatry evaluation
Peripheral vascular disease, limb amputation	Doppler flow studies
Gastroparesis	Gastric emptying study
Neuropathic problems	Electromyography, neurologist
Malnutrition	Serum albumin, dietary counseling, physical exam

Diabetic patients with ESRD are also those at greatest risk for complications and more likely to have other comorbid conditions. Only a multidisciplinary team of healthcare providers, including the nephrologist, ophthalmologist, vascular surgeon, transplant specialist, cardiologist, podiatrist, renal nutrition expert, and social worker, can provide optimal management to address the list of problems in the diabetic patient with ESRD (Table 55.7). As the transition from renal failure to ESRD occurs, new complexities in management emerge. For example, insulin requirements decrease, retinopathy progresses, hypertension (161) and fluid retention worsen, and gastroparesis becomes refractory to medication. Complications are severe in one half of the patients: One third are blind, one third have diagnosed coronary artery disease, and one in five have had a myocardial infarction. In turn, other uremic problems may be worsened by the presence of diabetes, including nausea, vomiting, impotence, neuropathy, and vascular disease. The functionally dependent diabetic patient with ESRD with multiple comorbid conditions requires increased care by the dialysis provider (162).

Although the optimal time to initiate dialysis has yet to be defined, dialysis needs to be initiated earlier in uremic diabetic patients, to avoid life-threatening events and acceleration of retinopathy. Goals of management include preservation of vascular access, control of hyperglycemia and hypoglycemia, reduction in cardiac mortality, maintenance of vision, avoidance of foot ulcers and limb amputation, and prevention of malnutrition.

Good glycemic management continues to be a priority when the diabetic patient reaches ESRD (163). Recent data suggest a high mortality risk associated with large weight gains resulting from hyperglycemia in diabetic patients receiving dialysis (165). Glycemic control may retard complications of microvascular disease (165), limit hyperkalemia (166), prevent catabolism, and minimize infection. It may also be associated with shorter hospitalizations, improved gastroparesis and orthostatic hypotension, decreased myocardial infarction, and higher serum albumin levels.

TABLE 55.8.	Consequences of Hyperglycemia in Patients
	with Diabetes on Hemodialysis

- Thirst, excessive fluid intake, weight gains between dialysis, hypertension
- Pulmonary edema
- Increased weight gains
- Severe hyperkalemia
- Diabetic ketoacidois
- Shifts in serum osmolality
- Anorexia, nausea, vomiting, weaknessIncreased risk of infection

Signs and symptoms of hyperglycemia are modified in the patient undergoing dialysis (167,168) (Table 55.8). Anorexia, nausea, vomiting, weakness, worsened gastroparesis, and altered mental status may also occur. Sustained severe hyperglycemia may produce only vague, nonspecific symptoms (169). However, insulin dosing and glucose regulation are more complex when diabetic patients become dependent on dialysis (170). Lower doses of insulin may suffice, and oral agents or even insulin may be discontinued in some patients. Alternatively, hypoglycemia is a potentially serious complication feared by diabetic patients receiving dialysis (171). Severe episodes cause significant morbidity, including new retinal hemorrhages and coronary ischemia or even death, and make tight glycemic control almost impossible. Mechanisms of hypoglycemia include decreased insulin clearance, causing inappropriate elevations of insulin levels, lack of gluconeogenesis by failed kidneys, and impaired sympathetic counterregulatory responses. Additional hypoglycemic factors are shown in Table 55.9.

In a recent review (172), 4% of admissions of patients with ESRD (one third of them were nondiabetics) were for hypoglycemia. Almost one half of admissions due to hypoglycemia were drug-related, but more than one third were due to sepsis. Hypoglycemia was often fatal if associated with sepsis or malnutrition. Drugs that are important causes of drug-induced hypoglycemia include sulfonylureas and nonselective β-blockers. Prolonged sulfonylurea-induced hypoglycemia may occur in diabetic patients with ESRD and cause hypoglycemic coma and brain damage (173). Renal failure is a well-recognized risk factor for hypoglycemia. Additional risk factors include reduced oral intake, previous hypoglycemic episodes, and long duration of diabetes. Biguanides and acarbose should be avoided. Glyburide carries a risk comparable to that of the first-generation sulfonylurea chlorpropamide and greater than that of other currently popular oral hypoglycemic agents because its weak metabolites are cleared by the kidneys. Avid binding to pancreatic islets by glyburide may be associated with a sustained insulin response. Acceptable oral hypoglycemic agents in ESRD

TABLE 55.9. Risk Factors for Hypoglycemia in End-stage Renal Disease

- Reduced intake
- Malnutrition
- Liver disease
- Alcohol ingestion
- Longer-duration diabetes
- Other drugs

include glipizide, newer thiazolidenediones, and possibly meglitimide. Diverse symptoms caused by hypoglycemia in chronic renal failure are predominantly neuroglycopenic and include headaches, nausea, vomiting, confusion, drowsiness, lethargy, tremors, seizures, and unconsciousness. Angina (174), silent myocardial infarction, and elevated systemic blood pressure may also occur. Hypoglycemic unawareness is frequent.

According to USRDS data for 1997, almost 24,000 diabetic patients with ESRD died. There were 270 deaths per 1,000 patient years, compared with 200 for nondiabetic patients with ESRD. Over the past few years, survival of diabetic patients receiving dialysis has remained constant or has even increased, despite the overall aging of the ESRD population with diabetes (175). However, by every account, morbidity and mortality remain significantly higher than for nondiabetic patients with ESRD (176). The worse prognosis for patients with diabetes receiving dialysis is due in large part to progression of comorbid conditions. The overall mortality risk is increased about 1.5-fold in diabetic versus nondiabetic patients with ESRD. Survival of patients with diabetes is slightly reduced at 1 year (Fig. 55.17) but falls to roughly one half at 5 years compared with patients with ESRD due to all other causes. Most of the excess mortality in diabetes is due to associated cardiovascular disease, which is greater in patients with type 1 or type 2 diabetes. A growing number of studies have reported predictors of survival in ESDR. As in patients without diabetes, the survival of patients with diabetes is affected by comorbid conditions (177). The number of preexisting comorbid conditions at the start of dialysis is greater for patients with diabetes than for patients without diabetes.

Ischemic heart disease poses the major threat to sustained survival of the patient with diabetes who is receiving dialysis. The risk of coronary artery disease is dramatically increased in patients with type 1 diabetes and nephropathy (178,179). In a recent study of more than 400 ESRD patients followed from the start of therapy for ESRD, diabetes independently predicted cardiac death over a mean follow-up of 41 months (180). Management must address individual coronary risk factors (181). With ESRD, high cholesterol levels tend to remit, whereas triglyceride levels, which are weaker coronary risk factors, worsen. In addition, the ApoB/ApoA1 (apolipoprotein B/apolipoprotein A1) ratio, an atherogenic index of uremia, is more elevated in patients with diabetes undergoing dialysis (182), as is lipoprotein (A), Lp(A), a recently emphasized risk factor (183). Finally, limited data support an inverse relationship between the frequency and duration of dialysis and coronary risk in diabetic patients.

Clinical strategies to achieve better cardiac outcomes must improve preventive measures and therapy for coronary disease. However, the efficacy of coronary preventive measures in the diabetic patient with ESRD is unclear. Because coronary risk is high, aggressive diagnostic testing for coronary artery disease is appropriate. Unfortunately, diabetes itself is associated with an increased rate of coronary restenosis following percutaneous transluminal coronary angioplasty (PTCA) (184,185) and of subsequent progression of coronary disease. Long-term outcomes have been relatively poor in dialysis patients receiving PTCA, in whom repeat procedures can be anticipated (186).

The management of hypertension in the uremic patient with diabetes is complicated by the presence of renal disease and renal replacement therapy. Calcium-channel blockers and ACE inhibitors are primary treatments. ACE inhibitors are underutilized because of the fear of hyperkalemia. Factors that need to be considered when hypertension is uncontrolled include poor drug absorption (in the presence of gastroparesis), dialyzability (atenolol, methyldopa, captopril), cost (methyldopa

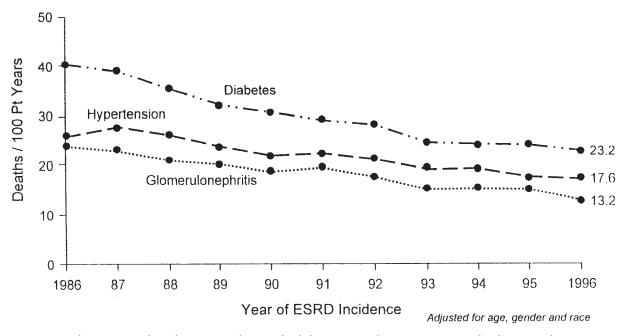

Figure 55.17. Adjusted 1-year mortality rates for diabetes versus other common causes of end-stage renal disease (ESRD) over a 10-year period in the United States. Adjusted by age, race, and gender. (Source: US Renal Data Systems.)

and clonidine are relatively inexpensive), and side effects. Long-term aggressive correction of hypertension in patients with diabetes may reduce the risk of coronary artery disease (187). However, the effects of antihypertensive regimens on cardiovascular disease or other diabetic complications in patients with uremia have not been adequately studied. Overtreatment of hypertension in diabetic patients with uremia who are at risk for coronary ischemia may be dangerous, especially because intradialytic hypotension is more likely in patients with diabetes.

Diabetes is the leading cause of blindness in uremic patients. The ocular complications in type 1 and type 2 diabetes are similar. Progression of retinopathy is a major problem for the diabetic patient receiving dialysis, although ophthalmologic screening programs can prevent vision loss and are cost effective (188). Almost all patients with type 1 diabetes have background or proliferative retinopathy when they start dialysis; 75% have visual disturbances, and 50% have significant visual loss (189). About half as many patients with type 2 diabetes are affected. With current technology, dialysis itself does not appear to exacerbate vision loss (190). The visual prognosis for uremic patients with diabetes has improved because of the collaboration among the nephrologist, diabetologist, and ophthalmologist. The stage of retinopathy determines the ophthalmologic treatment (191). Early intervention is mandatory. Visual acuity may be improved by resolution of macular edema following correction of anemia with erythropoietin (192). Raising the red cell mass by treatment with erythropoietin may also improve retinal hard exudates (193). With aggressive eye management, diabetic patients undergoing dialysis can achieve a visual prognosis similar to that of diabetic patients who have received a kidney transplant (194).

Amputations of the lower extremities are a major source of morbidity for diabetic patients receiving dialysis (195). Uremic diabetic patients with lower-limb disability make poor psychosocial adjustments to illness and should be psychologically prepared for long periods of convalescence (196). Many clinicians advocate the use of peritoneal dialysis as an alternative to hemodialysis for uremic diabetic patients. Nonetheless, peritoneal dialysis is the treatment option for less than one in four adults with diabetes in the United States (2). Although peritoneal dialysis has several potential advantages, actual data supporting an advantage of this type of dialysis in diabetic patients are limited but do suggest that techniques and patient survival have improved. Fewer than half of the patients on peritoneal dialysis remain on that modality after 2 years of treatment.

Glycemic control in patients receiving peritoneal dialysis is a desirable therapeutic goal. Intraperitoneal administration of insulin eliminates the need for injections, provides more consistent insulin absorption, lowers peripheral insulin levels, lessens the risk of hypoglycemia, and provides constant basal insulin dosing. The major benefit of intraperitoneal administration of insulin is improved glycemic control (197). Although significant clinical benefit has not been proven in clinical trials, intraperitoneal insulin is preferred in most patients receiving peritoneal dialysis (198). Hypoglycemic reactions are fewer and milder than in patients receiving hemodialysis (199). Survival data for patients receiving peritoneal dialysis are similar to those for patients receiving hemodialysis, as are the prevalent causes of mortality.

NOVEL APPROACHES TO TREATMENT OF DIABETIC NEPHROPATHY

Trials of a number of novel approaches to therapy are in the planning stages or are under way. All of these therapies are aimed at interfering with one or more of the mechanisms of diabetic nephropathy.

Protein kinase C (PKC) is a serine/threonine kinase that has been shown to play important roles in normal cell growth, cancerous cell growth, and a number of other intracellular processes. Studies, especially those of King and associates (200), have

946 JOSLIN'S DIABETES MELLITUS

shown that hyperglycemia leads to activation of isoforms of PKC, especially PKCβ. It has been suggested that PKCβ plays an important pathophysiologic role in the development of vascular, retinal, and other complications of diabetes mellitus. Using an inhibitor that specifically blocks PKCβ (LY333531), King and colleagues showed, in diabetic rats, that both retinopathy and nephropathy improved in animals treated with the PKCB inhibitor. In particular, the GFR and albumin excretion rate improved. These intriguing results have led to a worldwide trial of the PKC β inhibitor for retinopathy. Nephropathy trials will start in the near future, suggesting that PKC inhibitors may play an important role in future treatments for diabetic nephropathy.

As discussed in Chapter 51, oxidant stress in thought to be a critical factor in the development of diabetic nephropathy. Koya and colleagues studied the utility of vitamin E in reducing the progression of nephropathy (201) and found that the increase in albuminuria and GFR in rats was significantly reduced by vitamin E. Currently, a number of studies are aimed at determining whether antioxidants such as vitamin E have a therapeutic role in the treatment of diabetic nephropathy. So far, results have been equivocal with a variety of antioxidants, but trials of various agents and dosing regimens are ongoing.

Advanced glycation end-products (AGEs) are proteins that have reacted with glucose nonenzymatically. Although they exist normally, the number of AGEs increases significantly in patients with diabetic nephropathy. AGEs have been implicated in the development of the complications of diabetes (202). In particular, AGEs can cause collagen cross-linking and, by binding to specific receptors, can lead to the production of oxidants and to cellular damage. Administration of AGEs to animals can cause a number of changes seen in animals with diabetes. A number of ongoing trials of inhibitors of AGEs are attempting to determine whether these drugs can both help patients with established nephropathy and prevent diabetic nephropathy.

POSSIBLE APPROACHES TO THE COMPLETE PREVENTION OR CURE OF DIABETIC NEPHROPATHY

At this time there is no clear approach to the complete prevention or cure of diabetic nephropathy. Suggested approaches include the treatment of all patients with diabetes with ACE inhibitors or AR blockers as a preventive measure and islet cell/pancreatic transplantation (203). The suggestion of using blockers of ATII action is based on the idea that angiotensin plays a critical role in the development of diabetic nephropathy, although at this time, there is no evidence for this or for any effect of these drugs on the development of diabetic nephropathy. Considering that as many as 60% to 70% of patients with diabetes will not develop nephropathy, we believe that it is not appropriate for all patients to take these drugs until sufficient positive studies have been completed. On the other hand, if a patient with diabetes has hypertension, the use of ACE inhibitors or AR blockers makes sense, as they will lower blood pressure and possibly have other therapeutic benefits.

Pancreatic transplants have been shown to actually slow and reverse lesions of diabetic nephropathy. Mauer and colleagues studied patients up to 10 years after pancreatic transplantation and showed by renal biopsy that there was a clear regression of disease (203). Although this is very exciting, pancreatic transplantation is not widely used because the risks of immunosuppression and because the relative scarcity of pancreases make this approach useful only in a select number of patients. Of promise, however, is the new field of islet cell transplantation.

In theory, successful islet cell transplants should be as effective as pancreatic transplants.

SUMMARY OF RECOMMENDATIONS

- Screening of patients:
- Patients with type 1 diabetes should be screened for microalbuminuria yearly 5 years after diagnosis. Patients with type 2 diabetes should be screened early, starting at the time of diagnosis. The preferred screening method is the albumin/creatinine ratio.
- For patients with established microalbuminuria (>30 mg per 24 hours) or proteinuria (>300 mg per 24 hours):
 - Tight control of blood glucose is desirable (aim for HbA1c of <7%).
 - Tight control of blood pressure is desirable (aim for 130/80 mm Hg; if proteinuria >1 g per 24 hours, aim for blood pressure of 125/75 mm Hg).
 - Use ACE inhibitors or AR blockers in all patients (including normotensive patients).
 - Use above approaches to reduce proteinuria levels (goals, 50% reduction, aiming for <500 mg per 24 hours or as near to the normal range as possible). Prevention of increases in proteinuria is a main goal.
 - Evaluate diet and reduce protein if excessive. Consider low-protein diets in select circumstances.
 - Evaluate lipids and aim for control as near as possible to recommended, healthy ranges.
 - Encourage patient to stop smoking.

Last, much evidence suggests that a team approach that provides intensive follow-up is optimal. The patient and the healthcare team need to become partners in care. Thus internists, diabetologists, nephrologists, nurses, educators, dietitians, exercise physiologists, and the patient form a critical team that will provide the patient with the best possible outcome.

CHAPTER 56 The Nervous System and Diabetes

Roy Freeman

CLASSIFICATION 951 SYMMETRIC NEUROPATHIES 952 ASYMMETRIC NEUROPATHIES 954 PATHOLOGY OF PERIPHERAL NEUROPATHY 956 MANAGEMENT OF DIABETIC NEUROPATHY 958 AUTONOMIC NEUROPATHY 960 TREATMENT OF AUTONOMIC DYSFUNCTION 961 PAINFUL DIABETIC NEUROPATHY 962 TREATMENT OF PAINFUL NEUROPATHY 962

Most recognized neurologic complications associated with diabetes involve the peripheral nervous system, and it is these that will be emphasized in this chapter. The diabetic neuropathies include several distinctive clinical syndromes with differing clinical manifestations, anatomic distributions, clinical courses, and possibly underlying pathophysiologies.

Disorders of the nervous system associated with diabetes have long been recognized. Rollo is credited with having recorded this association in 1798, and until the middle of the 19th century, diabetes itself was attributed to a primary disorder of the central nervous system. It was Marchal de Calvi in 1864 who first suggested that diabetes might be the cause rather than the effect of neuropathy (1,2). Pavy's (3) description in 1885 of neuropathic symptoms is noteworthy for its completeness.

The usual account given by these patients is that they cannot feel properly in their legs, that their feet are numb, that their legs seem too heavy—as one expressed it, "as if he had 20 pound weights on his legs, and a feeling as if his boots were a good deal too large for his feet." Darting or "lightening" pains are often complained of. Or there may be hyperesthesia, so that a mere pinching of the skin gives rise to great pain; or, it might be, the patient is unable to bear the contact of the seam of a dress against the skin on account of the suffering it causes. Not infrequently there is deep-seated pain, located, as the pain describes it, in the marrow of the bones, which are tender on being grasped; and I have noticed that these pains are generally worse at night. With this there is the usual loss or impairment of the patellar tendon reflex.

CLASSIFICATION

There are several diabetic neuropathies. The most commonly used classification is based on the clinical presentation. Because the understanding of the etiology and pathophysiology of the diabetic peripheral neuropathies is incomplete, current classifications are based primarily on clinical manifestations. Many patients do not manifest a single type of diabetic neuropathy but rather a mixture of neuropathic features often dominated by one or another subtype.

Historical classifications begin with Leyden (4) who described hyperesthetic, paralytic, and ataxic forms of neuropathy. Jordan (5), on the basis of observations of patients treated at the Joslin Clinic, recognized three types of neuropathy: (a) a "hyperglycemic" type dominated by sensory symptoms, without neurologic signs, that was usually reversed by treatment of diabetes; (b) a chronic "circulatory-degenerative" type with advanced sensory, motor, and reflex abnormalities associated with arterial insufficiency of the legs; and (c) a "neuritic" type characterized by more-acute neuropathic symptoms and signs. In a similar classification Treusch (6) described (a) diabetes with pain in which control of diabetes improved symptoms, (b) ischemic neuropathy, (c) diabetic polyneuritis, and (d) visceral neuritis. Goodman et al. (7) listed (a) function neuropathy with uncontrolled diabetes without neurologic deficit, (b) organic neuropathy with neurologic signs and, (c) posttreatment neuropathy. These classifications all have the disadvantage of mixing clinical and uncertain pathophysiologic criteria. Locke (8) proposed a simpler anatomic classification system in which lesions of nerve roots produce radiculopathy; lesions of mixed nerves produce *polyneuropathy*.

More recent classifications continue to emphasize topographic body distribution (9) and are summarized by Dyck's classification (10) into (a) symmetric distal polyneuropathy with sensory, or sensorimotor motor involvement; (b) symmetric proximal lower limb neuropathy; (c) asymmetric focal neuropathy including cranial, truncal, limb plexus, multifocal entrapment, and ischemic neuropathies; (d) asymmetric neuropathy combined with symmetric distal polyneuropathy; and (e) mixed forms.

Perhaps the simplest and most widely used classification was initially proposed by Thomas (11). This approach divides the diabetic neuropathies into diffuse, generalized, or symmetric polyneuropathies (sensory, motor, and autonomic) and focal neuropathies (mononeuropathy, mononeuropathy multiplex, plexopathy, radiculopathy, and cranial neuropathy). A modification of this classification is shown in Table 56.1.

 - 3. Focal limb neuropathy
 - 4. Diabetic amyotrophy

SYMMETRIC NEUROPATHIES

Generalized Polyneuropathy

EPIDEMIOLOGY

Predominately sensory or sensorimotor distal polyneuropathy is the most common of the diabetic neuropathies. Epidemiologic studies suggest that the prevalence of diabetic peripheral neuropathy ranges from 5% to 100%. This large range is in part a consequence of variations in the study population, patient selection, the diagnostic criteria for the diagnosis of diabetes, the sensitivity of methods used to detect peripheral neuropathy, and the duration of diabetes in the study cohort. Diabetic peripheral neuropathy is more prevalent in tertiary care centers and diabetes clinic populations, where patients are more likely to have complications than are patients in the community. Similarly, prevalence is typically higher if ascertainment is based on electrophysiologic measurements, autonomic testing, or quantitative sensory testing and lower if it is based on subjective symptoms and physical findings. The prevalence of neuropathy also increases with age and increasing duration of diabetes.

In a large population-based epidemiologic study, Pirart (12) followed a cohort of 4,400 patients from 1947 to 1978 and, using clinical criteria, found evidence of neuropathy in 7.5% of patients at the time of diagnosis. The prevalence of neuropathy increased to 50% after 25 years of follow-up. In a controlled, longitudinal study of 132 patients with type 2 diabetes, Partenen et al. (13) documented the progression of polyneuropathy diagnosed using clinical criteria (pain and paresthesias) and electrodiagnostic studies. The prevalence of nerve-conduction abnormalities in the legs and feet increased from 8.3% at baseline to 16.7% after 5 years and to 41.9% after 10 years. The decline in sensory and motor action potential amplitudes was more prominent than the slowing of nerve-conduction velocity. After 10 years, more than 40% of patients no longer had ankle reflexes and 20% had vibration loss.

Several cross-sectional studies have examined the prevalence of diabetic polyneuropathy. In the Rochester diabetic neuropathy cohort, the prevalence was 54% in patients with type 1 diabetes and 45% in patients with type 2 diabetes (14). In the EURODIAB IDDM Complications Study, the prevalence of peripheral neuropathy in 3,250 randomly selected patients with insulin-dependent diabetic was 28% (15). Similar prevalences were reported in the Pittsburgh Epidemiology of Diabetes Complications Study (16), the multicenter, diabetic clinic-based study on the prevalence of diabetic neuropathy in Italy (17), and in a multicenter study of diabetic patients in the United Kingdom who were attending hospital-based diabetic clinics (18).

RISK FACTORS

Hyperglycemia is now well established as a risk factor in both patients with type 1 diabetes (19,20) and patients with type 2

diabetes (13). Other correlates and associations include age, duration of diabetes, quality of metabolic control, height, the presence of background or proliferative diabetic retinopathy, cigarette smoking, high-density lipoprotein cholesterol, and the presence of cardiovascular disease (15,16,18,21).

CLINICAL FEATURES

Numbness and paresthesia begin in the toes and gradually and insidiously ascend to involve the feet and lower legs. Sensory deficit usually occurs symmetrically in the distal territory of overlapping nerves, but not infrequently, asymmetric patterns of sensory loss in root or nerve distribution may be superimposed on this distal symmetric pattern of sensory loss. Because the distal portion of longer nerves are affected first, the feet and lower legs are involved before the hands, producing the typical "stocking-and-glove" pattern of sensory deficit. In most patients, the symptoms of polyneuropathy are mild and consist of numbness or paresthesia of the toes and sensory disturbances often described as "like walking on pebbles" or "having cotton bunched up under the toes." In some patients, "positive" symptoms are present. These include superficial burning, paresthesia, deep aching pains, dysesthesia, contact-induced discomfort, and paroxysmal jabbing pains. These symptoms are typically more severe at night. In more severe cases, distal portions of thoracic intercostal nerves are affected, producing an asymptomatic midline sensory loss in a teardrop distribution over the anterior thorax and abdomen that gradually spreads laterally (22). A similar pattern of deficits that gradually increase in size may occur on the vertex of the scalp and the central aspect of the face. This thoracic and abdominal sensory loss differs from focal thoracic truncal radiculopathy (23-25) in that it manifests as a painless, bilateral, symmetrical, and persistent form of neuropathy. Impaired touch and two-point discrimination in the fingertips may interfere with the reading of Braille (26). Sensory symptoms and signs are commonly accompanied by mild distal weakness and features of autonomic neuropathy.

Both lightly myelinated and unmyelinated small nerve fibers and the myelinated large nerve fibers are affected (Table 56.2). Dysfunction of small and large fibers occurs in varying combinations; however, in most cases the earliest deficits involve the small nerve fibers. Features characteristic of a smallfiber peripheral neuropathy include deficits in pain and temperature perception, paresthesias and dysesthesias, pain, deficits in the perception of visceral pain, dysautonomia, and predisposition to foot ulceration. Proprioception and deep tendon reflexes are relatively preserved. Nerve-conduction studies may be normal or minimally abnormal when small-fiber features dominate since these measurements are dependent on conduction in the surviving large, myelinated nerve fibers. This presentation, which resembles the dissociated sensory deficits that accompany as syrinx, has been described as pseudosyringomyelic. In contrast, features characteristic of large-fiber

TABLE 56.2. Features of Small- and Large-Fiber Neuropathy

Small-fiber dysfunction	Large-fiber dysfunction
Burning or lancinating pain Hyperesthesia Paresthesia Loss of pain and temperature sensation Dysautonomia Foot ulceration Loss of visceral pain	Loss of position and vibration sensation Areflexia Nerve-conduction abnormalities

peripheral neuropathy include loss of position and vibration perception sense and loss of deep-tendon reflexes. Nerve-conduction studies are usually abnormal. This presentation, which has features in common with the pattern of deficits that are associated with tabes dorsalis, has been termed pseudotabetic.

Marked distal muscle weakness with sparing of sensation occasionally occurs but often is due to mononeuropathy multiplex involving the peroneal or ulnar nerves. A pure or predominant motor polyneuropathy with few or no sensory symptoms or signs is rarely due to diabetes and should trigger a search for alternative causes of weakness, such as motor neuron disease, primary muscle disease, spinal cord disease, or other potentially treatable causes of peripheral neuropathy, such as chronic inflammatory demyelinating polyneuropathy (27). Once established, sensory and sensorimotor distal neuropathy is a permanent condition; although the course of painful manifestations is highly variable: It may last for months to years and may be exacerbated by intercurrent illness, infection, and depression. In one report, 36 patients with pain for at least 12 months showed no significant change in symptoms over a mean follow-up period of 4.7 years (28).

Although selected large-fiber neuropathies might be expected to cause muscle weakness, painless loss of vibration and position sense, and impaired tendon reflexes, pathologic (29,30), clinical (31), and quantitative sensory studies (32) have not demonstrated pure loss of large fibers in diabetic peripheral neuropathy (33). However, patients with disproportionate large-fiber involvement may manifest muscle weakness, atrophy of the intrinsic foot muscles, and weakness of the extensors and flexors of the toes and ankles with foot drop. When these deficits are combined with proprioceptive deficit in the toes and feet, a "pseudotabetic" gait ataxia may result. Neuropathy of this severity often coexists with diabetic retinopathy and neuropathy.

FOOT ULCERATION

Foot ulceration and neuropathic arthropathy are two of the more dreaded neurologic complications of diabetic neuropathy. Foot ulcers usually occur in patients with either small- or large-fiber neuropathy. Painless ulcers in weight-bearing areas occur on a background of insensitivity to pain, impaired proprioception, atrophy of intrinsic foot muscles, and the consequent maldistribution of weight-bearing, disturbed sweating, impaired capillary blood flow caused by autonomic neuropathy, and noninflammatory edema. Deformity of the foot due to muscle weakness and atrophy produces a maldistribution of weight-bearing and results in callus formation (34–37). The importance of a careful neurologic examination with careful attention to foot sensation cannot be overemphasized (38). The foot that is at risk for ulceration may be determined simply using the Semmes–Weinstein monofilaments (39).

Neuropathic arthropathy (Charcot joint or diabetic osteoarthropathy) is a rarer complication. This occurs primarily in the metatarsophalangeal and metatarsal-tarsal joints and is believed to be due to a combination of impaired deep pain, proprioceptive sensibility, and autonomic neuropathy. A good blood supply appears critical to the development of this complication (40). Trauma, even of a minor nature, or foot surgery may precipitate a Charcot joint. In addition, recurrent trauma may cause pathologic fractures of metatarsal bones with progressive external rotation and eversion deformities of the foot (35,41).

Acute Painful Neuropathy

Acute painful neuropathy (42) is a variant of sensory polyneuropathy in which severe burning pain of the extremities is combined with deep aching pain in proximal muscles, jabs of pain radiating from the feet to the legs, and striking hypersensitivity or allodynia of the extremities and trunk to touch, clothing, or

bed sheets that is often likened to sunburn. Objective sensory deficit is surprisingly mild in comparison with the painful paresthesia and dysesthesia. Nerve-conduction velocities are frequently normal or minimally abnormal.

Anorexia, weight loss, and depression are often so prominent that the term "diabetic neuropathic cachexia" as coined by Ellenberg (43) to describe this syndrome. This syndrome often correlates poorly with severity of diabetes or presence of other diabetic microangiopathic complications. Prognosis may be good in some patients, with gradual recovery over a period of months (42), particularly if the onset of symptoms follows a metabolic disturbance (44). The condition appears more commonly in males (45). Recurrent episodes may occur infrequently (46).

Treatment-Induced Neuropathy

Sensory neuropathy sometimes appears for the first time coincident with treatment with insulin or oral hypoglycemic agents (47,48) and has been referred to as a treatment-induced neuropathy (49). Although the cause is unknown, it has been suggested that improved glycemic control may initiate regenerating axonal sprouts, which generate ectopic nerve impulses (49). Alternately, it has been proposed that the pain is due to changes in the epineurial vasculature, such as arterial attenuation and tortuosity, arteriovenous shunting, and neovascular proliferation (50). There is usually gradual improvement as treatment continues and glycemic control is maintained.

Hyperglycemic Neuropathy

"Hyperglycemic" neuropathy refers to widespread paresthesias of the extremities and trunk that occasionally occur in patients with newly diagnosed or poorly controlled diabetes and that rapidly improve with control of hyperglycemia. The unique reversibility of this form of neuropathy and the diffuse rather than distal distribution of paresthesias suggest a pathophysiologic basis different from that for later-appearing diabetic sensory neuropathy. In an experimental model of diabetes, acute hyperosmolar hyperglycemia was associated with reduced nerve-conduction velocity and axon shrinkage (51).

Chronic Inflammatory Demyelinating Polyneuropathy

Several investigators have drawn attention to the association between chronic inflammatory demyelinating polyneuropathy (CIDP) and diabetes. The typical presentation of patients with superimposed CIDP includes symmetric weakness with demyelination and conduction block on electromyography and demyelination on nerve biopsy. The clinical progression is characteristically more rapid than that of diabetic polyneuropathy, weakness may be more prominent and there is often a satisfactory clinical response to immune modulation (51a–51d).

The differentiation from patients with diabetic polyneuropathy is not easily accomplished owing to several features in common. An elevated cerebrospinal fluid protein is present in both conditions, as are demyelinating changes on nerve conduction studies. The presence of conduction block on nerve conduction studies, however, is more suggestive of CIDP. The prevalence of conduction block appears similar in CIDP patients with and without diabetes mellitus (51b).

The characteristic nerve biopsy in both CIDP and diabetic polyneuropathy shows axonal and demyelinating changes (51a,51e). While a prominent inflammatory infiltrate on nerve biopsy may indicate CIDP, inflammation is only rarely seen in CIDP, and, furthermore, inflammation may also be present on

954 JOSLIN'S DIABETES MELLITUS

nerve biopsies of patients with a generalized diabetic peripheral neuropathy (51f,51g).

ASYMMETRIC NEUROPATHIES

Cranial Neuropathy

Cranial neuropathies also belong to the category of mononeuropathies. The majority of diabetic cranial neuropathies affect the third and sixth cranial nerves (52,53), whereas the fourth cranial nerve is rarely affected alone (52). Onset of diplopia is followed by complete ophthalmoplegia within several days. In cases of thirdnerve involvement, there may be complete ptosis but the pupil is typically spared. Weakness involves all extraocular muscles except the lateral rectus and superior oblique muscles. The pain, which is characteristically in the frontal and periorbital region, accompanies ophthalmoplegia in about 50% of cases. Unlike painful ophthalmoplegia associated with temporal arteritis (54), eye muscle weakness occurs in a specific nerve distribution rather than from ischemic muscle involvement. The suggestion that pain may be due to involvement of the first and second divisions of the trigeminal nerve in the cavernous sinus is supported by the occasional presence of sensory impairment in the distribution of the trigeminal nerve (52). However, a more likely explanation is that pain originates from ischemia or pain-sensitive terminals in the sheath of the third nerve (55). Differentiation from a neoplastic or vascular lesion in the orbital fissure, cavernous sinus, infarction at the base of the brain, or focal midbrain infarction (56) should be made with brain imaging studies such as magnetic resonance imaging (MRI). Sparing of the pupil may be a consequence of the relatively intact peripherally located pupillomotor fibers supplied by cavernous sinus blood and spared by the centrally placed nerve lesion. However, compressive lesions of the third nerve within the cavernous sinus also may spare the pupil (57) and should be excluded by brain imaging studies. Recovery without residual weakness always occurs and is usually complete within 3 months, supporting the notion that focal demyelination without axonal destruction is the responsible lesion (58).

Convincing evidence that other cranial nerve palsies occur with increased frequency in diabetes is lacking. In one uncontrolled study, impaired olfaction was reported in 35 of 58 patients with diabetes who showed no evidence of abnormalities of the nasal mucosa (59).

Optic disc edema indistinguishable in appearance from papilledema with associated hemorrhages of the nerve fiber layer and cotton-wool spots has been described in juvenile-onset diabetes (60,61). This usually is associated with only mild impairment in visual acuity and a favorable prognosis. This condition is of obscure etiology but is believed to be due to vasculopathy of the most superficial capillary layer of the disc and adjacent retina (60,61). Anterior ischemic optic neuropathy may occur in diabetes but is more closely associated with hypertension. This is an ischemic infarction of the anterior optic nerve that produces acute edema of the optic disc, profound visual loss, and subsequent development of optic atrophy. Optic atrophy and nerve deafness are associated with diabetes in Wolfram syndrome.

Facial paralysis due to seventh nerve palsy may occur with increased frequency in patients with diabetes (62), and the prognosis for recovery may be worse than in patients without diabetes (63). In view of the high frequency of this neuropathy in the general population, its designation as a diabetic mononeuropathy remains uncertain.

Proximal Motor Neuropathy

Diabetic amyotrophy was originally described by Bruns (64) in 1890 and again by Garland and Taverner (65) in 1953 as *diabetic*

myelopathy. Because clinical and pathologic evidence for spinal cord involvement was not forthcoming, this syndrome was subsequently designated *diabetic amyotrophy* (66), a deliberately noncommittal term with regard to localization of the disease process. An array of terms have subsequently been used for this syndrome, including *femoral neuropathy* (67,68), *asymmetric motor neuropathy* (69), *subacute proximal diabetic neuropathy* (70, 71), *proximal mononeuropathy multiplex* (72), *diabetic polyradiculopathy* (73), and *diabetic lumbosacral radiculoplexus neuropathy* (74). Asbury (75) has recommended that the term *diabetic amyotrophy* be dropped because of its ambiguity and that the term *proximal motor neuropathy* be used instead.

This neuropathy typically occurs with a peak incidence in the fifth or sixth decade in patients with type 2 diabetes. Many patients have mild or unrecognized diabetes at the time of diagnosis. In a recent series, diabetic amyotrophy was the presenting manifestation of diabetes in one third of the subjects (76). Some authors have emphasized an association with poor glycemic control (66,77,78).

The clinical picture is one of acute or subacute pain, weakness, and atrophy of the pelvic girdle and thigh musculature. The iliopsoas and quadriceps are usually involved, producing weakness of hip flexion and knee stabilization within several weeks of onset of pain. As a result, buckling of the knee and difficulty climbing stairs are typical symptoms. In some cases, coexistent weakness of the glutei, hamstrings, thigh adductors, and, less commonly, the peroneal and tibial muscles is present, indicative of the more widespread distribution of the disorder. Symptoms may have a monophasic or stepwise progression (77,79–83). Symptoms begin unilaterally but extend to the opposite extremity within weeks or months (74). Most patients have weight loss, and some appear cachectic. The extent of the weight loss highlights the systemic nature of the disorder. The weight loss may be compounded by anorexia caused by reactive depression or the use of narcotic analgesics.

Despite its designation as a motor neuropathy, subtle sensory symptoms and signs are commonly present in the form of paresthesias and sensory disturbance in the anterior thigh and anteromedial aspects of the lower leg typically in the anterior femoral cutaneous and saphenous nerve distribution. The knee jerk is nearly always reduced or absent on the affected side, whereas ankle jerks may be preserved unless compromised by a coexistent distal polyneuropathy.

Deep, aching pain is prominent and is localized to the hip, buttock, and anterior thigh. Pain is unrelieved by rest, is typically worse at night than during the day, and is not increased with straight leg raising or other mechanical maneuvers. The process is typically unilateral in onset, but subsequent involvement of the opposite leg often occurs within 3 to 4 months.

Despite early reports to the contrary (66), signs of myelopathy are absent and plantar responses are usually flexor. Pain, sensory abnormalities, and weakness in thoracic root distribution occasionally occur concomitantly (25), but isolated shoulder-girdle involvement is distinctly uncommon (73) and, when present, usually occurs in patients with marked leg weakness (70,78,79).

Differentiation from compressive lumbar nerve-root disease and neoplastic infiltration of lumbosacral plexus may be difficult, and laminectomies and laparotomies have occasionally been carried out in such patients in search of a structural cause. As originally pointed out by Root and Rogers (84), and more recently discussed by Hirsh (85), the absence of mechanical signs and symptoms, lack of back pain, prominent nocturnal pain with failure to respond to bed rest, and muscular atrophy and weakness involving more than one lumbar root usually distinguishes proximal motor neuropathy from nerve-root compression. The prognosis is usually good, with most patients showing resolution of pain followed later by gradual return of strength over a period of 6 to 18 months (73,77,78). Patients with unilateral and relatively focal pain and weakness seem to improve more rapidly and completely than patients with more widespread involvement. Because of the severe pain and disability associated with this syndrome, the ability to reassure affected patients of a favorable prognosis provides them great psychological relief.

There has been considerable debate concerning the etiology and proper classification of proximal motor neuropathy (75). Subramony and Wilbourn (86) have emphasized the heterogenicity of the syndrome, in that some patients with proximal motor neuropathy have clinical and electromyographic evidence of distal polyneuropathy whereas others appear to have a more localized process. The finding of slow nerve-conduction velocities in femoral and distal nerves (81,86-89) and of features of demyelination in nerve biopsy specimens in these patients indicates that "diabetic amyotrophy" is a form of diabetic neuropathy with a predilection for proximal nerves rather than a primary disorder of anterior horn cells of muscle. On the basis of extensive clinical electrophysiologic experiences, Bastron and Thomas (73) at the Mayo Clinic concluded that the disorder is a polyradiculopathy. Electromyography of patients with diabetic amyotrophy characteristically displays abundant fibrillations in the affected limb muscles and the paraspinal muscles. Nerveconduction studies are unable to differentiate patients with diabetic amyotrophy from those with a generalized polyneuropathy.

Recent studies have emphasized the likelihood that this disorder has a vascular basis (90,91). A vascular etiology was first proposed for the more acute case of diabetic amyotrophy by Raff and Asbury (72,75), who documented occlusion of intrafascicular artery of the obturator nerve and numerous small-vessel infarcts in the lumbosacral plexus and proximal nerve trunks of the patient who exhibited the rapid appearance of painful proximal asymmetric leg weakness.

The possibility that this disorder has an inflammatory etiology has led to the use of immune-modulating therapies. Intravenous immunoglobulins, plasmapheresis, and corticosteroids have all been used in open-label, uncontrolled studies (71,90,92). While preliminary results suggest some clinical benefit, the need for blinded, placebo-controlled trials is highlighted by the patient of Said et al. (91), who had a spontaneous remission shortly after biopsy and prior to the initiation of corticosteroid therapy (92a).

Thoracic Radiculopathy

This entity, also known as thoracoabdominal neuropathy, did not gain attention in the English-language literature until the late 1970s (23,24). Similar to painful proximal motor neuropathies of the legs, this disorder usually occurs in middleaged patients and often in those who have relatively mild diabetes. In many cases, patients with this syndrome have had previous or concomitant painful lumbar root syndromes in the lower extremities.

Onset of pain is usually acute, and the pain may be located in the back, chest, or abdomen. The character of the pain resembles that of herpes zoster and is usually deep and aching with some elements of superficial sharp or burning pain. Changes in pain with alterations of position or physical activity are variable. Paresthesia and cutaneous hypersensitivity are usually present but may be mild or absent, sometimes resulting in failure to recognize the neuropathic basis for pain. The pain is usually unilateral but is sometimes bilateral, may be distributed over more than one dermatomal segment, and often does not have a classic girdling radicular distribution. There may be an

accompanying area of sensory loss or dysesthesia in the distribution of one or more adjacent intercostal nerves, the dorsal or ventral rami, or their branches (93). Impairment in light touch and hypersensitivity to pin stimulation, however, are often absent. In severe cases, weakness and laxity of segmental paraspinal and abdominal muscles are present and abdominal hernia may even occur (94,95). Electromyography of paraspinal, intercostal, and abdominal muscles is diagnostically helpful and usually shows changes of acute denervation (24,25,96,97). As with proximal lower-extremity motor neuropathy, weight loss may be prominent, and because of the frequent absence of definite neuropathic symptoms and signs, exhaustive, unfruitful searches for an intrathoracic or intraabdominal neoplasm often are undertaken. The finding of electromyographic abnormalities usually leads to the correct diagnosis. Cases in which the distribution of symptoms and signs conforms to a single thoracic root should be evaluated with x-ray and MRI studies of the thoracic spine to exclude a compressive radiculopathy. The prognosis is usually better for the lower extremity radiculopathies, with a gradual recovery within a matter of months to a year (23).

Similar to other diabetic mononeuropathies and radiculopathies, the etiology of thoracic radiculopathy is obscure, although the acute onset and spontaneous recovery suggest a focal ischemic process. The observation that thoracic radiculopathy, proximal asymmetric motor neuropathy, and cranial mononeuropathy occur among middle-aged patients with type 2 diabetes, often appear in the same patient, improve spontaneously, and have a tendency to recur suggests a common physiologic mechanism. Although no pathologic studies of patients with thoracic radiculopathy have been published, postmortem studies of patients with diabetic polyneuropathy do show axonal and demyelinative lesions of nerve roots (81,98). Skin biopsies of patients with thoracic radiculopathy have shown a marked reduction in dermal and epidermal nerve fibers in the affected dermatome (98a).

Limb Mononeuropathy

Mononeuropathy is particularly common in persons with diabetes and may occur on the basis of focal ischemia, entrapment, compression, or trauma to superficially placed nerves (99). Any of the major peripheral nerves may be affected. Symptoms may present suddenly or gradually. When several nerves are involved simultaneously, the disorder is referred to as mononeuropathy multiplex. Many patients with diabetic polyneuropathy have electrophysiologic or clinical evidence of superimposed focal mononeuropathy at various common sites of entrapment or nerve injury, such as the median nerve at the wrist, ulnar nerve at the elbow, peroneal nerve at the fibular head, radial nerve above the elbow, and lateral cutaneous nerve of the thigh (99). This may be because nerves affected by segmental demyelination are known to be particularly sensitive to the effects of compression and anoxia. Differential diagnosis of mononeuropathy or mononeuropathy multiplex include vasculitis, paraproteinemic neuropathy, amyloidosis, acromegaly, hypothyroidism, sarcoidosis, Lyme disease, and bleeding into peripheral nerves caused by coagulation defects.

Carpal tunnel syndrome caused by median-nerve entrapment in the wrist is particularly common among persons with diabetes. A recent study report neurophysiologic evidence consistent with a carpal tunnel syndrome in 23% of patients with mild diabetic neuropathy. The carpal tunnel syndrome usually produces symptoms and signs similar to those in persons without diabetes. Occasionally, however, distal median-nerve mononeuropathy may occur in the absence of the usual pain and sensory symptoms of carpal tunnel syndrome. Although

956 JOSLIN'S DIABETES MELLITUS

entrapment is still possible in such cases, coexistent distal ulnar neuropathy and bilateral involvement may suggest distal polyneuropathy rather than nerve entrapment (100). Nerveconduction studies showing prolonged distal latencies in multiple nerves rather than limited to the median nerve will serve to distinguish distal polyneuropathy from entrapment.

Peroneal mononeuropathy typically produces sudden painless foot drop and, in addition to vascular factors, may be due to trauma because of the superficial location of the nerve at the fibular head. Ulnar mononeuropathy is probably also related to the vulnerable position of the nerve at the elbow. In this case, symptoms usually appear insidiously and may be due to chronic trauma rather than to acute injury or entrapment. Phrenic neuropathy, resulting in diaphragmatic paralysis, may occur rarely in patients with diabetes (101).

PATHOLOGY OF PERIPHERAL NEUROPATHY

Pathogenesis of Symmetric Neuropathies

The pathophysiologic basis of diabetic distal polyneuropathy remains uncertain. The two major prevailing theories relate the metabolic effects of chronic hyperglycemia and the effects of ischemia on peripheral nerves to the pathogenesis of this disorder (102,103). Alterations in neurotrophic factors and immunologic mechanisms also may play a pathogenetic role. It is likely that multiple interacting factors play a role in the pathogenesis of this disorder.

METABOLIC

The metabolic hypothesis proposes that hyperglycemia produces several metabolic derangements, including increased tissue levels of sorbitol and fructose (104,105), decreased concentrations of nerve *myo*-inositol and taurine (106), decreased Na⁺/K⁺ adenosine triphosphatase (ATPase) activity (104,105), nonenzymatic glycosylation of proteins, altered fatty acid metabolism, and abnormalities of axonal flow. Some or all of these factors may be responsible for functional and structural changes in nerve fibers.

Polyol Pathway Abnormalities

The polyol pathway may play a role in several of these metabolic changes. The hyperglycemic milieu results in activation of the polyol pathway and, in a reaction catalyzed by the enzymes aldose reductase and sorbitol dehydrogenase, leads to the conversion of glucose to the polyol sugars sorbitol and fructose. The accumulation of sorbitol results in reduced intracellular levels of *myo*-inositol and taurine, which in turn reduce Na⁺/K⁺ ATPase and contribute to the structural and functional changes (104).

Decreased levels of intracellular *myo*-inositol lead to reduced phosphoinositide synthesis and decreased production of diacylglycerol. This in turn impairs protein kinase C activation and may lead to decreased Na⁺/K⁺ ATPase activity. Impaired Na⁺/K⁺ ATPase activity results in abnormal decreased nodal Na⁺ membrane potentials, increased intraaxonal Na⁺, and possible nodal swelling and other structural change. Activation of the polyol pathway also may promote oxidative stress by depleting NADPH, a cofactor for both aldose reductase and glutathione reductase, which leads to a decrease in reduced glutathione and increase in oxidized glutathione (104).

Endoneurial concentrations of sorbitol and fructose are increased in the alloxan and streptozotocin model of diabetes. Aldose reductase inhibition reduces endoneurial sorbitol and restores Na⁺/K⁺ ATPase activity and *myo*-inositol and taurine levels in somatic and autonomic nerves (106,107). Treatment with aldose reductase inhibitors also leads to improved nerveconduction velocities in these diabetic rat models. These metabolic abnormalities may not perfectly replicate human diabetic neuropathy. While sorbitol levels are elevated in nerve biopsy specimens (and appear to be associated with loss of myelinated fibers), a concomitant decrease in *myo*-inositol levels has not been demonstrated (108,109).

Myo-Inositol

Myo-inositol and inositol levels are reduced within the peripheral nerve in the streptozotocin model of diabetes. Dietary supplementation with *myo*-inositol reverses the slowing of nerveconduction velocity and reduction in intracellular Na⁺/K⁺ ATPase that occurs in this experimental model of diabetic peripheral neuropathy (104,110). This, however, has not been replicated in human diabetic peripheral neuropathy. As noted above, a reduction in endoneurial *myo*-inositol is not apparent in human diabetic nerves (108,109,111).

Taurine

Osmoregulation, in order to maintain the intracellular milieu, may also result in endoneurial metabolic changes in diabetic neuropathy. The increase in intracellular osmolality due to shunting of glucose into the polyol pathway and the consequent accumulation of sorbitol may lead to compensatory depletion of the endoneurial osmolytes taurine and *myo*-inositol to maintain osmotic balance (106).

Abnormal Lipid Metabolism

Diabetes also results in alterations in the metabolism of essential fatty acids and prostaglandin. Hyperglycemia leads to inhibition of δ -6-desaturase, the enzyme that converts dietary linoleic acid to γ -linolenic acid. γ -Linolenic acid is a precursor of arachidonic acid that provides the substrate for several vasoactive prostanoids, including prostacyclin. In addition, γ -linolenic acid metabolites play a role in the nerve membrane structure, nerve blood flow, and nerve conduction (112).

Several studies in streptozotocin-diabetic rats have revealed that the deficits in nerve conduction can be reversed by a dietary supplement of evening primrose (113,114). This effect was attenuated by the cyclooxygenase inhibition with flurbiprofen (115).

Oxidative Stress

Oxidative stress also is implicated in the etiology of diabetic neuropathy. There is evidence that activity of oxygen-free radicals is enhanced in diabetes. Indices of increased oxidative stress such as malondialdehyde, conjugated dienes, and lipid hydroperoxides are increased in experimental diabetic neuropathy.

Furthermore, diabetes compromises antioxidant defense mechanisms. There are documented reductions in scavengers of oxygen free radicals, such as reduced glutathione, superoxide dismutase, catalase, ascorbic acid, and α -tocopherol (116).

Antioxidant therapy with a number of agents, including probuchol (117), vitamin E (117,118), glutathione (119), carvedilol (120), butylated hydroxytoluene (121), transitional metal chelating agents (122), and α -lipoic acid (123), have improved measures of nerve function in experimental diabetic peripheral neuropathy.

Advanced Glycosylation End Products

The reducing sugars glucose, fructose, and galactose react with the free amino groups of proteins to form early reversible Schiff bases and Amadori products. These in turn undergo a chemical rearrangement to form advanced glycosylation end products. In the setting of prolonged hyperglycemia, nonenzymatic glycosylation of proteins occurs, which results in structural changes to the components of the extracellular matrix (124,125). These structural changes may lead to functional neural and vascular abnormalities. Advanced glycosylated end products also may quench nitric oxide, thereby attenuating endotheliummediated vasodilatation (126). Aminoguanidine may inhibit the formation of advanced glycosylated end products and improve nerve and vascular function (124–128). There have been no reports of human trials with this agent.

Protein Kinase C Activation

Hyperglycemia leads to increased synthesis of diacylglycerol, which leads to activation of protein kinase C. Protein kinase C may also be activated by oxidative stress and advanced glycosylated end products. Protein kinase C activation causes increased vascular permeability, impaired nitric oxide synthesis, and changes in blood flow (129).

There is some evidence that impaired protein kinase C activity may contribute to reduced Na^+/K^+ ATPase activity. Recently data have emerged suggesting that there is increased protein kinase C activity in the retina, kidney, and the vasculature of nerve tissue.

Protein kinase C elevations compromise nerve regeneration in experimental models of diabetic peripheral neuropathy (130,131). In experimental models of diabetes, treatment with nonspecific (132) and β -specific protein kinase C inhibitors normalized the observed neurophysiologic abnormalities (132a).

Poly (ADP-Ribose) Polymerase

There is increasing evidence that poly (ADP-ribose) polymerase (PARP) plays a critical role in mediating several pathways of hyperglycemia-induced damage (activation of PKC isoforms, hexosamine pathway flux, and AGE formation). This most likely occurs by inhibiting GAPDH activity. DNA strand breaks due to oxidative stress are a major cause of PARP activation (132b, 132c). In streptozotocin-induced diabetic rats, the PARP inhibitors, 3-aminobenzamide and 1,5-isoquinolinediol, reversed deficits in nerve blood flow and conduction (132c).

Neurotrophic Factors

The neurotrophins are proteins that promote the growth, maintenance, survival, and differentiation of specific populations of neurons. There is evidence that failure of neurotrophic support is in part responsible for the pathogenesis of diabetic polyneuropathy. Nerve growth factor (NGF), the prototypical growth factor, has been particularly well studied, because it is necessary for the growth maintenance and survival of the sympathetic and small sensory nerve fibers. NGF also regulates the expression of the neuropeptides substance P and calcium gene–related peptides in dorsal root ganglion sensory neurons and sympathetic nerves.

Retrograde axonal transport from the target tissues to the neuronal cell body is impaired in diabetes (133,134). There is evidence of decreased expression of NGF in skin, sympathetic ganglia, and submandibular glands in experimental diabetic neuropathy. This reduction is attenuated or prevented by NGF. When administered to streptozotocin-induced diabetic rats, NGF maintained the response to thermal noxious stimulation (the tail-flick threshold) and prevented the observed reduction in levels of the neuropeptides substance P and calcitonin gene–related peptide measured from cervical dorsal root ganglia (135). Differential dosage effects may be present, as a recent report documented dystrophic changes in the sympathetic ganglia following the administration of NGF in an experimental model of diabetic autonomic neuropathy (136).

Neurotrophin-3 (NT-3) supports the survival and differentiation of large-fiber sensory neurons. Expression of NT-3 may also be reduced in diabetes. Tomlinson and coworkers reported that NT-3 messenger RNA (mRNA) is deficient in leg muscle from diabetic rats (137). Administration of recombinant NT-3 to diabetic rats increased the conduction velocity of sensory nerves. The motor conduction velocity was unaffected (137).

VASCULAR FACTORS

Hyperglycemia-related metabolic alterations produce interposed changes in tissues and the microvasculature that are then responsible for ischemic pathologic changes in nerve fibers. Animal models of diabetic neuropathy have demonstrated that the neuropathy is accompanied by reduced endoneurial blood flow, increased endoneurial vascular resistance, and reduced endoneurial oxygen tension (138,139). Therapy with vasodilators (140,141) or oxygen supplementation (142,143) may improve the conduction-velocity slowing/electrophysiologic and biochemical abnormalities that occur in these experimental models of diabetic neuropathy.

Microangiopathy

Early investigators emphasized macrovascular findings in peripheral nerves and, on the basis of studies of limbs amputated for arteriosclerotic gangrene, attributed the neuropathic changes to arteriosclerotic occlusive disease of the vasa nervorum (143). Fagerberg (145,146) described the presence of material positive for periodic acid–Schiff staining stenosis and hyalinization of intraneural vessels. Other authors have suggested the possible role of microvascular changes in capillary endothelial basement membranes, with thickening of the perivascular space, which is known to be more frequent in diabetic neuropathy than in other acquired neuropathies (147,148). Timperley et al. (149) described endothelial cell hyperplasia in endoneurial blood vessels of the sural nerve, with plugging of the vascular lumen by necrotic cellular material in patients with severe diabetic neuropathy.

Dyck and colleagues (150,151) observed thickening of capillary walls and documented capillary closure and platelet thrombi occlusions in the small arteries and arterioles that supply peripheral nerves that was more pronounced in patients with diabetic neuropathy than in age-matched controls. Malik and colleagues (152,153) also documented basement-membrane thickening, reduced capillary number (152), and endothelial hyperplasia (152,153).

Giannini and Dyck (154,155) recently confirmed the presence of a significant increase in reduplicated basement membranes with pericyte degeneration in diabetic sural nerves that resulted in an increase in mural area. In these studies, the number of endoneurial microvessels per square millimeter and the average luminal area and size distribution of these microvessels were not significantly different in the sural nerves of patients with diabetes mellitus compared with those of control subjects. Intravascular thrombi and vascular occlusions could not be confirmed in these studies. The most consistently reported ultrastructural microvascular abnormalities in diabetic neuropathy are thus basementmembrane thickening and endothelial-cell hyperplasia. Several studies have established a correlation between ultrastructural microvascular disease in peripheral nerve and severity of diabetic neuropathy (151,152,155,156).

Spatial Distribution of Nerve-Fiber Loss

Dyck (157) systematically studied the spatial distribution of pathologic abnormalities along the length of peripheral nerve in a population of diabetic patients and nondiabetic controls (157). In postmortem studies, nerve tissue was obtained from the fifth lumbar roots; segmental nerves in lumbar and sacral plexus; and proximal and distal portions of sciatic, tibial, peroneal, and sural nerves of patients with diabetic neuropathy and control subjects to determine the proximal-to-distal pattern of nervefiber damage. The number of myelinated fibers was counted in each level of nerve. In patients with diabetic neuropathy, a pattern of multifocal nerve-fiber loss was found to begin in proximal segmental nerves and to worsen distally. Dorsal roots were more affected than ventral roots.

These findings were felt to correlate best with a multifocal pathologic process of nerve beginning proximally and affecting multiple levels of nerve. Distal worsening of nerve-fiber degeneration was attributed to the cumulative effect of multiple random lesions along the course of the nerve (157). The strong similarity of this pattern of nerve-fiber loss to previously described patterns in necrotizing vasculitis and experimental studies of microsphere embolization (158,159) suggested that ischemia plays an important role in diabetic neuropathy.

Llewelyn and coworkers (160), however, compared the pattern of fiber loss in sural nerve biopsies of patients with type 1 diabetes, patients with hereditary sensory and motor neuropathy, and controls. They noted that a patchy, nonuniform pattern of fiber loss also was present in the biopsies obtained from patients with hereditary neuropathies—disorders unlikely to have a vascular basis, although the extent of the multifocal fiber loss was less than that reported by Dyck and coworkers.

Axonal and Demyelinating Features

At one time considerable debate existed concerning whether segmental demyelination or axonal degeneration is the primary abnormality in diabetic neuropathy. Some investigators (161,162) suggested a primary degeneration of motor and sensory nerve cell bodies with secondary degeneration of peripheral nerve and nerve root axons and centripetal degeneration of the posterior columns in spinal cord. According to this scheme, dysfunction of the nerve cell body causes the initial manifestations to appear at the periphery because of a "dying-back" process that begins distally and spreads proximally (29,163).

Chopra and colleagues (148,164) held that segmental demyelination, presumably the result of a metabolic disturbance of Schwann cell function, was the primary abnormality. Thomas and Lascelles (165), in studies of teased-fiber preparations, emphasized segmental demyelination and remyelination as the main pathologic change but also identified axonal degeneration in severe cases. Said et al. (29), found evidence of both primary and secondary demyelination, whereas Behse et al. (147), finding loss of large and small myelinated fibers and unmyelinated fibers, concluded that axonal degeneration and Schwann cell damage proceed independently of each other. Vital and coworkers (166,167) reported that both axonal degeneration and demyelination were present in nerve biopsy specimens (166,167), whereas Dyck and colleagues confirmed that a reduction in the number of myelinated fibers is the characteristic finding in the diabetic peripheral nerve but is a secondary response to axonal degeneration rather than part of a primary process of demyelination and remyelination (30,151).

Pathogenesis of Asymmetric Neuropathies

On the basis of the careful study of a very small number of cases, the pathologic basis of diabetic mononeuropathy and mononeuropathy multiplex is presumed to be ischemic infarction of nerve. Raff and Asbury (72) described a patient with an acute and rapidly progressive asymmetric neuropathy who was found to have numerous microinfarcts in the proximal portions of the obturator, femoral, sciatic, and tibial nerves. The occurrence of infarcts in bridging interfascicular bundles was similar to the distribution of microinfarcts in other ischemic mononeuropathies (168).

In a more recent study, biopsy of intermediate cutaneous nerve of thigh in ten patients with type 2 diabetes with diabetic

amyotrophy revealed the presence of an inflammatory infiltrate in the epineurium, perineurium, and endoneurium. In select cases, vasculitis of the epineurial and perineurial blood vessels has been observed (90,91).

Dyck and Windebank (168a) reported the pathology in distal cutaneous nerves (the majority sural nerves) of 33 patients with a diabetic lumbosacral radiculoplexus neuropathy. Common findings included multifocal fiber loss, perineurial thickening, neovascularization, and abortive regeneration of nerve fibers forming microfasciculi. In addition there was evidence of mural and perivascular inflammation, separation and fragmentation of mural smooth muscle layers of microvessels, and hemosiderinladen macrophages. The pathologic findings are suggestive of an immune-mediated microvasculitis leading to ischemic injury.

A vascular cause of diabetic ophthalmoplegia is strongly supported by postmortem studies (56,167,168) in which focal swelling together with axonal and demyelinative lesions were identified in the precavernous or cavernous sinus portions of the third nerve. Extensive hyaline thickening of nutrient vessels of the third nerve without vascular occlusion was found in all three cases. Subclinical oculomotor nerve injury may be present in diabetes (171).

Pathogenesis of Diabetic Autonomic Neuropathy

The pathologic basis of diabetic autonomic neuropathy is not completely understood. A number of investigators have identified abnormalities in paravertebral sympathetic ganglia, including neurons distended by lipid-rich material (172–174), vacuolar degeneration of neurons produced by dilation of endoplasmic reticulum (174), and mononuclear cell infiltration of autonomic nerve bundles and ganglia (174). Loss of myelinated nerve fibers has been described in sympathetic communicating rami (175,176), vagus nerves (175,177,178), splanchnic nerves (176), and nerves to the bladder wall (179).

MANAGEMENT OF DIABETIC NEUROPATHY

Treatment of Hyperglycemia

Management of diabetic neuropathy, whether painful or painless, begins with treatment of hyperglycemia. Although the precise relationship between poor diabetic control and peripheral neuropathy is uncertain, there is unequivocal evidence, based on multicenter, randomized, controlled trials, supporting strict control of blood glucose levels in patients with or without diabetic neuropathy (180–186). These conclusions are supported by experimental models of diabetes produced by streptozotocin or alloxan; reductions in nerve conduction velocity occur acutely and can, at least in early stages, be restored by treatment with insulin (187).

It is of historic interest that, as recently as 1986, a review of the existing literature regarding the relationship of the development and severity of neuropathy to glycemic control, conducted by the American Neurological Association Committee on Health Care issues, could not definitively support the concept that rigorous control of blood sugar prevents or ameliorates diabetic peripheral neuropathy (188).

Several uncontrolled retrospective studies had demonstrated that patients with poor diabetic control develop all diabetic complications, including neuropathy, earlier and more severely than do patients with better control (12,189). In addition, severity of hyperglycemia measured by fasting glucose and glycosylated hemoglobin levels in patients with newly diagnosed diabetes was inversely correlated with motor but not conduction velocity (190). Finally, in patients with newly diagnosed diabetes, improvement in blood glucose and glycosylated hemoglobin levels after treatment with oral hypoglycemic agents (191) or insulin (192) was associated with an improvement in motor but not sensory nerve conduction velocities.

In a groundbreaking study, the Diabetes Control and Complications Trial (DCCT) unquestionably established the necessity of meticulous control of hyperglycemia. Two cohorts of patients with type 1 diabetes were studied: a primary prevention group who had diabetes for 1 to 5 years without retinopathy or microalbuminuria and a secondary intervention cohort who had diabetes for 1 to 15 years and mild to moderate nonproliferative retinopathy and an albumin excretion rate less than 200 mg per 24 hours. A total of 1,441 patients were enrolled into the two cohorts at 29 centers between 1983 and 1989. When the study terminated in June 1993, the duration of follow-up ranged from 3 to 9 years (mean, 6.5 years). The subjects were randomized to two treatment arms: conventional therapy and intensive therapy. Conventional therapy was designed to prevent symptoms of hyperglycemia and hypoglycemia with one to two insulin injections per day whereas intensive treatment was designed to maintain blood glucose levels as close as possible to normal range and consisted of three or more insulin injections per day or insulin pump treatment. Within 6 months of enrollment, the mean levels of glycosylated hemoglobin A_{1c} decreased from 9% to 7% and this level of reduction was maintained throughout the trial (180).

In the DCCT, peripheral neuropathy was an exclusion criterion if "sufficiently severe to merit treatment." A confirmed clinical neuropathy (i.e., abnormal history, physical examination, or both confirmed by unequivocally abnormal neurophysiologic studies) was present at baseline in 3.5% of patients in the primary-prevention cohort and in 9.4% of patients in the secondary-intervention cohort. Intensive therapy significantly reduced the development of confirmed clinical neuropathy by 64% in the combined cohorts after 5 years of follow-up; 5% of the intensive-therapy group developed a confirmed clinical neuropathy compared with 13% of the conventional-therapy group. The prevalence of nerve-conduction abnormalities was reduced by 44%; 26% of the intensive-treatment group developed abnormal nerve conductions compared with 46% of the conventional-treatment group. Nerve-conduction velocities remained relatively stable in the intensively treated cohort but decreased significantly in the cohort treated with conventional therapy (19,180,193).

There are also data supporting the benefits of meticulous control of hyperglycemia in type 2 diabetes. A similar, albeit considerably smaller, trial was conducted in Kamamoto, Japan. One hundred ten Japanese patients with type 2 diabetes were randomly assigned to receive multiple or conventional insulin injections. The primary-prevention cohort comprised 55 patients without retinopathy and a urinary albumin excretion rate less than 30 mg per 24 hours, whereas the 55 patients in the secondary-intervention cohort had uncomplicated retinopathy and a urinary albumin excretion rate less than 300 mg per 24 hours. The appearance and the progression of retinopathy, nephropathy, and neuropathy were assessed every 6 months. After 6 years, the intensively treated cohort showed significant improvement in nerve-conduction velocities, whereas the conventionally treated group showed significant deterioration in the median nerve-conduction velocities and vibration threshold. This study relied on surrogate measures of neuropathy; symptoms and quality of life were not evaluated (182).

These studies show that it is feasible to maintaining meticulous control of blood sugars; however, it is not a risk-free endeavor. In the DCCT, 3,788 episodes of hypoglycemia occurred that were severe enough to necessitate assistance. Of these episodes, 1,027 were associated with coma and/or seizure. Hypoglycemia occurred almost twice as frequently in the intensively treated group than in the conventionally treated group (65% vs. 35%). The overall rate of severe hypoglycemia was 61.2 per 100 patient-years in the intensive group versus 18.7 in the conventionally treated group per 100 patient-years, a relative risk of 3.28. The relative risk for coma and/or seizure was 3.02 for intensive therapy.

PANCREATIC TRANSPLANTATION

Pancreatic transplantation in humans and animal models of diabetes restores the euglycemic state and obviates the need for exogenous insulin. In streptozotocin-induced experimental diabetic neuropathy, pancreatic transplantation reverses the nerveconduction abnormalities and autonomic defects (194,195). Several centers have consistently reported that pancreatic transplantation, in patients with well-established diabetes, improves nerve-conduction velocities, small- and large-fiber sensory thresholds, and measures of somatosensory and autonomic function (196–202). The degree of improvement in these studies has been quite modest. This is most likely due to the severity of the peripheral neuropathy at the time of transplantation.

Treatment of Metabolic Abnormalities

Based on our understanding of the pathogenesis of diabetic peripheral neuropathy, a number of different agents from diverse chemical classes have entered clinical trial. While some of these agents have shown promise in clinical trials, none are yet approved for clinical use.

ALDOSE REDUCTASE INHIBITORS

Specific treatment with aldose reductase inhibitors, which is directed at the presumed pathophysiologic basis of diabetic neuropathy, has been under investigation for a number of years. Alrestatin was the first aldose reductase inhibitor to be used in humans, but it produced equivocal results and a high incidence of adverse reactions (203). Sorbinil, a longer-acting aldose reductase inhibitor, underwent a more thorough clinical investigation. Results in these studies were equivocal, with some studies showing improvement in electrophysiologic and clinical parameters (204-206), whereas others were negative (207-209). Unfortunately, sorbinil was associated with a high frequency of hypersensitivity reactions, with rash, fever, lymphadenopathy, and abnormal liver chemistries occurring in approximately 10% of patients. The aldose reductase inhibitors, zenarestat and tolrestat also cause side effects, while trials with the aldose reductase inhibitors ponalrestat and zopolrestat failed to demonstrate effectiveness (209a).

The optimistic results obtained with aldose reductase inhibitors in preclinical studies have thus not been replicated in large human trials. While this may reflect inadequacies in the animal models of diabetes, several other factors are also likely to play a role in the failure of these clinical trials. As noted above, side effects, insufficient drug potency, and inadequate nerve penetration have limited other trials. It is possible that the trials were too short to demonstrate a difference between active drug and the control group, that the neuropathy had progressed beyond reversibility, or that the study end points did not reflect improvement in nerve structure or function. Trials with this class of agents are still in progress.

MYO-INOSITOL

Myo-inositol is an important component of the phospholipids that make up cell membranes and other cellular structures. The

960 JOSLIN'S DIABETES MELLITUS

concentration of *myo*-inositol is reduced in peripheral nerves of diabetic animals and is normalized by aldose reductase inhibitors and *myo*-inositol supplementation (210). Improved function in experimental and human diabetic nerves following treatment with aldose reductase inhibitors has been attributed in part to increased *myo*-inositol concentrations. However, despite an earlier report of reduced levels of *myo*-inositol in patients with diabetic neuropathy (211), more recent biochemical and pathologic studies have indicated that the nerve *myo*-inositol concentration is not reduced in diabetic patients with or without neuropathy (108,109,111). Furthermore, in controlled clinical trials, *myo*-inositol supplementation has not appeared to improve the features of diabetic peripheral neuropathy (210).

EVENING PRIMROSE OIL

Human studies, particularly in type 1 diabetes, replicate the deficient conversion of linoleic acid to γ -linolenic acid. There is preliminary evidence, based on small placebo-controlled trials of short duration, that treatment with γ -linolenic acid for 6 to 12 months improves or delays the progression of the clinical and neurophysiologic abnormalities of diabetic peripheral neuropathy. A typical dose of evening primrose oil used in these studies was 6 g, which contains approximately 480 mg of γ -linolenic acid (212–214).

α-LIPOIC ACID

The effects of the antioxidant α -lipoic acid (thioctic acid) were studied in two multicenter, randomized, double-blind placebocontrolled trials. In a 3-week trial, 328 patients with type 2 diabetes who had symptomatic peripheral neuropathy were treated with an intravenous infusion of α -lipoic acid using three doses (1,200 mg, 600 mg, 100 mg) or placebo. There was a symptomatic improvement in patients treated with the two higher doses of α -lipoic acid (215). A meta-analysis of more than 1,000 patients treated for 3 weeks with 600 mg per day, given intravenously, showed decreased symptoms of pain, paresthesias, and numbness (215a). In a placebo-controlled trial, 73 patients with type 2 diabetes with reduced heart-rate variability were randomized to receive a daily oral dosage of 800 mg of α-lipoic acid or placebo for 4 months. The root-mean-square successive difference and spectral power in the low-frequency band improved in the patients treated with α -lipoic acid. Seventeen patients failed to complete the study (216). A large 4-year multicenter trial is currently in progress.

NEUROTROPHINS

NGF is the neurotrophin most widely studied in humans. In a phase 2 trial of recombinant human (rh) NGF in 250 patients with diabetic polyneuropathy, improvements in signs and symptoms were seen after treatment with either 0.1 or 0.3 mg of rhNGF per kilogram administered subcutaneously three times a week for 6 months (217). The occurrence of local injection-site pain in over 90% of subjects receiving NGF may have unblinded this study. In a larger phase 3 trial, 1,019 subjects were randomly assigned to receive either placebo or 0.1 mg of rhNGF per kilogram by subcutaneous injection three times a week for 48 weeks. This trial failed to replicate the findings of the earlier trial. This may be related to the rhNGF manufacturing process, which differed in the two studies (218). There are no reported studies of NT-3 in the treatment of diabetic neuropathy. Insulin growth factor has not been tested in human clinical trials.

PROTEIN KINASE C β INHIBITION

In phase 2 trials, treatment with the specific protein kinase C β inhibitor roboxistaurin (32 and 64 mg) improved symptoms and

signs of peripheral neuropathy. Multicenter phase 3 trials are currently in progress.

AUTONOMIC NEUROPATHY

With the arguable exception of pain, the autonomic manifestations of diabetes are responsible for the most troublesome and disabling features of diabetic peripheral neuropathy and result in a significant proportion of the mortality and morbidity associated with the disease. A broad constellation of symptoms occur that affect cardiovascular, urogenital, gastrointestinal, pupillomotor, regulatory, and sudomotor functions. This topic has been covered in detail in a recent review (219). The impairment is usually gradual and progressive, although severe autonomic dysfunction occurs shortly after the diagnosis of type 1 diabetes in rare cases (220). The availability of sensitive, specific, and reproducible noninvasive tests of autonomic function has enhanced our understanding of the prevalence, pathophysiology, and clinical manifestations of this disorder (221). Estimates of the prevalence of diabetic autonomic neuropathy are dependent on the criteria used for diagnosis and the specific population under study. Few studies of diabetic autonomic neuropathy are without referral or selection bias. A communitybased population study in Oxford, England, showed a prevalence of autonomic neuropathy, defined by the presence of one or more abnormal heart-rate-variability test results, of 16.7% (222). The prevalence of symptomatic visceral autonomic neuropathy was 5.5% in a population-based study of diabetic patients in Rochester, Minnesota (14). The prevalence of symptoms of autonomic dysfunction and abnormal tests of autonomic nervous system function in diabetic clinic-based populations and tertiary referral centers is considerably higher.

Cardiovascular System

The cardiovascular autonomic neuropathy has diverse manifestations. An increased resting heart rate is observed frequently in diabetic patients; most likely this is due to the vagal cardiac neuropathy that results in unopposed cardiac sympathetic nerve activity. The tachycardia may be followed by a decrease in heart rate and, ultimately, a fixed heart rate due to the progressive dysfunction of the cardiac sympathetic nervous system (223–225).

Orthostatic hypotension, the most incapacitating manifestation of autonomic failure, is a common feature of diabetic cardiovascular autonomic neuropathy. This is a consequence of efferent sympathetic vasomotor denervation that causes reduced vasoconstriction of the splanchnic and other peripheral vascular beds. Diminished cardiac acceleration and cardiac output, particularly in association with exercise, also may play a role in the presentation of this disorder.

Several authors have drawn attention to the association between increased mortality and cardiovascular autonomic dysfunction in patients with diabetes. Estimates of the mortality associated with cardiovascular autonomic neuropathy range from 27% to 56% over 5 to 10 years. There is also an increased frequency of sudden death in patients with autonomic neuropathy. Proposed mechanisms by which the autonomic nervous system may result in sudden death or influence the outcome of patients with diabetes who have cardiovascular disease include absent or altered perception of myocardial ischemia and infarction; deficient hemodynamic response to cardiovascular stresses such as surgery, infection and anesthesia; increased predisposition to cardiac arrhythmias due to QT interval dispersion; and alterations in sympathetic–parasympathetic cardiac innervation balance (197,226–229a).

Urogenital System

Symptoms of bladder dysfunction have been observed in 37% to 50% of patients with diabetes, and physiologic evidence of bladder dysfunction is present in 43% to 87% of patients with type 1 diabetes (230–231). Bladder symptoms associated with autonomic neuropathy include hesitancy, poor stream, increased intervals between micturition, and a sense of inadequate bladder emptying. These symptoms may be followed by urinary retention and overflow incontinence (230,233,238).

Erectile dysfunction is a frequent and disturbing symptom in male diabetic patients. Reported incidence has ranged from 30% to 75% (235–238). Impotence may be the earliest symptom of diabetic autonomic neuropathy, although vascular, hormonal, and psychogenic etiologies, alone or in combination, may also be implicated. Nitric oxide is an important mediator of noncholinergic nonadrenergic corpus cavernosum relaxation (239). In vivo studies of isolated corpus cavernosum tissue from men with diabetes have demonstrated functional impairment in autonomic- and endothelial-dependent relaxation of corpus cavernosum smooth muscle (240). Impotence due to autonomic neuropathy progresses gradually but is usually permanent 2 years after onset. Sympathetically mediated ejaculatory failure may precede the appearance of impotence, although impotence can occur with retained ability to ejaculate and experience orgasm. Retrograde ejaculation will occur if the bladder neck fails to close. This function is also controlled by the sympathetic nervous system (241,242). There are few studies of genital autonomic neuropathy in female patients with diabetes (243).

Gastrointestinal System

Autonomic dysfunction occurs throughout the gastrointestinal tract, producing several specific clinical syndromes. Gastric emptying is delayed in 30% to 50% of both patients with type 1 diabetes and patients with type 2 diabetes (243,245). The term "gastroparesis diabeticorum" was first introduced by Kassander (246) to describe the altered gastrointestinal motility in diabetics. Food residue is retained in the stomach as a result of absent or decreased gastric peristalsis compounded by lower intestinal dysmotility (247). Diabetic gastroparesis may manifest as nausea, postprandial vomiting, bloating, abdominal distention and pain, belching, loss of appetite, and early satiety. Many patients, however, are asymptomatic despite impaired gastric motility (245). A gastric splash may be elicited on clinical examination. Gastroparesis is also associated with the development of bezoars (248) and bacterial overgrowth of the stomach and small intestine, esophagitis, gastric ulcers, and gastritis (249). Gastroparesis may impair the establishment of adequate glycemic control by mismatching plasma glucose and insulin levels. The absorption of orally administered drugs may also be affected (246,250). Recent studies have implicated hyperglycemia as a cause of impaired gastric and small intestinal motility during fasting and after food intake.

Diarrhea and other lower gastrointestinal tract symptoms also may occur. Diabetic diarrhea manifests as a profuse, watery, typically nocturnal diarrhea that can last for hours or days and that frequently alternates with constipation. Abdominal discomfort is commonly associated with diabetic diarrhea. The pathogenesis of diabetic diarrhea includes reduced gastrointestinal motility, reduced receptor-mediated fluid absorption, bacterial overgrowth, pancreatic insufficiency, coexistent celiac disease, and abnormalities in the metabolism of bile salts (251–253). Fecal incontinence, due to anal sphincter incompetence or reduced rectal sensation, is another manifestation of diabetic intestinal neuropathy (254,255). Incontinence is often exacerbated by diarrhea.

Sudomotor System

Sudomotor dysfunction is a common feature of diabetic autonomic neuropathy. This generally manifests as anhidrosis of the extremities, which may be accompanied by hyperhidrosis in the trunk. Initially, patients display a loss of thermoregulatory sweating in a glove-and-stocking distribution, which, with progression of autonomic neuropathy, extends from the lower to the upper extremities and to the anterior abdomen, conforming to the length dependency of diabetic neuropathy. This process ultimately may result in global anhidrosis (256).

Hyperhidrosis may also accompany diabetic autonomic neuropathy. Excessive sweating may occur as a compensatory phenomenon involving proximal regions such as the head and trunk that are spared in a dying-back neuropathy. Gustatory sweating, the abnormal production of sweat that appears over the face, head, neck, shoulders and chest after eating even nonspicy foods, is occasionally observed (257). In contrast to truncal hyperhidrosis, which does not occur in response to eating, gustatory hyperhidrosis is not likely to be a compensatory response to anhidrosis (258).

TREATMENT OF AUTONOMIC DYSFUNCTION

Treatment of Orthostatic Hypotension

The removal of potential reversible causes of orthostatic hypotension is the first and most important management step. Medications such as diuretics, antihypertensive agents, antianginal agents, and antidepressants are the most common offending agents.

Numerous agents from diverse pharmacologic groups have been implemented in the treatment of orthostatic hypotension. 9- α -Fluorohydrocortisone (fludrocortisone acetate), a synthetic mineralocorticoid, is the medication of first choice for most patients with orthostatic hypotension. Treatment is initiated with a 0.1-mg tablet and can be increased to 0.5 mg daily. Treatment may unfortunately be limited by supine hypertension. Other side effects include ankle edema, hypokalemia, and, rarely, congestive heart failure. Potassium supplementation usually is required, particularly when higher dosages are used.

A sympathomimetic agent can be added to fludrocortisone acetate should the patient remain symptomatic. The peripherally acting selective α -agonist midodrine, which recently has been approved by the U.S. Food and Drug Administration (FDA) to treat orthostatic hypotension, is the most widely used of these pressors. Patient sensitivity to this agent varies, and the dose should be titrated from 2.5 mg to 10 mg three times a day. Potential side effects of this agent include pilomotor reactions, pruritus, supine hypertension, gastrointestinal complaints, and urinary retention. Other sympathomimetic agents used are ephedrine and pseudoephedrine (259).

Treatment of Gastroparesis Diabeticorum

Frequent small meals and pharmacotherapy are standard treatments for this disorder. The dopamine agonist metoclopramide continues to be the first line of therapy for this gastroparesis. Given in doses ranging from 5 to 20 mg orally, 30 minutes before meals and at bedtime, metoclopramide accelerates gastric emptying and has a central antiemetic action. It also may release acetylcholine from intramural cholinergic neurons or directly stimulate antral muscle (260–262). Domperidone (10 to 20 mg four times a day), a peripheral D₂-receptor antidopaminergic agent, is frequently helpful in the treatment of this disorder (263–267). Erythromycin and related macrolide compounds may have motilin-agonist properties. Intravenous and oral erythromycin (250 mg three times a day) improves gastric emptying time in diabetic patients with gastroparesis (268).

Gastric antisecretory agents such as the H_2 antagonists and proton-pump inhibitors may be used as supplementary agents to treat the symptoms of gastroesophageal reflux. Most patients can be treated with these medical interventions, and placement of a jejunostomy tube is rarely necessary. Patients with severe cases with intractable vomiting may benefit from nasogastric suctioning.

Treatment of Erectile Dysfunction

Medications influencing autonomic function such as psychotropic and antihypertensive agents should be discontinued. Oral therapy with the selective phosphodiesterase 5 inhibitors is now the first-line therapy for male erectile dysfunction. These agents enhance blood flow to the corpora cavernosa with sexual stimulation. The most extensively used of these agents is sildenafil (50 mg) (269). Tadalafil (20 mg) (269a) and vardenafil (20 mg) (269b) are also effective in more than 60% of diabetic patients with erectile dysfunction. Unfortunately, some men with diabetes do not respond satisfactorily to this intervention. Furthermore, the medication is contraindicated in patients treated with nitrates and agents that compete with or inhibit the cytochrome P450 system. Angina, hypertension requiring treatment with multiple medications, and congestive heart failure are also contraindications (270,271). Other therapies include the injection of vasoactive substances such as papaverine, phentolamine, and prostaglandin E₁ into the corpus cavernosum; transurethral delivery of vasoactive agents (272-276); and the use of mechanical devices such as the vacuum erection device or constricting rings (277). Penile prosthetic implants may be used if these therapies fail or are not tolerated by the patient.

Treatment of Hyperhidrosis

This socially embarrassing phenomenon may be treated with anticholinergic agents such as trihexyphenidyl, propantheline, or scopolamine. High doses of these agents are usually required, and therapy is usually limited by other anticholinergic side effects, such as dry mouth, urinary retention, and constipation. Gustatory sweating may respond to topical anticholinergic agents (277a) and to injections of botulinum toxin type A (277b).

PAINFUL DIABETIC NEUROPATHY

Pain is one of the more distressing and difficult-to-manage symptoms of diabetic neuropathy and occurs in both focal neuropathy and symmetric polyneuropathy. In polyneuropathy, the incidence, severity, and duration of pain are quite variable, whereas in focal mononeuropathy and radiculopathy, pain is usually more severe but temporary.

The pathophysiologic basis for the pain of diabetic neuropathy has not been established. Several investigators have attempted to define the structural basis of painful diabetic polyneuropathy. Morphologic abnormalities that have been associated with neuropathic pain include axonal sprouting, acute axonal degeneration, active degeneration of myelinated fibers, and disproportionate loss of large-caliber nerve fibers. Recent controlled studies, however, have failed to support these associations. Brown et al. (278) described axonal degeneration and nervefiber sprouting predominantly involving small myelinated and unmyelinated fibers in sural nerve biopsies of two patients with painful distal diabetic neuropathy. Because small myelinated and unmyelinated fibers mediate pain sensation, it was proposed that pain results from increased ectopic activity in the regeneration of small-fiber nerve sprouts. In a later study that provided some support for this hypothesis, Said et al. (29) noted severe loss of unmyelinated and small myelinated axons with axonal sprouting in five patients with clinical features of small-fiber sensory diabetic neuropathy, autonomic dysfunction, and plantar ulceration. Three of these patients had painful manifestations.

This hypothesis has not been supported by all studies. Dyck et al. (279) found that painful diabetic neuropathy was correlated with acute breakdown of myelinated nerve fibers. There was no evidence of differential involvement of small and large nerve fibers. Archer et al. (42) found acute degeneration with regeneration in nerve fibers of all diameters in three patients with acute and severe painful polyneuropathy.

Britland et al. (280) found uniform degeneration and regeneration in large and small myelinated fibers and in small unmyelinated fibers in patients with either acute or chronic painful neuropathy, as well as in patients with painless neuropathy and neurotrophic foot ulcers. There were no differences in the extent of unmyelinated fiber pathology or acute axonal degeneration in patients with and without pain, but fibers with disproportionately large Schwann cells relative to axon diameter occurred exclusively in patients with painful neuropathy, raising the possibility that axonal atrophy may play a role in pain production.

Llewelyn and colleagues (281) noted that the presence of pain did not correlate with active degeneration of myelinated fibers or with regenerative activity in myelinated or unmyelinated axons, whereas Malik and colleagues (282) reported, based on morphologic data derived from 30 diabetic sural nerves, that there was no difference in myelinated and unmyelinated fiber pathology between patients with painless and patients with painful neuropathy. Sprouting of unmyelinated fibers was no more common in patients with painful neuropathy than patients with painless neuropathy.

TREATMENT OF PAINFUL NEUROPATHY

Treatment of pain requires attempts at strict control of blood glucose levels, as there is evidence that hyperglycemia may reduce the pain threshold. Because painful diabetic neuropathy may persist for months and occasionally for years, continued use of opiates should be avoided. When non-opiate analgesics are effective, they should be taken on a carefully timed, regular basis throughout the day, as in the management of cancer pain, not after the pain has been allowed to build in repeated crescendo fashion. Since the pain of diabetic neuropathy is characteristically worse at night, regular dosing of an analgesic in the early evening and again before sleep may improve sleep. A variety of agents from diverse pharmacologic classes, the socalled adjuvant analgesics, have been used to treat neuropathic pain (Table 56.3).

Tricyclic and Other Antidepressants

The tricyclic antidepressants and anticonvulsants are the agents used as first-line therapy for the treatment of neuropathic pain. The tertiary amine amitriptyline is the best studied of these agents and has been shown in several randomized, blinded clinical trials to significantly improve neuropathic pain

TABLE 56.3. Pharmacotherapy for Neuropathic Pain				
Agent	Initial dose	Dose increment	Effective dose	
Gabapentin	100–300 mg qd	100–200 q 3–5 d	300–1800 mg tid	
Tricyclic antidepressants	10–25 mg qd	10–25 mg/wk	25–150 mg	
Pregabalin	50–75 mg bid	25–150 q 3 d	50–200 mg tid	
Lamotrigine	25 mg qd	25–50 mg/wk	200–400 mg bid	
Topiramate	50 mg qd	50 mg qď	200 mg bid	
Carbamazepine	100–200 mg bid	100–200 mg q 2 d	200–400 mg tid	
Tramadol	50 mg qd	50 mg qd	50–100 mg qid	
Duloxetine	60 mg qd	30–60 mg	60 mg bid	
Venlafaxine	37.5 mg qd	37.5 q 3–5 d	75 mg bid	
Capsaicin	0.075% gid		0.075% gid	
Mexiletine	150 mg '	150 mg qd	150–300 mg tid	

(283–285). Side effects include drowsiness, constipation, dry mouth, weight gain, and orthostatic hypotension. The secondary amines nortriptyline and desipramine have a less troublesome side-effect profile (284–286). A meta-analysis of antide-pressant use in randomized placebo-controlled trials revealed that tricyclic agents provided at least a 50% reduction in pain intensity in 30% of individuals with neuropathic pain (287).

Current data suggest that selective serotonin reuptake inhibitors are not as effective as tricyclic agents in the management of diabetic neuropathic pain (285,288). The selective norepinephrine and serotonin reuptake inhibitors venlafaxine and duloxetine may prove useful in the treatment of painful diabetic polyneuropathy. These agents inhibit reuptake of serotonin and norepinephrine with the muscarinic, histaminic, and adrenergic side effects that accompany use of the tricyclics (288a,288b).

Anticonvulsants

Anticonvulsants from several classes have been used to treat painful diabetic neuropathy. Gabapentin is currently the most frequently prescribed anticonvulsant for the treatment of neuropathic pain. In blinded, randomized, placebo-controlled trials, this agent demonstrated effectiveness in the treatment of painful diabetic neuropathy (289). Gabapentin is well absorbed and not metabolized. It is not bound to plasma proteins. There is no hepatic metabolism, and the agent is excreted unchanged by kidneys. The clearance of gabapentin is reduced in patients with impaired creatinine clearance, and dose adjustment is required. Gabapentin does not compete for or inhibit the cytochrome P-450 system. Side effects include drowsiness, dizziness, and fatigue (290).

Pregabalin has shown effectiveness in alleviating pain associated with diabetic peripheral neuropathy. In a randomized, double-bind, placebo-controlled, parallel-group, multicenter, 8week trial, 146 patients were randomized to receive placebo or pregabalin, 300 mg per day. Pregabalin produced significant improvements versus placebo for mean pain scores, mean sleep interference scores, and measures of quality of life. Pregabalin has similar pharmacokinetic features to gabapentin, but, in contrast, displays linear pharmacokinetics (291).

The mechanism of the analgesic action of these agents is not fully elucidated. Pregabalin and gabapentin are structurally related to the neurotransmitter gamma-aminobutyric acid (GABA), although there is no evidence that they bind directly to GABA receptors or that they influence the uptake or breakdown of GABA. A proposed mechanism of action, based on the observation that gabapentin binds to the $\alpha_2\delta$ subunit of the voltage-dependent calcium channel, is that gabapentin modulates neurotransmission in the presynaptic dorsal horn neurons (291a–291d).

Carbamazepine was first used to treat trigeminal neuralgia and is approved by the FDA for this indication. This agent has also been used successfully to treat diabetic peripheral neuropathy (292). Side effects include dizziness; drowsiness; balance difficulties; skin rash; and rarely leukopenia, thrombocytopenia, and hepatic damage. Other anticonvulsants that may be effective for the treatment of neuropathic pain include phenytoin (293), lamotrigine (294), and topiramate (294a,b).

Antiarrhythmics

The class 1b antiarrhythmic agent mexiletine, a sodium-channel blocker, has been studied for the treatment of diabetic peripheral neuropathy (295–299). The rationale for sodium-channel blockers in the treatment of diabetic peripheral neuropathy is that they inhibit neuron depolarization and thereby impair spontaneous firing of regenerating fibers that have a low threshold for depolarization. The results with this anesthetic antiarrhythmic agent, which is structurally similar to lidocaine, have been inconsistent. Some have suggested that responsiveness to this agent may be predicted on the basis of the response to intravenous lidocaine (300). Side effects of this agent are frequent and include gastrointestinal disturbance, headache, dizziness, and tremor. Use of this agent is contraindicated in patients with second- or third-degree heart block. It may worsen cardiac arrhythmias.

Topical Agents

The use of topical agents to treat diabetic painful neuropathy offers several theoretical advantages. There are minimal systemic side effects, no drug interactions, and usually no need for drug titration. Also, the pharmacotherapeutic effect is applied directly to the site of pain generation, although chronic neuropathic pain usually results in changes at more proximal sites in the peripheral and central nervous system. Capsaicin, an extract of chili peppers, is the most widely used of these agents and is available in cream form. This neurotoxin initially activates and then depletes substance P from the terminals of unmyelinated C fibers. There is some evidence that the application of capsaicin produces degeneration followed by reinnervation of epidermal nerve fibers (301). The results of treatment trials with this agent

have been inconsistent (302-304). Side effects include cutaneous burning, erythema, and sneezing. Several local anesthetic creams are also available and may prove to be of benefit in the treatment of diabetic neuropathic pain (305).

Opiate and Atypical Opiate Analgesics

There is evidence that the "nonnarcotic" analgesic tramadol may be effective in the treatment of painful diabetic peripheral neuropathy (306). This agent, which is a mixed-opioid agonist, exhibits low-affinity binding to the µ opiate receptor. It is biochemically distinct from other opioids in that analgesia is only partially antagonized by naloxone. Tramadol inhibits reuptake of norepinephrine and serotonin. Side effects of this medication include dizziness, nausea, constipation, and drowsiness. This agent has a low potential for abuse but should be avoided in opiate-dependent patients and patients with a tendency to abuse drugs. The use of opioids to treat neuropathic pain remains controversial.

TREATMENT OF HYPERTENSION IN PATIENTS WITH DIABETES 972

Dietary and Lifestyle Modifications 972 Pharmacologic Therapy for Hypertension in Patients with Diabetes 972

Hypertension is a very common comorbid condition in diabetes and accounts for up to 85% of excess cardiovascular disease (CVD) risk. Conversely, patients with hypertension are more prone to diabetes than are normotensive patients. Hypertension substantially increases the risk for coronary heart disease (CHD), stroke, retinopathy, and nephropathy. When hypertension coexists with diabetes, the risk of stroke or CVD is doubled and the risk for developing end-stage renal disease is increased five to six times compared with the risk for hypertensive patients without diabetes. In type 2 diabetes, hypertension usually clusters with the other components of the cardiometabolic syndrome, such as microalbuminuria, central obesity, insulin resistance, dyslipidemia, hypercoagulation, increased inflammation, left ventricular hypertrophy (LVH), and hyperuricemia. In type 1 diabetes, hypertension is usually a manifestation of diabetic nephropathy, and hypertension and nephropathy appear to exacerbate each other.

Hypertension in individuals with diabetes has characteristic features, including volume expansion, increased salt sensitivity, isolated systolic hypertension, loss of the nocturnal dipping of blood pressure and pulse, and increased propensity toward orthostatic hypotension and albuminuria.

To maximize the CVD risk reduction in this high-risk population, they should be treated with aspirin and have their low-density lipoprotein (LDL)-cholesterol lowered to less than 100 mg/dL and their blood pressure lowered to a target of 130/80 mm Hg. Combination of two or more drugs is usually necessary to achieve the target blood pressure of 130/80 mm Hg. Thiazide diuretics, angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor (AR) blockers, β -blockers, and calcium-channel blockers are beneficial in reducing the incidence of CVD and stroke incidence in patients with diabetes.

RELATIONSHIP BETWEEN HYPERTENSION AND DIABETES

The major cause of mortality in patients with diabetes is CVD (1). Risk factors for CVD that cluster in diabetes (Table 57.1) include hypertension, central obesity, dyslipidemia, microalbuminuria, coagulation abnormalities, loss of nocturnal dipping of blood pressure and pulse, and LVH (2). Among those risk factors, hypertension is approximately twice as frequent in patients with diabetes as in those without diabetes and accounts for up to 85% of the CVD risk. Conversely, patients with hypertension are more prone to diabetes than are normotensive persons (2). In a large prospective study of 12,550 adults, type 2 diabetes was almost 2.5 times as likely to develop in patients with hypertension as in their normotensive counterparts after adjustment for age, sex, race, education, adiposity, family history with respect to diabetes, physical activity level, and other health-related behavior (3). The association between hypertension and insulin resistance, and the resultant hyperinsulinemia, is well established. In untreated patients with essential hypertension, fasting and postprandrial insulin levels were higher than in normotensive controls, regardless of the body mass index (BMI), with a direct correlation between plasma insulin concentrations and blood pressure. On the basis of these results, the authors concluded in this study that essential hypertension is an insulin-resistance state (4). Another study of 24 adults documented that patients with hypertension, whether treated or untreated, are insulin resistant, hyperglycemic, and hyperinsulinemic compared with a well-matched control group (5). Insulin resistance and hyperinsulinemia are also present in rats with genetic hypertension, such as Dahl hypertensive and spontaneously hypertensive rat strains (6,7). On the other hand,

Central obesity Microalbuminuria Low HDL-cholesterol levels High triglyceride levels Small, dense LDL-cholesterol particles Hyperinsulinemia/insulin resistance Endothelial dysfunction Increased apolipoprotein B levels Increased fibrinogen levels Increased PAI-1 levels Increased C-reactive protein and other inflammatory markers Absent nocturnal dipping of blood pressure and pulse Left ventricular hypertrophy Increased uric acid levels Premature coronary artery disease

HDL, high-density lipoprotein; LDL, low-density lipoprotein; PAI-1, plasma-activator inhibitor-1.

the association of insulin resistance and essential hypertension does not occur in secondary hypertension (8). These data suggest a common genetic predisposition for essential hypertension and insulin resistance, a concept that is also supported by the finding of altered glucose metabolism in normotensive offspring of hypertensive patients (9,10).

HEMODYNAMIC AND METABOLIC CHARACTERISTICS OF HYPERTENSION IN DIABETES

Hypertension in patients with diabetes, compared with hypertension in those without diabetes, has unique features, such as increased salt sensitivity, volume expansion, loss of nocturnal dipping of blood pressure and pulse, increased propensity to proteinuria and orthostatic hypotension, and isolated systolic hypertension (2). Most of these features are considered risk factors for CVD (Table 57.1) and are particularly important for selecting the appropriate antihypertensive medication, for example, low-dose diuretics for treatment of volume expansion and ACE inhibitors or AR blockers for proteinuria.

Salt Sensitivity and Volume Expansion

Alterations in sodium balance and extracellular fluid volume have heterogeneous effects on blood pressure in both normotensive and hypertensive subjects (11). Increased salt intake does not raise blood pressure in all hypertensive subjects, and sensitivity to dietary salt intake is greatest in the elderly; those with diabetes, renal insufficiency, and low renin status; and African Americans (12,13). Studies demonstrated that salt sensitivity in normotensive subjects is associated with a greater age-related increase in blood pressure (14). This is particularly important to consider in the management of hypertension in patients with diabetes, especially elderly persons, since the prevalence of both diabetes and salt sensitivity increases with age. Thus, a decreased salt intake along with other aspects of diet such as reductions in fat and free carbohydrates and an increase in potassium are important to institute in these patients (2).

Loss of Nocturnal Decline in Blood Pressure

Normotensive individuals and most patients with hypertension have a reproducible circadian pattern to blood pressure and heart rate during 24-hour ambulatory monitoring (15). Typically, the blood pressure is highest while the patient is awake and lowest during sleep, a pattern called "dipping," in which blood pressure decreases by 10% to 15%. Patients with loss of nocturnal decline in blood pressure, "non-dippers," have a less than 10% decline in blood pressure during the night compared with their daytime blood pressure values (16). Patients with diabetes and many of those with the cardiometabolic syndrome have a loss of nocturnal dipping, as demonstrated by 24-hour ambulatory monitoring of blood pressure. This is particularly important since the loss of nocturnal dipping conveys excessive risk for stroke and myocardial infarction. In fact, ambulatory blood pressure has been reported to be superior to office blood pressure in predicting target-organ involvement such as LVH (17,18). About 30% of episodes of myocardial infarction and 50% of strokes occur between 6:00 a.m. and noon. This is particularly important in deciding strategies for the optimal dosing of antihypertensive medications, for which drugs that provide consistent and sustained 24-hour blood pressure control will be advantageous (19).

Microalbuminuria

There is considerable evidence that hypertension in type 1 diabetes is a consequence, rather than a cause, of renal disease and that nephropathy precedes the rise in blood pressure (20). Persistent hypertension in patients with type 1 diabetes is often a manifestation of diabetic nephropathy, as indicated by an elevation of urinary albumin at the diagnosis of the disease (20). Hypertension and nephropathy appear to exacerbate each other. In type 2 diabetes, microalbuminuria is associated with insulin resistance (21), salt sensitivity, loss of nocturnal dipping, and LVH (22). Elevated systolic blood pressure is a significant determining factor in the progression of microalbuminuria (23,24). Indeed, there is increasing evidence that microalbuminuria is an integral component of the metabolic syndrome associated with hypertension (21,22). This concept is important to consider in selecting pharmacologic therapy for hypertension in patients with diabetes, for which medications that decrease both proteinuria and blood pressure, such as ACE inhibitors and AR blockers, have evolved as increasingly important tools for reducing the progression of nephropathy. Further, aggressive blood pressure lowering, often requiring several drugs, is very important in controlling the progressive diabetic renal disease.

Isolated Systolic Hypertension

With the progression of atherosclerosis in patients with diabetes, the larger arteries lose elasticity and become rigid. The systolic blood pressure increases disproportionately because the arterial system is incapable of expansion for any given volume of blood ejected from the left ventricle, leading to isolated systolic hypertension, which is more common and occurs at a relatively younger age in patients with diabetes (2,25).

Orthostatic Hypotension

Pooling of blood in dependent veins when an individual rises from a recumbent position normally leads to a decrease in stroke volume and systolic blood pressure with concomitant increases

in systemic vascular resistance, diastolic blood pressure, and heart rate. In patients with diabetes and autonomic dysfunction, excessive venous pooling can cause immediate or delayed orthostatic hypotension that might cause a reduction in cerebral blood flow, leading to intermittent lightheadedness, fatigue, unsteady gait, and syncope (26-28). This is important to recognize in patients with diabetes and concomitant hypertension because it has several diagnostic and therapeutic implications; for example, discontinuation of diuretic therapy and volume repletion might be necessary for the treatment of chronic orthostasis. Also, in the subset of patients with "hyperadrenergic" orthostatic hypertension, as manifested by excessive sweating and palpitation, the use of low-dose clonidine might be necessary to blunt an excess sympathetic response (29). Furthermore, increased propensity for orthostatic hypertension in patients with diabetes renders β-adrenergic receptor blockers less desirable and second-line agents for these patients. In addition, doses of all antihypertensive agents must be titrated more carefully in patients with diabetes, who have greater propensity for orthostatic hypertension while having a high supine blood pressure.

TARGET BLOOD-PRESSURE LEVELS IN PATIENTS WITH DIABETES

The Hypertension Optimal Treatment (HOT) (30) and the United Kingdom Prospective Diabetes Study (UKPDS) (31) demonstrated improved outcomes, particularly in preventing stroke, in patients assigned to lower blood pressure targets. In the HOT trial, improved outcomes were achieved in the group assigned to a target diastolic blood pressure of less than 80 mm Hg (30). Epidemiologic studies also suggest an increase in CVD events and mortality with a blood pressure of greater than 120/70 mm Hg, and a target blood pressure of less than 130/80 mm Hg is currently recommended by the Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VII) (32) and the American Diabetes Association (ADA) (33). The treatment algorithm (Fig. 57.1) reflects the new JNC-VII treatment goal of blood pressure less than 130/80 mm Hg as well as the latest recommendations regarding drug therapy and reflects the results

971

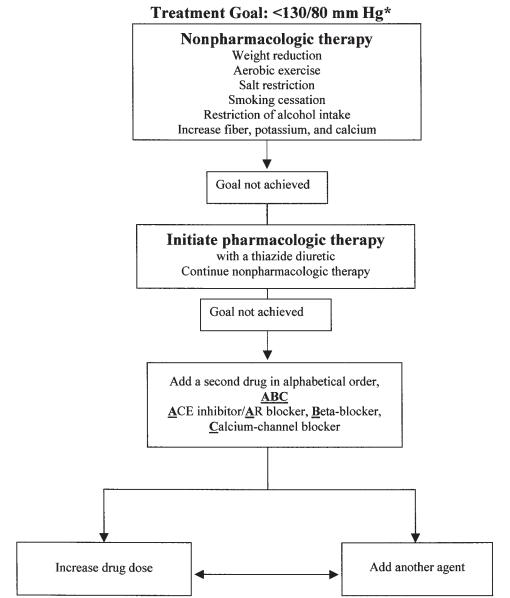

Figure 57.1. Treatment of hypertension in patients with diabetes. *In patients with >1 g proteinuria and renal insufficiency, blood pressure goal is <125/75 mm Hg. ACE, angiotensin-converting enzyme; AR, angiotensin receptor.

of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) study (34,35).

TREATMENT OF HYPERTENSION IN PATIENTS WITH DIABETES

Dietary and Lifestyle Modifications

Both JNC-VII and ADA recommend lifestyle and dietary modifications as an integral part of the management of hypertension in patients with diabetes. Addressing other CVD risk factors such as smoking, inactivity, and elevated LDL-cholesterol is also emphasized (32,34). Dietary and lifestyle modifications recommended for patients with hypertension are listed in Table 57.2. Based on the results of the Dietary Approaches to Stop Hypertension (DASH) study (36), both the reduction of sodium intake to levels below the current recommendation of 100 mmol per day and the DASH diet lower blood pressure substantially, with greater effects when the combination is used (37). Dietary management and exercise in patients with diabetes should be integrated in the overall nutritional and lifestyle management of these patients.

Pharmacologic Therapy for Hypertension in Patients with Diabetes

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors were first introduced in the early 1980s as antihypertensive agents. Subsequently, their ability to attenuate albuminuria and the progression of renal disease led to their use as renoprotective agents in diabetic nephropathy (38,39); more recently, randomized controlled trials have shown that ACE inhibitors provide cardiovascular and microvascular benefits and may also improve insulin resistance and prevent the development of diabetes (40-42). These cardiovascular benefits are greater than those attributable to the decrease in blood pressure, per se, and are particularly pronounced in people with diabetes (42). In patients with type 1 diabetes and proteinuria, treatment with an ACE inhibitor was associated with a 50% reduction in the risk of the combined endpoints of death, dialysis, and transplantation (38). Furthermore, ACE inhibitors provide considerable benefits in diabetic patients with heart failure. In the Studies of Left Ventricular Dysfunction (SOLVD) trial, ACE inhibitors reduced left ventricular mass and left ventricular dilation and significantly reduced mortality and hospitalization for heart failure (43).

Treatment with ACE inhibitors is associated with cough in a substantial minority of patients (up to 15%) (44) and is probably due to the accumulation of bradykinin and related substances.

TABLE 57.2. Dietary and Lifestyle Modification in the Management of Hypertension

- 1. Weight loss [maintain normal body weight (BMI, 18.5–24.9)]
- 2. Exercise (aerobic physical activity) 30–45 min at least three times per week
- 3. Reduced sodium intake to 100 mmol (2.4 g) per day
- 4. Smoking cessation
- 5. Adequate intake of dietary potassium, calcium, and magnesium
- 6. Reduced alcohol intake to <1 oz of ethanol (24 oz of beer) per dav
- 7. Diet rich in fruits and vegetables but low in fat

BMI, body mass index.

Angioedema is rare and unpredictable but a potentially lifethreatening adverse effect, particularly if the upper airway is involved. It requires immediate discontinuation of the drug and supportive care, including airway protection (45). ACE inhibitors reduce aldosterone secretion and may cause hyperkalemia, especially at the initiation of therapy (46). This is of particular concern in patients with diabetes and in those receiving potassium-sparing diuretics. Concomitant use of thiazide or loop diuretics and dietary modification of potassium intake should allow the use of ACE inhibitors without inducing hyperkalemia. It is also important to note that, in patients with normal renal function, ACE inhibitors have little effect on glomerular filtration. However with reduction in renal function, these agents might precipitate uremia. Because of the high risk of renal failure, ACE inhibitors are also contraindicated in patients with bilateral renal-artery stenosis and unilateral stenosis in those with one kidney.

ANGIOTENSIN II RECEPTOR BLOCKERS

There are at least four types of angiotensin II receptors (ARs) (47). Of these, the AT1 receptors mediate most of the effects of angiotensin II, including vasoconstriction, aldosterone release, increased sympathetic outflow, and stimulation of sodium resorption. AR blockers selectively inhibit the binding of angiotensin II to the AT1 receptors; therefore they are also called AT1 receptor blockers (48). Unlike ACE inhibitors, AR blockers have no effects on the bradykinin system and therefore are very well tolerated, with a lower incidence of side effects such as cough (49). Angioedema may occur rarely but much less commonly than with ACE inhibitors. Although there are no specific recommendations, AR blockers should not be used in patients who developed angioedema while receiving ACE inhibitors, since angioedema is a potentially life-threatening condition (50,51). In addition, because of inhibition of aldosterone release by AR blockers, hyperkalemia is a concern, especially in those with renal insufficiency; as with ACE inhibitors, progressive azotemia and renal failure might occur in those with bilateral renal artery stenosis or those with one kidney and unilateral stenosis of the renal artery.

The INC-VII recommended the use of AR blockers as one of several alternative first-line therapies for patients with hypertension who cannot tolerate or do not respond to the recommended first-line medications (32). In addition, AR blockers were also recommended as an initial therapy for those who could not tolerate ACE inhibitors (usually because of cough) and in whom ACE inhibitors are recommended (52), such as patients with diabetes and proteinuria, heart failure, systolic dysfunction, postmyocardial infarction, and mild renal insufficiency. However, three major studies, the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study (53), the Irbesartan Microalbuminuria Type 2 Diabetes in Hypertensive Patients (IRMA II) study (54), and the Irbesartan in Diabetic Nephropathy Trial (IDNT) (55), showed that AR blockers are effective in reducing the progression of renal disease in patients with type 2 diabetes and hypertension. Blood pressure control was similar in the placebo- and AR blocker-treated groups, indicating that AR blockers protect the kidney independent of blood pressure reduction. In the RENAAL trial, the risk of the primary endpoint (a composite of doubling of serum creatinine, end-stage renal disease, or death from any cause) was reduced by 16% with losartan. The risk of doubling of serum creatinine was reduced by 25% and the risk of end-stage renal disease was reduced by 28% over a follow-up period of 3.4 years (53). The study also documented reduction in the initial hospitalization for heart failure. In the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE trial) study (56), losartan

resulted in a statistically greater reduction in CVD morbidity and mortality in diabetic patients with hypertension and LVH than did atenolol. Losartan especially reduced the incidence of fatal and nonfatal strokes by 25%, major causes of death and disability in diabetic patients. Finally, in the LIFE trial, losartan reduced the new onset of diabetes by 25% compared with atenolol. These benefits were above and beyond those attributable to blood pressure reduction alone. On the basis of this evidence and because of the better tolerability, AR blockers are recommended as a first-line therapy for patients with diabetes and hypertension, along with ACE inhibitors.

β-BLOCKERS

β-Blockers are very useful antihypertensive agents in the treatment of hypertension in patients with diabetes (2). In the UKPDS study, atenolol reduced microvascular complications of diabetes by 37%, strokes by 44%, and death related to diabetes by 32%. In that study the efficacy of the β -blocker atenolol was equal to that of the ACE inhibitor captopril in reducing the microvascular and macrovascular complications of diabetes, most probably secondary to their ability to modulate the renin-angiotensinaldosterone system. In a nonrandomized study, hypertensive patients receiving a β -blocker had a 28% higher risk of diabetes than did those receiving no medication. In contrast, patients with hypertension who received thiazide diuretics, ACE inhibitors, or calcium-channel blockers were found to be at no greater risk for subsequent development of diabetes than were patients receiving no medication (3). However increased risk for the development of diabetes with β -blocker therapy was not found in other randomized studies (57). Despite the potentially adverse metabolic effects of β -blockers, they have proved to have significant long-term favorable effects on CVD in hypertensive patients with diabetes and, therefore, should be used in patients with diabetes, particularly those with coronary disease.

CALCIUM-CHANNEL BLOCKERS

For patients to achieve a target blood pressure of 130/80 mm Hg, clinical studies suggest that at least 65% of them require two or more different antihypertensive agents (58-60). In patients with diabetes, additional therapies beside ACE inhibitors and diuretics may include a long-acting calcium-channel blocker (CCB) (25). A nondihydropyridine CCB such as verapamil or diltiazem may have greater beneficial effects on proteinuria than a dihydropyridine CCB such as nifedipine (61). However, with the use of an ACE inhibitor (or an AR blocker) as a first-line treatment, together with a diuretic, the addition of a long-acting dihydropyridine such as amlodipine, nifedipine, or felodipine will reduce both proteinuria and the rate of CVD events. If the blood pressure goal is still not achieved, a low-dose β -blocker or an α/β -blocker can be added. It is important to note that the Appropriate Blood Pressure Control in Diabetes (ABCD) trial demonstrated that ACE inhibitors were superior to CCBs in reducing CVD events; however, these differences are likely the result of the beneficial effects of ACE inhibitors rather than a negative effect of the CCBs, and the use of these agents is particularly helpful in achieving the target blood pressure, especially in patients with isolated systolic blood pressure not responding to the addition of a low-dose diuretic (62).

DIURETICS

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was designed to determine whether treatment with a CCB or an ACE inhibitor lowers the incidence of coronary heart disease (CHD) or other CVD events compared with treatment with a diuretic (35). Of a total of 33,357 participants aged 55 years or older with hypertension and at least one other CHD risk factor, 15,297 had diabetes (36.0% of the entire cohort) (63). Of these individuals, 50.2% were male, 39.4% were African American, and 17.7% were Hispanic. The diabetic cohort in ALLHAT provided valuable information about the treatment of hypertension in older diabetic patients at risk for incident CVD. Thiazide-type diuretics were effective as part of combined therapy that reduced stroke. Therefore, they are recommended as preferred antihypertensive therapy (Fig. 57.1). Diuretics have generally been shown to prevent CVD complications and usually enhance the antihypertensive efficacy of a multidrug regimen, as indicated in Figure 57.1.

FIXED-DOSE COMBINATIONS

The use of fixed-dose combination therapy has the potential of enhancing compliance and reducing side effects and the cost of medications (64). Several diuretic-based combinations are available, including one with a β -blocker, one with an ACE inhibitor, and one with an AR blocker. The use of these agents is increasing (65). Other useful fixed-dose combinations include ACE inhibitors and calcium antagonists. These combination medications have the potential to improve control and compliance (2,64,65).

NEED FOR MULTIPLE MEDICATIONS

To achieve the recommended target blood pressure of 130/80 mm Hg, patients with hypertension and diabetes will need two or more drugs. Data from our group and others indicate that multiple medications are usually necessary to achieve such a goal (58-60). Addition of a second drug from a different class should be initiated when use of a single drug in adequate doses fails to achieve the blood pressure goal. The JNC-VII recommends initiation of therapy with two drugs when blood pressure is 20/10 mm Hg above goal (32). This will probably increase the likelihood of achieving the blood pressure goal.

EVALUATION OF RISK FACTORS 1001

Heart disease was thought to be associated with diabetes as early as 1883, when Vergeley recommended testing the urine of patients with angina for glucose (1). However, as more patients with diabetes survived following the discovery of insulin and improvements in treatments for renal failure and infection, there was a marked increase in morbidity and mortality from cardiovascular disease. Diabetes is the seventh leading cause of death in the United States, with much of that mortality a result of cardiovascular disease (2). However, because these statistics are based on the underlying cause of death, they underestimate the true impact of diabetes on mortality.

Ultimately, atherosclerosis accounts for 65% to 80% of all deaths among North American patients with diabetes, compared with one third of all deaths in the general North American population (3–5). A two- to fourfold excess in mortality due to coronary artery disease (CAD) among individuals with diabetes has been noted in a number of prospective studies encompassing

976 JOSLIN'S DIABETES MELLITUS

a variety of ethnic and racial groups (6). Diabetes also increases the likelihood of severe carotid atherosclerosis (7,8), and mortality from stroke is increased almost threefold in patients with diabetes (9). Both type 1 and type 2 diabetes are therefore powerful and independent risk factors for CAD, stroke, and peripheral arterial disease (3,9,10). Furthermore, when patients with diabetes develop clinical events, they sustain a worse prognosis than patients without diabetes (11). Coupled with these macrovascular complications are such microvascular complications as retinopathy, neuropathy, and nephropathy, all of which account for most of the morbidity and mortality associated with diabetes mellitus. Although diabetes may be a problem of glucose metabolism, the American Heart Association (AHA) has recently stated that "diabetes is a cardiovascular disease" (3).

EPIDEMIOLOGY

More than 10 million Americans carry the diagnosis of diabetes mellitus, and another 5 million are estimated to have undiagnosed diabetes (3). The prevalence of type 2 diabetes, which accounts for 90% of all cases of diabetes, is increasing in the United States and around the world because of the advancing age of the population, improved screening and detection, and the increase in risk factors such as obesity and physical inactivity. A growing ethnic diversity in the United States, including ethnic groups particularly susceptible to type 2 diabetes such as Hispanics, blacks, and South Asians, also contribute to the increasing prevalence of type 2 diabetes (3,12). The obesity epidemic will result in an increasing number of patients with diabetes. In 1998, obesity affected 18% of the U.S. population (13). The problem of obesity is anticipated to grow with the increasing weight of the U.S. population. Between 1991 and 1998, the body weight of the American male increased by 3% and that of the American female increased by 5%.

Diabetes and Cardiovascular Mortality

A meta-analysis of several studies estimated the risk of death from CAD in patients with diabetes at 2.58 in men and 1.85 in women (14). These values are in contrast with those from the Rancho Bernardo Study (15), which followed subjects aged 40 to 79 for 14 years and found that while death rates were also increased in subjects with diabetes, the risk factor–adjusted relative odds were 3.3 in women and 1.9 in men. Factors associated with an increase in mortality rates among those with diabetes include male gender, black race, longer duration of diabetes, and insulin use (16). Overall, cardiovascular disease, which includes coronary artery and cerebrovascular disease, accounts for 65% of all deaths among persons with diabetes. Although much of these data are based on findings in patients with type 2 diabetes, patients with type 1 diabetes have similar causes of death, including CAD and renal failure (17,18).

Life expectancy is shortened, with diabetic males living, on average, 9.1 years less and diabetic females living 6.7 years less than their nondiabetic counterparts (19). Haffner and colleagues examined the mortality among 1,000 persons with type 2 diabetes and 1,300 subjects without diabetes and found that the mortality of those with diabetes was similar to that for those without diabetes who had a myocardial infarction (MI) (20) (Fig. 58.1). These data suggest that caregivers should treat individuals with type 2 diabetes as if they had experienced an MI. Mukamal et al. (21) studied 1,935 patients hospitalized with an acute MI and found that the mortality among those with diabetes in the short-term period was similar to that of the patients without diabetes who had an MI previously and twice that of patients without diabetes who had suffered their first acute coronary event. Malmberg et al. (22) evaluated the findings of the OASIS (Organization to Assess Strategies for Ischemic Syndromes) registry and found that patients with diabetes hospitalized for unstable angina or non-Q-wave MI had the same long-term morbidity and mortality as patients without diabetes with established cardiovascular disease.

Over the past three decades, there have been significant decreases in cardiovascular mortality in the United States. However, the effect on mortality in patients with diabetes has lagged well behind that in the general population (23). The death rate among nondiabetic men with CAD decreased by 36.4% as compared to a decrease of 13.1% for diabetic men, and the death rate among nondiabetic women decreased by 27% as compared to an increase of 23% among diabetic women (23).

Prevalence and Risk Factors for Coronary Artery Disease in Type 1 Diabetes

Long-term follow-up of patients with type 1 diabetes has demonstrated that the first cases of clinically manifest CAD occur late in the third decade or in the fourth decade of life regardless of whether diabetes developed early in childhood or during late adolescence. CAD risk increases rapidly after the age of 40, and by the age of 55 years, 35% of men and women with type 1 diabetes die of CAD (18) compared with 8% of those without diabetes. Women with type 1 diabetes lose most of the inherent protection from CAD observed in women without diabetes (18,24,25). The occurrence of severe coronary atherosclerosis before the age of 55 in a subset of patients with type 1 diabetes regardless of whether diabetes developed in childhood or adolescence suggests that diabetes mainly accelerates the progression of early atherosclerotic lesions that commonly occur, even in the absence of diabetes, at a young age in the general population (18).

Diabetic nephropathy, which develops in approximately 30% to 40% of patients with type 1 diabetes, dramatically increases the prevalence of CAD (18,26). Patients with persistent proteinuria who were followed in the Steno Memorial Hospital had a 37-fold increased mortality from cardiovascular disease relative to that of the general population, while patients without proteinuria had a cardiovascular mortality that was only 4.2 times higher (26). Patients with type 1 diabetes followed from the onset of microalbuminuria developed CAD eight times more frequently than patients without microalbuminuria (27). Krolewski et al. (17) reported that the risk of development of CAD in patients with persistent proteinuria was 15 times higher than the risk among those without proteinuria. Angiographic studies have shown that almost all patients with diabetic nephropathy older than age 45 have one or more clinically significant coronary stenoses (28). Microalbuminuria in type 1 diabetes is therefore not only a marker for renal disease but also a potent marker of CAD risk.

Several mechanisms contribute to the atherosclerotic process in the presence of diabetic nephropathy, including hypertension, lipid abnormalities, fibrinolysis, and coagulation alterations, all of which are detectable in the early stages of diabetic nephropathy when renal function is still normal (29). Hypertension is frequently present in patients with diabetic nephropathy even when the creatinine concentrations remain normal and can intensify CAD in patients with type 1 diabetes. Diabetic nephropathy is associated with an atherogenic lipoprotein profile that includes elevated levels of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL), decreased levels of high-density lipoprotein (HDL), and elevated [Lp(a)] levels of lipoprotein a (30-32). Furthermore, a hypercoagulable state characterized by increased levels of plasminogen-activator inhibitor-1 (PAI-1), factor VII, and (plasma) fibrinogen, has been described in microalbuminuric patients with type 1 diabetes (33). Finally, reduced renal function leads to the accumulation of advanced glycosylation end products (AGEs) in the circulation and tissue (34,35).

The risk for the development of diabetic nephropathy is only partially determined by glycemic control and is highly influenced by genetic susceptibility (26,27). Several studies have established that a genetic susceptibility contributes to the high prevalence of CAD among patients with type 1 diabetes with nephropathy. CAD is twice as common a cause of death among parents of diabetic patients with nephropathy than among parents of diabetic patients without nephropathy. Among patients with diabetes with nephropathy, those who had a cardiovascular event are six times more likely than patients who did not have such an event to have a familial history of cardiovascular disease. A history of cardiovascular disease in both parents or in the father of a patient with type 1 diabetes increases the risk of nephropathy in the offspring tenfold and threefold, respectively (36). Parents of diabetic offspring with nephropathy also have higher blood pressure than parents whose diabetic offspring do not have diabetic nephropathy (37).

Interestingly, recent studies have shown that an association between the angiotensin-converting enzyme insertion/deletion (ACE I/D) polymorphism, potentially affecting the level of angiotensins and kinins in the kidney, can affect the development of renal disease in patients with type 1 diabetes (38). The same polymorphism has been linked to MI in patients without diabetes (39), as well as in patients with type 1 diabetes (40,41) and type 2 diabetes (42).

Prevalence and Risk Factors for Coronary Artery Disease in Type 2 Diabetes

Type 2 diabetes increases relative risk of cardiovascular disease two- to fourfold compared with the risk in the general population (43–46). The increase in cardiovascular risk is particularly high in women. The protection against atherosclerosis in premenopausal women is almost completely lost in women with diabetes (47,48).

While traditional risk factors play an important role in the development of atherosclerosis in subjects with diabetes, the rate of cardiovascular mortality and morbidity in persons with diabetes exceeds by 50% the rate predicted by these risk factors. Several other risk factors may account for this discrepancy. Possible nontraditional risk factors include insulin resistance, insulin levels, and hyperglycemia.

Many of these patients with type 2 diabetes have several of these risk factors for CAD. The term *metabolic syndrome* was first used by Gerald Reaven in 1988 (49) to describe this clustering of risk factors including hypertension, dyslipidemia, hyperglycemia, and insulin resistance. The National Cholesterol Education Program Adult Treatment Panel III (ATPIII) guidelines for cholesterol management in 2001 recognized that the metabolic syndrome is a collection of the risk factors mentioned above, as well as abdominal obesity (50).

PATHOPHYSIOLOGY OF DIABETIC CARDIOVASCULAR COMPLICATIONS

The increased risk of cardiovascular disease in individuals with diabetes is explained in part by the clustering of risk factors, including dyslipidemia, hypertension, hyperglycemia, hyperinsulinemia, and prothrombotic factors. Some of these risk factors are described in detail subsequently.

Insulin Levels, Insulin Resistance, and Hyperglycemia

Insulin resistance that is present many years or more before the clinical onset of overt diabetes resistance is associated with other atherogenic risk factors, such as hypertension, lipid abnormalities, and a procoagulant state (51–57) (Table 58.1) that promotes atherosclerosis many years before overt hyper-glycemia ensues (58,59). Indeed, several studies have shown an inverse correlation between insulin sensitivity and atherosclerosis (60–62). Investigators using the Bruneck Study database suggest (63) that these risk factors are present in 84% of patients with type 2 diabetes. Thus, an increased prevalence of CAD is apparent in patients with impaired glucose tolerance (44,46,64)

TABLE 58.1. Cardiovascular Risk Factors Associated with Insulin Resistance

Hypertension (51,52) Abdominal obesity (53,57) Dyslipidemia (54–56,281) Increased very-low-density lipoprotein–triglyceride Decreased high-density lipoprotein Small dense atherogenic low-density lipoprotein particles Postprandial lipemia Elevated PAI-1 activity (58)

PAI-1, plasminogen activator inhibitor-1. From Aronson D, Johnstone MT. Coronary artery disease in diabetes. In: Johnstone MT, Veves A. *Diabetes and cardiovascular disease*. Totowa, NJ: Humana Press, 2001. Reprinted with permission from Humana Press.

and in those with newly diagnosed type 2 diabetes (65,66). The duration of insulin resistance among hyperglycemic and diabetic individuals probably contributes to the development of atherosclerosis. However, no obvious association between the extent or severity of macrovascular complications and the duration or severity of type 2 diabetes (24,67) has been found, most likely because the duration of insulin resistance is often unknown.

Another possibility is that the serum insulin level and not insulin resistance has direct cardiovascular effects. Despres and colleagues (68) followed 2,000 diabetic men without clinically overt CAD for 5 years and found that those who had a cardiovascular event had serum insulin levels that were 18% higher than those in controls.

Serum glucose levels may be an important risk factor for cardiovascular disease. Andersson and Svardsudd (69) demonstrated that fasting serum glucose levels are independently related to all-cause and cardiovascular mortality. The San Antonio Heart Study (70) showed similar findings for subjects in the highest quartile of fasting glucose levels, who had a 4.7 times greater risk of cardiovascular disease than did those in the first two quartile levels combined.

The direct relationship between glucose levels and cardiovascular disease also is seen in patients with type 1 diabetes. A 1% increase in levels of glycosylated hemoglobin doubled the increase in cardiovascular disease (71). Several studies have shown a direct relationship with the serum glucose levels on clinical events, including MI and strokes, with glucose levels ranging from an abnormal glucose tolerance test to frank diabetes (72–74). This graded effect of serum glucose levels on clinical events may be due in part to a direct effect on the vasculature, as evidenced by a similar direct relationship of serum glucose levels to the intima-media thickness of the carotid (as a marker for the presence and degree of atherosclerosis). The Atherosclerosis Risk in Communities (ARIC) study demonstrated that fasting glucose tolerance was directly related to carotid wall thickness in individuals free of symptomatic cardiovascular disease (8).

The level of chronic hyperglycemia, as determined by measurements of glycosylated hemoglobin, may also be an independent risk factor for coronary heart disease, particularly in women (75,76). Recent prospective studies demonstrated that microalbuminuria in patients with type 2 diabetes is also an independent predictor of increased cardiovascular mortality (77,78). Insulin resistance may play an important role as a risk factor in the development of diabetic cardiovascular disease. Hyperinsulinemia may be the mechanism by which the effect of hyperglycemia results in atherosclerosis. Insulin level is elevated in patients with the metabolic syndrome. The possibility that insulin resistance could result in an increase in cardiovascular disease was first demonstrated in population studies that showed an association between fasting insulin levels and cardiovascular mortality (60,79–81). In the Insulin Resistance Atherosclerosis Study, subjects were evenly divided among patients with normal serum glucose, hyperglycemia with normal glucose tolerance, and diabetes. The relationship of insulin levels and cardiovascular disease is further strengthened by basic research studies that showed the effect of insulin on various possible mediators for the development of atherosclerosis, specifically the increase in PAI-1 and the mitogenic effect on smooth muscle cells *in vitro* (82).

Dyslipidemia

An important mechanism for the development of diabetic atherosclerosis is dyslipidemia. The central feature of diabetic dyslipidemia is increased levels of VLDL due both to increased production of VLDL and to decreased catabolism of triglyceride-rich lipoproteins, including chylomicrons. The increase in hepatic production of VLDL occurs in response to increased delivery of fatty acids from (a) decreased free fatty acid uptake from the striated muscle and (b) increased delivery of the free fatty acids from the increased adipose tissue associated with central obesity.

The increase in triglyceride-rich lipoproteins accumulates not only because of increased VLDL production but also because of decreased catabolism of triglyceride lipoproteins. Lipoprotein lipase, which plays an important role in the metabolism of triglyceride-rich lipoproteins and in particular chylomicrons, is decreased in uncontrolled type 2 diabetes.

The increased level of triglyceride-rich lipoproteins provides an increase in substrate for the cholesterol ester transfer protein. This promotes the flux of cholesterol from HDL particles, which results in decreased HDL levels, a common finding in type 2 diabetes. Yet other mechanisms must be involved, because low HDL levels can occur in the absence of hypertriglyceridemia. The degree of HDL reduction is not related to the degree of control of diabetes or to the mode of treatment in type 2 diabetes. One mechanism of the protective effect of HDL against atherosclerosis may be its ability to prevent oxidation of LDL. There may be qualitative differences in HDL from patients with poorly controlled diabetes that may make it a less effective antioxidant than HDL from normal individuals (83).

Although the dyslipidemia of diabetes is not characterized by marked elevations of LDL, there are differences in the LDL type found in patients with type 2 diabetes. Specifically, the LDL is smaller and denser than typical LDL particles (84). These smaller, denser LDL particles have a greater tendency to undergo oxidation, which accelerates the atherosclerotic process.

Increased Oxidative Stress in Diabetes

There is recent evidence that increased oxidative stress in diabetes contributes to the development of diabetic complications (85). This increased stress may be due in part to the decreased availability of antioxidants such as ascorbic acid, vitamin E, uric acid, and glutathionine. In addition, there may be an increase in lipid peroxidation products and superoxide anion products, which may lead to altered vascular function (85–87).

The increase in oxidative stress may be the result of several pathways, including advanced glycation end product (AGE) production; small, dense LDL formation; altered polyol activity; or imbalance in the redox state (88). The activation of this polyol pathway is due to the conversion of glucose to sorbitol via aldolase reductase, which has been associated with microvascular complications (89,90).

The recent data from the Heart Outcomes Prevention Evaluation (HOPE) study have shown that treatment with the antioxidant vitamin E at 400 IU per day for a mean of 4.5 years had no apparent effect on cardiovascular morbidity or mortality in both diabetics and nondiabetics (91). King's group has had rather intriguing results demonstrating that therapy with high doses of vitamin E (1800 IU per day) normalizes retinal hemodynamic abnormalities and improves renal function without improving glycemic control in patients with type 1 diabetes of short duration (92). Whether this effect is via antioxidant-dependent or -independent pathways remains to be elucidated.

Oxidative stress also precedes the formation of some AGEs, including pentosidine and N- ϵ -carboxymethyllysine (CML), and the activation of the diacylglycerol–protein kinase C (DAG-PKC) pathway.

Advanced Glycation End Products in Diabetes

AGEs occur as a result of the nonenzymatic glycation of both lipids and proteins. Initially, a labile covalent bond develops between the aldehyde of the glucose molecule and the amino acid side chain on both sugars and lipids. Specifically, glucose is covalently bound mainly to lysine residues in proteins, forming fructose-lysine residues. This reaction results in the development of a Schiff base, which, in turn, undergoes another chemical reaction to form a ketoamine, termed an Amadori product. These products result in cumulative oxidative damage to proteins. These products include CML (93) and pentosidine (94). The increased levels of pentosidine and CML correlate with the severity of diabetic complications, including nephropathy, retinopathy, and vascular disease. One such Amadori product is glycated (or glycosylated) hemoglobin A_{1c} (HbA_{1c}), which is commonly used to monitor glycemic control in diabetic patients. Since both free-radical oxidation and glycation are involved, these substances are also called glyoxidation products.

AGEs cross-link to the proteins composing the extracellular matrix and vascular basement membrane, which results in reduced solubility and decreased enzymatic digestion (95,96). AGE formation also prevents proper assembly of basement proteins, thereby altering their function. This in turn may alter the ability of cells to bind to their substrates.

AGEs are derived from oxidation of lipids (97,98). The side chains of unsaturated fatty acids undergo oxidation, which yields reactive carbonyl-containing fragments [malondialdehyde (MDA), glyoal 4-hydroxynonenal (4-HNE)] and then react with amino groups, mainly lysine residues.

Enhanced glycation, oxidation, and glyoxidation of lipoproteins have been postulated as a possible cause for the development of diabetic macrovascular disease. Certainly there are increased levels of AGE-modified LDL-apoprotein and LDLlipid in persons with diabetes relative to levels in persons without diabetes (99). This would suggest that even in the face of similar glycemic control and other cardiovascular risk factors, the development of diabetic vascular complications would depend on differences of oxidative stress as well as on the tissue level of antioxidants.

The evidence for this possible role of these altered lipoproteins includes the presence of oxidized lipoproteins in the vessel wall (100,101) and the demonstration of lesion regression with antioxidants (102). One study (103) showed that the susceptibility of LDL to oxidation was correlated with the degree of atherosclerosis in 35 male survivors of an MI.

Vlassara and colleagues (104) identified a specific receptor for AGEs on monocyte/macrophages, termed RAGE (receptor for AGEs). The subsequent interaction with the AGE and its receptor may induce the release of the cytokines tumor necrosis factor (TNF) and interleukin-1 (105). Other cytokines that have been demonstrated include the synthesis and release of procoagulant activity and platelet-activating factor (PAF) by endothelial cells (106,107), as well as the induction of platelet-derived growth factor (PDGF-AA), which can be indirectly responsible for fibroblast and smooth muscle proliferation (108). Furthermore, increased AGE-receptor interaction has been shown to result in the enhanced expression of vascular cell adhesion molecule (VCAM) (109–111), which in turn results in increased atherogenesis.

The important role of the AGE receptor in the development of atherosclerosis was further strengthened by the demonstration that atherosclerosis was less severe in the usually atherosclerotic apolipoprotein E-knockout mice when they were administered an antibody-fragment that neutralized RAGE (112). This effect was seen without any effect on glycemic control or lipoprotein profile.

Thrombosis and Fibrinolysis in Diabetes

Plaque disruption with overlying thrombosis is a major cause of acute coronary syndromes, including MI, sudden death, and stroke. Because patients with type 1 and type 2 diabetes, particularly those with type 2 diabetes, have higher rates of acute coronary syndromes than the population without diabetes, heightened arterial prothrombotic reactivity may play a pivotal role in the development of these macrovascular complications.

There are three underlying mechanisms for this prothrombosis: heightened platelet reactivity, increased procoagulant activity, and decreased antithrombotic and fibrinolytic activity. The principal components of a thrombus are platelets and fibrin. The coagulation is initiated by the exposure of tissue factor within the arterial plaque at the time of plaque disruption. This results in the activation of factor VII/VIIa, which forms the "tenase complex" with factors X and V, resulting in the activation of thrombin. Thrombin stimulates platelet reactivity and the conversion of fibrinogen to fibrin, producing a thrombus.

The platelets of diabetic individuals appear to have an increased adherence to the vessel wall and increased circulating platelet mass (113). Platelet aggregometry studies that measure *in vitro* platelet reactivity have demonstrated increased aggregation of platelets in response to the agonists ADP, collagen, and thrombin and even spontaneous aggregation of platelets without any agonist (114–118). Assessment of platelet reactivity *in vivo* by measurement of blood or urine metabolites released from activated platelets such as thromboxane B₂ has shown increased reactivity relative to that of normal healthy controls (114,115).

Patients with diabetes have increased concentrations of fibrinogen, von Willebrand factor, and factor VII (119–121). Although the mechanisms of the increased concentrations of these factors have yet to be elucidated, the level of serum fibrinogen correlates with the levels of proinsulin and insulin in the blood (122). However, neither the plasma level of fibrinogen control nor the level of the plasma prothrombin fragment 1+2, a cleavage product of prothrombin, is reduced with improved metabolic control.

Several reports indicate that the activity of antithrombotic factors, including protein C and antithrombins, are decreased in subjects with diabetes, which further potentiates the hypercoagulable state (123–126).

Fibrinolysis is also impaired in individuals with diabetes, particularly those with type 2 diabetes (127,128). This

980 JOSLIN'S DIABETES MELLITUS

impairment may be due to the increased activity of PAI-1 in the blood, which counteracts the action of native tissue plasminogen activator (t-PA) to induce fibrinolysis. PAI-1 is elevated not only in resting states but also in response to physiologic stimuli. The serum level of PAI-1 may be elevated as a result of several factors, including elevated serum levels of insulin, lipids, and glucose (129). The impairment of the fibrinolytic system can potentially exacerbate the development and persistence of thrombi, resulting in an increased risk of vascular occlusion.

Endothelial Function and Diabetes

Alterations in endothelial function may play an important role in the development of diabetic complications. Decreased blood flow in many organs has been reported, including the kidney, retina, and peripheral retinal nerves. Patients with recent diabetes have decreased retinal blood flow, as indicated by increased vascular resistance. The mechanism of this increased vascular resistance is probably partly due to the increase in the intercellular signal transduction kinase, protein kinase C (PKC) (130–133). This increase in PKC may result in an increase in endothelin-1. It has been documented that abnormalities in hemodynamic profiles precede diabetic nephropathy. This increase in glomerular filtration is probably due to the effect of hyperglycemia on arteriolar resistance.

The vascular endothelium has been shown to be important in modulating blood cell-vessel wall interaction, regulating blood flow, angiogenesis, lipoprotein metabolism, and vasomotion. An important mediator in maintaining vascular homeostasis is endothelium-derived relaxing factor (EDRF) (134), which has since been found to be nitric oxide (135). The release of nitric oxide activates soluble guanylate cyclase, resulting in the formation of cyclic guanosine monophosphate (cGMP), which, in turn, activates cGMP-dependent protein kinases, resulting in relaxation of vascular smooth muscle (136-139). Alterations in the expression, release, or activity of EDRF may play an important role in the initiation and progression of both micro- and macrovascular disease. Several studies have shown that endothelial-dependent vasodilator function is impaired in patients with type 1 diabetes without hypertension and dyslipidemia (140). This impairment is in contrast to that in patients with type 2 diabetes, who have an impairment of both endothelial-dependent and endothelial-independent (smooth muscle) vasodilator function (141,142).

Although the mechanism is unknown, several possibilities are present. Acute hyperglycemia impairs endothelial-dependent vasodilation in both macro- and microvessels (143). Insulin also may play a role. Insulin results in vasodilation due in part to nitric oxide production. Glucose-clamp experiments with insulin infusion have shown that subjects with type 2 diabetes have little improvement in endothelial-dependent vasodilation relative to that in subjects without diabetes (143). As stated previously, there appears to be an increase in oxygen-derived free radicals in the diabetic state. Several studies have shown that high doses of vitamin C can improve endothelial-dependent vasodilation in patients with both type 1 and type 2 diabetes (144,145). Intensive lipid lowering by statin therapy does not improve vasoreactivity in patients with type 2 diabetes, suggesting that mechanisms other than dyslipidemia are responsible for endothelial dysfunction (146).

Another possible culprit for this impairment of endothelial function found in individuals with diabetes may be the endogenous competitive inhibitor of nitric oxide synthase, asymmetric dimethylarginine (ADMA) (147). ADMA has been found to be elevated in subjects with diabetes (148,149).

CLINICAL FEATURES OF CARDIOVASCULAR DISEASE IN DIABETES

Angiographic Features of Coronary Artery Disease in Patients with Diabetes

Autopsy, angiographic, and angioscopic studies have documented the severe and diffuse nature of the atherosclerotic coronary involvement in patients with diabetes. Early autopsy data have shown that patients with diabetes have a greater number of coronary vessels involved, with more diffuse distribution of atherosclerotic lesions (150,151). Large angiographic studies comparing patients with diabetes to matched controls in the setting of acute MI (152) or elective angioplasty (153) or prior to coronary bypass surgery (154) have all shown that diabetes is associated with significantly more severe proximal and distal CAD (Table 58.2). An important finding with regard to the pathogenesis of acute coronary syndromes is the autopsy (155) and angioscopic (156) evidence suggesting a significant increase in plaque ulceration and thrombosis in diabetic compared with nondiabetic patients.

Silent Ischemia

The propensity of patients with diabetes to present with either silent or unrecognized MI is well established (157,158). Atypical symptoms such as confusion, dyspnea, fatigue, or nausea and vomiting were the presenting complaint in 32% to 42% of patients with diabetes with MI compared with 6% to 15% of patients without diabetes (157,159). Several groups have reported that the detection of silent ischemia by various noninvasive techniques, including treadmill exercise testing (160,161), ambulatory Holter monitoring (162), and exercise thallium scintigraphy (163–166), is more common in patients with diabetes than in those without diabetes. This finding, however, is not supported by all studies (167,168).

A plausible explanation for painless infarction and ischemic episodes in patients with diabetes is autonomic neuropathy with involvement of the sensory supply to the heart. In autopsies of patients with diabetes who died of silent MIs, typical diabetic neuropathic changes were found in the intracardiac sympathetic and parasympathetic fibers (169), and several studies correlated abnormalities in autonomic function in patients with silent ischemia (160,162,164,170). The anginal perceptual threshold—the time from the onset of myocardial ischemia (assessed by ST segment depression) to the onset of chest pain during exercise testing—is prolonged in patients with diabetes compared with those without diabetes. This delay in the perception of pain may be related to the impairment of autonomic nervous function (170).

Acute Coronary Syndromes in Patients with Diabetes

Acute ischemic events represent a major cause of death in the diabetic population (65). Diabetic patients who suffer an MI have a higher mortality than nondiabetic patients both in the acute phase and on long-term follow-up. Numerous studies have shown that in-hospital mortality rates from MI in patients with diabetes are 1.5- to 2-fold higher than in patients without diabetes (152,171–174). Diabetes remains an independent predictor for a poor prognosis in the thrombolytic era. In the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) trials, the in-hospital mortality rate was nearly twice as high in patients with diabetes, with more congestive heart failure and twice the rate of clinically recognized reinfarction (152). In the

TABLE S	TABLE 58.2. Angiographic Studies in Patients with Diabetes ^a

^aBecause most patients undergoing initial angioplasty have single-vessel disease, they have milder coronary artery disease than patients with acute myocardial infarction, who have an array of single-, double-, and triple-vessel disease, or patients undergoing coronary bypass grafting, who usually have double- and triple-vessel disease. ^bMultivessel disease is defined by the presence of two or more vessels with at least one stenosis <75%. ^cFor men. Correspondending values for women are 63% and 41%, respectively.

^aNot all patients underwent angiography.

"Patients were selected for angioplasty, and therefore this study includes a larger proportion of patients with single-vessel disease.

TAMI, Thrombolysis and Angioplasty in Myocardial Infarction; TIMI, Thrombolysis in Myocardial Infarction; BARI, Bypass Angioplasty Revascularization Investigation; NHLBI, National Heart, Lung and Blood Institute; CASS, Coronary Artery Surgery Study.

Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO-I) trial, mortality at 30 days was highest among patients with diabetes treated with insulin (12.5%) compared with patients with diabetes not treated with insulin (9.7%) and nondiabetic (6.2%) patients (p < 0.001) (175). Similar results have been reported from the other large studies (176–178). Diabetes is also a risk factor for cardiogenic shock in the setting of acute ischemic syndromes (179). Overall, despite the overall improvement in survival from an acute MI with thrombolysis, the in-hospital mortality rates in patients with diabetes remain 1.5 to 2 times higher than in patients without diabetes (175,178).

This increased in-hospital mortality among patients with diabetes with acute MI is due predominantly to an increase in the incidence of congestive heart failure (172,174,180,181), although increases in the incidence of reinfarction, infarct extension, and recurrent ischemia have also been reported (172–174,181,182).

Studies using serial determinations of total creatine kinase activity (180,181), radionuclide ventriculography (183), or echocardiography have found no evidence that patients with diabetes sustain more extensive infarctions than their nondiabetic counterparts (184). Thus, congestive heart failure and cardiogenic shock are more common and more severe in subjects with diabetes than would be expected from the size of the index infarction (178,180,181,183,185,186). The observation that clinical manifestations of heart failure occur in patients with diabetes despite a modest decrease in left ventricular ejection fraction (EF) led to the suggestion that preexisting diastolic dysfunction is a major culprit in the congestive symptoms (174). Indeed, subclinical diabetic cardiomyopathy, which is characterized by diastolic dysfunction (187), is likely to be an important factor in this setting.

It should be emphasized, however, that reductions in both left ventricular EF (183,188) and the regional EF of the noninfarcted myocardium (152,183,187) have been well documented in patients with diabetes following MI as compared with patients without diabetes. For example, early angiography in the TAMI trials has demonstrated worse ventricular function in the noninfarcted zone in patients with diabetes (152). The performance of the left ventricle following MI is determined largely by the extent of coronary disease (189) and the quality of collateral circulation. Thus, the diffuse nature of coronary atherosclerosis (Table 58.2) in diabetes may contribute to systolic dysfunction of the noninfarcted myocardium. Moreover, a recent study has shown that patients with diabetes have a reduced ability to develop collateral blood vessels in the presence of CAD (190), a finding that also may explain the more frequent occurrence of postinfarction angina and infarct extension (173,174,182,184).

Patients with diabetes surviving MI also suffer higher late mortality rates than patients without diabetes (174,182, 191–193). Late mortality is related primarily to both recurrent MI and the development of new congestive heart failure (176, 178,184,192–194).

MEDICAL THERAPY FOR CORONARY ARTERY DISEASE IN PATIENTS WITH DIABETES

Diabetes exerts a deleterious effect on the short- and long-term course following MI through diverse mechanisms, some of which (e.g., cardiomyopathy) cannot be modified at the time of presentation. Because patients with diabetes are at greater risk, application of effective preventive and treatment measures may result in a particularly large survival benefit.

Insulin

One possible mechanism for the increased mortality among diabetic patients with acute MI may be the altered metabolism of the myocardium. The diabetic state results in increased fatty acid metabolism, compromising glycolysis in both ischemic and nonischemic territories. Free fatty acids and their intermediates may potentiate ischemic injury. One way to attenuate free fatty acid oxidation is by the intravenous infusion of insulin-glucose. It was that rationale that led Malmberg and colleagues (195) to evaluate the effect of insulin-glucose infusion followed by multidose insulin treatment in patients with diabetes [Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) Study] (Fig. 58.2). Patients with diabetes with an acute MI within the previous 24 hours were randomized to two separate arms. Insulin-glucose infusion was given for the first 24 hours and until stable normoglycemia in the experimental arm. Then subcutaneous multidose insulin was given to maintain normoglycemia for a 3-month period. Control patients received standard coronary care unit care and did not receive insulin unless clinically indicated.

The 3-month mortality was not significantly different for the control and experimental groups. However, the 1-year mortality was 18.6% in the experimental group and 26% in the control group, or a relative risk reduction of approximately 30%. This improvement in mortality continued for a total of 3.4 years, with an absolute reduction of mortality of 11% (196).

Aspirin

Studies have shown an increased platelet adhesiveness and aggregability (197), with a concomitant increased release of thromboxane A_2 (115) in subjects with diabetes. On the basis of these data, several authors stated that patients with diabetes may require larger doses of aspirin to suppress the synthesis of thromboxane A_2 (115,198). Furthermore, in the Second International Study of Infarct Survival (ISIS-2) study, there was no reduction in mortality in subjects with diabetes receiving 160 mg of aspirin daily (199).

The Antiplatelet Trialists' Collaboration meta-analysis quantified the benefit of aspirin in patients with diabetes who had had a previous cardiovascular event (200). The relative benefit on vascular events was 17% in the patients with diabetes and 22% in those without diabetes. Although the number was lower for patients with diabetes than for patients without diabetes in terms of percentage benefit, the absolute number of events prevented was similar in the two groups (38 \pm 12 per 1,000 compared with 36 \pm 3 per 1,000, respectively), probably because of the higher event rates in patients with diabetes.

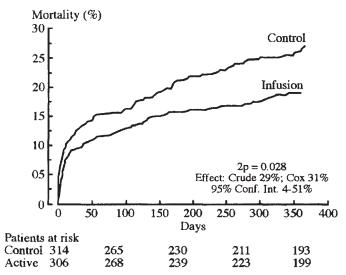

Figure 58.2. Actuarial mortality curves in the patients receiving insulinglucose infusion and in the control group of the present Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study during 1 year of follow-up. Randomized trial of insulin-glucose infusion followed by subcutaneous insulin treatment in diabetic patients with acute myocardial infarction (DIGAMI study): effects on mortality at 1 year. *J Am Coll Cardiol* 1995; 26:57–65, with permission. Copyright 1995, with permission from Excerpta Medica.)

Data from the U.S. Physicians' Health Study and the Early Treatment Diabetic Retinopathy Study (ETDRS) indicate that aspirin may also be efficacious as primary prevention in patients with diabetes (201).

A major risk of aspirin therapy is gastric mucosal injury and gastrointestinal hemorrhage. These effects are dose related and are reduced to placebo levels when enteric-coated preparations of 75 to 325 mg are used once daily (202). The ETDRS established, using serial retinal photography, that aspirin therapy is not associated with an increased risk of retinal or vitreous hemorrhage.

The American Diabetes Association (ADA) recommends the use of aspirin therapy (81 to 325 mg/day) as secondary prevention in any patient with evidence of large-vessel disease. Aspirin is also recommended as primary prevention in patients with diabetes with the following: (a) family history of CAD, (b) cigarette smoking, (c) hypertension, (d) obesity, (e) albuminuria, (f) LDL >130 mg/dL, (g) HDL <40 mg/dL, or (h) triglycerides >250 mg/dL (202).

β-Blockers

β-Blockers are effective in reducing reinfarction and sudden death in patients with diabetes, perhaps to a greater extent than in patients without diabetes. Early treatment of MI with βblockers resulted in a 37% reduction in mortality in patients with diabetes compared with a 13% reduction in mortality in all patients, whereas reduction in long-term mortality was 48% and 33% in diabetics and all patients, respectively (203).

In a controlled study evaluating the use of atenolol in patients with, or at risk for, CAD who had noncardiac surgery, diabetes was the strongest predictor of death after 2 years of follow-up, with twice the mortality compared with that in patients without diabetes (204). Compared with patients without diabetes, patients with diabetes receiving atenolol had no increased risk of death, whereas those given placebo had a fourfold increase in risk (204). It should be emphasized that the deterioration in glycemic control or blunted counterregulatory response to hypoglycemia is seldom a serious clinical problem, especially when cardioselective β_1 -blockers are used (203,205).

Angiotensin-Converting Enzyme Inhibition

Inhibition of the angiotensin-converting enzyme (ACE) is now unequivocally associated with a substantial mortality reduction in patients surviving MI with left ventricular dysfunction (EF <40%) (206). The investigators of the Third Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI-3) compared the effect of early administration (within 24 hours of admission) of lisinopril in patients with and without diabetes presenting with MI (207). Compared with placebo, lisinopril dramatically reduced both 6-week (30% vs. 5%) and 6-month (20% vs. 0%) mortality in patients with diabetes versus those without diabetes. These findings are corroborated by subgroup analysis of the Survival and Ventricular Enlargement (SAVE) study (208). A retrospective analysis using data from the Trandolapril Cardiac Evaluation (TRACE) study, a randomized, double-blind, placebo-controlled trial evaluating trandolapril in patients after acute MI who had an EF less than or equal to 35%, has shown a 36% reduction of death from any cause and a 62% reduction in the risk of progression to severe heart failure (209). Recently, the HOPE study has shown that ramipril substantially lowers the risk of death, MI, stroke, coronary revascularization, heart failure, and complications related to diabetes in a high-risk group of patients with preexisting vascular disease (210,211) (Fig. 58.3).

ACE inhibitors have become the primary agents of choice for the treatment of hypertension associated with diabetes because they do not adversely affect the glycemic control and lipid profile (212,213). In fact, ACE inhibitors may actually enhance insulin sensitivity in patients with type 2 diabetes, with or without hypertension (214–216). ACE inhibitors are especially desirable in patients with evidence of diabetic nephropathy.

Serum potassium and creatinine should be monitored closely in the first few weeks of therapy. A rapid decline in renal function can occur in patients with bilateral renal artery stenosis, which is more common in patients with diabetes. Hyporeninemic hypoaldosteronism is frequently associated with diabetes and predisposes the patients to clinically significant hyperkalemia when ACE inhibitors are initiated.

Glycoprotein IIb/IIIa Antagonists

Glycoprotein IIb/IIIa (GpIIb/IIIa) antagonists, which are antiplatelet agents, have become an important therapeutic modality in the treatment of unstable angina and non–Q-wave MIs. In particular, these agents have been shown to be of equal, if not greater, benefit in the diabetic population than in its nondiabetic counterpart. The Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study (217,218) compared heparin with heparin plus the GpIIb/IIIa inhibitor tirofiban in 1,208 patients, with 362 patients having diabetes. The cumulative endpoint at 7 days of death, MI, refractory angina, or rehospitalizations for unstable angina was reduced to 21.4% in patients receiving heparin alone and to 14.8% in those receiving heparin plus tirofiban in the diabetic group; and to 16.7% in patients receiving heparin alone and to 12.4% in those receiving heparin plus tirofiban in the nondiabetic group. There was no difference in the ability of the standard dose of tirofiban required to result in an inhibition in platelet aggregation of over 80% after a 12-hour infusion in the patients with and without diabetes, despite the hyperaggregability of platelets in patients with diabetes.

The EPILOG study (219), which evaluated percutaneous coronary angioplasty plus the GpIIb/IIIa antagonist abciximab versus angioplasty alone, found no significant difference in acute events, while the longer term follow-up revealed a higher rate of subsequent revascularization involving the target vessel in the subjects with diabetes. The Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT) Trial (220), which evaluated coronary stenting plus abciximab and heparin versus stenting plus heparin alone, demonstrated a marked decrease of target vessel revascularization in patients with diabetes. The rate of target vessel revascularization in patients with diabetes randomized to stenting and heparin was 16.6%, whereas the rate among those randomized to stenting and abciximab was 8.1%, a 50% decrease. One recent study (221) did not demonstrate a difference in efficacy of two glycoprotein IIb/IIIa receptor inhibitors, abciximab and tirofiban, when used in patients with diabetes undergoing percutaneous coronary intervention.

Thrombolytic Therapy

Thrombolytic therapy is of substantial benefit in patients with diabetes. In the Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries (GUSTO-I) angiographic substudy, early infarct-related artery patency [TIMI (Thrombolysis in Myocardial Infarction) flow grade 3] and reocclusion rates were similar among diabetics and nondiabetics (222,379).

984 JOSLIN'S DIABETES MELLITUS

Patients with diabetes treated with various fibrinolytic agents benefit by the same mortality reduction as nondiabetic patients (152,223) (Table 58.3). In an overview of fibrinolytic trials in patients with MI, the relative reduction in 35-day mortality was slightly, but not significantly, greater in patients with diabetes than in nondiabetic patients (21.7% vs. 14.3%) (223). In these trials, no increase in serious bleeding complications or stroke was observed in patients with diabetes. Retinal bleeding is an extremely uncommon complication of thrombolytic therapy in patients with diabetes. In the GUSTO-1 study, 300 of 6,011 patients with diabetes had proliferative retinopathy, but none developed intraocular hemorrhage (224). It is unlikely that thrombolytic therapy would increase vitreous hemorrhage, which is due to vitreous detachment in patients with diabetic retinopathy. Thus, the concern that many clinicians have with regard to thrombolytic therapy in patients with diabetic retinopathy is not supported by the results of large clinical trials. It is probably unjustified to deny these patients the proven life-saving benefit of thrombolysis.

REVASCULARIZATION PROCEDURES IN PATIENTS WITH DIABETES

Because CAD is a major health problem in patients with diabetes, the need for a revascularization procedure frequently arises. Therefore, many patients with diabetes require some form of revascularization procedure. A significant and increasing proportion of patients undergoing angioplasty are diabetic. In the 1977 to 1981 National Heart, Lung and Blood Institute (NHLBI) registry, 9% of patients undergoing angioplasty had diabetes (225). More recent large trials suggest that the prevalence of diabetes

among patients undergoing angioplasty increased to approximately 17% to 19% (226,227). The influence of diabetes on outcome after revascularization procedures received attention following the results of the Bypass Angioplasty Revascularization Investigation (BARI) study, which suggested that patients with diabetes with significant CAD involving the left anterior descending coronary artery had improved mortality if they underwent coronary artery bypass grafting (CABG) (228). The results of the Coronary Angioplasty versus Bypass Revascularization Investigation (CABRI) investigators (229) demonstrated that the mortality among patients with diabetes is double that of patients without diabetes, independent of the means of revascularization, be it CABG or percutaneous transluminal coronary angioplasty (PTCA). Among patients with and without diabetes, there was no significant mortality difference between PTCA and CABG, although there was a trend favoring CABG, especially in the diabetic population (229).

Angioplasty

Angioplasty provides effective relief of angina in most patients and is performed with similar success in patients with and without diabetes (153). However, increased restenosis rates in patients with diabetes greatly limit long-term benefits from angioplasty. The importance of diabetes as a clinical risk factor for restenosis after percutaneous interventions has been demonstrated in multiple studies. The initial report from the NHLBI Angioplasty Registry indicated that the angiographic restenosis rate in patients with diabetes was 47%, as compared with 32% in patients without diabetes (230), and subsequent studies have reported restenosis rates of 49% to 71% among patients with diabetes (231–236).

^bThe 35-day mortality.

New angioplasty devices also have failed to have any major impact on the restenosis rate among patients with diabetes. Diabetes is associated with a twofold increase in recurrent clinical events after directional coronary atherectomy (237–239), and diabetic patients have higher restenosis rates after excimer laser angioplasty (240). Recently, intracoronary stents have been shown to decrease restenosis as compared with rates with PTCA (241). Several groups have reported that, even with stents, patients with diabetes have higher restenosis rates than patients without diabetes (242–245), although this finding is debated (246).

The full impact of the higher rates of restenosis following angioplasty on the cardiovascular morbidity of patients with diabetes is significant. Numerous studies have shown that patients with diabetes experience a greater need for repeat revascularization (angioplasty or CABG), a higher rate of cardiac events, and lower overall survival rates following coronary angioplasty compared with their nondiabetic counterparts (153,237,239,247–250). Recent data from the EPISTENT and other studies (251) suggest that the combination of stenting with platelet glycoprotein IIb/IIIa blockade may decrease the incidence of death, MI, and target vessel revascularization among patients with diabetes (252).

Although vessel recoil also may contribute to loss of luminal size, the increased restenosis rate in patients with diabetes following stent placement underscores the role of enhanced proliferation of smooth muscle cells as the major mechanism for restenosis in these patients, because coronary artery stenting decreases elastic recoil and vascular spasm at the treated site (244). A study using intravascular ultrasound found exaggerated intimal proliferation in patients with diabetes at the site of angioplasty-induced arterial injury, and this proliferative response was particularly striking in restenotic lesions (253). Thus, the diabetic state promotes proliferation of smooth muscle cells and deposition of extracellular matrix following arterial injury. Surprisingly, the possibility that strict glycemic control may reduce restenosis rates among patients with diabetes (254) has not been addressed clinically or experimentally. Ongoing studies are examining means of reducing the restenosis rate, including the use of beta-radiation [Anti-Proliferative Effect of Beta-Radiation on Restenosis Prevention in Diabetic Patients after Coronary Stent Implantation (ANTIPODES)].

Subjects with diabetes with restenosis following percutaneous intervention have less intimal hypercellular tissue in the restenotic lesion relative to that in subjects without diabetes (255). Sobel's group has found an increase in the intramural synthesis of PAI-1 in the vessel walls of rabbits subjected to experimental angioplasty (256,257). PAI-1 synthesis is stimulated by insulin. In turn, PAI-1 may inhibit the remodeling and proteolysis that normally occurs after PTCA, resulting in the accumulation of the extracellular matrix and lipid, with a relative decrease in the relative amount of migration and proliferation of smooth muscle cells. One recent development has suggested that haptoglobin phenotype may determine which patients with diabetes may develop restenosis after coronary stent implantation (258).

Coronary Artery Bypass Surgery

CABG is as effective in relieving anginal symptoms in patients with diabetes as in patients without diabetes (154). Diabetes is not associated with increased perioperative mortality during bypass graft surgery, although wound infections and the average hospital stay are increased (259,260). With respect to vein grafts, several reports have noted decreased survival of vein grafts in patients with diabetes (261–263). Intimal proliferation that causes luminal loss in the first years following bypass surgery with venous conduit may be accelerated in patients with diabetes (264). In contrast, the benefit of internal mammary artery conduits is well documented among patients with diabetes (263,265). Data from the Duke registry indicate that the long-term benefit of one internal mammary artery graft is at least as great in patients with diabetes as in those without diabetes (265). Nonetheless, the long-term survival rate after bypass surgery remains consistently lower in patients with diabetes than in those without diabetes (265–267).

Angioplasty versus Coronary Artery Bypass Surgery in Multivessel Coronary Artery Disease

Coronary angioplasty has been widely accepted as the initial revascularization procedure for treatment of most single-vessel CAD, whereas CABG has been the standard form of revascularization for multivessel disease. However, in the past decade, angioplasty has been proposed and evaluated as an alternative to CABG in patients with multivessel disease.

The influence of diabetes on outcome after PTCA for patients with multivessel disease received attention following the results of the BARI study (228). The BARI study enrolled 1,829 patients (including 353 patients with diabetes [19%] with angiographically documented multivessel CAD and either clinically severe angina or objective evidence of marked myocardial ischemia requiring revascularization. Cause of death was classified as cardiac if it occurred less than 1 hour after onset of cardiac symptoms or within 1 hour to 30 days after a documented or probable MI or as a result of intractable congestive heart failure, cardiogenic shock, or another documented cardiac cause.

A review of 5-year all-cause mortality rates showed a near doubling of mortality among patients with diabetes receiving insulin or oral therapy assigned to multivessel angioplasty compared with those assigned to surgery (35% vs. 19%, p = 0.003). In contrast, the 5-year mortality among patients without diabetes and patients with diabetes not receiving drug treatment was 9% with both revascularization strategies. Cause-specific 5.4-year cardiac mortality rates were 3.5 times higher in the PTCA group (20.6% vs. 5.8%) (228). These results raised concern about selection of revascularization procedures in patients with diabetes with multivessel CAD and prompted a clinical alert by the NHLBI stating that CABG should be the preferred initial revascularization choice in medically treated patients with diabetes who have multivessel CAD (268).

A subsequent report from the BARI investigators indicated that the survival benefit of CABG is limited to patients with diabetes receiving an internal mammary artery (IMA) graft. Cardiac mortality after 5.4 years was 2.9% when IMA was used and 18.2% when only saphenous vein graft conduits were used. The latter rate was similar to that for patients receiving PTCA (20.6%) (269). The mortality benefit afforded by IMA was most apparent in those experiencing MI during follow-up (an effect seen also in patients without diabetes). As an IMA graft is less susceptible to atherosclerosis, it may provide an alternative source of perfusion to maintain ventricular function in regions of hypoperfusion resulting from coronary occlusion.

Three recent studies examined the effect of revascularization strategies in patients with diabetes. In a large prospective cohort of 3,220 patients with multivessel disease, of whom 770 (24%) had diabetes, Barsness and associates evaluated the relationship between diabetes and survival after revascularization with either PTCA or CABG (270). Although diabetes was strongly associated with a worse long-term prognosis, the 5-year survival for patients with diabetes undergoing PTCA

986 JOSLIN'S DIABETES MELLITUS

was 76%, whereas the rate for those without diabetes was 88%. Similarly, in the group of patients undergoing CABG, 5-year survival was 74% in those with diabetes and 86% in those without diabetes. Unlike other studies, however, no significant differential effect of diabetes was seen on outcome between patients treated with PTCA and those treated with CABG. In a similar study, Weintraub and associates (271), using an observational database, prospectively compared the outcome of PTCA (n = 834) and CABG (n = 1,805) in patients with diabetes with multivessel coronary disease. Correcting for baseline differences, they found no difference in survival for the group as a whole. However, in the insulin-requiring subgroup, 5- and 10-year survival rates were 68% and 36% after PTCA and 75% and 47% after CABG, respectively.

Gum et al. (248) performed a retrospective outcome analysis of 525 patients with diabetes who underwent coronary revascularization. Overall, actuarial survival curves showed a nonsignificant trend favoring the CABG group for survival at 6 years (30% vs. 37%; p = 0.08).

A crucial question is why CABG may be superior to PTCA in patients with diabetes in the setting of multivessel disease. The only difference between the diabetic groups in the BARI study was the revascularization procedure chosen. Hence, the difference in prognosis is likely to be related to the relative efficacy of these revascularization procedures.

The major advantage of CABG over PTCA is the ability to achieve complete revascularization (272,273). The superiority of CABG over angioplasty in providing complete revascularization is exemplified in the BARI study itself. In the BARI population, 3.1 grafts were placed per patient undergoing CABG (274), whereas the mean number of successfully treated lesions in the PTCA group was 2.0 (269). Similar numbers are reported by other studies comparing multivessel angioplasty and CABG (248,270,271).

Previous CABG studies have emphasized that complete revascularization is essential for obtaining survival benefit in patients with multivessel disease (273). If complete revascularization (which is accomplished almost exclusively through CABG surgery) is essential for survival benefit, the successful

application of multivessel angioplasty (which entails a strategy that selectively targets high-priority lesions) requires that a comparable proportion of myocardium supplied through high-priority lesions be revascularized by each of the two strategies. Because multiple treatment sites can result in restenosis independently when multivessel angioplasty is performed (243), it is likely that this goal is frequently not achieved in patients with diabetes, given their high restenosis rates (Table 58.2). Thus, the worse outcome of patients with diabetes undergoing PTCA may be mediated in part by the frequent occurrence of incomplete revascularization (248). Van Belle and colleagues suggest that restenosis, especially in its occlusive form, is a major determinant of long-term mortality in patients with diabetes after coronary angioplasty. When these investigators studied 604 patients with diabetes who underwent angioplasty, followed by a 6-month follow-up angiogram and long-term follow-up, they found that the group that had no restenosis had a 10-year mortality of 24% compared with a 35% mortality in the group with nonocclusive restenosis and a 59% mortality in the group that had occlusive restenosis (p < 0.0001) (256,275). The impact of incomplete revascularization may be more pronounced in view of the more diffuse and distal CAD (154,247) and worse coronary vasodilatory reserve in patients with diabetes (276). Thus PTCA may fail to alter the aggressive natural course of CAD in patients with diabetes rather than leading to increased mortality (269).

MANAGEMENT OF RISK FACTORS

It is important to identify the risk factors of an individual patient in order to develop a plan for risk reduction. The goals for risk reduction are summarized in Table 58.4, which is adapted from a recent review from an AHA executive summary (277).

Cholesterol Reduction

The Scandinavian Simvastatin Survival Study (4S) has demonstrated the effectiveness of cholesterol-lowering therapy

TABLE 58.4. Goals for Management of Risk Factors in Patients with Diabetes				
Risk factor	Goal of therapy	Recommending body		
Cigarette smoking	Complete cessation	ADA		
Blood pressure	<130/85 mm Hg	JNC VI (NHLBI)		
	<130/80 mm Hg	ADA		
LDL cholesterol	<100 mg/dL	ATP III (NHLBI), ADA		
Triglycerides 200–499 mg/dL	Non-HDL cholesterol <130 mg/dL	ATP III (NHLBI)		
HDL cholesterol <40 mg/dL	Raise HDL (no set goal)	ATP III (NHLBI)		
Prothrombotic state	Low-dose aspirin therapy (patients with CHD and other high-risk patients)	ADA		
Glucose	Hemoglobin A _{1c} <7%	ADA		
Overweight and obesity (BMI ≥25 kg/m²	Lose 10% of body weight in 1 yr	OEI (NHLBI)		
Physical inactivity	Exercise prescription dependent on patient status	ADA		
Adverse nutrition	See text	ADA, AHA, and NHLBI's ATP III, OEI, and JNC VI

From Grundy SM, Garber A, Goldberg R, et al. Prevention Conference VI: Diabetes and Cardiovascular Disease: executive summary. *Circulation* 2002;105:2231–2239, with permission from Lippincott Williams & Wilkins. (278,279) for secondary prevention of death and morbidity in patients with angina or prior infarction. Compared with the placebo group, the relative total mortality and cardiovascular mortality were 0.57 and 0.64, respectively.

Subjects in the 4S study had relatively high LDLcholesterol levels at baseline (~185 mg/dL). However, the majority of patients with coronary disease (including those with diabetes) have lower LDL-cholesterol levels. The Cholesterol and Current Events (CARE) study, which included 586 patients with diabetes, determined the effect of cholesterol-lowering therapy in patients with coronary disease with average cholesterol levels (mean, 139 mg/dL). In the 586 subjects with diabetes and CAD, 40 mg of pravastatin was associated with a 25% decrease in coronary events and revascularization procedures, similar to a 23% decrease observed in patients without diabetes (280).

These results strongly suggest that cholesterol lowering improves the prognosis of diabetic patients with CAD. The absolute clinical benefit achieved by cholesterol lowering may be greater in diabetic patients than in nondiabetic patients with CAD because patients with diabetes have a higher absolute risk of recurrent CAD, higher case-fatality rates (184), and more atherogenic LDL-cholesterol (58,99,281,282).

Several recent publications have argued against the relevance of the traditional classification to primary and secondary prevention in the setting of diabetes (20). The rationale for this approach stems from both the high event rates in patients with diabetes without clinical evidence of CAD (presumably due to the very high rates of subclinical atherosclerosis) (20), as well as to the worse prognosis in patients who have had a clinical event compared with nondiabetic subjects (184). These data suggest that LDL-cholesterol should be lowered to less than 100 mg/dL even in diabetic subjects without prior CAD.

Tight glycemic control is the cornerstone of therapy for diabetic dyslipidemia. HMG CoA reductase inhibitors reduce coronary risk even when the LDL level lies within the average range in individuals with type 2 diabetes (283,284). However, tight glycemic control does not completely reverse the lipid profile in patients with type 2 diabetes. Tan and colleagues (285) found that patients with excellent control of their glucose levels (average HbA_{1c} <6.6%) continued to have a low HDL level and a predominance of small dense LDL particles.

The target level of LDL-cholesterol should be 100 mg/dL. This can first be achieved by diet with the addition of statins if necessary. If the triglyceride level is greater than 200 mg/dL even in the face of an LDL less than 100 mg/dL, fibrate therapy should be considered. The recent Veterans Affairs High-density Lipoprotein Cholesterol Intervention Trial demonstrated that the fibrate gemfibrozil reduced both coronary events and strokes (286). Recent data suggest that when the LDL level is less than 125 mg/dL, the triglyceride and HDL levels are significantly stronger predictors of recurrent cardiac events than when the LDL levels are greater than 125 mg/dL (287). This only strengthens the rationale for treating patients with low HDL or elevated triglyceride levels.

Nicotinic acid can both lower triglyceride levels and raise HDL levels. However, its beneficial effect on lipids in the patient with diabetes is offset by its tendency to worsen hyperglycemia, making it relatively contraindicated in such patients.

Treatment of Hypertension

Hypertension is about twice as frequent in patients with diabetes as in the general population (288,289). Isolated systolic hypertension is considerably more common in patients with diabetes. The combined presence of hypertension and diabetes considerably accelerates the development of both macrovascular and microvascular diabetic complications. However, the most significant manifestation of this combination of diseases is that they confer a greater risk of ischemic heart disease, stroke, and peripheral vascular disease in affected individuals. The high cardiovascular risk associated with the coexistence of hypertension and diabetes led the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure to include hypertensive patients with diabetes in the same risk group as hypertensive patients who have clinically manifest cardiovascular disease (290). These patients should be considered for prompt pharmacologic therapy even if they have high-normal blood pressure.

Current evidence suggests that, for the prevention of cardiovascular events, ACE inhibitors (291,292) and low-dose diuretics (293) are the preferred first-line agents for hypertensive patients with diabetes, whereas a controversy exists with regard to the efficacy of calcium antagonists in preventing cardiovascular complications (294). In the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, patients in the nisoldipine group had a fivefold higher risk of fatal and nonfatal acute MI than did the enalapril group (291). In the Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial (FACET), patients receiving fosinopril had half the risk of the combined outcome of acute MI, stroke, or hospitalized angina than did those receiving amlodipine (295). However, the combined therapy resulted in a lower incidence of cardiovascular events than either treatment alone and could be interpreted as evidence that combination therapy is the preferred strategy (295). Control of hypertension is unlikely to be achieved by monotherapy in patients with diabetes, as demonstrated in the ABCD trial (291).

The Systolic Hypertension in Europe (Syst-Eur) compared outcomes of treatments with nitrendipine versus placebo in patients with isolated systolic hypertension. Endpoint reduction achieved by active treatment was significantly larger in the subgroup with diabetes (69% vs. 26% cardiovascular events), indicating a remarkable benefit from first-line treatment with a calcium antagonist (296). Similarly, the results of the Hypertension Optimal Treatment (HOT) trial showed a reduction in the rate of MI events in patients with diabetes (n = 1,501, representing the largest trial of a calcium antagonist in patients with diabetes) with the long-acting dihydropyridine calcium antagonist felodipine (297).

The evidence for aggressive antihypertensive treatment in patients with type 1 diabetes, hypertension, and nephropathy is now overwhelming (298,299). ACE inhibitors are particularly useful in this population, with clear evidence that these agents reduced the progression of kidney dysfunction and the number of patients who will develop end-stage renal failure (215,216).

The HOPE study (and the MICRO-HOPE substudy) (Fig. 58.3) demonstrated that ramipril significantly reduced the rates of MI, stroke, and deaths in patients with diabetes without overt cardiovascular disease and one other risk factor (211). The importance of blocking the renin-angiotensin system was further strengthened by the results of the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study (300). These results demonstrated that lorsartan reduced total and cardiovascular mortality more than did atenolol in patients with diabetes with hypertension and left ventricular hypertrophy.

The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VI) has incorporated these principles for the treatment of hypertension in the presence of diabetes and has included a more aggressive program of blood pressure reduction, aiming for a target of less than 135/85 mm Hg in patients with type 1 and type 2 diabetes (290). The ADA aims for the lower target blood pressure of 130/80 mm Hg (289).

In addition, the ADA guidelines included a target of 125/75 mm Hg in patients with proteinuria of greater than 1 g per day. ACE inhibitors are recommended as the initial antihypertensive drug of choice in patients with diabetes (290,298,299).

Glycemic Control

A central issue in the treatment of patients with diabetes is whether tight glycemic control will reduce CAD morbidity and mortality. The Diabetes Control and Complications Trial (DCCT) conclusively showed that the greater the average blood glucose in patients with type 1 diabetes (as assessed by HbA_{1c}), the greater the risk of developing retinopathy, neuropathy, and nephropathy (301). Although the number of combined major macrovascular events was almost twice as high in the conventionally treated group as in the intensively treated group, the differences were not statistically significant (p = 0.08) because patients participating in this study were young and early in the course of their disease (301,302). However, hyperglycemic animals develop fatty streaks resembling those of human type II atherosclerotic lesions in the absence of hyperinsulinemia (303), and data from the Stockholm Diabetes Intervention Study indicate that, in patients with type 1 diabetes, tight control retards the development of atherosclerosis, as measured by the development of carotid intima-media thickening (304). Thus, tight control is indicated in patients with type 1 diabetes for prevention of both microvascular and macrovascular complications. It is noteworthy that the average total insulin dose in the intensive-treatment group of the DCCT trial was less than 10% higher than in the conventional-treatment group. Thus, unless acceleration of atherosclerosis is exquisitely sensitive to small differences in exogenous insulin dose, it is unlikely that this form of therapy increases the risk for cardiovascular disease.

The United Kingdom Prospective Diabetes Study (UKPDS) was a prospective, randomized intervention trial aimed at determining whether patients with type 2 diabetes can clinically benefit from intensive glycemic control. In this study, 3,867 patients with newly diagnosed type 2 diabetes were randomly assigned to an intensive-treatment policy or to a conventionaltreatment policy. Compared with the conventional-treatment group, the intensive-treatment group demonstrated a 16% reduction in risk (p = 0.052) for fatal and nonfatal MI, but allcause mortality did not differ between these two groups (305). In this study, intensive therapy resulted in a 0.9% difference in median HbA_{1c} between the intensive (7.0%) and conventional (7.9%) groups over 10 years. Alternatively, as recent data from the DCCT indicate, for all microvascular complications (306), there is probably a continuous relative-risk reduction relationship over the range of HbA_{1c} for CAD (307).

The current recommendations of the ADA set the goal for glycemic control in patients with type 2 diabetes at a fasting (preprandial) glucose level of less than 120 mg/dL and an HbA_{1c} level of less than 7% (normal range 4% to 6%) (308). It is reasonable to believe that the mechanisms by which hyper-glycemia promotes atherosclerosis and cardiovascular events are operative in all individuals with hyperglycemia. Because the major morbidity and mortality in patients with type 2 diabetes is a consequence of accelerated atherosclerosis, improved glycemic control is likely to result in a reduction of macrovascular events and probably in a reduction in mortality.

Specific metabolic abnormalities induced by diabetes can adversely affect mechanical performance or increase the myocardial vulnerability to ischemic insults. Thus, insulin administration and improved metabolic control during the acute phase of MI may reduce myocardial damage, improve contractility, and decrease mortality (184). In one study, insulin-glucose infusion in the immediate period after infarction resulted in a significant decline in mortality (309). However, this approach has not been proven to be useful in the *acute* phase of MI in other studies (195,196).

In a recent study, intensive glycemic control in patients with diabetes with MI was associated with a 52% reduction in the 1-year mortality rate (196), and the survival advantage was maintained for up to 5 years (310,311). These findings demonstrate that glycemic control may be valuable even in patients with diabetes with established CAD. More studies are needed to better delineate the importance of metabolic derangements in patients with diabetes during myocardial ischemia.

The Metabolic Syndrome

The ATPIII guidelines present an opportunity for physicians to identify patients with the metabolic syndrome who are at increased risk for developing CAD. The Diabetes Prevention Program demonstrated that either a rigorous regimen of diet and exercise or metformin can prevent or delay diabetes (312). Diagnosing the metabolic syndrome in these patients would allow earlier treatment and thereby reduce the likelihood of their developing CAD (Fig. 58.4).

CONGESTIVE HEART FAILURE AND DIABETES

Paralleling the incidence of CAD in patients with diabetes is the incidence of heart failure. Heart failure is a frequent clinical manifestation of the end stage of cardiovascular complications that afflicts patients with diabetes. The Framingham Study was the first study that showed the risk of symptomatic heart failure was increased 2.4-fold in men with diabetes and fivefold in women with diabetes (313). Population-based studies have revealed that 15% to 25% of patients with heart failure are diabetic, as are 25% to 30% of patients hospitalized for heart failure (314–316).

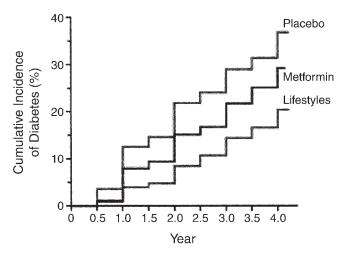

Figure 58.4. Cumulative incidence of diabetes according to study group. The incidence of diabetes differed significantly among the three groups (p < 0.001 for each comparison). (From Knowler WC, Barrett-Connor E, Fowler SE, et al. Reduction in the incidence of type 2 diabetes with lifestyle intervention or metformin. *N Engl J Med* 2002;346:393–403, with permission. Copyright © 2002 Massachusetts Medical Society. All rights reserved.)

However, these epidemiologic studies do not reveal the frequency of diabetic cardiomyopathy. Whether diabetic cardiomyopathy exists as a separate entity is controversial. The diagnosis of diabetic cardiomyopathy is defined as heart failure in the absence of an identifiable etiology. The presence of congestive heart failure in the person with diabetes in the absence of CAD and hypertension is uncertain.

In the Framingham Study (313), few patients with heart failure did not have CAD, hypertension, or rheumatic disease. The presence of CAD was diagnosed solely on the basis of clinical symptoms and electrocardiographic evidence and not by noninvasive testing or coronary angiography. Therefore, CAD that did not manifest symptoms or typical electrocardiographic changes may have led to the development of heart failure. Patients with diabetes are more prone to silent MIs, accounting for nearly 30% of cases (317). CAD is the most common cause of congestive heart failure in the overall U.S. (318) and diabetic (31) populations. Diffuse CAD can lead to nontransmural infarction with patchy necrosis and myocardial fibrosis, resulting in an impairment of systolic function. Myocardial ischemia may result not only in systolic dysfunction but also in diastolic dysfunction (319,320). In the setting of an acute MI, patients with diabetes have been reported in some studies to develop heart failure up to 50% of the time (321). The GUSTO-1 trial demonstrated that heart failure developed in 27% of the subjects with type 1 diabetes compared with 20% of those with type 2 diabetes and 15% of those in the nondiabetic group. This amounts to the occurrence of heart failure almost twice as frequently in the diabetic population relative to the nondiabetic population (174). Persons with diabetes are also almost twice as likely as those without diabetes to develop heart failure as a result of an acute coronary syndrome (7.2% vs. 3.8%).

Not surprisingly, the presence of heart failure in the diabetic population is associated with a poorer long-term prognosis. The GUSTO-1 study demonstrated that cardiac mortality at 30 days in the subjects with type 1 diabetes was 12.5% compared with 9.7% in those with type 2 diabetes and 6.2% in those without diabetes. This poorer outcome was not the result of a larger MI but may have been due to response of the noninfarcted myocardium to the infarct. The MILIS database demonstrated that the prognosis of patients with diabetes was worse relative to that of patients without diabetes (4-year cardiac mortality rates of 25.9% in those with diabetes and 14.5% in those without diabetes), despite the presence of smaller infarcts [as measured by peak creatine phosphokinase (CPK) or area under the curve] and fewer Q-wave infarcts (174). The GUSTO-1 study also found that vessel patency after MI did not explain this worse prognosis either, since there were similar degrees of infarct-related patency at 90 minutes in the patients with and without diabetes (221). Compensatory hyperkinesis of the noninfarcted walls, which is frequently found in the subject without diabetes immediately after MI, is often blunted in the patient with diabetes (221). This may account for the increased incidence of heart failure.

As discussed earlier in this chapter, hypertension occurs in 40% to 60% of patients with type 2 diabetes (322). Hypertension is the most common cause of heart failure in persons with diabetes after CAD, accounting for 24% of the cases. Diabetes increases the likelihood of development of heart failure 1.8-fold in hypertensive men and 3.7-fold in hypertensive women (322).

DIABETIC CARDIOMYOPATHY

The question whether diabetes itself, distinct from CAD and hypertension, results in a dilated cardiomyopathy, remains con-

troversial. The term diabetic cardiomyopathy was first coined by Rubler in 1972 (323). In the 35- to 64-year-old Framingham cohort, diabetes increased the risk of congestive heart failure in men fourfold and in women eightfold, even after adjustment for blood pressure, age, cholesterol, weight, and a history of CAD (313). The more recent Washington DC Dilated Cardiomyopathy Study used case-controlled analyses to determine that there was an association between diabetes and idiopathic cardiomyopathy (324,325).

Persons with diabetes, and especially women, have greater left ventricular mass and higher heart rates than their nondiabetic counterparts. Some studies report that patients with diabetes may have an abnormal exercise response, with an attenuation of augmentation of left ventricular EF relative to that of healthy persons without diabetes (326–330). Furthermore, various groups have reported diastolic abnormalities using various parameters, including prolonged isovolumic relaxation time (331–333), decreased rates of left ventricular diastolic filling (334–336), and abnormal transmitral flow velocities (187, 336–339). Increased echo density has also been reported despite normal wall thicknesses, which could suggest increased collagen deposition present in the myocardium (340).

Pathologically, postmortem studies of patients with diabetic cardiomyopathy have revealed that they have features similar to those of patients with other forms of nonischemic cardiomyopathy. This includes myocyte hypertrophy, interstitial fibrosis, and infiltration with periodic acid-Schiff–positive materials, with coronary arterioles having thickened basement membranes, as well as the presence of intramyocardial microangiopathy (341–343).

Theories abound regarding the possible mechanism or mechanisms underlying diabetic cardiomyopathy. These include both cellular and molecular perturbations, as well as metabolic abnormalities. Insulin may play a central role in the cellular and mo-lecular mechanisms of diabetic cardiomyopathy. Studies with a line of transgenic mice in which the gene for the insulin-regulated glucose transporter GLUT4 has been deleted demonstrate hyperinsulinemia and cardiomyopathy (344,345). Calcium homeostasis may be altered and has been reported in various animal models of diabetes, suggesting a diminished but prolonged increase in intracellular calcium concentration (346). Hyperglycemia increases calcium-activated signaling through protein kinase C, which may in turn result in cardiac dysfunction. Abnormalities in myofibrillar proteins, including altered phosphorylation of troponin I and myosin light chains, also may play a role in diabetes-associated impairment of contractile function (347,348). Advanced glycosylation results in abnormal collagen cross-linking, which may contribute to decreased compliance and, in turn, to diastolic dysfunction (349).

Several metabolic perturbations may contribute to the development of diabetic cardiomyopathy. Glucose contributes 10% to 15% of the energy of the heart under normal conditions. However, during insulin stimulation, increased workload, and ischemia, the metabolism of glucose is increased. Studies using diabetic animal models have demonstrated that diabetic hearts have a blunted uptake of basal and insulin-stimulated myocardial glucose (350). The glucose that is transported into the heart of a diabetic animal is often shunted to glycogen because of increased fatty acid utilization (351,352). Increased fatty acid uptake and oxidation itself may decrease cardiac function. Ketoacidosis may occur in diabetes. The ketones produced are avidly taken up by the diabetic heart and reduce coenzyme A, which in turn inhibits the citric acid cycle, thereby reducing the energy capability of the muscle and resulting in myocardial dysfunction (353,354).

DIABETIC AUTONOMIC NEUROPATHY

Autonomic neuropathy is a common complication of both type 1 and 2 diabetes. Common clinical manifestations of diabetic autonomic neuropathy (DAN) include orthostatic hypotension, gastroparesis, and resting tachycardia (355). Cardiovascular autonomic neuropathy (CAN) of diabetes confers both an increased risk for the development of cardiovascular disease and a poorer prognosis for those individuals once they develop clinically apparent CAD (356-359). The symptoms of CAN include postural hypotension and resting tachycardia described previously, as well as painless myocardial ischemia. Patients with diabetes with CAN do not have the morning increase in MIs and acute cardiovascular disease events ("circadian variation") found in the patients without diabetes but rather show an even distribution of such events throughout the day (360–362). Parasympathetic nerve fibers are affected first, leading to a relative increase in sympathetic tone that results in a resting tachycardia and attenuation of the expected increase in heart rate and blood pressure with exercise (363,364). The decrease of parasympathetic tone may be responsible for the exaggerated coronary vasoconstriction, which may result in worsening ischemia (365,366). Postural hypotension is a principal clinical manifestation of sympathetic dysfunction (367).

The development of CAN parallels the occurrence of endorgan damage, including retinopathy and nephropathy, and generally occurs in those patients with diabetes of long duration with poorer glycemic control. However, subclinical CAN may occur relatively early in the disease. An important method for early detection is reduced heart-rate variability, which is measured over a 24-hour period (368,369). Alternative methods for early detection of CAN include cardiac radionuclide imaging using the norepinephrine analogue metaiodobenzylguanidine (MIBG), which evaluates cardiac sympathetic activity. The activity is reduced in patients with diabetes with CAN, suggesting reduced sympathetic activity (370).

The estimates of the prevalence of CAN vary depending on the methods used to diagnose its presence and the population studied. In a series of patients with newly diagnosed type 1 diabetes, the incidence of CAN was 8% (368), whereas in a large series including patients with type 1 and type 2 diabetes, the incidence of reduced heart-rate variability was 50% (369). In one small series, 75% of patients with diabetes for 10 years and no significant CAD had evidence of adrenergic denervation as determined by MIBG imaging (370).

As stated earlier, the diagnosis of CAN is a harbinger for serious cardiovascular complications and increased mortality in individuals with diabetes (357–359). The 5-year mortality in a cohort of individuals with type 1 diabetes and CAN was fivefold greater than that in individuals with type 1 diabetes without CAN (358). Although the presence of CAN in patients with type 2 diabetes is not as well characterized as that in patients with type 1 diabetes, one study did show that those individuals with type 2 diabetes had a higher cardiovascular mortality in the subsequent 5 years than those with type 2 diabetes who were free of CAN (356).

Numerous experimental and clinical studies have shown that the perturbations in autonomic activity may be important in the development of cardiac arrhythmias. The demonstration of restricted heart-rate variability in persons with diabetes has been shown to be associated with the development of both cardiac arrhythmias and sudden cardiac death, particularly in post-MI patients with left ventricular dysfunction (371–373). The severity of the autonomic dysfunction has been shown to be associated with a higher incidence of arrhythmias. Because individuals with symptomatic clinical CAN usually have had diabetes for a longer time and have poorer glucose control, this may represent a subgroup with more advanced disease and more cardiovascular complications, including previous MIs.

The mechanisms for the increased morbidity and mortality associated with CAN include increased risk of ventricular arrhythmia, silent myocardial ischemia, impaired coronary vasomotor regulation, and increased resting heart rate. Sudden cardiac death has long been known to be associated with diabetes in the absence of cardiovascular disease (357). Transient decreases in heart-rate variability preceded the onset of ST-segment shift and precipitated life-threatening arrhythmias in a group of diabetic patients with CAD who were survivors of sudden cardiac arrest (374). The Honolulu Heart Program also demonstrated that diabetes was independently associated with the risk of sudden cardiac death (375). Prolongation of the QT interval in individuals with diabetes has been shown to correlate with the degree of autonomic neuropathy (376) and may be a method to screen for those persons with diabetes at risk for sudden cardiac death. One group used QT dispersion as a means to evaluate for the presence and degree of autonomic neuropathy. QT dispersion was defined as the longest corrected QT interval minus the shortest corrected QT interval. These investigators found that the greater the QT dispersion, the greater the risk for ventricular arrhythmias and that increased dispersion was more likely in diabetic individuals with CAN (376).

It has long been recognized that patients with diabetes have less severe anginal pain or no pain at all associated with myocardial ischemia (160,169,170,377). Patients with diabetes may present with rather atypical symptoms, including shortness of breath, diaphoresis, gastrointestinal complaints, or profound fatigue. This blunted or altered pain response to myocardial ischemia in patients with diabetes has been attributed to CAN. Zarich and colleagues (361) showed that 90% of ischemic episodes were asymptomatic in a group of patients with diabetes with documented CAD who underwent ambulatory electrocardiographic (ECG) monitoring.

The altered anginal response is further complicated by the resting tachycardia, which alters the threshold for myocardial ischemia. Myocardial oxygen demand is determined largely by the heart rate–blood pressure product. The resting tachycardia, as a result of parasympathetic denervation, increases myocardial oxygen demand. Therefore any activity puts the diabetic patient with CAD closer to his or her ischemic threshold. Cardiac autonomic neuropathy also can affect coronary blood flow independent of the altered endothelial function (365). One study evaluated the cold pressor test in patients with diabetes and found that the increase in flow in response to cold was lower in those with sympathetic nerve dysfunction (366).

The presence of autonomic neuropathy results in a twofold to threefold increase in cardiac morbidity and mortality in patients with diabetes undergoing noncardiac surgery. This increased risk of general anesthesia in this group of patients with diabetes may be due in part to the relative hemodynamic instability that often occurs (378).

SCREENING FOR THE PRESENCE OF CORONARY ARTERY DISEASE

Little is known about the appropriate screening tests for CAD in patients with no clear evidence of CAD. The American Diabetes Association/American College of Cardiology (ADA/ACC) (311) have developed a consensus as to which patients are

at increased risk for cardiac events; which patients should be screened; and what is the appropriate follow-up to a positive test result. The potential benefit of diagnosing CAD in patients with diabetes allows for the initiation of both preventive measures and anti-ischemic therapy, including medication or revascularization therapy. Although no evidence exists for risk intervention in patients with diabetes and asymptomatic CAD, aggressive therapy has been shown to reduce cardiovascular mortality in diabetic individuals with known CAD (as discussed earlier in this chapter). Thus, the identification of CAD

aggressive secondary preventive measures. Although stress testing is clearly indicated for those diabetic individuals who have established CAD, it is not clear what test would be appropriate in patients who do not have known CAD. Table 58.5 lists those indications set by the ADA/ACC Consensus Panel (311). Stress testing is warranted if the patient has typical or atypical cardiac symptoms. Silent ischemia is a frequent occurrence in diabetic individuals. A resting ECG showing evidence of an infarction or ischemia warrants stress testing. The presence of peripheral or carotid occlusive arterial disease is strongly associated with CAD. Therefore, any diabetic individual with evidence of peripheral vascular disease should undergo stress testing. Multiple risk factors in the same patient increase the possibility of identifying significant CAD. The addition of two other risk factors to diabetes increases the cardiovascular death rate by threefold. Autonomic neuropathy has been strongly associated with cardiac morbidity and mortality; however, data are insufficient regarding whether this is an independent risk factor and enough to warrant stress testing. Microalbuminuria is also an important risk factor for cardiovascular mortality, and therefore warrants stress testing.

in asymptomatic patients is important in order to institute

Asymptomatic patients with diabetes and one or no risk factors along with a normal ECG do not require cardiac testing. Those patients with carotid or peripheral vascular disease, beginning a vigorous exercise program, with minor ST-T wave changes on ECG, or with two or more risk factors should undergo an exercise stress test. If these patients are limited by an inability to exercise, they should undergo a pharmacologic (dobutamine) stress echo or persantine thallium nuclear test. If these patients have a baseline ECG making a proper assessment of an ECG stress test difficult, they should undergo nuclear or echocardiographic stress testing. Patients with clear evidence of

TABLE 58.5. Indications for Cardiac Testing in Patients with Diabetes

- 1. Typical or atypical cardiac symptoms
- 2. Resting electrocardiographic findings suggestive of ischemia or infarction
- 3. Peripheral or carotid occlusive arterial disease
- 4. Sedentary lifestyle, age 35 years, and plans to begin a vigorous exercise program
- 5. Two or more of the risk factors listed below in addition to diabetes:
 - a. Total cholesterol ≥240 mg/dL, LDL cholesterol ≥160 mg/dL, or HDL cholesterol <35 mg/dL
 - b. Blood pressure >140/90 mm Hg
 - c. Smoking
 - d. Family history of premature coronary artery disease
 - e. Positive micro-/macroalbumininuria test

an MI or who have ischemia on their ECG, should also undergo stress perfusion imaging or a stress echo test.

A negative test at a high workload, defined as completing 9 minutes or stage 3 of a Bruce treadmill protocol, should provide some reassurance of a favorable prognosis with regard to cardiovascular disease. However, these patients must be routinely followed and, should their symptoms change, undergo a repeat stress test. Those individuals who have mildly positive tests [defined as 1- to 1.5-mm ST depression at a moderate to high exercise level (Bruce stage 3)] are also in a low-risk group. These patients may require perfusion imaging or a stress echo test to determine if this is a false-positive result, especially since many of these patients underwent stress testing prior to beginning a vigorous exercise program. If either of these tests is negative, these patients can have regular clinical evaluations and have a repeat stress-testing every 2 years or when they develop new symptoms. A moderately positive test in an asymptomatic person with diabetes should warrant a stress echo or cardiac nuclear test, since a large perfusion defect indicates a significant risk for cardiac events in the next 1 to 2 years. If the defect is moderate or large, as determined by echo or perfusion testing, the threshold for having the patients undergo cardiac catheterization should be low. A markedly positive stress test is defined as hypotension with exercise, a positive test at a heart rate of less than 120 beats per minute, an exercise capacity of less than 6 minutes, and greater than 2-mm ST depression. The asymptomatic patient with diabetes who has such a test should undergo cardiac catheterization.

EVALUATION OF RISK FACTORS

Table 58.5 (277) reviews the evaluation of the risk factors in such patients with diabetes. In summary, to develop a plan for risk reduction, it is important to identify the risk factors of an individual patient. To evaluate for risk factors in patients with diabetes, it is important for the patient to have a careful medical history and physical examination along with certain laboratory tests. Such tests include a lipoprotein analysis to evaluate not only the LDL level but also the levels of HDL and triglycerides. Predisposing risk factors need to be assessed, including family history, degree of obesity, and level of physical activity. This assessment should also include an evaluation of the renal status, including the determination for the presence of microalbuminuria or macroalbuminuria. The presence of microalbuminuria in the patient with type 2 diabetes signifies an increased risk for cardiovascular disease. Patients with proteinuria of greater than 1 g per day may require more aggressive goals (<125/75 mm Hg) for blood pressure control. ACE inhibitors frequently are regarded as the initial antihypertensive drug of choice in patients with diabetes (290,298,299).

The medical management of patients with clinical cardiovascular disease includes risk reduction and can be defined as secondary prevention. However, a significant portion of the diabetic population has no overt evidence of cardiovascular disease. Such evidence would make it necessary to institute less aggressive management of cardiovascular risk factors for primary prevention.

In patients with type 2 diabetes, the years of insulin resistance can result in atherogenesis long before the onset of hyperglycemia. Clinical evidence of insulin resistance includes abdominal obesity, high-normal blood pressure, high-normal triglycerides (150 to 250 mg/dL), reduced HDL (<40 mg/dL in men; <50 mg/dL in women), borderline high-risk LDL (130 to 159 mg/dL), and in some patients, impaired fasting glucose (110 to 126 mg/dL). The detection of impaired fasting glucose is a strong risk factor for type 2 diabetes. Therefore, it becomes important to follow the guidelines in Table 58.4 not only to reduce the risk of cardiovascular disease but also to delay the onset of type 2 diabetes.

Recent evidence suggests that either lifestyle intervention or treatment with metformin also can reduce the development of diabetes in persons at high risk (312). It is presumed that measures that reduce the development of diabetes also will reduce the incidence of diabetes' most important sequela, cardiovascular disease.

Male sexual dysfunctions are classified into dysfunctions of libido, problems with emission/ejaculation/orgasm, impotence, and priapism. Erectile dysfunction (ED) or impotence is the most common of the various sexual dysfunctions, and because multiple advances have been realized in understanding the physiologic and biochemical mechanisms involving penile erection and in clinical techniques of improving ED, this chapter will be devoted primarily to the sexual dysfunction of impotence.

Erectile dysfunction or impotence is the consistent inability to achieve or sustain an erection of sufficient rigidity to permit satisfactory sexual intercourse (1). It has been estimated from data collected in 1948 that 10 million American males, or approximately 1 in 10 men, have impotence (1,2). New epidemiologic research in a random, community-based population of aging men suggests that the prevalence of impotence among men 39 to 70 years of age is greater than 50% (3). Contemporary studies indicate that impotence afflicts over 30 million American men.

The prevalence of impotence is particularly high in certain groups of patients. In the previous study (3), aging, treated hypertension, treated heart disease, and treated diabetes were among several physiologic variables found to strongly predict impotence. The prevalence of self-assessed complete impotence was more than three times higher among men with diabetes than among men without diabetes. Impotence is an age-dependent disorder (2,4,5) that affects the diabetic male an average of 10 to 15 years earlier than it does his nondiabetic counterpart. Other studies have demonstrated this higher prevalence of impotence among men with diabetes than in the general male population. Depending on the investigators and the study population, the reported prevalence of impotence in diabetic men has ranged from 35% to 75% (6–12).

Impotence in men with diabetes develops insidiously over a period of months or years (9). Patients frequently describe diminished penile rigidity and reduced ability to sustain an erection. Impotence, however, is not always a late progressive complication of the disease but can occur early in its natural history. Libido may persist despite poor erectile performance (8,9).

ANATOMY OF THE PENIS

The penis has two paired corpora cavernosa and a corpus spongiosum, which surrounds the urethra and distally forms the glans penis. Each corpus cavernosum is surrounded by a thick fibrous sheath, the tunica albuginea, which is composed of wavy collagen and elastin that allows erectile tissue to expand and elongate. Formation of tunica plaques (Peyronie disease) can result in loss of tunica compliance, penile curvature, and veno-occlusion dysfunction (4). The erectile tissue consists of multiple, interconnected lacunae lined by vascular endothelium. The walls of the lacunae, the trabeculae, are composed of thick bundles of smooth muscle and a fibroelastic frame (5).

The internal pudendal artery enters the perineum through the Alcock canal and gives rise to four terminal branches (dorsal artery, cavernosal artery, bulbar artery, and the scrotal artery). Along with the nerves that run within the Alcock canal (pudendal nerves), the blood vessels in this region are vulnerable to compression injuries such as those that may occur during bicycle riding (13). It has been recently demonstrated that the dorsal artery interconnects with the cavernosal artery (14). This communication is responsible for the success of microvascular penile bypass surgery between the inferior epigastric artery (donor vessel) and the dorsal artery (recipient vessel) in patients with cavernosal artery occlusion. Last, accessory pudendal arteries provide additional blood flow to the corpora cavernosa. Injury to these arteries during radical retropubic prostatectomy may explain why some patients experience ED following successful nerve-sparing procedures (15).

Multiple muscular helicine arteries branch off each cavernosal artery and open directly into the lacunar spaces. Blood drains from the corporal bodies through subtunica venules located between the periphery of the erectile tissue and the tunica albuginea. Subtunica venules coalesce to form larger emissary veins that pierce the tunica albuginea (16,17).

The peripheral innervation of the penis consists of sympathetic nerves arising from the 11th thoracic to the second lumbar spinal cord segments and from parasympathetic and somatic nerves arising from the second, third, and fourth sacral spinal cord segments. Somatic innervation is via the pudendal nerve, which is composed of efferent fibers innervating the striated musculature of the perineum and of afferent fibers from the penile and perineal skin (18).

PHYSIOLOGY OF ERECTION

Central Mechanism of Erection

Penile erections are elicited by local sensory stimulation of the genital organs (reflexogenic erections) and by central psychogenic stimuli received by or generated within the brain (psychogenic erections) (18,19). Recently, specific regions of the brain (inferior temporal cortex, right insula, right inferior frontal cortex, and left anterior cingulated cortex) activated by visual evoked sexual arousal have been identified by positron emission tomography (20). The medial preoptic area and the paraventricular nucleus within the hypothalamus appear to integrate visual (occipital area), tactile (thalamus), olfactory (rhinencephalon), and imaginative (limbic system) input and send neural projections to the thoracolumbar sympathetic and sacral parasympathetic centers of the spinal cord (21). Dopamine and oxytocin are thought to play important roles in mediating the pre-erectile response in the medial preoptic area and the paraventricular nucleus respectively (22). In contrast, the nucleus paragigantocellularis (nPGi) in the brainstem exerts an inhibitory effect on sexual arousal (23). Nerves from the nPGi project to sacral segments of the spinal cord and release serotonin. This has been postulated as the reason specific serotonin reuptake inhibitors (SSRIs) depress sexual function. Because men treated with SSRI drugs most commonly exhibit delayed or blocked ejaculation, cases of premature ejaculation have also been successfully managed with SSRI treatment. The locus ceruleus also exerts inhibitory input via sympathetic nerves that interface with hypothalamic nuclei as well as with the spinal cord. Withdrawal of sympathetic input due to suppressed activity of the locus caeruleus during rapid eye movement (REM) sleep is thought to lead to episodes of nocturnal penile tumescence (22,24). The pudendal nerve, which is the afferent limb for reflexogenic erections, collects somatic sensation from the genital skin. The autonomic nerve fibers that arise from the sacral parasympathetic center (S2–S4) make up the efferent limb for this reflex, innervating the penile smooth muscle. Reflexogenic and psychogenic erectile mechanisms probably act synergistically in the control of penile erection (18,25–31).

Erection follows relaxation of arterial and trabecular smooth muscle (32). Dilation of the cavernosal and helicine arteries increases blood flow into the lacunar spaces. Relaxation of the trabecular smooth muscle dilates the lacunar spaces, accommodating a larger volume of blood and thus engorging the penis. The expansion of the relaxed trabecular walls against the tunica albuginea compresses the plexus of subtunica venules (16,33,34). This results in increased resistance to the outflow of blood with increased lacunar space pressure, making the penis rigid. The reduction of venous outflow by the mechanical compression of subtunica venules is known as the corporal venoocclusive mechanism (Fig. 59.1).

Contraction of penile smooth muscle results in detumescence. Activation of sympathetic constrictor nerves causes an increase in the tone of the smooth muscle of the helicine arteries and the trabeculae, resulting in a reduction of arterial inflow, a collapse of the lacunar spaces with decompression of subtu-

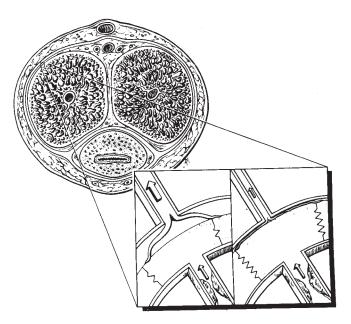

Figure 59.1 Schematic cross-section of the penis including two corporal bodies and a corpus spongiosum. **Insets:** Enlargements of the subtunica space between the trabeculae and the tunica albuginea. Drainage from erection tissue passes via subtunica venules into emissary veins that drain through the tunica. When the penis is in the flaccid state (**left inset**), the contracted corporal smooth muscle allows blood to drain from the erectile tissue to the subtunica venules under conditions of low outflow resistance. When the penis is in the erect state (**right inset**), following activation of efferent autonomic nerves, the elevated pressure in the lacunar space expands the trabecular structures against the tunica albuginea. The expanded volume of the corporal tissue both mechanically compresses and physically stretches the subtunica venules, greatly increasing the resistance to flow through the subtunica venules is called the corporal veno-occlusive mechanism.

nica venules (16,33,34), an increase in venous outflow from the lacunar space, and a return of the penis to the flaccid state.

Peripheral Mechanisms of Erection

NEUROGENIC REGULATION OF PENILE ERECTION

Erectile function in the penis is regulated by autonomic (parasympathetic and sympathetic) and somatic (sensory and motor) pathways to the erectile tissues and perineal striated muscles. Three sets of peripheral nerves innervate the penis, the sympathetic nerves, the parasympathetic nerves, and the pudendal nerves.

The sympathetic nerves (T10-L2), which are responsible for detumescence and maintenance of flaccidity, project to the corpora, as well as to the prostate and bladder neck via the hypogastric nerves. Postganglionic noradrenergic fibers pass posterolateral to the prostate in the so-called nerves of Walsh to enter the corpora cavernosa medially. Adrenergic tone is crucial in initiating detumescence and in maintaining the flaccid state of the penis, because the smooth muscle of the arteries and cavernosal trabeculae must remain actively contracted. Contraction of cavernosal trabecular smooth muscle in response to norepinephrine is mediated by α_1 -adrenergic receptors. Prejunctional α_2 -adrenergic receptors on adrenergic nerves inhibit neurotransmission and provide a self-regulating negative feedback loop for secreted norepinephrine. Cholinergic nerves act on prejunctional muscarinic receptors to also inhibit adrenergic nerve activity.

It is possible that adrenergic imbalance toward vasoconstriction impairs erection. While specific factors that contribute to this imbalance remain unknown, aging and/or associated disease states may cause selective upregulation of specific adrenergic receptor subtypes, resulting in higher efficacy for norepinephrine action. Since norepinephrine is a key modulator of erectile function, it is plausible that α -adrenergic receptor antagonists may prove useful in the treatment of ED. Clinical experience with drugs such as yohimbine and phentolamine have had varying efficacy in men with ED. The role of α -adrenergic receptors in the physiology of penile erection is reviewed more completely elsewhere (35,36).

The parasympathetic nerves, originating in the intermediolateral nuclei of the S2 to S4 spinal cord segments, provide the major excitatory input to the penis and are responsible for vasodilation of the penile vasculature and subsequent erection. Exiting through the sacral foramina, these nerves pass forward lateral to the rectum as the pelvic nerve and synapse in the pelvic plexus with postganglionic nonadrenergic, noncholinergic (NANC) nerve fibers, which travel within the cavernous nerves to the corpora cavernosa. Vasoactive intestinal peptide (VIP) and nitric oxide (NO) are two NANC neurotransmitters that are often co-localized in the same nerves in penile tissue. However, the role of VIP as a modulator of penile erection remains unclear because the experimental results with this peptide on erectile function are inconsistent. Intracavernosal administration of VIP in animals and humans has yielded varying results, ranging from no effect to partial tumescence to full erection. Furthermore, the lack of specific and effective antagonists for VIP hinders experimental investigation concerning its role in erectile function.

The primary mediator of NANC parasympathetic input is NO. The ability of NO, a highly reactive and unstable gas, to regulate a wide array of physiologic functions in mammals has become evident only within the last two decades. Along with carbon monoxide, NO is a unique primary effector molecule with the characteristics of an intracellular second messenger that defies previous classification schemes. It is apparently syn-

thesized on demand with little or no storage, and it directly activates a soluble enzyme (guanylate cyclase) rather than a "traditional" receptor molecule. NO is produced by nitric oxide synthase (NOS), which uses the amino acid L-arginine and molecular oxygen as substrates to produce NO and L-citrulline. NO can readily cross plasma membranes to enter target cells, where it binds the heme component of soluble guanylate cyclase. This activation of guanylate cyclase stimulates the production of cyclic guanosine monophosphate (cGMP), with the resultant activation of the cGMP-dependent protein kinase, which regulates the intracellular events, leading to relaxation of trabecular smooth muscle. The levels of cGMP also are regulated by phosphodiesterases, which break down cGMP and terminate signaling. Sildenafil (Viagra) is a potent, selective, and reversible inhibitor of phosphodiesterase type 5, the major enzyme responsible for cGMP hydrolysis in penile erectile tissue (37). Inhibition of this enzyme leads to the increase in levels of intracellular cGMP and enhancement of the relaxation of smooth muscle in response to stimuli that activate the NO/cGMP pathway. This activity may explain the success of sildenafil in the treatment of male ED (38).

Recently, it has become evident that NO interacts directly with other cellular targets, including receptors, ion channels, and pumps, that may modulate the contractility of smooth muscle cells, independently of the cGMP pathway (39–41). Thus, NO has intracellular targets in addition to guanylate cyclase that may play a role in the regulation of vascular and trabecular smooth muscle contractility.

The activity of NANC nerves may be modulated by cholinergic nerves, which facilitate NANC relaxation by stimulating the synthesis and release of NO and other vasodilatory neurotransmitters such as VIP. Thus, the release of acetylcholine may coordinate withdrawal of adrenergic input and increase of NANC input by binding to prejunctional muscarinic receptors on adrenergic and NANC nerves (24). In certain disease states, such as diabetes, the ability of the corpus cavernosum to synthesize and release acetylcholine is diminished (42). Such processes may be responsible in part for the compromised erectile function associated with diabetes. Parasympathetic nerves are also vulnerable during surgical procedures, such as abdominoperineal resection of the rectum and radical prostatectomy (15,43).

The pudendal nerves comprise motor efferent and sensory afferent fibers innervating the ischiocavernous and bulbocavernous muscles as well as the penile and perineal skin. Pudendal motor neuron cell bodies are located in the Onuf nucleus of the S2 to S4 segments. The pudendal nerve enters the perineum through the lesser sciatic notch at the posterior border of the ischiorectal fossa and runs in the Alcock canal (pudendal canal) toward the posterior aspect of the perineal membrane. At this point, the pudendal nerve gives rise to the perineal nerve, with branches to the scrotum and the rectal nerve supplying the inferior rectal region. The dorsal nerve of the penis emerges as the last branch of the pudendal nerve. It then turns distally along the dorsal penile shaft, lateral to the dorsal artery. Multiple fascicles fan out distally, supplying proprioceptive and sensory nerve terminals to the dorsum of the tunica albuginea and the skin of the penile shaft and glans penis.

NON-NEURONAL MODULATORS OF PENILE ERECTION

In addition to neurogenic mechanisms, local paracrine/ autocrine factors, with vasoactive and/or trophic effects, profoundly influence the function of the smooth muscle in the penis. These include endothelins, prostanoids, NO, and oxygen.

Endothelin-1 (ET-1), a member of the endothelin family of peptides, is one of the most potent vasoconstrictors known at

1002 JOSLIN'S DIABETES MELLITUS

this time. Similar to NO, the release of endothelin from the intimal lining of vascular compartments can be induced by shear stress. However, little is known about the physiologic or cellular mechanisms that regulate its production. In human corpus cavernosum, ET-1 is synthesized by the endothelium and elicits strong, sustained contractions of corpus cavernosum smooth muscle. Both major subtypes of endothelin receptors (ET_A and ET_B) have been identified in penile corpus cavernosum and are distributed on both the endothelium and the smooth muscle. It has also been suggested that endothelin may exert vasodilatory effects at low concentrations through a "super-high" affinity form of the ET_B receptor potentially by stimulating NO production. However, the significance of this

mechanism in penile erection remains unclear. In rabbit models of disease, ET_B receptors in penile corpus cavernosum were upregulated in alloxan-induced diabetic rabbits and downregulated in hypercholesterolemic Watanabe rabbits. Additionally, elevated plasma endothelin levels have been reported in both diabetic and nondiabetic men with ED. Thus, endothelin may contribute to the maintenance of penile flaccidity by providing sustained tone to the trabecular smooth muscle, and alterations in endothelin production may result in impaired erectile function. Several selective antagonists of endothelin receptor subtypes have been developed, but their efficacy and safety in the treatment of ED have not been fully evaluated.

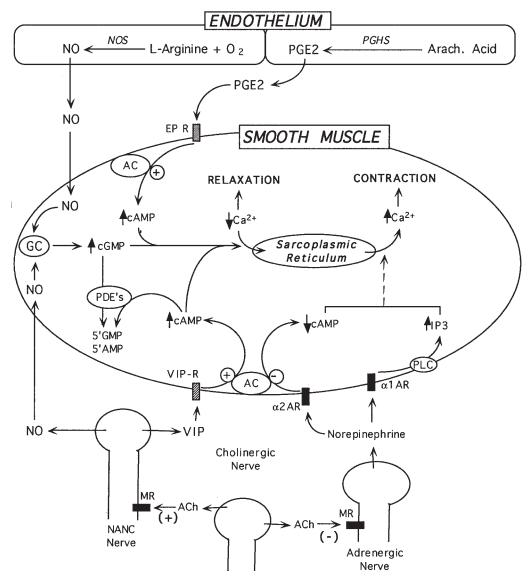

Figure 59.2. Schematic diagram of the neurogenic and endothelium-derived mechanisms that exert local control of corporal smooth muscle tone. Neurogenic mechanisms involve three neuroeffector systems: adrenergic (constrictor) using norepinephrine as a neurotransmitter; cholinergic (dilator) using acetyl-choline (AC) and/or vasoactive intestinal polypeptide (VIP) as a neurotransmitter; and nonadrenergic, noncholinergic (NANC) (dilator) using nitric oxide (NO) as a neurotransmitter. Endothelium-derived vasoactive substances such as NO (dilator), prostaglandins (PGs) (both constrictor and dilator), and endothelin (constrictor) also may contribute to the control of trabecular smooth muscle tone. AC, adeny-late cyclase; Ach, acetylcholine; AR, adrenergic receptor; CAMP, cyclic adenosine monophosphate; CGMP, cyclic guanosine monophosphate; EP R, PGE receptor; GC, guanylate cyclase; IP3, inositol trisphosphate; MR, muscarinic receptor; NOS, nitric oxide synthase; PDE, phosphodiesterase; PGHS, prostaglandin G/H synthase; PLC, phospholipase C.

Nitric oxide is synthesized and released not only by the NANC nerves but also by the vascular endothelium. Vasodilators such as acetylcholine and bradykinin act by binding their respective membrane receptors and increasing intracellular Ca²⁺ within endothelial cells. Physical stimuli, such as shear stress, are also known to enhance NO production in endothelium. In the penis, shear-induced NO production by endothelium is most likely to occur during the onset of erection, when blood flow into the cavernosal bodies is rapidly increased. The mode of action of endothelium-derived NO is identical to that of nerve-derived NO, as described in the previous section (Fig. 59.2).

Prostaglandins (PG) are prostanoids (as are eicosanoids), which are 20-carbon derivatives produced by the action of cyclooxygenases on the common precursor arachidonic acid in both endothelial and smooth muscle cells of the corpora cavernosa. Prostanoids act locally and exert both trophic and tonic effects in an autocrine and paracrine manner. Although the precise physiologic role of prostaglandins in penile erection remains poorly defined, experimental evidence indicates that they may play an important role in the regulation of the production of extracellular matrix. Further, the antiplatelet-aggregating effects of PGI₂ (prostacyclin), similar to those of NO, may be important in preventing coagulation of blood, since blood flow within the cavernosal bodies is negligible during full penile tumescence. The five primary active prostanoid compounds in the penis are the prostaglandins PGD_2 , PGE_2 , $PGF_{2\alpha}$, PGI₂, and thromboxane A₂ (TXA₂). Prostanoids can induce both relaxation and contraction in penile corpus cavernosum. PGE is the only endogenous prostaglandin that appears to elicit relaxation of human trabecular smooth muscle; the others cause constriction or have no effect on smooth muscle tone. There are five major groups of prostanoid receptors, termed DP, EP, FP, IP, and TP, which mediate the effects of PGD, PGE, PGF, PGI, and thromboxane, respectively. The multifunctional, dose-dependent effects of prostanoids may be explained by the coupling of receptor subtypes and isoforms to different second messenger systems. Clinically, PGE₁ (alprostadil) has been developed as the first U.S. Food and Drug Administration (FDA)-approved intracavernosal injectable drug for the treatment of ED.

Oxygen tension plays an active role in regulating penile erection. Measurements of cavernosal blood Po2 in human volunteer subjects indicate that oxygen tensions change rapidly from venous (~35 mm Hg) to arterial (~100 mm Hg) levels during the transition of the penis from the flaccid to the erect state. Maintenance of constant oxygen tension is a critical imperative in most tissues of the body. The penis is the only organ that changes from venous to arterial oxygen tensions during the course of its normal function. This transition is the basis of a unique regulatory mechanism that takes advantage of key synthetic enzymes that utilize molecular oxygen as a cosubstrate. NO synthase and prostaglandin synthase are two well-studied examples of a class of enzymes known as dioxygenases. At low oxygen tension, measured in the flaccid state of the penis, the synthesis of NO is inhibited, preventing relaxation of trabecular smooth muscle. This inhibition of NO production is probably necessary for the maintenance of penile flaccidity. Following vasodilation of the resistance arteries, the increase in arterial flow raises oxygen tension. In the oxygen-enhanced environment, autonomic dilator nerves and the endothelium are able to synthesize NO, mediating relaxation of trabecular smooth muscle. The synthesis of prostanoids is similarly regulated in the flaccid versus the erect state. Therefore, oxygen tension may regulate the types of vasoactive substances present in the vascular bed. At low oxygen tension, norepinephrine- and endothelin-induced contraction may predominate, while at high oxygen tension, NO and prostaglandins are produced

because of the availability of molecular oxygen required for their synthesis.

PATHOPHYSIOLOGY OF DIABETES-RELATED ERECTILE DYSFUNCTION

Although impotence in men with diabetes may be primarily psychogenic, several reports have documented that a primarily organic origin is more common (8,9). In patients with diabetes, the erectile disorder is rarely reversible, lending support to an organic cause (11,44). Organic impotence can be differentiated from psychogenic impotence by monitoring nocturnal erections associated with REM. Men with diabetes have been found to have a decrease in such REM-associated erections (45), lending support to an organic basis of their impotence.

Vasculopathy and neuropathy are common complications associated with the natural history of diabetes mellitus. It is hypothesized that cavernosal artery insufficiency, corporal veno-occlusive dysfunction, and/or autonomic neuropathy are the major organic pathophysiologic mechanisms leading to persistent erectile impairment in men with diabetes mellitus (46). The role of hormonal abnormalities in the pathophysiology of organic-based impotence is controversial.

Neurogenic Erectile Dysfunction

Penile autonomic neuropathy has a major role in the pathophysiology of ED in men with diabetes. The incidence of peripheral and autonomic neuropathy is significantly higher in impotent than in potent men with diabetes (8,47). Erectile failure is a common feature of diabetic autonomic neuropathy (48) and may precede the appearance of neuropathy (49).

Until recently, clinical tests of the integrity of the autonomic nerves to the corpora have been performed exclusively by indirect testing, such as tests of nocturnal penile tumescence. Since patients with diabetes commonly have associated hemodynamic abnormalities, indirect testing is not reliable as a technique for accurate documentation of cavernosal nerve integrity (50).

The presence of bladder areflexia and bladder or bowel dysfunction provides indirect support for the impairment of the motor efferent autonomic cavernosal nerves, since the bladder and penis receive autonomic innervation from a common origin (8,51). Ellenberg (8) found that 82% of impotent patients with diabetes had evidence of neuropathic bladder by cystometric diagnosis, whereas only 10% of age-matched potent patients with diabetes had bladder involvement. Vascular reflexes such as beat-to-beat variation in heart rate provide another indirect measurement of autonomic parasympathetic neuropathy. Several studies have also documented abnormal vascular reflexes in the impotent patient with diabetes (52).

The possibility of direct testing of the autonomic innervation of the corpora is now being investigated by recording the electrical activity of the corporal smooth muscle with the use of intracavernosal electromyographic needles or surface electrodes on the penile shaft (53). With use of single-potential analysis, waveforms of a defined duration, amplitude, and polyphasicity can be recorded in healthy subjects (54). In patients with peripheral neuropathy secondary to diabetes, the single-potential analysis of cavernous electrical activity may reveal potentials that are of abnormal duration and amplitude (54,55). Because this technique is at the initial development phase and is available in only a few centers, further investigations will be needed for its validation as a test of the autonomic nervous system.

Several tests are used in the evaluation of the presence of neuropathy in the sensory afferent nerves from the penile skin and the motor efferent nerves to the perineal skeletal musculature. These tests include perineal electromyography, sacral latency testing, evaluation of dorsal nerve somatosensoryevoked potential, and testing of vibration-perception sensitivity (56–59). An abnormal result in somatic testing may suggest, but does not prove, the co-existence of autonomic neuropathy in the corpora cavernosa. Faerman et al. (60) reported morphologic alterations in the unmyelinated nerves in the corpus cavernosum of impotent men with diabetes. Ultrastructural studies of penile nerves in rats with long-term streptozotocin-induced diabetes reveal axonal degeneration with loss of axonal filaments, tubules, and mitochondria (61). The most prominent finding we observed in the penile nerves of impotent patients with diabetes was a thickening of the Schwann and perineurial cell basement membranes (62).

The nerves in patients with diabetes can exhibit biochemical abnormalities, which are subject to some degree of improvement with strict glycemic control (63). Excessive nonenzymatic glycosylation of myelin proteins and polyol pathway activity and abnormal metabolism of myoinositol and its phospholipid derivatives have been proposed as possible biochemical mechanisms in the pathogenesis of diabetic neuropathy (64). In addition, neural ischemic insult has been proposed as a possible mechanism for diabetic polyneuropathy (65). It is now known

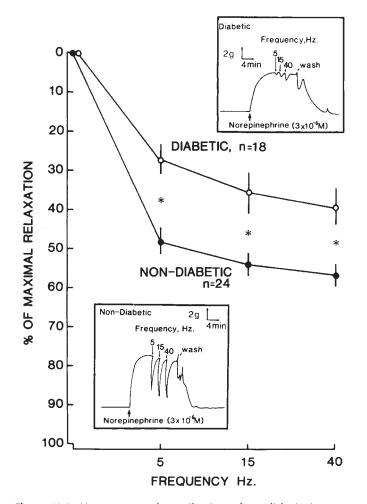

Figure 59.3. Human corporal erectile tissue from diabetic impotent patients reveals electrical field stimulation relaxation responses to 5, 15, and 40 Hz that average 28% to 35% of maximal relaxation, responses that are significantly diminished in comparison to those in nondiabetic tissues. This finding suggests a functional impairment of the neurogenic dilator mechanism of penile smooth muscle in diabetic impotent men.

that hyperglycemia induces decreases in endoneurial blood flow and nerve conduction velocities (66).

Melman et al. (67) were the first to report diminished levels of norepinephrine in the tissues of patients with diabetes. Norepinephrine depletion was most severe in patients with insulindependent diabetes. These results were corroborated by Lincoln et al. (68), who also found diminished levels of norepinephrine and a marked reduction in acetylcholinesterase-positive fibers in corpus cavernosum tissue of patients with diabetes. These findings suggest the possibility of a depletion in the number of cholinergic nerves in corpus cavernosum of patients with diabetes. Impotent men with diabetes have a functional impairment of the neurogenic dilator mechanism of penile smooth muscle (69) (Fig. 59.3). Corporal tissue from impotent men with diabetes accumulates and releases less acetylcholine than does corporal tissue from impotent men without diabetes (70). Because relaxation of penile smooth muscle is necessary for erection and the cholinergic neuroeffector system facilitates this smooth muscle relaxation, the dysfunction of penile cholinergic nerves may be contributory to the development of impotence in men with diabetes. The duration of diabetes is negatively correlated to the ability of the cholinergic nerves to synthesize acetylcholine (70). Therefore, patients with long-standing diabetes are more likely to present with penile autonomic neuropathy.

Several studies have reported a decrease in the tissue levels of VIP and the number of VIP-like immunoreactive fibers in human corpus cavernosum from patients with diabetes (68,71). Findings are similar in rats with streptozotocin-induced diabetes (72).

Vasculogenic Erectile Dysfunction

Vascular disease, of either large or small vessels, is a major contributor to the morbidity and mortality of diabetes (73,74). Diabetic microangiopathy produces alterations and decompensation of local microvascular blood flow (75). There is progressive venule dilation, periodic arteriolar vasoconstriction, and sclerosis of the walls of the arterioles, capillaries, and venules (76). Endothelial cell metabolism and function, thickness of the basement membrane of the vessel wall, oxygen transport, bloodflow properties, and hemostasis also are altered in diabetic microangiopathy (77). Similarly, large-vessel disease is strongly associated with diabetes. Intimal, medial, and luminal changes observed in obliterative atherosclerosis have been well-documented (78). There is growing evidence supporting a role of hyperglycemia in increasing levels of diacylglycerol (79,80), which induces activation of protein kinase C (PKC) (79,81). Activation of this enzyme leads to vascular dysfunction by disrupting NO signaling, which is thought to be a factor contributing to the vascular and neural abnormalities seen in patients with diabetes. In addition, hyperglycemia induces decrease in Na⁺-K⁺-ATPase activity (82). A reduction in the activity of this enzyme may enhance vascular smooth muscle vasoconstriction and impaired veno-occlusion. PKC activation has been postulated to mediate the hyperglycemia-induced decrease in Na⁺-K⁺-ATPase activity. Finally, PKC activation may increase the expression of vascular endothelial growth factor (VEGF) and vascular permeability factor (VPF). These factors have been implicated in the pathogenesis of diabetic macular edema and diabetic retinopathy (79,81).

Atherosclerotic vascular disease and ED are strongly related. Arteriosclerosis is the most common organic disorder leading to impotence (83). Among men with clinically significant peripheral arterial disease, 40% to 50% complain of impotence, and in 80% of these cases, the primary cause of the impotence is organic (84). ED develops when more than 50% of the major arterial supply to the penis is involved in atherosclerotic occlusive disease (85). Atherosclerosis has also been observed to have an adverse effect on the ultrastructure of corpus cavernosum in 40% to 45% of men with diabetic impotence; as the smooth muscle cell content decreases, the severity of symptoms and clinical findings increases (86–89).

Postmortem examinations of impotent diabetic men have revealed numerous penile arterial vascular abnormalities, including fibrous proliferation of the intima, medial fibrosis, calcification, narrowing, and obliteration of the lumen. Such vascular alterations in the penile arteries impede blood flow to the cavernous bodies at the time of erection and are thus in part responsible for the ED (90).

Impotent men with diabetes may also have associated vascular risk factors, such as cigarette smoking, hypertension, and hyperlipidemia (1). Cigarette smoking is a statistically significant independent risk factor in the development of angiographically confirmed atherosclerotic arterial occlusive disease to the hypogastric-cavernous arterial bed. Five, ten, and twenty packyear (1 pack, or 20 cigarettes, per day for 1 year) histories of exposure to cigarette smoking are associated with 15%, 30%, and 70% incidence, respectively, of arterial occlusive disease within the common penile artery (90,91). Hypertension also was noted in 45% of impotent men, while hyperlipidemia or other disturbances of lipid metabolism were found in 40% to 50% of impotent men (84).

Diabetes-associated vascular disease affects the physiology of erection by many routes—at the level of large inflow vessels, the penile microvasculature, the lacunar space endothelium, and the penile fibroelastic frame. One mechanism of diabetesinduced, atherosclerosis-associated ED is the lowering of arterial perfusion pressure and arterial inflow to the lacunar spaces of the corpora cavernosa (92–94). The clinical consequences of these hemodynamic changes are a diminished rigidity of the erect penis and a prolongation of the time to maximal erection. Another mechanism is interference with corporal veno-occlusion. In all men with organic impotence, the incidence of corporal veno-occlusive dysfunction may be as high as 86% (95).

Corporal veno-occlusive dysfunction associated with diabetes can be due to a structural alteration in the fibroelastic components of the trabeculae (1). Loss of compliance of the fibroelastic frame of the penis may be the result of altered synthesis of collagen or elastin, altered tissue cellularity (96-98), or alterations in the reactivity of the smooth muscle of the corpus cavernosum and the endothelial cells of the lacunar space (99). Activation of PKC has been implicated in the hyperglycemiainduced increases in expression of transforming growth factor β (TGF- β), a potent prosclerotic cytokine that facilitates accumulation of extracellular matrix protein in the corpus cavernosum, which reduces penile compliance and impairs veno-occlusion in patients with diabetes (100). Functional studies in isolated human corporal tissue have demonstrated decreased endothelium-dependent relaxation of the penile smooth muscle and loss of compliance of the penile fibroelastic frame. These may result in an inability of the trabeculae to expand against the tunica albuginea and compress the subtunica venules. The clinical consequences of such hemodynamic alterations are excessive outflow of lacunar blood, which prevents the attainment of adequate penile rigidity and duration of erection.

Endocrinologic Erectile Dysfunction

Studies in the 1940s through the 1960s demonstrated abnormal endocrinologic factors, primarily hypogonadotropic hypogonadism, in association with diabetic impotence. These conclusions were based on the presence of both pituitary gonadotropin and 17-ketosteroids in the urine and on the documentation of infiltration of testicular interstitial matrix with collagen-like material and abnormalities in the seminiferous tubules in testicular biopsy material (7).

Endocrine studies of men with diabetes that have been carried out since the advent of radioimmunoassay analyses have had variable results (8,9,60,101,102). Total serum testosterone values are not consistently altered in impotent men with diabetes. In some series, values were normal or low or the magnitude of the increase following stimulation with human chorionic gonadotropin was attenuated in men with diabetes. In one series, a deficit of gonadal function was inferred from high urinary excretion of luteinizing hormone and free testosterone levels in serum. In another study (103), a decrease in concentration of luteinizing hormone followed a lowering of the blood sugar level in impotent men with diabetes but not in potent controls, suggesting that hyperglycemia may be responsible for these endocrine abnormalities.

The etiologic significance of the hypothalamic-pituitary-testicular axis in ED is unclear. Androgens influence the growth and development of the male reproductive tract and secondary sexual characteristics (104). Their effect on libido and sexual behavior is well established (105), but the effect of androgens on normal erectile physiology is poorly understood. Androgenreceptor sites have been demonstrated in the sacral parasympathetic nucleus and on neurons of the hypothalamus and limbic system, suggesting possible hormonal regulation of these centers involved in erection. In animals castration has also been found to reduce the size of some motor neurons, dendritic length, number of chemical synapses onto the somatic and dendritic membranes, and gap junctions between motor neurons in the spinal nuclei (106–108).

Patients with castration levels of testosterone can achieve erections comparable in quality to those achieved by men with normal levels of testosterone in response to visual sexual stimulation (109). This observation suggests that the neurovascular mechanisms that control erection are functional in the presence of low levels of androgens. On the other hand, it has been shown that hypogonadal men have decreased nocturnal penile erectile activity and show improved activity when they receive androgen replacement (105).

Thyroid disease, pituitary disorders, adrenal disease, and hyperprolactinemia, in addition to hypogonadism, may all be associated with ED in men with diabetes. One study found serum prolactin to be similar in normal and diabetic patients, while another study reported an above-average incidence of hyperprolactinemia in diabetic patients (101,110). Declining libido and impotence can be seen as early symptoms in patients with hyperprolactinemia. Hyperprolactinemia is associated with low circulating levels of testosterone, which appear to be secondary to the inhibition by elevated levels of prolactin of normal pulsation of gonadotropin-releasing hormone. In approximately one-half of impotent patients with hyperprolactinemia and low levels of testosterone, potency is not restored by normalization of serum testosterone levels, implying that prolactin may have an antagonistic effect on the peripheral action of testosterone (1). Hyperthyroid states are commonly associated with diminished libido and, less frequently, with impotence. Impotence associated with hypothyroid states has been reported and may be secondary to associated low levels of testosterone secretion and elevated levels of prolactin (110). Although endocrine-related impotence does not play a major role in the overall pathogenesis of diabetic impotence, a recognized hormonal abnormality may be amenable to medical treatment; thus, endocrine screening is recommended for impotent patients with diabetes.

EVALUATION OF ERECTILE FUNCTION IN PATIENTS WITH DIABETES

The process of care model for the evaluation and treatment of erectile dysfunction was developed with input from a multidisciplinary panel of experts in family medicine, internal medicine, endocrinology, psychiatry, psychology, and urology to advance new guidelines for the diagnosis and treatment of ED in the primary care setting (111). These guidelines begin the management of patients with ED with the identification and diagnosis of the problem. ED is the persistent or repeated inability, for a duration of at least 3 months, to attain and/or maintain an erection sufficient for satisfactory sexual performance (112), and the diagnosis is based on the patient's self-report in conjunction with a clinical evaluation. In some cases, it may be necessary for physicians to carefully inquire about sexual functioning, paying special attention to the sensitivity of the topic and to the patient's comfort level. Validated sexual questionnaires, such as the International Index of Erectile Function (IIEF), may be helpful tools in the evaluation of erectile function (113). The cornerstone of the patient evaluation is a comprehensive and detailed sexual, medical, and psychosocial history; physical examination; and focused laboratory testing. Specialized diagnostic tests, such as nocturnal tumescence, biothesiometry, and penile vascular studies (duplex Doppler ultrasound, dynamic infusion cavernosometry, and cavernosography), although not always indicated, may corroborate the impressions discovered on the initial evaluation. As a general rule, for the diabetic patient with ED, sophisticated invasive testing should be considered only under unusual conditions. It should be stressed that the secondary psychologic reaction to these organic factors must not be ignored. Successful treatment of the impotent patient with diabetes who has primary organic and secondary psychologic impotence demands attention to both dysfunctions.

Sexual, Medical, and Psychosocial History

A detailed and comprehensive sexual history should include past and present assessment of sexual desire (libido), orgasms, ejaculatory function, and erectile capabilities (rigidity, spontaneity, sustaining capabilities) during both sexual and nonsexual circumstances (nocturnal erections). In addition to physiologic erectile responses, overall sexual satisfaction should also be assessed.

The medical history should include focused questions on medical illness (chronic/medical illness; e.g., diabetes, anemia, renal failure), neurologic illness (e.g., spinal cord injury, multiple sclerosis, lumbosacral disk disease), endocrinologic illness (e.g., hypogonadism, hyperprolactinemia, thyroid disorders), atherosclerotic vascular risk factors (e.g., hypercholesterolemia, hypertension, diabetes, smoking, family history), medications/recreational drug use (e.g., antihypertensives, antidepressants, alcohol, cocaine), pelvic/perineal/penile trauma (e.g., bicycling injury), surgical (e.g., radical prostatectomy, laminectomy, vascular bypass surgery), and psychiatric history (e.g., depression, anxiety).

Given the personal, interpersonal, social, and occupational implications of sexual problems, a brief psychosocial history is mandatory for every patient. Current psychological state, selfesteem, and history of sexual trauma/abuse, as well as past and present relationships and social and occupational performance, should be addressed.

Physical Examination

A routine physical examination with special emphasis on the genitourinary vascular and neurologic systems may confirm aspects of the medical history (e.g., penile curvature, neuropathies) and occasionally may reveal unsuspected physical findings such as penile plaques (Peyronie disease) and small testes (hypogonadism) responsible for the patient's ED.

Laboratory Testing

Laboratory testing is strongly recommended. Standard serum chemistries, complete blood cell count and lipid profiles may elucidate vascular risk factors such as hypercholesterolemia, diabetes, and renal failure. Determinations of serum prostatespecific antigen (PSA) following the American Urological Association guidelines and serum thyroid-stimulating hormone (TSH) may be indicated in select cases.

The integrity of the hypothalamic-pituitary-gonadal axis should be examined in every patient with ED. It is unclear which testosterone assay (total, free, and bioavailable) is the best; however, there is a consensus that at least one of these assays should be performed. Although pituitary adenomas are a rare cause of sexual dysfunction, this potentially life-threatening disease and reversible cause of ED should not be forgotten. Abnormalities in any of these tests may correlate clinically with diminished sexual desire and with atrophic testis on physical examination

Patient/Partner Education

Patient and partner education is a critical component in the diagnosis of ED and should be carried out whenever possible. The results of the history, physical examination, laboratory testing, and the need for additional diagnostic testing should be reviewed in detail with the patient and his partner, and if indicated, appropriate referrals should be made. Patient and partner education not only facilitates physician-patient-partner communication it enhances patient compliance and treatment adherence.

Specialized Diagnostic Testing

The introduction of sildenafil in 1998 dramatically changed the need for specialized testing. Diagnostic modalities such as duplex Doppler ultrasound, cavernosometry, caversonography, and selective pudendal arteriogram expand the physician's and patient's understanding of the pathophysiologic mechanisms, but disadvantages such as invasiveness, cost, and the associated risks and complications have reduced the indications for specialized testing.

Nocturnal penile tumescence testing is one of the most common specialized diagnostic tests performed today, but its ability to evaluate axial rigidity is poor. The use of this popular diagnostic tool should be limited to the discrimination between organic and psychogenic ED (114).

Penile biothesiometry, a noninvasive specialized diagnostic modality that measures vibratory thresholds, provides further understanding of the somatosensory pathway and has proved helpful in the management of diabetic patients with ED.

Noninvasive and invasive vascular testing of diabetic patients with ED has been reported in numerous series (115,116). These include office intracavernosal injection testing, duplex Doppler ultrasound, studies of the penile brachial index, penile plethysmography, cavernosal artery systolic occlusion pressure in the erect state, recordings of the change in the diameter of the cavernosal artery in the flaccid and erect state, and selective internal pudendal arteriography in the erect state. The incidence of suspected vascular pathology by such vascular testing is 33% to 87% (4).

59: ERECTILE DYSFUNCTION AND DIABETES 1007

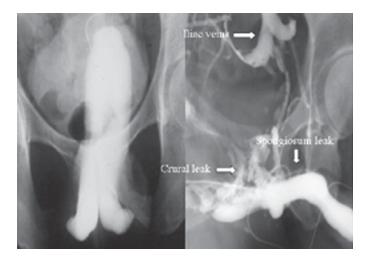

Figure 59.4. Pharmacocavernosography following administration of intracavernosal vasoactive agents in an impotent nondiabetic patient with normal corporal veno-occlusion (**left**) and in an impotent diabetic patient with abnormal "diffuse" corporal veno-occlusion (**right**). In the nondiabetic patient, no veins draining the corporal body are visualized. In the diabetic patient, numerous veins draining the corporal body are visualized.

Pharmacocavernosography of diabetic men with ED typically shows a diffuse pattern of venous leaking (50,117,118), including the dorsal, cavernosal and crural veins; corpus spongiosum; and glans penis. It has been inferred from the diffuse pattern of abnormal vein visualization seen in patients with diabetes that the primary basis of the pathology is a pancavernosal pathosis such as poor compliance or abnormal smooth muscle function (Fig. 59.4). The diffuse diabetic pattern is different from the pharmacocavernosographic pattern of abnormal visualization of veins in impotent patients with Peyronie disease (119), following trauma (50), or as a consequence of a penile fracture (120). The focal cavernosal pathology of these latter disorders is reflected by the focal site-specific abnormalities seen on pharmacocavernosography.

Indications for Referral

Primary care physicians should manage the vast majority of patients with ED. However, there are several indications for referrals:

- 1. Young patients with presumed pure cavernosal artery insufficiency secondary to pelvic/perineal trauma. These patients may be candidates for curative vascular reconstruction.
- 2. Patients with significant penile curvature (e.g., Peyronie disease or congenital penile deformity). Surgical correction may be necessary to facilitate sexual intercourse.
- 3. Patients with aortic aneurysm or bulbosacral disc disease that requires vascular or neurosurgical intervention.
- Patients with complicated endocrinopathies such as hypogonadism and pituitary adenoma.
- Patients with complicated psychiatric or psychosexual disorders (e.g., refractory depression, and transsexualism).
- 6. Patient or physician request for specialized evaluation.
- 7. Medical or legal reasons (occupational or iatrogenic injuries).

Modifying Reversible Causes

Health professionals should work with patients to modify reversible causes of ED such as psychogenic ED, hypogonadism, hyperprolactinemia, specific drug-related ED, and cavernosal artery insufficiency secondary to blunt perineal trauma.

Diabetic men with ED who are determined to be hypogonadotropic on the basis of several repeat determinations of low serum testosterone levels in early morning specimens should receive hormonal therapy. In these cases, testosterone replacement is used to maintain normal serum levels of testosterone and to restore potency and libido. Because of the relatively unpredictable serum levels of testosterone obtained following oral administration of testosterone and its poor efficacy and associated hepatic side effects (121), testosterone enanthate administered intramuscularly in doses of 200 to 300 mg every 2 to 3 weeks is preferred. The amount and frequency of administration will vary with the individual and can be titrated (122). Newer topical preparations (patch or gel) are better tolerated and more efficacious and have a significantly better side effect profile.

Testosterone may induce a marked increase in libido without exerting a positive effect on erectile capabilities in patients with diabetes who do not have hypogonadal disorders. Testosterone is contraindicated in patients with adenocarcinoma of the prostate, because testosterone may increase the rate of growth of the adenocarcinoma of the prostate (123). In addition, testosterone replacement should be used with caution in patients with a history of bladder outlet obstruction or with coronary artery disease.

Before testosterone replacement therapy is initiated, it is recommended that a digital rectal examination be performed and that determinations of serum levels of PSA, liver function, and lipid profile be carried out. This practice should be repeated regularly.

The treatment of hyperprolactinemia in patients with diabetes consists of (a) the cessation of medication causing hyperprolactinemia (e.g., estrogens, α -methyldopa), (b) the administration of bromocriptine, or (c) the surgical ablation or extirpation of a pituitary prolactin-secreting tumor. Treatment with exogenous testosterone to supplement the diminished levels of serum testosterone usually seen with this disorder does not appear to reverse the ED (124,125).

Sexual therapy alone or in conjunction with therapy with vasoactive agents has been proven efficacious in the treatment of psychogenic ED.

Thiazide diuretics and β -blockers are the antihypertensive agents most commonly associated with ED. α -Adrenergic blockers are perhaps least likely to cause erectile difficulties. Digoxin, a Na⁺-K⁺-ATPase inhibitor, appears to be commonly associated with ED. Psychotropic agents such as SSRIs, neuroleptics, and antipsychotics, have been associated with ED and with ejaculatory, orgasmic, and sexual desire difficulties. Luteinizing hormone–releasing hormone agonists and antiandrogens, commonly used in the treatment of advanced prostate carcinoma, also are associated with ED and diminished sexual desire.

Patients with destructive behaviors, alcoholism, cigarette smoking, and recreational drug use should be counseled on the potential etiologic role of these factors in ED.

Pure cavernosal artery insufficiency, secondary to blunt perineal trauma, is a reversible cause of ED. In consequence, a small and selected group of young patients may benefit from microvascular arterial bypass surgery, which was introduced in the early 1970s. The aim of arterial reconstructive surgery for impotence is to increase blood flow to the penis by bypassing arterial obstruction. These procedures showed that bringing a new source of blood to the corporal tissue could restore potency.

Contemporary procedures of penile microvascular arterial bypass surgery involve anastomosis of the inferior epigastric

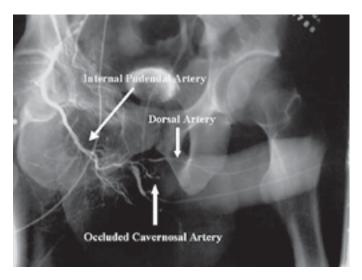

Figure 59.5. Selective internal pudendal arteriograms showing a focal cavernosal artery occlusion at the level of the Alcock canal.

artery to a dorsal artery (126). It appears that patient selection for these procedures is most critical and strongly influences the results of the surgery. The best candidates appear to be younger men with discrete lesions in the pudendal artery, the common penile artery, or both as a result of pelvic or perineal trauma (Fig. 59.5), rather than older men with more generalized arteriosclerotic occlusive disease involving the hypogastric system (126–128). Surgical technique and adherence to principles of vascular and microvascular surgery, especially those that result in preservation of endothelium, are also essential for anastomotic patency.

Patients with diabetes are thus only rarely considered good candidates for this procedure. Those who are considered should have undergone duplex Doppler ultrasound, as well as dynamic infusion cavernosometry caversonography (invasive diagnostic modality that provides quantitative assessment of the cavernosal arterial system and the veno-occlusive mechanism) and selective internal pudendal arteriography.

FIRST-LINE THERAPY

First-line interventions, characterized by ease of administration, reversibility, noninvasive nature, and low cost, include oral erectogenic agents (e.g., sildenafil, apomorphine, oral phentolamine), vacuum erection devices, and psychosexual or couples therapy.

Oral Erectogenic Agents

The introduction of *sildenafil* in 1998 revolutionized the management of men with ED (38). Sildenafil not only has allowed patients and health care professionals to openly discuss human sexuality it has also increased the number of patients using other therapeutic modalities, such as intracavernosal injections and penile prostheses.

Sildenafil, a potent (50% inhibitory concentration $[IC_{50}] = 3.5$ nM) and selective inhibitor of phosphodiesterase type 5 (PDE 5), which blocks the hydrolysis of cGMP, enhances the accumulation of cGMP, and potentiates the relaxant effects of NO. The absorption of this drug is rapid, and the availability is 40% after oral administration. Peak of plasma concentration is 30 to 120 minutes, with a mean of 60 minutes (129,130). Fatty foods decrease

the maximal concentration to 29% (129,131). Sildenafil is metabolized in the liver by the cytochrome P450 and is excreted in feces (80%) and urine (13%) (129,131). Sildenafil is used on demand (prn), and the recommended initial dose is 50 mg taken 1 hour before sexual activity. The dose can be adjusted based on efficacy and tolerability. The maximum recommended dose is 100 mg, no more than once per day, independent of the dosage used. In general terms, the vast majority of patients (75%) use 100 mg, and only 2% of patients use 25 mg (38). The initial dose in patients older than 65 years of age, in patients with renal or liver insufficiency, or in patients receiving drugs that inhibit cytochrome P450 (erythromycin, cimetidine) is 25 mg.

Sildenafil is contraindicated in patients taking nitroglycerine. The most recent package label update recommended use of sildenafil under careful medical supervision, in patients who have suffered a cardiovascular accident, myocardial infarction, or severe arrhythmia within the previous 6 months; or in patients with hypotension (< 90/50 mm Hg), severe hypertension (> 170/110 mm Hg), cardiac insufficiency, unstable angina, or retinitis pigmentosa. The American College of Cardiologists and the American Heart Association (ACC/AHA) also recommended the use of sildenafil with caution in patients receiving complex antihypertensive regimens; with coronary artery disease, borderline blood pressure, or renal or liver insufficiency; or who use drugs that inhibit cytochrome P450 (130).

The rate of discontinuation of this agent is extremely low (0.4% to 1.2%) (132), most likely because of its low side effect profile and high efficacy. The most common side effects of sildenafil are headaches (16%), facial flushing (10%), dyspepsia (7%), nasal congestion (4%), and diarrhea (3%) (131). In addition, at the 100-mg dose, 2% to 3% of men may experience transient alterations in color vision.

Sildenafil is effective in treating ED caused by many different factors (133–136), including diabetes. Recently, a study of 268 diabetic patients (type 1, 21%; type 2, 79%) showed that sildenafil improved erectile function in 57% of patients, compared with 10% in the placebo group, with a successful rate of sexual activity of 48% versus 12% for the placebo group (137).

Yohimbine hydrochloride, an α_2 -adrenergic blocking agent, has long been considered an aphrodisiac. Reports of its efficacy in ED were first published 30 years ago (138). In a prospective, doubleblind, placebo-controlled study in patients with predominantly organic disease, including patients with diabetes-related impotence, the rate of response to yohimbine was not statistically increased over that to placebo. However, 21% of the patients who received yohimbine achieved a complete response (139,140).

Phentolamine is an α_1 - and α_2 -adrenergic antagonist that decreases adrenergic tone, thus facilitating erectile function and delaying detumescence. Oral phentolamine is absorbed rapidly, with the peak plasma concentrations achieved in 30 to 60 minutes and a half-life of 5 to 7 hours (141). A prospective, doubleblind, and placebo-controlled efficacy and safety trial of oral phentolamine (60 mg) reported a 36.7% success rate compared with 13.4% for placebo (142). The most common side effects were nasal congestion (10%), headache (3%), dizziness (3%), tachycardia (3%), and nausea (1%) (141). This moderately efficacious drug has recently been recently withdrawn from FDA review, but it is available in some countries in Europe and Central and South America.

Apomorphine is a central dopamine agonist known to induce mild to moderate penile erection in men (143). When administered sublingually, apomorphine has a very rapid rate of absorption and onset of action (20–30 minutes). Two recent phase 3 clinical trials involving 977 men with mild to moderate ED treated with sublingual apomorphine reported the achievement of erections firm enough for sexual intercourse (144). However, significant side effects such as nausea (25%–44%), headache (12%–19%), dizziness (5%–16%), and yawning (10%–16%) were reported during the first 4 weeks of treatment. In addition, occasional episodes of syncope at the higher doses (5–6 mg) also were noted. The efficacy and tolerability of apomorphine in diabetic patients with ED was evaluated in a multicenter, double-blind, crossover study (145). The percentage of attempts resulting in erections firm enough for sexual intercourse varied from 18% to 45% compared with 18% to 26% for placebo. The most common side effect was nausea (16%) with doses of 2, 4, 5, or 6 mg. Despite a significant placebo effect, the investigators concluded that apomorphine is an efficacious and safe treatment for ED in patients with diabetes. Apomorphine HCL has recently been withdrawn from FDA review.

Vardenafil, a potent (IC₅₀ 0.7 nM) and selective PDE 5 inhibitor, is currently in clinical trials. Preliminary reports of a multicenter, randomized, double-blind, placebo-controlled phase 3 trial in patients with diabetes mellitus and ED showed a statistically significant improvement in the rate of erection of 72% for the 20-mg group compared with the placebo group (P < .0001). Vardenafil also improved IIEF (International Index of Erectile Function) scores and rates of successful penetration when compared with those for placebo (P < .0001). The success rates were dose-related and the side effects generally mild or moderate.

Cialis is also a potent and selective PDE 5 inhibitor, but it has a long half-life. A European multicenter, double blind, placebocontrolled study to assess the efficacy and safety of daily Cialis in men with mild to moderate ED (n = 294) showed statistically significant increases in all domain scores of the IIEF ($P \le .002$) (146). Responses to IIEF question 3 and question 4 were significantly increased with all doses of Cialis compared with placebo (P = .001). Both the percentage of successful intercourse attempts and the number of satisfying intercourse attempts were increased with Cialis. It was well tolerated with no significant changes in blood pressure, laboratory values, or electrocardiogram. The most common adverse events were headache, back pain, myalgia, and dyspepsia. Interestingly, no color vision alterations were observed.

Protein kinase C b inhibitors are being studied as possible agents for treatment of ED. It has been postulated that activation of PKC-β may be responsible for the deleterious effects of hyperglycemia on neurovascular structure and function. Some of the physiopathologic mechanisms involve decreased NO activity, enhanced expression of TGF-β, and modulation of VEGF/VPF signal transduction. In preclinical models of diabetes, inhibitors of PKC-β prevented or reversed hyperglycemia-induced vascular and neurogenic dysfunction (66). A phase 3 study of efficacy of a PKC-β inhibitor in males with diabetes and ED is ongoing.

The simplicity, noninvasiveness, and safety of topical administration make vasoactive agents ideal for the treatment of patients with sexual dysfunction. Recently, a double-blind, placebo-controlled study of *Topiglan* (1% alprostadil in a formulation with 5% SEPA [soft enhancer of percutaneous absorption]) reported significant changes in penile rigidity with minimal side effects (skin erythema, mild warmth or burning) when applied to the glans penis in patients with mild to moderate ED in an office-based setting (147). In contrast, when Topiglan is applied to the entire penis, the rates of penile erythema and discomfort were higher. Further research is needed before this agent can be established as a first-line therapy agent.

Vacuum Constrictive Devices

The use of vacuum constrictive devices, a well-established noninvasive first-line therapy recently approved by the FDA for

over-the-counter distribution, is a viable therapeutic option for diabetic patients with ED because of the absence of significant complications associated with the use of these devices and their high degree of acceptance among patients who elect to use them (148-150). A variety of external penile appliances are now available for the management of diabetic impotence. The majority have three common components: a vacuum chamber, a vacuum pump that creates negative pressure within the chamber, and a constrictor or tension band that is applied to the base of the penis after erection is achieved. While standing, the patient places his penis in the chamber, which is attached to a pump mechanism that can produce a negative pressure within the chamber. The negative pressure draws blood into the penis to produce an erection-like state. When adequate tumescence and rigidity have been achieved, the patient transfers a constrictor band at the base of the chamber to the base of the penis, thereby "trapping" blood within the penis (Fig. 59.6).

Vacuum-induced erection is significantly different from a physiologically induced erection. The latter is achieved by the initial relaxation of the corporal smooth musculature, thus allowing for engorgement of blood into the lacunar spaces. With vacuum-induced erection, corporal smooth muscle relaxation does not occur initially and blood is simply trapped in both the intracorporeal and extracorporeal compartments of the

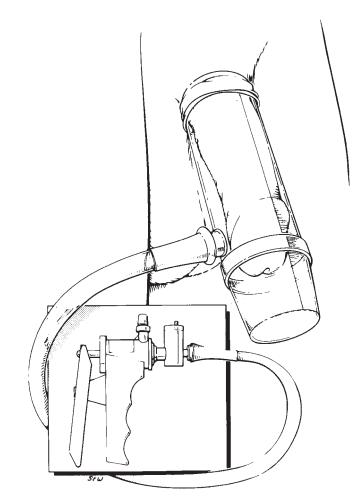

Figure 59.6. Although many different devices are manufactured, the majority have three components in common: a vacuum chamber, a vacuum pump that creates negative pressure within the chamber, and a constrictor or tension band that is applied to the base of the penis after erection is achieved.

1010 JOSLIN'S DIABETES MELLITUS

penis. Venous stasis and decreased arterial inflow are observed from the constricting band at the base of the penis to the glans penis distally. This may result in penile distension, edema, and cyanosis if the device is used for too long. In most cases, manufacturers recommend that the vacuum-induced erection be maintained for less than 30 minutes. Second, a physiologically induced erection will cause rigidity along the entire length of the corpora, whereas a vacuum-induced erection causes rigidity only distal to the constricting band, permitting the penis to pivot at its base.

In monkeys, increases in cross-sectional corporal area secondary to vacuum-induced erections were found to be only 50% of those induced by intracavernosal papaverine (see below). This limited corporal expansion may be secondary to the continued smooth muscle contraction of the corpora (151). In humans, vacuum constrictive devices may induce an expansion of penile diameter equal to or greater than that attained during a physiologically induced erection, presumably secondary to the entrapment of blood in extracorporeal tissues. Venous drainage from the corpora proximal to the constrictor device is not altered (152).

Theoretically, in almost all men with ED, the vacuum constrictor devices should create penile rigidity sufficient for vaginal penetration. Men with diabetic ED who have had a penile prosthesis explanted may also be treated successfully with a vacuum constrictor device (153). However, patients with significant intracorporeal scarring, such as those with severe Peyronie disease, after priapism, or previously infected penile implants, may not be able to develop adequate rigidity. Patients who do not obtain sufficient penile rigidity with intracavernosal pharmacotherapy alone could be candidates for a vacuum constrictor device used in conjunction with self-injection therapy.

To date the complications from the use of these devices have been minor and self-limited (148–150,154). They have included difficulty with ejaculation, penile pain, ecchymoses, hematomas, and petechiae. Patients taking aspirin or warfarin are more likely to develop vascular complications. Many of the devices manufactured have a valve that limits the vacuum pressure (<250 mm Hg), a feature that might decrease the complication rate. Patient acceptance and satisfaction with vacuum constrictive devices in all types of impotence, including diabetic impotence, has been reported to be 68% to 83%. The reasons for discontinuation of this treatment have included premature loss of penile tumescence and rigidity, penile pain, pain during ejaculation, and inconvenience (155).

Sexual Therapy: Individual or Couples

Sexual therapy addressing relationship distress, sexual performance concerns, and dysfunctional communication patterns is likely to enhance sexual functioning. It is recommended that both patient and partner participate in the sexual therapy.

Sexual therapy is also indicated and beneficial in patients or couples who desire to resume sexual activity after a prolonged period of abstinence. Last, sexual therapy is effective in addressing psychological reactions to the medical or surgical treatment.

SECOND-LINE THERAPY

Second-line therapy is indicated in cases of partial or minimal response to first-line therapy or when the associated side effects are not well tolerated. In addition, a small group of patients may prefer more invasive but efficacious or reliable therapies.

Intraurethral Alprostadil

Intraurethral alprostadil, an FDA-approved medication for the treatment of men with ED, is shaped in the form of a semisolid pellet. This compound is the same as that used for intracavernosal injection, but the doses required are significantly larger (125–1,000 μ g). A double-blind, placebo-controlled study of 1,511 men, 27 to 88 years of age, with ED of various etiologies showed that, when tested in an office setting, 65.9% of patients had erections sufficient for intercourse, and that 50% achieved successful intercourse in the home situation (156). The most common side effect was penile pain (10.8%), with hypotension-related symptoms the next most common (3.3%). No patients had priapism or penile fibrosis. Intraurethral application of alprostadil is a relatively safe and moderately effective second-line therapy for the treatment of ED.

Intracavernosal Self-Injection

One of the most important advances in the treatment of impotence during the past decade has been that of self-administration by intracavernosal injection of vasoactive agents that either relax the corporal smooth musculature directly or block adrenergic tone of the corporal smooth muscle (157). The pioneering work in this area involved the use of papaverine hydrochloride (158), a direct smooth-muscle relaxant, or phenoxybenzamine (159) or phentolamine mesylate (160), both α -adrenergic blocking agents. As the clinical use of these agents became more widespread, several issues became apparent. Intracavernosal injection of phentolamine alone was not as effective as injection of papaverine in producing an erection. In addition, injection of papaverine alone was not as effective as injection of papaverine and phentolamine together. More recently, the FDA approved two synthetic formulations of PGE1: alprostadil sterile powder and alprostadil alfadex for intracavernosal administration. They are identical with respect to pharmacology, efficacy, and safety. The majority of responders (85%) required 20 µg or less. A variety of solutions containing the above agents are presently being used in clinical practice (161,162).

The mechanism of action of papaverine hydrochloride and prostaglandin El (PGE₁) is that of direct relaxation of smooth muscle. Therefore, injected intracavernosally, they will maximize arterial inflow as well as corporal veno-occlusion by relaxing the arterial and trabecular smooth musculature, respectively. Phentolamine, on the other hand, blocks adrenergically induced muscle tone and therefore does not, by itself, initiate erections but does prolong the erectile response (163).

Intracavernosal injections will work best in patients with diabetic ED whose arterial inflow and corporal veno-occlusion mechanism are normal. These would include diabetic patients with purely neurogenic ED or those with psychogenic impotence. Patients with diabetic ED caused by arterial insufficiency also may respond by virtue of the long-acting and maximal dilator effects provided by this therapy. Diabetic patients with ED caused by significant corporal veno-occlusive dysfunction, however, would be those least likely to respond to such therapy (164).

In general, intracavernosal pharmacotherapy, like vacuum constrictor therapy, can be offered to most patients with organic diabetic impotence. Those diabetic patients with poor manual dexterity, poor visual acuity, morbid obesity, or for whom a transient hypotensive episode may have deleterious consequences (e.g., patients with unstable cardiovascular disease and transient ischemic attacks) should be offered this option only after careful consideration. Diabetic patients taking aspirin or warfarin have been treated successfully with intracavernosal injections. Patients with significant psychiatric disease or who might misuse or abuse this therapy should be excluded from treatment. Once patients are offered intracavernosal pharmacotherapy, they should be informed of the risks and complications of this form of therapy and informed that it will not affect orgasm or ejaculation and that it is used solely for restoration of erectile capabilities. The usual therapeutic goal is for the patient to achieve a rigid erection lasting 30 minutes to 1 hour that is rigid enough for satisfactory vaginal penetration (164).

Diabetic patients who enter a program for pharmacologic treatment of inadequate erectile response should first be asked to read and sign a detailed informed-consent form that clearly states the known complications of this treatment and discusses the possibility of long-term side effects. A dosage-determination phase defines the lowest dose required for the achievement of an appropriate erectile response. Diabetic patients with purely neurogenic ED would first be given an extremely low dose since they are the patients most likely to respond. Patients with vascular disease will usually start with a higher dose, which is subsequently increased by increments. To minimize pain and bleeding, an insulin syringe with a 27- to 30-gauge needle usually is used. Patients also are taught to compress the site of injection for 3 minutes following injection. After an appropriate dose has been determined, the patient is instructed in proper injection techniques. When patients are in the more sexually stimulating home environment, it is very common for them to decrease the dose from that determined in the office. The patient also is instructed in sterile technique. Patients are told not to administer an injection more frequently than once a day.

Follow-up information has been obtained on approximately 4,000 impotent patients throughout the world, including many with diabetic impotence, who have been treated with papaverine alone or in combination with phentolamine (165). Reported side effects have included hematomas, burning pain after injection, urethral damage, cavernositis or local infections, fibrotic changes of the corpora cavernosa, curvature, and prolonged erections or priapism. Cavernositis or infection has been extremely rare. Burning pain at the time of injection has been most common with PGE₁ and appears to be less of a problem when PGE₁ is mixed with other agents. Hematomas were noted in a small percentage of patients undergoing self-injection therapy; these usually resolve within a few days without any permanent sequelae.

The two most important complications are prolonged erections and localized fibrotic changes of the corpora cavernosum. Prolonged erections usually occur during the dosage-determination phase and have been reported in 2.3% to 15% of all patients treated. Patients must be cautioned to call their physician if an erection persists for 4 hours or longer. In the majority of patients, detumescence of these prolonged erections will occur without medical intervention; however, some patients will require an intracavernosal injection of an α-adrenergic agonist such as epinephrine, phenylephrine, or metaraminol. An initial intracavernosal injection of 200 µg of phenylephrine has been successful and may be repeated as necessary until detumescence (166). Following the dosage-determination phase, the complication of prolonged erection is quite rare (less than 1% of injections) and, if treated according to the protocol described previously, should not produce any permanent sequelae.

The most frequent side effect (reported in 1.5% to 60% of patients treated for 1 year) of intracavernosal pharmacologic therapy is the formation of painless fibrotic nodules within the corpora cavernosa, which sometimes leads to penile curvature. In one series, the development of fibrotic nodules was related to the frequency of injection and the duration of treatment (166). The complications of corporal fibrosis and prolonged erections

have been seen less frequently in men treated with PGE₁ alone. We feel that the formation of cavernosal fibrotic nodules is to some extent secondary to trauma and bleeding within the corpus and for this reason stress the importance of application of compression over the injection site for 3 minutes.

In addition, attempts to decrease the amount of fluid injected are encouraged. The goal of therapy is the injection of less than 0.5 mL of drug mixture intracavernosally. Diabetic patients injecting 1 mL or more of the papaverine and phentolamine mixture can reduce this volume by adding PGE₁—thus the use of a three-drug mixture.

There have been several cases of diffuse fibrosis of the corpora following intracavernosal injections. These have almost invariably been associated with the development of ischemic priapism. Theoretically, these patients should not respond to intracavernosal therapy, but there are several reports in the literature that documented successful treatment of ED due to corporal fibrosis with intracavernosal injection of a combination of papaverine and phentolamine (168). Therefore, the degree of corporal scarring and fibrosis required to obviate the positive results of intracavernosal pharmacotherapy has not been determined.

Systemic side effects of this treatment have included vasovagal episodes and syncope, which are probably related to hypotension. These side effects are infrequent and usually occur during the dosage-determination phase. It would be expected that diabetic patients with significant corporal veno-occlusive dysfunction would exhibit an increase in systemic distribution of intracavernosal agents and therefore be more susceptible to this side effect. As mentioned previously, diabetic patients for whom transient hypotensive episodes may have significant deleterious effects should be carefully evaluated before receiving this therapy. Intracavernosal pharmacotherapy with papaverine has been associated with hepatotoxicity. In the first 201 patients we treated, only three cases (1.5%) of abnormal liver function tests were reported during a mean follow-up period of 26 months (166). Others have seen essentially no changes in liver function during this therapy, while one series reported at least one chemical abnormality of liver function in 40% of patients.

Forskolin, a naturally occurring alkaloid that directly activates the catalytic domain of adenylate cyclase, has demonstrated efficacy as an auxiliary vasoactive agent in a preliminary study of patients who had previously failed high-volume, highconcentration injection therapy (169). Forskolin is especially useful in patients with diabetes or post-radical prostatectomy ED who develop significant corporal pain with the use of intracavernosal PGE₁ as FDA-approved Caverject and EDEX or as standard three-agent pharmacotherapy (papaverine, phentolamine, and PGE₁). The mechanism of PGE₁-induced pain in such patients is related, in part, to the development of diabetic or postoperative penile autonomic neuropathy, lowering the threshold of nociceptive (pain) nerve fibers to mechanical stimulation causing a hyperalgic effect. Preliminary reports on the use of intracavernosal forskolin, papaverine, and phentolamine as a salvage tri-mix in the management of post-radical prostatectomy ED when PGE₁ alone or standard three-agent pharmacotherapy results in clinically significant penile pain showed that 83% of patients had satisfactory and sustained axial rigidity for sexual intercourse. None of these patients experienced corporal pain.

Although penile self-injection therapy is highly effective (70%–90%), the average dropout rate is 64% (range, 46%–80%) (170,171). A recent study demonstrated that keeping the cost of therapy low and ensuring patient and partner education and continued support throughout treatment reduces dropout rates (172).

THIRD-LINE THERAPY

Surgical Prostheses

Third-line treatment interventions are highly invasive, irreversible, and associated with multiple devastating complications such as device infection, erosion, and malfunction. Penile prostheses should be viewed only as a last-resort therapy in patients with treatment-refractory ED. Despite their significant cost and potential invasiveness, penile prostheses have been associated with high rates of patient satisfaction in several studies.

The urologic subspecialty of ED developed in the early 1970s, following the development of an intracorporeal penile prosthesis by Small and Carrion (173) and Scott et al. (174). Through the 1970s and early 1980s, the development of penile prostheses proceeded along two distinct lines: the malleable or rigid prosthesis and the multicomponent inflatable prosthesis. Self-contained inflatable devices were introduced more recently. Last, modifications of the three-piece inflatable device subsequently led to the introduction of a two-piece inflatable device.

Initially, the postoperative complication rate following placement of malleable devices was relatively low and implantation was relatively simple. Therefore, the rates of component failure and re-operation were kept to a minimum. With these devices, the length and girth of the penis do not change in the "tumescent" and "detumescent" phases, which at times results in an aesthetically less desirable "tumescent" phase. The inflatable devices, unlike the malleable devices, are based on hydraulic principles, thus allowing the patient to inflate and deflate the device to simulate tumescent and nontumescent phases. This provided an improved aesthetic result, especially in the "detumescent" phase, but initially was coupled with a relative increase in component failure and reoperation. Activation of the multicomponent inflatable device allows for an increase in penile girth during the "tumescent" phase (50).

Subsequent improvements of inflatable devices have markedly reduced the likelihood of re-operation and component failure (Fig. 59.7). Self-contained inflatable devices have been designed to preserve the aesthetic qualities of an inflatable device and combine them with ease of surgical implantation and a potential decrease in component failure. Further ease of implantation of an inflatable device was attained with the introduction of two-piece inflatable devices. The second- and thirdgeneration prostheses have been designed to increase aesthetic results, increase penile girth at times, decrease the likelihood for component failure, and, when possible, facilitate implantation.

Contemporary data indicate that surgical success with inflatable penile prosthesis is 95% to 97% (175,176), but surgical success does not always represent patient satisfaction. To answer this important question, we performed a phase 2, multiinstitutional, large-scale, retrospective study, with independently analyzed medical records and questionnaire data from consecutive eligible patients of seven physician investigators (177). Among those who returned the questionnaire, 89% of patients with Mentor Alpha-1 answered that it fulfilled their expectations as a therapy for ED, including 28% who claimed fulfillment as expected, 31% better than expected, and 30% much better than expected. Satisfaction responses of 80% or greater were noted with regard to intercourse ability and confidence, device rigidity, and function. Interestingly, implantation of inflatable penile prosthesis did not result in 80% or greater satisfaction responses in changes in partner relationship (as judged by the patient), feelings of the partner about the relationship (as judged by the patient), or increased confidence in social activities and work. Such information is important when providing preoperative

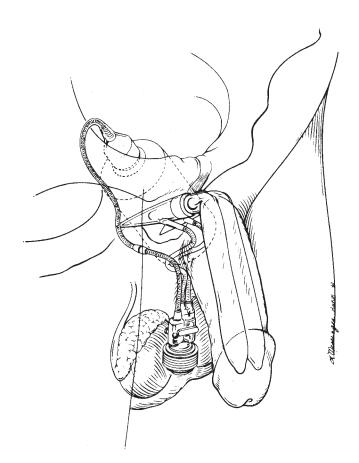

Figure 59.7. Inflatable devices are based on hydraulic principles, thus allowing the patient to inflate and deflate the device to simulate tumescent and nontumescent phases. The multicomponent device depicted, a Mentor Alpha-1, allows for an increase in penile girth during the simulated tumescent phase. The three components consist of a reservoir placed in the retropubic space, two penile cylinders placed in the corpora cavernosa, and a pump apparatus with inflate and deflate mechanisms placed in the scrotum. The advantage of this device is its lack of connectors or connector components between the pump and the cylinders, the known high-pressure portion of a hydraulic device.

counseling to patients so that postoperative expectations will be appropriate.

With the advent of newer and more effective first- and second-line therapies such as sildenafil, intracavernosal pharmacotherapy, and vacuum erection devices, many physicians now consider the implantation of a penile prosthesis the last treatment option for ED. Thus, penile implantation is offered to diabetic patients with organic impotence after other, nonsurgical, forms of therapy have been attempted and failed. Patients whose ED is thought to be psychogenic, who have not responded to appropriate psychological or behavioral sex therapy, and who have no psychological contraindications for therapy may be treated in the same manner.

Certainly, appropriate counseling of diabetic patients before implantation of a prosthesis is essential to the success of this surgery. The purpose of the prosthesis is to simulate an erection by providing penile rigidity sufficient for intercourse. The ability of the patient to ejaculate and have an orgasm is not altered by the implantation of a prosthesis but in some cases may be restored. In addition, diabetic patients undergoing the surgery should be informed of the potential complications of prosthetic surgery, as well as of their consequences and sequelae. The postoperative complications of penile implant surgery usually are relegated to those of component failure, postoperative infec-

tion, or device erosion. Probably the most significant complication of prosthetic surgery is infection. The best defense against infection is prophylaxis. We request that patients scrub their genitalia and perineum for 10 minutes each day for 7 days with chlorhexidine digluconate soap (e.g., Hibiclens), before the surgery (50). In addition, oral quinolones are prescribed for 3 days before the surgery. Patients also are given intravenous perioperative antibiotics (vancomycin and gentamicin), and surgical technique must be meticulous. The incidence of infections following penile prosthetic surgery ranges between 1% and 9% (178).

Following implantation, the time frame for the presentation of infection will vary depending on the organism involved. Infections with more virulent and aggressive bacteria will usually present within the first few postoperative days, with the patient presenting with fever, pain, and swelling overlying the prosthesis accompanied by purulent wound drainage. However, a group of patients will complain of prolonged pain overlying the device but will have not obvious purulent drainage from the wound. Prolonged pain, fixation of the pump or tubing to the overlying scrotal skin, elevated white blood cell count and sedimentation rate, and hyperglycemia in diabetic patients may all be helpful in diagnosing a possible infection by less virulent organisms. Duplex Doppler ultrasound may also be helpful in cases in which clinical findings are not conclusive (179).

The re-operative rate for penile prosthetic surgery has been reported to be between 3% and 44%, with newer series showing a markedly lower rate (180). Penile prostheses have been accepted by patients and physicians worldwide, with over 80% of patients reporting satisfaction after prosthetic surgery (50).

Should penile prosthesis insertion be indicated, the Mentor alpha-1 inflatable penile prosthesis is the device that provides the widest diameter penile erection during inflation and the lowest mechanical failure rate (1.3%). The Bioflex material has an increased abrasion resistance and higher tensile strength than do silicone-based devices. The superior outcome data in terms of mechanical reliability have remained durable over the past 10 years.

Venous Surgery

At present, most diabetic patients who show evidence of corporal veno-occlusive dysfunction by pharmacocavernosometry and cavernosography should not be considered for surgical and/or radiologic options to increase venous outflow resistance (181,182). In diabetic patients, the dysfunction may be related to a pancavernosal alteration in corporal tissue compliance. In such patients, cavernosography may reveal a more generalized corporal veno-occlusive dysfunction with visualization of the glans, corpus spongiosum, dorsal vein, and cavernosal vein. The available procedures (crural plication, ligation, or excision of the deep dorsal vein of the penis; ligation of cavernosal veins; spongiolysis; or a combination of the above, including the radiologic administration of coils or sclerosing agents), have not demonstrated long-term success in impotent diabetic patients (181,182). Complications reported from the various procedures, especially those involving proximal penile dissection, include diminished penile sensation and shortened penile length.

GENERAL CARE OF THE DIABETIC PATIENT WITH REGARD TO INFECTION AND IMMUNIZATION 1029

Immunizations 1029 Perioperative Glucose Control 1030

It is commonly believed that the incidence of infection is higher in persons with diabetes mellitus and that such infections result in complications and death more frequently than would be anticipated in otherwise healthy individuals (1,2). Older studies, upon which much of this information is based, focus particularly on infections of the urinary tract, the respiratory tree, and the extremities and derive their data from autopsy cases. However, in these studies the degree to which infection at these sites actually contributed to the cause of death is frequently not clear, and control groups are typically lacking. More recent studies, while documenting excess mortality among patients with diabetes, have ascribed this largely to cardiovascular disease rather than to uncontrolled infection (3,4).

In diabetes mellitus, a number of factors greatly complicate efforts to assess risk of infection and resulting complications. The most basic is the problem of determining an appropriate estimate of the population at risk, which may be difficult to obtain for diabetes and is rarely if ever presented. Furthermore, in diabetes, as in other chronic diseases in which the natural history for any individual may span decades, historical controls are of limited utility, given the expected improvements in the general health of a population, the development of more effective diagnostic techniques, earlier medical intervention, and the availability of expanded therapeutic options, including more active and better tolerated antimicrobial agents. A number of variables, including duration of illness, severity of noninfectious complications, concurrent illnesses, level of glucose control, and even degree of medical supervision, result in a very heterogeneous group of individuals at risk even within a more narrowly defined time frame. Finally, some infections that may be particular to diabetics, such as emphysematous cholecystitis, are so uncommon that information regarding risk factors and management options is limited.

Despite these limitations, much is known both about those uncommon infections that occur predominantly in patients with diabetes mellitus and about the more common infections that, while not restricted to those with diabetes, will often complicate the general management of this group of patients. To acknowledge such limitations in advance is to underscore the need for careful individualization in the approach to diagnosis and therapy for any diabetic patient with suspected or proven infection.

DIABETES AND THE IMMUNE SYSTEM

Defining altered host responses in diabetes has long been hampered both by the complexity of the systems in question and by

1018 JOSLIN'S DIABETES MELLITUS

the rather limited availability of techniques to study these responses. In vivo the various arms of the immune system are highly dynamic and interdependent. It is thus simplistic to study any single component of it in vacuo. Historically, however, methodologic constraints did in fact limit such studies to individual aspects of host defenses, such as leukocyte adherence or phagocytosis, exclusive of other components of the system. Even more recent has been the increase in the appreciation of complex interactions, not only among the various cellular elements of the immune system itself but also among the elements of the immune system and other body components such as the vascular endothelium. As the approaches to the investigation of these issues evolve, it becomes increasingly more difficult to compare studies. It is for these reasons that, even after decades of investigation, questions remain about whether diabetes itself results in specific immunologic defects and how such defects might predispose to infection (5).

Function of Polymorphonuclear Leukocytes

MOBILIZATION AND CHEMOTAXIS

Using the Rebuck skin window technique, which was to remain the standard for many years, Perillie et al. (6) studied polymorphonuclear leukocyte (PMN) chemotaxis in ten patients with well-controlled diabetes, six patients with diabetic ketoacidosis, four patients with nondiabetic uremic acidosis, and ten healthy controls. An abrasion was created on the volar forearm, and sterile coverslips were serially applied over the next several hours. Mobilization of PMNs to the area of inflammation was graded by microscopic examination of the coverslip after staining. The PMNs of all acidotic patients had a diminished early (24 hour) response. This response time became normal in the four patients with diabetes whose acidosis was corrected. In an ambitious analysis of leukocyte function, Brayton et al. (7) examined chemotaxis with use of a modified Rebuck technique in 18 patients with fairly well-controlled diabetes, five of whom were acidotic at the time of study. At 2 and 4 hours, mobilization of the PMNs of all diabetic subjects was diminished. However, at later time points, no differences were seen between the mobilization responses of the PMNs of diabetic subjects and those of healthy controls. The PMNs of acidotic uremic patients had a chemotactic response similar to that of controls at all time points.

Mowat and Baum (8), in an in vitro study using a modified tissue-culture chamber, studied chemotaxis of PMNs from 31 diabetic patients with various degrees of glycemic control. A chemotactic index was derived by comparing the original number of PMNs with the number that had completely crossed a filter barrier in response to chemoattractants. The PMNs of all patients with diabetes had a lower chemotactic index (i.e., diminished response), without any correlation between chemotactic index and type of therapy or fasting blood glucose levels. Incubation of the PMNs from 11 controls with glucose at concentrations of 100 to 900 mg/dL did not change the chemotactic index of the PMNs. Incubation of the PMNs of diabetic patients with insulin at concentrations of 10 to 100 μ U/mL improved the chemotactic index of PMNs of the diabetic patients if glucose was also present. Molenaar et al. (9) used a bacterial factor from Escherichia coli as a chemoattractant and found a lower chemotactic index for the PMNs of 52 firstdegree relatives of 15 patients with diabetes as compared with the chemotactic index for the PMNs of controls. Not all the subjects with diabetes had PMNs with a depressed chemotactic index, but the average chemotactic index was lower than that for the PMNs of their relatives. A later study (10) that used a similar technique (Boyden modified chamber) with cells washed free of plasma found no difference in the chemotactic

index of the PMNs of control subjects and those of patients with insulin-dependent diabetes mellitus (IDDM) with various degrees of glucose control or duration of disease.

Shortly after the above studies were conducted, there was a shift to the subagarose technique for assaying chemotaxis. This technique yielded more reproducible results and corrected for chemokinetic movement. Measurements are made of the migration from a center well in an agarose plate toward a chemoattractant (zymogen-activated plasma) and of random migration toward a control well. With this technique, the average chemotactic index of the PMNs of 58 patients with diabetes was found to be depressed (11). Chemically defined chemotactic activity of PMNs under agarose was investigated by Naghibi et al. (12) for 26 patients receiving oral hyperglycemic agents, daily insulin injections, or continuous insulin infusion before an intensive control regimen and in 11 of these patients after institution of the intensive regimen. Chemotaxis of the PMNs of all groups was comparable to that of control PMNs.

PHAGOCYTOSIS

Bybee and Rogers (13) studied leukocyte phagocytosis in 31 patients with well-controlled diabetes, seven patients with diabetic acidosis, and a control group. Washed PMNs and an equal number of *Staphylococcus aureus* or *Staphylococcus epidermidis* were incubated together for 60 minutes in 10% human serum. Phagocytosis was considered to be present if at least one bacterium was ingested. There was no quantitation of the number of organisms engulfed per cell. Only the PMNs of ketotic diabetic patients were found to exhibit diminished phagocytosis. This defect was corrected if acidosis was reversed but not if the cells were incubated with normal serum. Control PMNs functioned normally if they were incubated with serum from acidotic diabetic patients. However, serum factors may have been diluted out, given that a 10% concentration of serum was used.

Bagdade et al. (14) used a similar system, but with 90% serum, to examine phagocytosis of Streptococcus pneumoniae type 25 by leukocytes from eight patients who were not acidotic but had poorly controlled diabetes. Decreased phagocytosis was especially notable when fasting blood glucose levels were higher than 250 mg/dL. After the patients' glucose levels were controlled, phagocytic activity improved but did not attain control values. In contrast to the findings of Bybee and Rogers (13), the activity of control PMNs was diminished when the cells were incubated with serum from patients with diabetes, whereas the activity of PMNs from patients with diabetes was increased when the cells were incubated with normal serum. The work of Rayfield et al. (15) supported the possibility of an opsonization defect affecting PMNs of individuals with diabetes. Normal PMNs had decreased uptake of radiolabeled E. coli or S. aureus in the presence of serum from patients with diabetes.

Using the lysostaphin assay technique, which allows differentiation between phagocytosis and intracellular killing, Tan et al. (16) demonstrated a defect in phagocytosis of S. aureus by the PMNs of 31 patients with adult-onset diabetes. The presence of the defect showed no correlation with level of glycemic control or history of recurrent infections. The addition of normal serum had no effect. Using shorter observation periods, Nolan et al. (17) found that PMNs from 17 patients with poorly controlled diabetes ingested a smaller proportion of an inoculum of 106 S. aureus after 20 minutes (the interval during which most engulfment takes place under normal physiologic conditions) than did control PMNs. This difference vanished at 60 minutes. Davidson et al. (18) measured engulfment of Candida guilliermondii over a 45-minute period by PMNs from 11 patients with moderately well-controlled diabetes. The ratio of white cells to organisms was such that 90% of the control cells

would have ingested at least one yeast cell in 30 minutes. Phagocytosis was diminished in the PMNs of the patients with diabetes, regardless of levels of glycosylated hemoglobin 1C (HbA_{1c}). A defect in opsonization was suggested, since preopsonized yeast particles added to serum from diabetic patients with PMNs from control subjects were engulfed at normal levels. Alexiewicz et al. (19) demonstrated impaired phagocytic ability of PMNs from patients with newly diagnosed, non-IDDM, which correlated inversely with fasting serum glucose level. Both phagocytosis and glucose control improved significantly after 3 months of therapy with glyburide. The authors also demonstrated an inverse relationship between cytosolic calcium concentrations in PMNs and phagocytic function and postulated that the functional defect may relate to the high calcium levels.

ADHERENCE

Comparatively few papers have specifically addressed the question of adherence by the leukocytes of patients with diabetes. Peterson et al. (20) found that the PMNs of six of seven patients with poorly controlled diabetes exhibited impaired adherence to a glass-wool column. Adherence improved 1 to 2 months later when glycemic control had improved. However, no control patients were examined. Bagdade et al. (21) showed an enhancement of adherence of PMNs to a nylon-fiber column following an improvement in the control of blood glucose levels. Adherence increased from 53% to 74% of control values. In another study, Bagdade and Walters (22) demonstrated a direct relationship between degree of glucose control and PMN adherence.

Andersen et al. (23) pointed the study of adhesion in a dramatic new direction by devising a more physiologic system. Noting that vascular endothelium is not a passive participant in the inflammation cascade, they examined the ability of PMNs from 26 patients with diabetes and from age-matched controls to bind to bovine aortic endothelium. The PMNs of 60% of the patients with diabetes had severely depressed function that did not correlate with HbA_{1c} levels. PMN–PMN aggregation was not defective. No quantitative defect in fibronectin was seen, but a qualitative defect could not be excluded.

BACTERICIDAL ACTIVITY

Early studies, such as that of Dziatkowiak et al. (24), compared the number of live S. aureus bacteria in a granulocyte with the total number engulfed to calculate the proportion of organisms killed. Several studies (16) demonstrated diminished killing by the PMNs of patients with diabetes while others did not. Repine et al. (25) took a more quantitative and functional approach. Instead of using a single low ratio of bacteria to PMNs, they used five different ratios (1:1 to 100:1). Study patients included infected and noninfected individuals with and without diabetes. Cells were incubated with S. aureus for 1 hour, after which colonies were counted. The rates of intracellular killing of bacteria by PMNs from uninfected controls and by PMNs of persons with well-controlled diabetes were comparable. PMNs from uninfected patients with poorly controlled diabetes functioned less well, especially when the higher ratios of bacteria to white cells were used. Although the functioning of PMNs from infected patients with well-controlled diabetes was on a par with the functioning of those from uninfected controls, the PMNs from the infected patients with diabetes did not display the increase in killing activity seen in the PMNs of infected patients without diabetes. The bactericidal function of PMNs from infected patients with poorly controlled diabetes was the lowest of all the groups. Naghibi et al. (12), using a single low ratio of bacteria to PMNs, found depressed bactericidal function of the PMNs of patients against *Pseudomonas aeruginosa*, but they did not study any infected patients. Serum from patients with diabetes had an inhibitory effect on PMNs from both normal controls and diabetic subjects before and after intensive glucose management. Bactericidal activity of PMNs from the patients with diabetes remained depressed even after intensive management.

Stimulated PMNs display a burst of oxidative metabolism that produces superoxide anions and other oxygen-derived species implicated in bacterial killing. These reactions produce chemiluminescence, a sensitive indicator of oxidative metabolism that correlates with antimicrobial activity. Shah et al. (26) looked at the production of superoxide anion and chemiluminescence of PMNs from patients with diabetes, examining the cells in both the resting state and in response to soluble and particulate stimuli. In resting PMNs from patients with diabetes, the chemiluminescence of cells placed in serum from patients with diabetes was comparable to that of cells placed in control serum. Superoxide production was higher in autologous serum from patients with diabetes than in normal serum. The significance of these findings taken together was unclear. When stimulated, the PMNs from patients with diabetes showed a blunted response with regard to both superoxide production and chemiluminescence. Cross-incubation serum studies effected no change, suggesting that an intracellular defect rather than an inhibitory serum factor might have been present. The precise role of defective in vitro bactericidal activity of PMNs, associated with impaired superoxide production, as a predisposing factor for infection is uncertain, however. Such defects can be demonstrated in patients with diabetes who have not been subject to recurrent or particularly serious infections (27).

Sato et al. (28) reported improvement in chemoluminescence measurements related to O_2^- and OCl⁻ production by PMNs of patients with diabetes after 4 weeks of therapy with an aldose reductase inhibitor, although levels did not reach those of PMNs from healthy controls. This observation could not be attributed to improvement in glucose control, as both the postprandial glucose and HbA_{1c} levels were unchanged. It has been suggested that advanced glycation products associated with diabetes may bind to specific motifs common to lactoferrin, lysozyme, and other antimicrobial proteins found in PMNs and interfere with the antimicrobial function of these host defense molecules (29).

The PMNs of patients with diabetes have shown a decreased prostaglandin E and thromboxane B_2 response to stimulation by zymosan or killed *S. aureus* (30). The synthesis and release of leukotriene B_4 by these cells also were diminished compared with those of the PMNs of sex- and age-matched controls (31). The significance of these findings is not known.

Monocyte Function in Diabetes

Geisler et al. (32) found a decrease in the total number of circulating monocytes in 14 patients with diabetes. These cells displayed diminished phagocytosis of *Candida albicans* but not of latex particles or sheep red blood cells. Glass et al. (33) proposed that monocytes from patients with diabetes have a diminished activity of "lectinlike" receptors necessary for the recognition of cell-wall components of microorganisms. Attachment of *S. epidermidis* to these monocytes was impaired, but attachment to coated sheep red blood cells, which are recognized by the Fc receptor, was normal. It could not be assessed whether the proportion of monocytes with the lectinlike receptors was reduced, each receptor had a lower affinity, or each monocyte had fewer receptors. Katz et al. (34) described subpopulations of monocytes with a reduced ability to phagocytose *Listeria monocyto*-

1020 JOSLIN'S DIABETES MELLITUS

genes. Impaired monocyte chemotaxis has also been reported (35). Monocytes from patients with diabetes have been found to exhibit increased adhesion to fibronectin. Although this property may play a role in the genesis of atherosclerosis (36), its relationship to antimicrobial function is not known. The metabolic activity in response to the ingestion of zymosan particles by the monocytes from patients with diabetes is increased, as reflected by higher levels of chemiluminescence, superoxide production, and hexose monophosphate shunt activity than those exhibited by control monocytes (37). The consequences of this increased activity have not been evaluated. Studies of monocytes from patients with diabetes report upregulated secretion of inflammatory mediators such as tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and prostaglandin E₂ (38).

Cell-Mediated Immunity

Reports of defects of cell-mediated immunity *in vitro* in patients with diabetes abound. Unfortunately, results are piecemeal both because of the complex interrelationships involved in the cell-mediated immune system and because of the evolution of study techniques over time.

MacCuish et al. (39) found that lymphocyte transformation in response to the mitogen phytohemagglutinin (PHA) was diminished in patients with poorly controlled diabetes. Meanwhile, Casey et al. (40,41) determined that the transformation of lymphocytes of patients with diabetes in response to PHA was normal regardless of the patient's glycemic control but that the response to a staphylococcal antigen was decreased. These authors did not mention any ketotic patients. In a study by Speert and Silva (42), the lymphocytes of children with diabetic ketoacidosis had a decreased mitogenic response that reverted to normal when metabolic derangements were corrected. There may be a diminished release of migration-inhibition factor by T lymphocytes from patients with diabetes (43,44). T-lymphocyte subsets have been studied with regard to the possibility of an autoimmune basis of diabetes. While alterations of CD4-to-CD8 lymphocyte ratios during the evolution and progression of diabetes have been noted (45-47), no relationship of these changes to infection has been detected. No agreement has been reached as to whether the number and function of T and B cells in patients with diabetes is increased, decreased, or normal as compared with those in controls (10).

An acquired defect in the production of IL-2 by T cells has been demonstrated in patients with IDDM (48), as have increased levels of receptors for this cytokine (49). Decreased responsiveness to interferon of natural killer cells from patients with IDDM has been observed (50). The implications of these abnormalities with regard to defense against infection remain speculative at the present time.

Miscellaneous Factors

Abnormalities in the microvascular circulation of individuals with diabetes may result in decreased tissue perfusion (51). While it is intuitively understandable that such abnormalities might facilitate the acquisition of infection and impair response to therapy, it is unclear what role microvascular defects actually play in the pathogenesis of infections relatively specific for patients with diabetes, such as mucormycosis, malignant external otitis, and emphysematous cholecystitis. Reviews of these topics often mention the arteriolar narrowing seen on pathologic examination, but comparisons with control specimens have not been reported. It appears that the white blood cells of patients with diabetes may play a role in producing damage to the capillary and venular endothelium (52,53).

INFECTIONS STRONGLY ASSOCIATED WITH DIABETES

Mucormycosis

THE ORGANISM AND HOST RESPONSE

The term *mucormycosis* connotes a variety of infections caused by fungi belonging to the order Mucorales, members of the class Zygomycetes (54,55). Zygomycosis and phycomycosis are synonyms that have been rendered obsolete by ongoing reclassification. Rhizopus species (especially Rhizopus oryzae and Rhizopus arrhizus) are the most commonly isolated pathogens, followed by Mucor organisms. Cunninghamella (56) and other species have also been found to cause disease. These molds produce large, thick-walled, nonseptate hyphae that branch at more-or-less right angles. Ubiquitous in the environment, these organisms are most often found in decaying matter. Humans commonly inhale the spores, which have a low virulence potential. The ability of the spores to germinate successfully is dependent on specific host factors. Most information regarding pathogenesis comes from studies in rabbit and mouse models. After inhalation of spores, normal animals do not become ill, whereas diabetic animals develop a rapidly progressive pulmonary disease (57). Alveolar macrophages from normal mice, but not those from diabetic mice, will ingest the spores and inhibit their germination into the invasive hyphal forms. Experimentally, neither hyperglycemia nor metabolic acidosis alone is sufficient to permit infection (58), despite the propensity for the development of certain mucormycosis syndromes among acidotic patients with diabetes. In contrast to normal human serum, the serum of patients with diabetes with ketoacidosis does not inhibit the growth of R. oryzae (59). It has been proposed that acidosis disrupts the ability of transferrin to bind iron, a deficiency that results in the release of free iron into the serum and perhaps to an interference in the host defenses against Rhizopus (60), an iron-requiring organism (61). Credence has been lent to the proposed role of iron regulation in host defense by the increasing recognition of the occurrence of deferoxamine-associated mucormycosis in patients undergoing dialysis. In this situation, it appears that Rhizopus organisms may be able to use the iron mobilized by the chelating agent, a capability that has been demonstrated in other organisms (61).

CLINICAL SYNDROMES

Mucormycosis may present as a rhinocerebral, pulmonary, cutaneous, gastrointestinal, or disseminated form of the disease. Rhinocerebral mucormycosis was first recognized more than 50 years ago (62). It occurs primarily in persons with diabetes, although other immunocompromised patients may be affected, and is one of the most fulminant forms of fungal disease affecting that population. The typical patient presents with ketoacidosis. Fungal elements gain entry through the nasopharynx, where tissue invasion may result in nasal discharge that may be tinged with blood. Close inspection of the infected region may reveal necrotic areas with black eschar involving the nasal mucosa or hard palate. The patient is likely to have a fever and to remain lethargic even after metabolic derangements have been corrected. Commonly, by the time the diagnosis is suspected, headache and/or facial pain already reflect extension of the process into the paranasal sinuses and possibly into the orbit of the eye. Occasional patients present with a dramatic, rapid onset of ocular proptosis and vision loss caused by invasion of the orbit. Rapid progression of clinical findings is the result of invasion of blood vessels, with vascular occlusion and subsequent necrosis of tissues dependent on the affected vessels. Progression of thrombosis can include the cavernous sinus

(63) and the internal carotid artery (64). Invasion of the brain results in meningoencephalitis and/or abscess formation with deterioration of neurologic function.

Progression usually occurs over a matter of hours to days and is invariably fatal if the patient is not treated early. Diagnosis must be established by demonstration of characteristic invasion of tissues by hyphal elements in biopsy specimens. A careful search for evidence of vascular invasion must be conducted. Culture results will often be negative. Spinal fluid findings are nonspecific (65). Sinus films may show mucosal thickening and clouding with some spotty destruction of the orbit (66). Computed tomography (CT) scans, with special orbital views, can help define the extent of involvement, although the extent estimated by this method may underestimate the actual extent of involvement determined at surgery (67). Angiography has been used to define the degree of large-vessel involvement. Magnetic resonance imaging offers the potential to provide useful information on the extent of infection, including assessment of soft tissue and vascular structures. Extension beyond the orbit carries a poor prognosis.

Aggressive surgical management is mandatory in all situations; radical debridement sometimes necessitates orbital exenteration. Repeated debridement may be necessary. Concomitantly, underlying metabolic disorders must be addressed. Amphotericin B remains the standard antifungal therapy and must be used in conjunction with surgery (54,68,69). Aggressive antifungal therapy should be used, and although the exact duration of treatment and the total dosage administered have not been well defined, it is reasonable to aim for a total dosage of at least 2 g. The currently approved azole antifungal agents have no defined role in therapy (70). Repeated imaging is necessary to follow the response to treatment, and repeated biopsy may be necessary (71). With optimal therapy, mortality remains at 50%, despite some reports of more encouraging results (72). The nature of the almost universal neurologic residua depends on the anatomic structures that have already been compromised by the time the infection is brought under control.

The remaining forms of mucormycosis do not have a predilection for a specific host, although the pulmonary disease may have a distinctive presentation in patients with diabetes. In contrast to the fatal pneumonia and extensive thrombosis that is typical in immunocompromised patients, diabetic patients have been noted to develop endobronchial and large-airway lesions that may follow a less fulminant course. The main complication of pulmonary mucormycosis is massive hemoptysis. Lesions may respond to aggressive local resection in combination with intravenous therapy with amphotericin B (73–76).

Malignant External Otitis

In 1968, Chandler (77) described a series of patients with a disorder termed malignant external otitis (MEO). Occasionally referred to as progressive, invasive, or necrotizing external otitis, these names attest to the destructive nature of the process. These terms connote a slowly progressive cellulitis that begins in the soft tissues of the external auditory canal. As it penetrates more deeply into the subcutaneous tissue, this process may spread via the fissures of Santorini (clefts in the cartilaginous floor of the external canal) into the mastoid air cells. Access to the temporal bone (osteomyelitis) occurs through the cartilaginous/osseous junction in the outer ear canal (78). The great majority of cases are due to P. aeruginosa even though this is not a normal colonizer of the ear in any patient group (79). Most patients are elderly, and 75% to 90% have diabetes. There does not appear to be a distinct relationship between MEO and ketoacidosis or the magnitude of hyperglycemia (80).

Typically, patients will present with a 2- to several-week history of external otitis unresponsive to local therapy. The evolution into MEO, with localized invasion of soft tissue and osseous structures, is heralded by unrelenting, severe otalgia often accompanied by purulent discharge (81). It is unusual for patients to appear systemically ill or to have a fever and an elevated white blood cell count. One of the hallmarks of MEO that distinguishes it from simple external otitis is the finding of granulation tissue, usually at the junction of the cartilaginous and osseous portion of the canal, in more than 90% of cases. A swollen, reddened, moist-appearing canal is usual. The tympanic membrane is normal in the rare cases in which it can be visualized. The extent to which the process has progressed toward the base of the skull is reflected clinically by progressive involvement of cranial nerves. The facial nerve may be impaired at presentation in up to 50% of cases (78,82), the result of swelling of the soft tissue surrounding the styloid foramen where the nerve exits the skull or of direct invasion of the bone at the foramen itself. The function of cranial nerves IX, X, and XI can be affected next as the jugular foramen becomes involved (82,83). Finally, the hypoglossal canal can be destroyed. In the most extreme cases, contralateral cranial nerves are compromised as the destructive process erodes the base of the skull. Meningitis may result by extension into the subarachnoid space.

Plain films of the ear canal are of limited sensitivity and specificity for this condition. While technetium scanning is highly sensitive, it is of low specificity, as is gallium scanning. CT scanning, with special views, is a useful imaging modality (84), although tumors cannot be reliably distinguished from MEO. Magnetic resonance imaging provides excellent detail and is, perhaps, the most widely used modality for the initial assessment of patients suspected of having this disorder.

In Chandler's original series (77), the mortality rate from MEO was 50%. A 1981 review of this entity cited a mortality rate of 20% (80). Cure rates since 1985 may have reached 90% (85). The improvement in survival may be attributable in part to the development of more effective antipseudomonal antibiotics. As important, however, is the likelihood that increased awareness by physicians of this entity has led to earlier recognition of affected patients and thus to the possible control of infection with antibiotic therapy and local debridement and to a diminished need for the more radical surgical procedures necessitated by more advanced disease.

Standard antibiotic regimens for treatment of MEO due to P. aeruginosa previously consisted of an antipseudomonal penicillin plus an aminoglycoside for a prolonged period (4 to 6 weeks or more) (82,86). With the advent of newer, potentially less-toxic antipseudomonal agents, new regimens have evolved. Monotherapy with the antipseudomonal third-generation cephalosporin, ceftazidime, for 4 to 6 weeks, much of it as home therapy, realized a rate of favorable response of 92% in a series of 20 patients, 30% of whom presented with ipsilateral facial palsy (87). Follow-up at 1 year showed no recurrences. While the results are encouraging, it is of note that two of the patients in this series did not even need debridement, indicating that some presented with the extreme of mild disease. In another study, 21 of 23 patients with MEO were successfully treated with 6 weeks of oral therapy with ciprofloxacin (88). However, only 65% of the patients in this study had diabetes. At present, therapy with an antipseudomonal fluoroquinolonewhich may permit oral administration-appears to be an acceptable approach in most patients with a susceptible organism. However, close medical supervision is necessary, as repeated debridement may be required (89). While emergence of resistance has not been a frequent problem in studies using

monotherapy (or combination therapy), this possibility should be considered in patients for whom therapy fails.

Emphysematous Pyelonephritis

Severe bacterial urinary tract infection in the patient with diabetes may result in emphysematous pyelonephritis. The precise definition of this rare entity varies among authors. The most rigorous definition includes a requirement for the presence of gas within the renal parenchyma, which may enter the perinephric space by extension. Gas can occur in the calices, collecting system, or bladder, but if it is limited to these sites, these entities are distinct from true emphysematous pyelonephritis and carry different prognoses. The differential diagnosis includes iatrogenic manipulation with introduction of air and fistula formation arising from the digestive system. The first reference to emphysematous pyelonephritis is usually cited as 1898 (90), although in retrospect, it appears that this patient probably had gas only in the collecting system. A number of cases have been reported, but the disorder is rare (91-95). Between 85% and 100% of patients have had diabetes mellitus. Up to 40% of patients may have had concomitant obstruction, which is present in almost all nondiabetic patients with emphysematous pyelonephritis. At presentation, it is not possible clinically to distinguish emphysematous from uncomplicated acute pyelonephritis unless gas has spread beyond the bounds of perirenal tissues to cause subcutaneous crepitation. Pneumaturia is distinctly unusual.

Plain radiographs (96) ultrasound, or abdominal CT scans will reveal gas within the renal parenchyma. A plain x-ray film may show a mottled renal parenchyma with gas bubbles, often in a radial distribution. As the infection advances, gas may be seen outside the renal cortex either outlining the kidney or forming thin crescents, although this classic finding is unusual. Abdominal CT scanning is especially useful for documenting the spread of gas beyond the Gerota fascia. About 10% of patients have bilateral involvement (93). Radiologic evaluation should be undertaken if a suspected case of acute pyelonephritis does not respond to adequate antibiotic therapy within a few days. CT scans may also uncover previously unsuspected abscesses.

The usual causative organisms are typical urinary pathogens, including *E. coli, Klebsiella pneumoniae, Proteus mirabilis,* and *Enterobacter aerogenes*. There are case reports implicating other organisms, including *Candida* species (97); typically, anaerobes are not found. It is not clear why the microbes involved produce gas in a specific clinical situation. The presence of glycosuria, while providing a substrate for production of gas by fermentation, is clearly not the sole factor, given the rarity of emphysematous pyelonephritis and the frequency of glycosuria.

While it is clear that therapy with antibiotics directed at the offending organisms and management of underlying diabetes are imperative, the role of surgical intervention is much less well defined. The lack of prospective, controlled studies is understandable given the rarity of the syndrome. Obstruction should always be sought and relieved as necessary. Some authors suggest following the resolution of gas radiographically and proceeding with nephrectomy only if the patient fails to respond to appropriate antibiotics (93). Others have recommended total nephrectomy as soon as the diagnosis is made, citing the possibility of rapid clinical deterioration in some patients (92). A reasonable approach in an otherwise relatively stable patient might be to try medical management with potent antibiotics, relieve any obstruction, undertake percutaneous drainage as appropriate, and consider nephrectomy if clinical

improvement does not occur. Nephrectomy may be especially appropriate if the affected kidney is shown to be nonfunctioning, as occurs in about one half of the patients (94). However, clinical decisions are often not straightforward, as in the case of bilateral emphysematous pyelonephritis or disease in a solitary functioning kidney.

The duration of antibiotic therapy is not addressed in various reviews, but a several-week course would appear prudent. Reported mortality rates range from 10% to 40% (92,93,98). At autopsy, 50% of 42 patients had severe acute and chronic necrotizing pyelonephritis with multiple cortical abscesses, 20% had papillary necrosis, and 20% had intrarenal vascular thrombi (95). In one fourth of the cases, the kidney could not even be identified. Currently, this rare entity may carry a better prognosis if a high index of clinical suspicion is maintained to ensure early imaging studies.

Emphysematous Cholecystitis

Emphysematous cholecystitis is a rare complication of acute cholecystitis in which air is found in the lumen and wall of the gallbladder, with possible extension to the pericholecystic space. It was first diagnosed at surgery in 1908, with the first preoperative diagnosis made by abdominal roentgenography in 1931 (99). In 1975, Mentzer et al. (100) published their comprehensive study, which encompassed the 161 cases reported to date in the literature and three cases of their own. More than one third of the patients in this series had diabetes. In contrast to acute cholecystitis, for which almost three fourths of the patients are female, males account for three fourths of the cases of emphysematous cholecystitis. Perforation and gangrene of the gallbladder are 30 times and three times more common, respectively, and mortality is ten times higher in patients younger than 60 years old but only twice as high for those older than 60 years than in patients with acute cholecystitis. Diabetes does not appear to be an independent factor relative to a worse prognosis. Cholelithiasis is present about one half of the time.

Patients present with pain in the right upper quadrant, nausea and vomiting, and fever. During the next 48 hours, gas develops within the gallbladder lumen and wall, with progression into the surrounding tissues in the next 48 hours (101). Even during this time, one cannot reliably distinguish acute uncomplicated cholecystitis from emphysematous cholecystitis at the bedside. Diagnosis is established by radiographic documentation of gas in the aforementioned areas. On plain films, one may initially see a globular shadow representing the airfilled gallbladder. Soon afterwards, intramural-usually submucosal-air may be visualized (99). Air may sometimes be seen only in the biliary radicles (102). Air under the diaphragm suggests perforation and is a poor prognostic sign (99). Differential diagnosis of these radiographic findings includes the presence of enterovesicular fistula. Ultrasonography has proven a useful tool, although plain films must still be obtained to rule out a porcelain gallbladder or a heavily calcified stone as the source of high-density echoes (103,104). CT is another useful modality in making the diagnosis.

Given the high complication rate of emphysematous cholecystitis, it is important to consider this diagnosis early in the patient with diabetes who is suspected of having acute cholecystitis. It has been recommended that cholecystectomy be performed as soon as the diagnosis is established (101). Typically, a crepitant gangrenous gallbladder is found at surgery. Cultures are positive 50% to 90% of the time, a frequency much higher than that for simple acute cholecystitis. *Clostridium perfringens* is isolated from 25% to 50% of positive cultures, along with more typical enteric organisms such as *E. coli*. Antibiotic coverage should include anaerobes as well as both gram-positive and gram-negative facultative organisms.

The issue of elective cholecystectomy for asymptomatic gallstones in patients with diabetes has been a source of controversy. Because of the perceived increased risk of mortality or severe complications among diabetic patients with acute cholecystitis, for many years it was recommended that those with cholelithiasis undergo prophylactic cholecystectomy. However, complications appear to be uncommon when diabetic patients with asymptomatic stones are followed without surgery. Del Favero et al. (105) followed 47 non-insulin-requiring diabetic patients with asymptomatic gallstones over 5 years; only 15% developed any symptoms, and only two patients developed acute cholecystitis or jaundice. A retrospective controlled study suggested that diabetes alone was not correlated with a higher mortality rate during an episode of acute cholecystitis (106). In a decision-analysis model, it was found-under a broad range of assumptions-that, when managed expectantly (i.e., observed without surgery), diabetic patients with asymptomatic gallstones did no worse than nondiabetic patients (107). Other work suggests a higher rate of infectious complications following cholecystectomy for acute cholecystitis among diabetic than nondiabetic patients (108). In treatment of acute cholecystitis, the trend has been toward expeditious (within 24 hours) surgery (101). The outcome of this approach, in contrast to that of surgery following a "cooling-off" period, has not been rigorously examined in relation to patients with diabetes. Nevertheless, while severe complications are infrequent when diabetic patients with asymptomatic gallstones are observed expectantly, laparoscopic techniques have also reduced the morbidity of cholecystectomy. Therefore, decisions regarding benefits of elective cholecystectomy can be made on a case-bycase basis (109).

INFECTIONS CAUSED BY THERAPEUTIC INTERVENTIONS

Insulin Therapy

Standard self-administered insulin injections result in abscesses remarkably rarely. Preservatives added to insulin have antibacterial activity. Before the 1970s, glass syringes stored in methylated industrial spirit were used. The inadvertent substitution of surgical spirit, which contains a larger number of additives, was more often, although still rarely, associated with abscess formation (110,111). Disposable syringes have largely replaced glass syringes. Manufacturers and many medical practitioners recommend discarding plastic syringes after a single use. However, repeated use of syringes for a month or more has not been reported to result in an increased rate of infection if the syringe is refrigerated between uses, if the needle is wiped with alcohol, or if the syringe–needle unit is soaked in alcohol between uses (112).

In an investigation of the actual insulin injection practices of a group of patients with diabetes, no injection-site infections or significant bacterial contamination of equipment was found. This was despite a lack of "traditional practices" such as wiping the vial and skin or even washing the hands before injection (112,113). Half the patients reused their syringes many times. In a study of jet insulin injectors, for which cleaning every 2 weeks was recommended, no significant growth was seen in cultures of any of the injectors from 19 patients (114). On the other hand, continuous subcutaneous insulin infusion (CSII) has been more commonly associated with infectious complications, typically in the form of abscesses at the needle site (115,116). This is among the most common reasons cited by patients for discontinuing this form of therapy (117). No association between the staphylococcal carrier state and infection at the injection site has been shown (118).

Penile Implants

Men with diabetes make up one fourth to one third of the approximately 17,000 patients each year who undergo penile implant procedures for impotence. The implant apparatuses available range from rigid rods placed in the paired corpora cavernosa to the new, more commonly used, inflatable devices (119,120). Included among the inflatable implants are those with multiple components placed in the scrotum, abdominal wall, and corpora cavernosa that have been available since 1973 and several similar types of succeeding units. The most recent implants are contained entirely in the corpora cavernosa. All types are inserted with a single incision. There is no correlation between the type of prosthesis or incision and the rate of infection (119,120). The infection rate ranges from 0.8% to 8%, with most series having an average of 2% to 3%. This is an improvement from the 15% rate seen before antibiotic prophylaxis became routine. In several series, no increased incidence of infection in patients with diabetes was noted (121,122). S. epidermidis is the infecting organism in 40% to 80% of the infections, with coliforms being isolated in most of the others. Infection is thought to originate at the time of surgery primarily as a result of contamination with microorganisms of the skin or colorectal area. Rarely, late infection caused by hematogenous seeding has been reported (122).

Evidence of infection is seen 2 weeks to 2 years after implantation, with the gram-negative organisms tending to present in the earlier part of the range. Systemic signs and symptoms are usually absent. The degree of local findings can be subtle, such as tenderness with manipulation, mechanical malfunction, mild hyperemia or erosion over the mechanism, or formation of periprosthetic adhesive tissue. More dramatic evidence of infection, such as pain, swelling, induration, fistula formation, or extrusion of the device, tends to occur with infections with gram-negative organisms, although not exclusively. Findings at surgical exploration can range from minor adhesions to gross purulence. Immediate therapy consists of removal of the prosthesis, therapy with broad-spectrum intravenous antibiotics, and postoperative drainage. The rate of infection is increased for implants after the first procedure.

Prevention of infection of penile prostheses focuses on the time of surgery. As with all procedures incorporating prosthetic material, concurrent infection, particularly of the urinary tract, is a contraindication to surgery. Antibiotic prophylaxis, an appropriately clean operating room environment, extensive skin preparation, and copious intraoperative irrigation have all been recommended as means of decreasing the chance of infection (120).

Organ Transplantation

Renal transplantation is an option for a number of diabetic patients with end-stage renal disease. For patients receiving a living-related kidney allograft, 1-year patient and graft survival rates are approximately 97% and 90%, respectively (123). Although immunosuppression methods have improved greatly over the years, permitting the use of lower doses of immuno-suppressive drugs, infection is still a significant problem in this population. The sources of infection can be the endogenous flora, reactivated latent infection, infection with opportunistic pathogens, or primary transmission from the donor allograft (124,125). Kontoyiannis and Rubin (126) proposed a now-classic

timetable for infections that occur in renal transplant recipients. Although exceptions occur, this timetable serves as a useful tool in thinking about likely infections at various time points following transplantation. In the first month following transplantation, these patients present with the same kinds of infectious complications seen in any postoperative patient (i.e., wound, urinary tract, pulmonary, and intravenous catheter bacterial infections). The most serious opportunistic infections are unlikely during the early part of this period. Cumulative immunosuppression is at its height 1 to 6 months after transplantation, and it is during this period that the patient is at greatest risk of opportunistic infections, such as those due to cytomegalovirus, Pneumocystis carinii, and Aspergillus species, among others. After these first 6 months, the recipient is susceptible to chronic forms of viral disease contracted earlier in his or her course, some opportunistic infections, and diseases found in the community. For further information, the reader is directed to in-depth reviews of the large body of data on this topic (123,126,127).

Since the course of immunosuppression for pancreatic transplantation follows essentially the same pattern as that for renal transplantation, it would be expected that the time frame for infectious complications of the two would be similar. Urinary tract infection is the most common cause of readmission to the hospital in this population (128,129). A study of heart transplantation in carefully selected patients with diabetes revealed no increased risk of infection (130).

Infections Associated with Dialysis

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

Various forms of ambulatory peritoneal dialysis constitute a common modality of therapy for end-stage renal disease in patients with diabetes. Like any indwelling foreign body, dialysis catheters inserted into the peritoneum carry a risk of infection. For continuous ambulatory peritoneal dialysis (CAPD), one to two episodes of catheter-related peritonitis per patient per year, on average, can be anticipated, although it appears that some patients suffer multiple episodes whereas others have fewer than the expected number (131–133). The rate of CAPD-related infection does not appear to be greater in diabetic than nondiabetic patients (134,135). This is also true for patients receiving chronic intermittent peritoneal dialysis (136) for whom the overall risk of infection is lower than that for patients receiving CAPD.

The source of infection (132) can be intraluminal, from touch contamination of the apparatus at insertion, a break in the tubing or attachment site that permits ingress of bacteria, or contamination at bag changes caused by poor technique. Contamination of dialysate is another potential route of entry of microorganisms. Infection also can occur by the periluminal route, for the skin never makes a complete seal with the catheter at the exit site. Both these routes can result in infection with organisms of the endogenous skin flora. Coagulase-negative staphylococci account for 40% of the cases of peritonitis in patients undergoing CAPD (137), and other gram-positive organisms, such as S. aureus and streptococci, are responsible for another 30%. Gram-negative organisms are seen in almost 30% of cases, often reflecting a third route of infection (i.e., contamination of the peritoneum and then the catheter from an intestinal source). Such contamination can occur without an overt disruption in the bowel mucosa. A bowel source is suggested by findings of multiple organisms or anaerobes in the dialysate. It is uncommon for blood cultures to be positive as the result of CAPD peritonitis. The risk of septicemia of all causes among patients undergoing peritoneal dialysis was estimated to be

approximately 1% per year in a recent study (138). Positive blood cultures should prompt a search for a source that has led to hematogenous seeding. Fungi, especially *Candida* species, account for almost 5% of cases of CAPD-associated peritonitis, with the rate no higher in patients with diabetes. *Mycobacterium tuberculosis* is seen in fewer than 3% of cases. A number of unusual causes of CAPD peritonitis have been seen (139).

Patients with exit-site infections may be unaware of any problems until an examiner notes erythema at the site. Serous or purulent discharge may be present. Infections in the subcutaneous tunnel can be very difficult to diagnose, especially when no concurrent exit-site infection is present, because signs may be absent early in the course of infection. Ultrasound imaging may be helpful in finding a localized collection around the tunnel, but one may not be present. Either an exit-site or a tunnel infection may exist without causing peritonitis, but each increases the risk of peritoneal infection. Patients with peritonitis may have very mild symptoms of abdominal discomfort with or without a low-grade fever, but almost all will note a cloudy dialysate. Some individuals may present with acute illness and appear septic, particularly if they have S. aureus infection. Regardless of patient presentation, CAPD peritonitis is documented by noting more than 100 cells/mm³ (mostly PMNs) in the dialysate, which normally contains 50 to 100 cells/mm³ with a predominance of macrophages. For infection to be documented definitively, an organism must be demonstrated in the dialysate, either by Gram staining or culture (133). Culture of large volumes of dialysate (50 to 100 mL) can greatly improve yield. The Gram stain is positive in fewer than 50% of cases, even when concentrated dialysis fluid is examined. Noninfectious causes of cloudy dialysate should not result in increased cell counts. With treatment, patients should improve clinically, culture results become negative, and cell counts fall dramatically in 4 to 5 days. It should be kept in mind that cell counts can vary with the time that dialysate is permitted to dwell within the peritoneum. Sequential sampling for evaluation of cellular response should be performed at comparable time points of the dialysis cycle. If resolution of infection is delayed, a tunnel infection or other complicating factor should be ruled out. If cultures remain negative and the patient is not improving, the possibility of tuberculosis should be considered.

The route of delivery, type of antibiotic, and duration of therapy have not been studied in a prospective, controlled manner, and conventional regimens can vary by institution. Empiric initial coverage should include both gram-positive and gram-negative organisms. A number of antibiotics can be mixed directly into the dialysate and given intraperitoneally (140). Oral or intravenous therapy is sometimes used. Catheter removal is generally included in the treatment for fungal and mycobacterial peritonitis (131). The traditional approach of removal of the catheter for patients with pseudomonal infection has not been reevaluated since the advent of more effective and less toxic antipseudomonal agents. Catheter removal may be needed in other cases of infection that are refractory to treatment with appropriate antibiotics alone.

HEMODIALYSIS

Many diabetic patients with end-stage renal disease undergo hemodialysis, which may be carried out with a vascular catheter intended for either temporary or long-term use. In the latter case, catheters are tunneled subcutaneously and cuffed to permit anchoring of the catheter to the tissues (141). The attendant risks and the principles of management of infections of these lines are analogous to those for any deep intravascular access lines.

Permanent access for hemodialysis can be attained with an arteriovenous fistula, which can be accomplished in several ways. If vessels are of sufficient caliber and patency, an autologous graft can be surgically created between the radial artery and the cephalic vein (or other suitable vessels). A bovine heterograft can be placed between the vessels, or prosthetic material such as polytetrafluoroethylene (PTFE) can be used as a graft. Vascular access–related infections are more frequent with temporary or permanent catheters than with grafts or native fistulas (142,143).

Standard vascular surgery prophylaxis is used for placement of fistulas. The expected 1% of fistulas that become infected perioperatively typically has only a delay in maturation. The true incidence of late infections is difficult to determine because many series focus on hospitalized patients, whereas many of these infections are successfully treated on an outpatient basis. Localized graft infections typically manifest as tenderness, warmth, and erythema over the graft-perhaps with exudate. Findings may, however, be much more subtle, consisting of hemorrhage or mechanical malfunction caused by infectionrelated destruction of the anastomotic site. As many as one third of patients who present with bacteremia caused by accesssite infection have an unremarkable fistula on examination. Blood cultures (not obtained through the access site) and cultures of any pus are the keys to bacteriologic diagnosis. Grafts can also be infected by hematogenous spread of microorganisms from a distant site of infection.

S. aureus is estimated to cause up to 80% of graft infections (144), with gram-negative organisms and coagulase-negative staphylococci being responsible for much of the remainder. Endocarditis, osteomyelitis, or septic pulmonary emboli caused by distant seeding increase mortality and the rate of primary treatment failure (145,146). Mortality rates among patients with grafts are also higher if the identifiable focus for the bacteremia is other than the graft (144). It is generally agreed that patients with S. aureus bacteremia related to graft infection should receive a prolonged course of antibiotic therapy (e.g., 6 weeks) (132,144). The use of transesophageal echocardiography to detect cardiac vegetations increases the likelihood of identifying patients with endocarditis who might benefit most from prolonged antibiotic therapy (147). However, high rates of focal infection of bones, joints, or other sites in hemodialysis patients with S. aureus bacteremia often mandate prolonged courses of antimicrobial therapy even if echocardiographic evidence of endocarditis is lacking. How to manage the graft itself, particularly if it is prosthetic, is controversial. While excision of the graft is the approach most likely to prove curative, the desire to preserve the graft is often paramount. In selected cases with localized infection of access grafts, it appears that bypass of the involved segment, with removal of the focally infected material, can be accomplished successfully, with salvage of the graft (148).

INFECTIONS POSSIBLY RELATED TO DIABETES

Urinary Tract Disease

BACTERIURIA

An association between urinary tract infection and diabetes mellitus was noted in autopsy series in the 1940s (149). Since then, numerous studies have been published regarding the prevalence of bacteriuria in persons with diabetes. The number of studies documenting an increased prevalence and the number that have not are approximately equal. Those studies that did demonstrate an increase found it almost exclusively in adult women. Reports have varied regarding presence and/or type of controls, clinical setting, definition of diabetes, and definition of infection, making it difficult to compare studies. Three papers examining the prevalence of asymptomatic bacteriuria in outpatients with diabetes found a prevalence of approximately 9% in women (i.e., two- to fourfold higher than that in controls) (149–151). It is of note that these investigations can remark only on *prevalence*, as subjects were tested at one point in time. Therefore, it cannot be determined whether women with diabetes are more prone to episodes of bacteriuria or if they simply experience the same frequency of bacteriuria as nondiabetic women but that episodes persist for more prolonged periods.

Lower urinary tract disease in patients with diabetes is of concern because of the perception that these patients have more-complicated infections of the upper urinary tract. The incidence of bacteremia due to the Enterobacteriaceae also is increased in patients with diabetes, presumably because of the increased incidence of urinary tract infections (152). Information relating disease in the urinary tract specifically to asymptomatic or symptomatic bacteriuria is lacking. It is also not known how often asymptomatic bacteriuria progresses to symptomatic bacteriuria. Thus, the benefit, if any, of treating asymptomatic episodes in this population is not clear. Some of the presumed predisposing factors that have been examined include age, neurogenic bladder, duration of diabetes, and degree of glycemic control. Results do not all agree, and since several of the conditions may be closely interrelated, it is often not possible to demonstrate definitively any independent associations. Although it might appear intuitive that the presence of a large postvoiding residual volume of urine would predispose an individual to bacteriuria, there is no consistent evidence of such a causal relationship (152). A neurogenic bladder can predispose to infection because of the high likelihood of instrumentation for diagnosis and/or therapy in these patients. It is not known whether the risk of infection posed by instrumentation is higher than usual in patients with diabetes. The distribution of organisms found in the urine of patients with diabetes is similar to that in other populations. Diabetes was found not to be a risk factor for recurrent urinary tract infections in postmenopausal women (153).

PYELONEPHRITIS AND RENAL PAPILLARY NECROSIS

While the precise incidence of pyelonephritis in individuals with diabetes as compared with that in persons without diabetes is not well documented, patients with diabetes have been shown to be at increased risk for renal papillary necrosis, which is often, although not always, a result of pyelonephritis. One study has shown that diabetic patients with proteinuria are more apt to develop infections with P-fimbriated strains of *E. coli*, which are more likely than nonfimbriated strains to cause ascending infection (154). There is a suggestion from work done in a diabetic rat model that polyuria facilitates the ascent of bacteria from the bladder by creating vesicoureteral reflux (155).

Infection may be both a cause and an effect of renal papillary necrosis. Most patients who are symptomatic for this entity have concomitant pyelonephritis (156). In addition to the colicky flank pain that is possible from the passing of a papillary fragment, there may be fever, chills, flank tenderness, and pyuria. Renal papillary necrosis should be suspected in patients with diabetes who have frequently relapsing or difficult-toeradicate pyelonephritis as well as in those who have a particularly fulminant presentation of pyelonephritis accompanied by hematuria. Diabetes is estimated to be present in 30% to 50% of patients with renal papillary necrosis. Of note is evidence for other risk factors, such as analgesic use, in these patients (157,158). Autopsy series of persons with diabetes have noted renal papillary necrosis in about 5% (156). A study of diabetic outpatients with and without asymptomatic bacteriuria found mild or moderate papillary necrosis by intravenous pyelography in 18 of 76 patients, but in none of 34 nondiabetic control subjects (156). The percentage of patients who had experienced more than three urinary tract infections was higher in those with papillary necrosis. Women account for 80% of patients with papillary necrosis among both diabetic and nondiabetic patients.

Eradication of infection is a requirement for effective treatment. Catheter drainage or percutaneous nephrostomy may be required for obstruction and pyelonephrosis. Debris may be dislodged with irrigation or direct urologic manipulations (157). The appropriate duration of antibiotic therapy, which should be directed at usual urinary pathogens, has not been clearly established.

RENAL ABSCESSES

It has been stated that renal abscesses occur with twice the frequency in persons with diabetes as in persons without diabetes (159,160). However, controls have often been compiled retrospectively or merely extrapolated from diagnoses at discharge. Renal parenchymal abscesses can be divided into renal carbuncles (cortical abscesses) and corticomedullary abscesses. Carbuncles are formed from multiple interconnecting cortical microabscesses. More than 90% of them are due to S. aureus, and almost all result from hematogenous seeding of the kidney from a distant focus. Only rarely are they due to ascending urinary tract infection (162). Corticomedullary abscesses are typically associated with some underlying abnormality of the urinary tract such as reflux or obstruction, often in association with instrumentation (159). Bacteriologic studies usually reveal the involvement of gram-negative enteric organisms that commonly cause urinary tract infections, such as E. coli, Klebsiella species, and Proteus species. Patients with parenchymal abscesses can present with flank pain, fever, chills, or abdominal pain. Nausea and vomiting are common. Dysuria may be absent, and urinalysis may reveal no abnormalities. A flank mass can be palpated about half the time. Blood cultures may be positive. CT is a useful modality for diagnosing and following parenchymal abscesses (162). Ultrasound can also be helpful. There is a chance that these abscesses will resolve with antibiotic therapy alone, but if no clinical improvement is seen within a few days, if a collection is large, or if obstructive uropathy is present, prompt drainage is required (161). Drainage may initially be attempted with a percutaneous catheter. A prolonged course of antibiotic therapy is generally required. Open incision and drainage may be needed for those who do not respond to closed drainage.

PERINEPHRIC ABSCESS

Diabetes is routinely mentioned as a major contributing factor in perinephric abscess. Various series report that 14% to 75% of patients with perinephric abscess also have diabetes (161). Frequently, however, many patients in these series have also had previous urinary tract infection, undergone urologic surgery, or had other risk factors, and it cannot be determined which of these individuals have had concomitant diabetes.

A perinephric abscess consists of purulent material between the Gerota fascia and the capsule of the kidney and most often results from rupture of a renal parenchymal abscess. Rarely, it may be the result of contiguous extension of a local process such as osteomyelitis or intraabdominal infection. The bacteria isolated from the abscess thus reflect the source of the infection. *S. aureus* (usually from a renal carbuncle) and gram-negative enteric organisms (as from rupture of a corticomedullary abscess) are the most common. As with any abscess, presentation may be fulminant or the course may be indolent and the presentation delayed (163,164). Fever and flank tenderness are the most common signs. Urinalysis can reveal abnormalities if ascending urinary tract infection is the underlying cause. A high clinical suspicion is usually needed to make the diagnosis. Often a patient with undiagnosed perinephric abscess will be treated for pyelonephritis without the symptoms resolving within 4 to 5 days. This delay in response should prompt radiographic evaluation, preferably with an abdominal CT scan, which can reveal suggestive or even characteristic findings. Perinephric abscesses can track along any of several fascial planes, leading to peritoneal, retroperitoneal, or pleural space collections. The utility of CT scanning in the diagnosis of perinephric abscesses may be responsible for a recent decrease in the mortality rate from 50% to one of 0% to 5% (163). In contrast to parenchymal abscesses, perinephric abscesses mandate drainage in combination with a prolonged course of antibiotics. Placement of a catheter for closed drainage, often under CT guidance, may suffice, but open drainage may be needed for collections that are slow to resolve or multiloculated or if the patient is failing to improve with closed drainage of the abscess.

Fungal Infections

ORAL CANDIDIASIS

Although persons with diabetes are often said to experience an increased incidence of oral candidiasis (165), most papers address the issue of colonization only. Hill et al. (166) using the direct swab technique, found that a level of HbA_{1c} of $12\overline{\%}$ or greater correlated with yeast colonization. Analyzing a much larger group of patients (412 patients), Fisher et al. (167) found no correlation between level of glycemic control and yeast colonization as determined by the oral rinse technique. Both these studies and others have documented an increased rate of candidal carriage as well as an overall increase in colony counts in patients with diabetes who wear dentures as compared with those who do not. A study of the incidence of overt denture stomatitis failed to show any difference between the incidence in diabetic and nondiabetic persons with dentures (168). Bartholomew et al. (165) examined cytologically the oral mucosa of a group of 60 diabetic inpatients and 57 age- and sexmatched controls, none of whom had clinically apparent oral candidiasis. Almost 75% of the patients with diabetes, versus 35% of controls, were colonized. Although no difference was found between the incidence of antibiotic usage in patients with diabetes who were colonized and those who were not, there were no control patients receiving antibiotics.

Treatment of clinically overt oral candidiasis in patients with diabetes is the same as that for nondiabetic patients. Clotrimazole troches offer an alternative to nystatin solutions. For refractory cases, oral systemic therapy is an option. Fluconazole has proven useful for treatment of even severe candidal mucositis such as that seen in chronic mucocutaneous candidiasis, which in rare cases is associated with diabetes mellitus, and for treatment of oral candidiasis associated with AIDS (169).

VULVOVAGINAL CANDIDIASIS

Although there is an often-repeated anecdotal association between diabetes and vulvovaginal candidiasis, no prospective controlled trials have addressed the issue, and the confounding effect of concomitant antibiotic use has not been factored out in most studies. A study of the vaginal microbial flora of diabetic and nondiabetic women showed no difference in the isolation of *C. albicans* (170). Most experts agree with the statement of Sobel (171) that vulvovaginal candidiasis is "unlikely to be the only manifestation of occult diabetes"; none of 85 women with recurrent vaginal candidiasis who were referred to that author for evaluation of diabetes mellitus had an abnormal 2-hour glucose tolerance test (171). The incidence of candidal vulvovaginitis increases during pregnancy, a change that may be due to an estrogenic effect that results in an increase in vaginal glycogen stores. This change in ambient glycogen levels has also been postulated to occur in persons with diabetes (172). Various azoles are available for intravaginal use. Therapy with intravaginally administered miconazole results in a 90% cure rate after 1 week. Oral fluconazole therapy may be useful in some cases (140).

FUNGAL URINARY TRACT INFECTION

C. albicans and, less commonly, Candida (formerly Torulopsis) glabrata, are found in the urine of a small percentage of healthy women (173). The use of antibiotics or the presence of an indwelling urinary catheter are conditions frequently predisposing to increased colonization with these fungi. Although there is debate concerning how many colonies are indicative of urinary tract infection, 10⁵ colonies/mL of urine is generally considered significant, although true infection can occur with even lower colony counts. Lower urinary tract infection is typically antecedent to ascending infection. Most patients have the previously mentioned risk factors and/or an abnormal urinary tract. It is not clear precisely what role diabetes itself plays. A review of C. glabrata infections noted that three of nine patients with "significant urinary tract infections" had undergone urologic surgery and, oftentimes, had been treated with antibiotics (174). Discontinuation of antibiotics or removal of an indwelling catheter may be sufficient to clear candidal organisms from the urine. More often, however, because many of these patients have residual urinary tract abnormalities that may hinder clearance, therapy may be required. In the past, local instillation of amphotericin B into the bladder, either intermittently or with constant irrigation, was favored. More recently, fluconazole has been preferred for treatment of infection due to susceptible Candida species in most circumstances because it can be administered orally and high concentrations are achieved in the urine.

Pyelonephritis due to candidal organisms can result from hematogenous spread in systemic candidiasis (175), for which diabetes is not a risk factor. Manifestations of upper urinary tract disease related to initial cystitis, with infection ascending to the upper tract, can manifest as fungus balls (176), which are aggregates of pseudohyphae that can be found in the renal pelvis or ureters and appear as irregular, radiolucent filling defects (177). Fungus balls may be found more frequently in patients with diabetes. Removal of the obstructing mass, either by closed methods such as with a basket or by an open surgical procedure, is required. The antifungal therapy in this situation must be individualized. Bladder irrigation alone is not adequate because the upper tract is not reached. Systemic antifungal therapy with azoles or amphotericin B is required for parenchymal upper tract disease.

A form of fungal ball that is particularly unusual and difficult to deal with is the renal aspergilloma (178). Several of the reported patients have had diabetes, sometimes in conjunction with other possible predisposing conditions such as immunosuppression. Patients typically give no evidence of disseminated aspergillosis and present with symptoms suggestive of renal colic associated with kidney stones or sloughed renal papillae. Retrograde pyelography is the most informative radiologic test. The recovery of aspergillus from fungal urine cultures is higher than the recovery when routine (bacterial) culture techniques are used. The cornerstone of therapy is the removal of the obstructing mass. The means by which the fungal ball is removed can range from spontaneous evacuation by the patient to multiple open procedures, and possibly even nephrectomy when the mass is not expelled or otherwise removed. Amphotericin B has been used in this setting, but the precise role of amphotericin therapy and the optimal regimens for its use are still unclear.

STAPHYLOCOCCUS AUREUS INFECTIONS

It has generally been maintained that the frequency of carriage of S. aureus by persons with diabetes, particularly those who use daily insulin injections, is higher than that in diabetic subjects using oral hypoglycemic agents and in nondiabetic subjects. However, studies addressing this issue are often difficult to evaluate and even more difficult to compare because of the lack of consistent control groups and stratification of patients. Smith and O'Connor (179) found a 75% rate of nasal carriage in diabetic children as compared with a 44% rate in hospitalized nondiabetic children. Healthy adults and patients with diabetes receiving oral hypoglycemic agents had a 35% carriage rate, whereas patients with diabetes using insulin had a 53% carriage rate. The idea that the use of needles could be an important factor was examined by Tuazon et al. (180), who found a 35% rate of carriage of S. aureus in both intravenous drug abusers and insulin-using diabetic patients but an 11% rate in diabetic patients receiving only oral hypoglycemic therapy and in nondiabetic subjects who did not receive injections. Chandler and Chandler (181) reported a higher rate of carriage of S. aureus in patients with diabetes than in subjects without diabetes, but statistical analysis was minimal; all of the patients with diabetes being considered as one entity regardless of therapy, which ranged from dietary therapy alone to daily insulin injections. A population-based study by Boyko et al. (182) did not demonstrate an increased prevalence of S. aureus carriage among patients with non-insulin-dependent diabetes, regardless of the form of therapy they were receiving. Lipsky et al. (183) considered a number of factors, including recent hospitalizations, level of glycemic control, type of therapy, age, and recent antibiotic use, in a group of diabetic outpatients. Of the 44 controls, 11% had nasal colonization with S. aureus, whereas 30.5% of the 59 patients with diabetes were colonized. The rate of colonization was no different for those who injected insulin and those who did not. However, the level of glycemic control was inversely related to S. aureus colonization (i.e., the higher the glucose levels, the higher the rate of colonization). This factor has typically not been looked at as a distinct variable in earlier studies. Overall, one of the few definitive statements that can be made regarding this issue is that certain groups of persons with diabetes may have an increased rate of staphylococcal carriage and that this increase may be related to the level of glycemic control or to injection therapy. Suspicion regarding a role for the latter is based on evidence for higher carriage rates among intravenous drug abusers and patients undergoing hemodialysis. It may well be, however, that use of injections is simply a confounding factor when studying the diabetic population.

What are the consequences of an increased rate of carriage of *S. aureus*? In all populations, the rate of postoperative wound infection may be higher among carriers (184). Although patients with diabetes often are categorized as being at high risk for staphylococcal infection in general, investigations of this issue are not abundant. For many years, the "definitive" work was that of Greenwood (185), who in 1927 found a 2.4% rate of erysipelas, furuncles, and carbuncles in a diabetic population. His study included neither cultures nor controls. A paper published in 1942 documented no increased rate of infection (186). Although extensive reviews of staphylococcal infections may include a number of patients with diabetes (187), the insufficiency of the data presented makes it impossible to derive a denominator for the num-

ber of patients with diabetes at risk. A study of the rate of *S. aureus* carriage in a population of patients undergoing CAPD noted a 77% carriage rate among those with diabetes as compared with a 36% rate among those without diabetes (188). All carriers had a higher rate of exit-site infections, but only patients with diabetes had a higher rate of tunnel infections.

While many series have examined the incidence and outcome of staphylococcal bacteremia (189), it is again impossible to draw conclusions about the proportional risk in the diabetic population. Studies are often retrospective and without controls (190). For the same reason, it is difficult to determine the role of diabetes as a risk factor for the development of endocarditis in the setting of staphylococcal bacteremia. Diabetes often is found as a comorbid condition in those who appear more likely to have a poor outcome with endocarditis (191). Cooper and Platt (192) did not find an increased mortality among diabetic patients with diabetes with S. aureus endocarditis as compared with nondiabetic patients with S. aureus endocarditis or with diabetic patients with S. aureus bacteremia without endocarditis. Of note is that all cases of endocarditis due to a primary focus of infection occurred in the diabetic group. Five of six of the diabetic patients with endocarditis had chronic infection with S. aureus in an extremity—in distinction to the situation in which the primary focus is an intravenous catheter, which is usually quickly identified as the source and removed and for which a short course (2 to 3 weeks) of intravenous therapy is often adequate. The risk for diabetic patients with bacteremia related to a promptly removed focus is not known, and a conservative course of therapy (4 to 6 weeks) is reasonable.

Soft-Tissue Infections

Consideration of soft-tissue infections is complicated by confusing nomenclature and a lack of uniform terminology (193,194). One approach has been to use definitions based on the anatomic structures (tissues and tissue planes) involved, but this cannot always be ascertained reliably unless surgical exploration is undertaken. In addition, because of the close relationship of various tissues and potential spaces of the soft tissues, various designations often reflect progressive stages of a single infection. Classification by causative organisms has also been used, but any organism may cause a variety of clinical syndromes, depending on what other microbes are present and what level of tissue is infected. Progress in culture techniques has revealed that polymicrobial infection with a broader spectrum of organisms than has previously been appreciated is often present. The issue is further confounded by the frequent use of eponyms. In recent years there has been debate about the utility of any of the present designations. Obviously, the point of classification should be to organize in a rational fashion the features of an illness to permit accurate communication and judgments about progression, prognosis, and intervention. An attempt has been made here to use the most common terms found in the literature. The reader is referred to any standard surgery or infectious disease text for additional information on this extensive topic.

NECROTIZING FASCIITIS

In several series (195–198), 20% to 80% of patients with necrotizing fasciitis had diabetes. In the most general terms, necrotizing fasciitis is any necrotizing soft-tissue infection that spreads along fascial planes, either with or without overlying cellulitis. It is sometimes categorized bacteriologically as type 1 or type 2, with type 1 referring to an infection involving at least one anaerobe and one or more facultative anaerobes such as streptococci or Enterobacteriaceae (basically, organisms of the

intestinal flora) and type 2 referring specifically to an infection with group A streptococci alone or in combination with S. aureus. Persons with diabetes are prone to type 1 infection. It is most common on the extremities, especially the legs, but can also affect the perineum, abdominal wall, and perianal region. It can also occur almost anywhere as a postoperative wound infection. At presentation, patients are almost universally febrile with systemic signs of moderate to severe toxicity. Initially, examination of the involved site may reveal only edema, warmth, and tenderness. However, as the infection progresses, causing necrosis of the subcutaneous tissues, the vessels supplying the overlying skin become thrombotic, resulting in overlying bullae, gangrene, ulcerations, or discoloration accompanied by anesthesia. Sometimes a small area of overt skin injury belies a large area of underlying fascial necrosis. Underlying musculature becomes involved less frequently (myonecrosis) because of its richer blood supply. Crepitation is reported in about 50% of patients. Necrotizing fasciitis due to group A streptococci may be associated with streptococcal toxic shock syndrome, a dramatic and often fatal condition. A description of this syndrome and a discussion of pathophysiology and recent concepts in treatment are presented elsewhere (199).

The cornerstone of management of necrotizing fasciitis is a high index of clinical suspicion and prompt surgical exploration, with debridement of all the tissues found to be involved. Repeated explorations and ensuing debridement are usually necessary (194–196,199). Grafting may ultimately be necessary. Antibiotic coverage should be aimed at enteric gram-negative organisms, anaerobes, and streptococci. Antistaphylococcal therapy is appropriate when these organisms are suspected. The diagnosis carries a high mortality rate that worsens with delay in surgical intervention and when underlying disease is present.

FOURNIER'S GANGRENE

Fournier's gangrene, first described in 1883, is a rare, anatomically based subclassification of necrotizing fasciitis that occurs around the male genitalia (200-202). It is generally associated with some form of perirectal or urologic disease, often in combination with diabetes. Infection in the periurethral area can spread through the vascular corpus spongiosum to penetrate the tunica albuginea, thus spreading to involve Buck's fascia of the penis. It can then progress along dartos fascia of the scrotum and penis, a direct extension of Colles scrotal fascia, which in turn is an extension of Scarpa's fascia of the anterior abdominal wall. Perirectal infections can have their entry point at Colles fascia and then follow the same tract. Penetration of Colles fascia can result in spread to the buttocks and thigh (201). The typical bacteriologic finding is a mixture of gram-negative bacteria, anaerobes, and possibly streptococci, again reflecting intestinal organisms. Cellulitis is evident relatively early because of the lack of subcutaneous tissue in the penis and scrotum. There is much pain, with swelling, erythema, crepitation, and possible breakdown of the skin with overlying bullae, along with signs of systemic toxicity. Progression is rapid, particularly if the abdominal fascial planes become involved. The testicles are spared because they have a blood supply separate from the fascial and cutaneous circulation of the scrotum. Wide surgical debridement of devitalized tissue is necessary, whereas orchiectomy is not (201,202). Fortunately, the scrotal skin has excellent regenerative properties, and skin grafting may not be necessary. The mortality rate is high, remaining in the range of 40% to 50% even with aggressive management. Incidence of diabetes mellitus in series (there are only about 400 cases in the literature) ranges from 0 to 40%. Whether diabetes increases the risk of death from this syndrome is unknown.

The counterpart of Fournier's gangrene in the female carries no eponym and is less well described, but it involves the vulva and perineum (203). Predisposing factors may include diabetes and pelvic surgical procedures, including episiotomy and pudendal block. Early recognition and surgical debridement are again paramount.

SYNERGISTIC NECROTIZING CELLULITIS

Some sources consider synergistic necrotizing cellulitis as a distinct category of necrotizing soft-tissue infection that preferentially affects patients with diabetes (204). Several authors suggest it may be the severe end of the spectrum of type 1 necrotizing fasciitis that occurs in those with underlying illnesses. The flora is generally made up of one or more species of gram-negative aerobic (or facultative) bacteria and an obligate or facultative anaerobe. A "synergistic" relationship between the infecting organisms has been postulated, given the occurrence of two organisms with differing oxygen requirements. However, the flora may simply reflect the source of the cellulitis, such as the bowel. The role of anaerobes in typical necrotizing fasciitis has come to be appreciated more in the last 10 years. Swartz (205) considers synergistic necrotizing cellulitis to be a variant of necrotizing fasciitis with prominent involvement of skin and muscle as well as of the subcutaneous tissues and fascia. There is classically thin, brown, and malodorous "dishwater pus" seen coming from small ulcers in the skin with surrounding blue-gray gangrene. Normal-appearing skin between the ulcers belies extensive necrosis of underlying muscles and intervening tissue. Early recognition and therapy with broadspectrum antibiotics combined with wide surgical debridement, including debridement of necrotic muscle, are imperative (204,205). As might be surmised from the aggressive nature of this infection, mortality rates are higher than those for a typical necrotizing fasciitis.

NONCLOSTRIDIAL ANAEROBIC CELLULITIS

Although clostridial infection of soft tissue does not occur with increased frequency in the diabetic population, nonclostridial cellulitis (206), which can present in a similar fashion, does. Many non-spore-forming anaerobes have been found mixed with facultative bacteria such as streptococci, enteric gram-negative organisms, or staphylococci. Although the bacteriologic composition of the infection is comparable to that of synergistic necrotizing cellulitis, nonclostridial anaerobic cellulitis sharply contrasts with this entity in its lack of muscle involvement. The cellulitis typically occurs around a lower-extremity wound. Extensive gas is found on radiologic examination, and crepitation is typically palpable. Other skin findings are minimal. There is moderate systemic toxicity. Antibiotic therapy is aimed at a mixed anaerobic and aerobic infection. Surgical debridement of necrotic tissue with exploration to exclude involvement of deeper tissues is undertaken as necessary.

Tuberculosis

The purported relationship between diabetes and tuberculosis dates back to Roman times. Autopsies in the 18th and 19th centuries were supportive of this association as well, although the tubercle bacillus was not discovered until 1882 (207). However, as in so many conditions frequently thought to be associated with diabetes, the actual increased risk is difficult to assess because of the lack of controlled prospective studies. In addition, studies have tended to draw from populations that may, for other reasons, have a higher incidence of tuberculosis. Such groups at increased risk might include clinic populations and hospitalized patients. In an extensive recent review of the epi-

demiology of tuberculosis, Rieder et al. (208) drew on three large surveys from the 1950s that included some form of control group and/or information on the population. The combined data suggest a relative risk of tuberculosis in individuals with diabetes that is 2.0 to 3.6 times the risk in those without diabetes. In Papua New Guinea, the frequency of occurrence of tuberculosis in patients with diabetes was found to be 11 times the expected rate in the general population (209). An association between tuberculosis and diabetes has been noted recently in the United States as well. In a case-control study using hospital discharge data from California, diabetes was identified as an independent risk factor for tuberculosis in Hispanic and, to a lesser extent, non-Hispanic white patients (210). The Centers for Disease Control and Prevention (CDC) still identifies diabetes mellitus as a medical condition that increases the risk of tuberculosis and justifies tuberculin skin-test screening of affected individuals (211).

GENERAL CARE OF THE DIABETIC PATIENT WITH REGARD TO INFECTION AND IMMUNIZATION

Generally speaking, the selection of antibiotics for the treatment of infections in patients with diabetes is influenced by the same factors that affect the choice of drugs for any other individual. An extra measure of caution should be applied when considering potentially nephrotoxic drugs. Because many patients with diabetes have or are at risk for diabetic nephropathy, it would be especially desirable to prevent the added insult of toxic injury. When such drugs must be used, careful attention should be directed to measures of renal function, drug dosing, and measurement of serum levels of drug if applicable. By the same token, consideration should be given to possible difficulties arising from the use of potentially ototoxic (auditory and/or vestibular) antibiotics in patients with visual loss due to diabetic retinopathy. In this group, difficulties with hearing or balance may have greater significance than in the general population. When orally administered antibiotics are used in patients with diabetic gastroenteropathy, the possibility of unreliable drug absorption should be kept in mind.

Immunizations

Patients with diabetes should receive immunizations according to the guidelines set forth by the CDC (212). None of the available toxoids or vaccines is contraindicated solely on the basis of diabetes (212). There are two vaccines for which diabetics should be given special consideration: the influenza vaccine and the pneumococcal vaccine (213). Immunization of individuals with diabetes, who are at risk of serious complications from influenza and pneumococcal disease, is a national public health objective in the United States (214). The influenza vaccine, a combination of inactivated viral strains that is modified annually (215), is 70% to 90% effective if the circulating virus is homologous to the vaccine strains. Immunization with influenza vaccine is particularly important for the elderly, who experience excess morbidity and mortality from the complications of influenza (216). In one study, when patients with diabetes who had influenza were stratified by age into those older and those younger than 45 years, those older than 45 years had excess morbidity and mortality if they also had cardiovascular disease (217). Good antibody responses have been documented in individuals with well-controlled diabetes (218) receiving either insulin or oral therapy (219,220). Immunization with influenza vaccine can substantially reduce hospital admissions of individuals with diabetes during influenza outbreaks (221).

1030 JOSLIN'S DIABETES MELLITUS

The pneumococcal vaccine available since 1984 is a 23-valent vaccine containing capsular polysaccharide antigens of at least 85% to 90% of those strains responsible for invasive disease (222). The vaccine appears to be effective in individuals with diabetes (223). While the techniques of measuring antibody responses to pneumococcal vaccine have been controversial (224), it appears that people with diabetes do have an adequate antibody response (225). It is not clear whether diabetes alone increases the risk of pneumococcal disease or its complications. Diabetes has often been present in patients with serious pneumococcal infection, but usually as a comorbid condition (225). Diabetic patients with cardiac disease may be at some increased risk for serious pneumococcal infection, and pneumococcal vaccination is suggested in these cases as for patients with cardiopulmonary disease in general (212,213,223,226).

The hepatitis B vaccine is worth noting in connection with diabetes in that questions had been raised about whether adequate antibody levels are achieved after the usual dosing schedule of 0, 1, and 6 months (227–229). It appears that most young diabetic individuals do respond to a standard regimen with adequate antibody titers (230). Further studies may determine which populations, if any, might benefit from booster doses of this vaccine.

Perioperative Glucose Control

Intriguing new information suggests that good control of blood glucose levels in the immediate perioperative period may reduce the risk of postoperative infection in patients with diabetes. Data supporting this concept have derived from studies of patients undergoing cardiac (231–233) or major intraabdominal (233) surgical procedures. Although it is conceivable that early postoperative hyperglycemia merely reflects infection or extensive tissue injury that may predispose to infection, evidence is pointing to the likelihood that hyperglycemia itself is a likely risk factor for serious infection in the postoperative period (234).

PREGESTATIONAL DIABETES 1035

Fetal Risk 1036 Maternal Risk 1038 Complications of Diabetes during Pregnancy 1039 Managements of Diabetes in Pregnancy 1040 Treatment of Diabetes during Pregnancy 1040 Fetal Monitoring 1041 Labor and Delivery 1041 Postpartum Management 1041

GESTATIONAL DIABETES 1042

Definition and Incidence 1042 Pathogenesis 1042 Screening and Diagnosis 1042 Management 1043 Labor and Delivery 1044 Postpartum 1044

Pregnancy may be complicated by diabetes in two distinct forms: gestational and pregestational diabetes. Gestational diabetes typically is diagnosed during the second half of pregnancy and occurs when the β -cell reserve is unable to counterbalance the insulin resistance caused by placental hormones. Although gestational diabetes mellitus usually is asymptomatic, the consequences may be substantial. Fetal complications include stillbirth, macrosomia, increased risk of birth trauma, and neonatal hyperbilirubinemia and/or hypoglycemia. In the United States, the definition of gestational diabetes is based on the results of the 3-hour 100-g oral glucose tolerance test. The interpretation of this test remains controversial, in part because the diagnostic thresholds define future risk of type 2 diabetes rather than fetal outcomes and because laboratory techniques for measuring glucose have changed over time (1). At this time, the American College of Obstetrics and Gynecology (ACOG) accepts two different diagnostic criteria for gestational diabetes (2), one of which is recommended by the American Diabetes Association (ADA) (3) (Table 61.1). To complicate matters, the World Health Organization (WHO) defines gestational diabetes on the basis of the 2-hour 75-g glucose tolerance test (4). The use of multiple diagnostic criteria used in the United States and worldwide underscores the lack of outcome data from randomized clinical trials.

Diabetes that antedates pregnancy is called pregestational diabetes. Because of differences in the age-specific incidence rates of the two diseases in relation to the childbearing years, most of the patients in the population at the Joslin Clinic with pregestational diabetes have type 1 rather than type 2 diabetes. However, the prevalence of obesity in childhood and adulthood has resulted in a higher prevalence of type 2 diabetes and its onset at younger ages. Many centers are seeing increasing rates of pregestational type 2 diabetes, especially in Hispanic and Native American communities (5). In addition, as women delay childbearing into their fourth and fifth decades, type 2 diabetes

is seen during pregnancy with increasing frequency in these women. Often women do not seek medical attention until they become pregnant, so it may rest with the obstetrician to make the diagnosis of diabetes and determine the type of process underlying the diagnosis. The importance of the ADA recommendation to screen the population at high risk for "gestational diabetes" as soon as feasible during pregnancy cannot be overemphasized. In fact, the purpose of early screening in highrisk patients is to identify undiagnosed pregestational type 2 diabetes (6). Features that identify patients at high risk are discussed in the specific section on gestational diabetes.

Pregnancies complicated by pregestational diabetes, either type 1 or type 2, carry additional risks to both the mother and the fetus beyond the effects on fetal growth and development in midpregnancy and late pregnancy that occur with gestational diabetes. Metabolic derangements present at the time of conception and during blastogenesis and organogenesis increase the risk of spontaneous abortions and congenital malformations. Placental vasculopathy in patients with diabetic complications may adversely affect the necessary flow of oxygen and nutrients to the fetus later in pregnancy.

This chapter discusses these two categories of diabetes and pregnancy: gestational diabetes and pregestational diabetes. Discussion of the management of pregestational diabetes focuses on defining and reducing fetal and maternal risks. The pathogenesis, diagnosis, and treatment of gestational diabetes are reviewed. We first will consider the management of women with pregestational diabetes.

PREGESTATIONAL DIABETES

Most women with diabetes hope and expect to be able to bear children, and for only a few of them is pregnancy absolutely contraindicated. Yet there is a broad range of risk to both the mother

TABLE 61.1. Two Diagnostic Criteria forGestational Diabetes				
	Plasma glucose levels (mg/dL) after 100 mg oral glucose

Fasting 1 h 2 h 3 h	≤95 ≤180 ≤155 ≤140	≤105 ≤190 ≤165 ≤145		

American Diabetes Association recommends Carpenter and Coustan criteria (3). American College of Obstetrics and Gynecology accepts both criteria (2). In either case, two or more venous plasma samples must exceed diagnostic levels to be positive.

and the fetus within this group of women. Concurrent conditions or complications, including retinopathy, nephropathy, neuropathy, hypoglycemia unawareness, hypertension, hypercholesterolemia, maternal age, obesity, and behaviors such as smoking and poor glycemic control, may impact risk. Thus, an assessment of risk should be made for every woman *prior* to pregnancy, and her individual risk should be discussed with her and with her spouse or partner. All attempts should be made to optimize any modifiable risk factors. To accomplish this, during their reproductive years, all women should be educated by their primary care physicians and/or diabetes healthcare provider on the importance of pregnancy planning to ensure the most successful pregnancy possible. The infants of patients who receive preconception counseling incur fewer congenital malformations and lower healthcare costs (7).

More than 50 years ago at the Joslin Clinic, Priscilla White devised a classification system to stratify fetal and maternal risk in pregnant women with diabetes (8). The White classification of diabetes during pregnancy was defined by duration of diabetes,

Table 61.2. White Classification of Diabetes During Pregnancy (Revised)

Gestational diabetes	Abnormal glucose tolerance test, but euglycemia maintained by diet alone or diet alone insufficient, insulin required
Class A	Diet alone sufficient, any duration or age of onset
Class B	Age at onset ≥20 y and duration <10 y
Class C	Age at onset 10–19 y or duration 10–19 y
Class D	Age at onset <10 y or duration ≥20 y or background retinopathy or hypertension (not preeclampsia)
Class R	Proliferative retinopathy or vitreous hemorrhage
Class F	Nephropathy with proteinuria >500 mg/dL
Class RF	Criteria for both classes R and F coexist
Class H	Arteriosclerotic heart disease clinically evident
Class T	Prior renal transplantation

Women in classes below A require insulin therapy. Women in classes R, F, RF, H, and T have no criteria for age at diabetes onset or duration of diabetes but usually have long-term diabetes. The development of a complication moves the patient to the next class.

Copyright \bigcirc 1980 American Diabetes Association. From Hare JW, White P. Gestational diabetes and the White classification. *Diabetes Care* 1980;3:394. Reprinted with permission from the American Diabetes Association.

age of onset, and concurrent complications. The premise of the White classification was that younger age at diagnosis and longer duration of diabetes increase the risk of microvascular and macrovascular complications and that these complications affect maternal and fetal outcomes. An updated version of the White classification is shown in Table 61.2 (9).

In current medical practice, almost all women with preexisting diet-controlled diabetes will require insulin during their pregnancies because the goals for fasting and postprandial glucose levels have been lowered since the original classification system was first devised. Thus, the women who would previously have been in "class A," defined by preexisting dietcontrolled diabetes at any age of onset or duration, would now be assigned to class B or below, defined as age of onset at 20 years of age or younger and a duration of less than 10 years. Class C is defined by age of onset at 10 to 19 years of age or duration of 10 to 19 years. Class D includes women with age of onset at less than 10 years of age or duration of 20 years or more or women with a shorter duration of diabetes or with older age of onset who also have background retinopathy or hypertension. Hypertension caused by preeclampsia is not included in class D diabetes. Class F indicates the presence of diabetic nephropathy as defined by proteinuria of greater than 500 mg per day or albuminuria of greater than 300 mg per day. A normal spot urine microalbumin value of less than 20 µg per milligram of creatinine has increased both the sensitivity and the specificity of ruling out diabetic nephropathy and eliminated the need for a baseline 24-hour urine (10). Class R includes women who have proliferative retinopathy or vitreous hemorrhage. Class RF patients meet criteria for both R and F. Class T includes patients with prior renal transplantation. Patients in class H have clinically apparent coronary artery disease.

Studies from the Joslin Clinic (11,12) and other institutions demonstrate very little difference in outcomes in classes B, C, and D, whereas class F diabetes increases the risk of maternal hypertensive complications and fetal intrauterine growth retardation and prematurity (12-21), with reduced perinatal survival ranging from 89% to 100% but averaging approximately 95% in a series of 10 different studies compiled by Reece and colleagues (21). Microalbuminuria has been shown to be a risk factor for preeclampsia. Of 158 normotensive women with microalbuminuria as defined by urinary excretion of 190 to 499 mg of protein per 24 hours, 31% developed preeclampsia. In patients with hypertension plus microalbuminuria, the incidence of preeclampsia was 50% (22-24). A lower-case "f" could be used to distinguish this additional risk in classes B, C, D, and R. For example, a 30-year-old woman who has had diabetes for 8 years and has microalbuminuria would be defined as "Bf." If this woman also has hypertension, she would be classified as "Df" (although additional studies are needed to evaluate the risk from lower levels of microalbuminuria). Changes in the classification system would require consensus but could provide additional useful clinical information.

Fetal Risk

CONGENITAL MALFORMATIONS AND SPONTANEOUS ABORTIONS

In the 1940s, just 20 years after the discovery of insulin, congenital malformations accounted for about 15% of the 20% to 30% perinatal mortality rate among infants of mothers with diabetes (25). Advances in medical and obstetric care, including home blood glucose monitoring, fetal monitoring to detect fetal distress, and the ability to assess fetal lung maturity, have reduced the incidence of stillbirth and respiratory distress syndrome due

to prematurity. More recently, the perinatal mortality rate for infants of diabetic women remains elevated, at approximately 3%, compared with 1.5% in the general population. However, 50% of perinatal deaths in infants of diabetic women are due to lethal fetal anomalies, which now account for most of the excess perinatal mortality.

An increased incidence of congenital malformations in diabetic pregnancies was first suggested in the 1940s by Priscilla White and others (8,18,26). In 1971, Kucera pooled data from 47 reports published between 1945 and 1965 that included different geographic areas and ethnic populations. Of 7,101 infants born to diabetic mothers, 4.8% had congenital malformations compared with 0.65% of 431,764 reported in the general population by WHO (27). More recent studies report incidences of 5% to 9% in clinics treating women with pregestational diabetes (28) as compared with approximately 2% in the general population. Ten malformations have been identified with a higher frequency in infants of diabetic women than in infants of the general population (27) (Table 61.3). The malformations most commonly associated with diabetes, including neural tube, renal, and cardiac defects, occur before the 7th week after conception (29). The finding of multiple associated anomalies suggests a "hit" during blastogenesis that occurs during the first 4 weeks of fetal development. Anomalies during blastogenesis tend to be more severe than those that occur during organogenesis (weeks 4 to 5 after conception) and may increase the risk of spontaneous abortions (30). Thus, interventions to control glycemia and reduce the risk of malformations must begin before conception and continue through the first 7 weeks after conception.

The suggestion that maternal hyperglycemia was associated with anomalies was made by Leslie et al. (31), who reported three affected infants among a total of five infants of diabetic mothers with poor metabolic control as defined by levels of hemoglobin A_{1c} (HbA_{lc}). Miller et al. (32) reported that for patients with HbA_{1c} levels of 8.5% of less, the incidence of malformations was 3.4% as compared with an incidence of 22.4% in patients with HbA_{1c} levels greater than 8.5%. Although one study suggested a threshold for increased malformations as 12 standard deviations (SD) above the mean (33), a continuum of risk may be present with more modest elevations (34) (Table 61.4). Furthermore, an increased incidence

of spontaneous abortions also has been reported in patients with elevated HbA $_{\rm lc}$ levels (28).

Because congenital malformations occur early in the first trimester of pregnancy, studies have been focused on improving glycemic control beginning before conception. For ethical reasons, these studies are not randomized, and patients who present for preconception counseling tend to be a self-motivated group. These studies reveal a 2% to 3% risk of malformations in infants of the subjects who receive preconception counseling, compared with a 6% to 10% risk in infants of patients who present for diabetes management after conception (40-48). These findings are consistent with the belief that optimization of blood glucose levels before conception can reduce this risk of malformations to a level near that of the general population. Despite the potential benefit of preconception counseling, fewer than 50% of diabetic pregnancies are planned. Women who plan their pregnancies tend to be married, nonsmokers, and white; have higher income and education levels; and report supportive relationships with their healthcare providers. Of note, women whose doctors discourage pregnancy are more likely to have unplanned pregnancies than are women who are encouraged and supported (49).

MACROSOMA AND CESAREAN SECTION

Large-for-gestational age infants are defined as those greater than the 90th percentile weight for gestational age. The incidence of macrosomia has been reported to be 28.5% among infants of patients with type 1 diabetes as compared with 13.1% among infants of controls without diabetes (50). Macrosomic infants experience increased rates of birth trauma, neonatal hypoglycemia, hyperbilirubinemia, respiratory distress, erythrocytosis, and hypertrophic cardiomyopathy. A relationship between maternal glycemic control in one or more trimesters of pregnancy and macrosomia has been noted in many (50-54) but not all (55,56) studies. Fasting glucose level appears to have less effect than nonfasting glucose level on macrosomia. Greater maternal weight gain during pregnancy has also been associated with higher infant birth weight. Factors inversely related to infant birth weight include maternal blood pressure higher than 140/90 mm Hg at any time during pregnancy and class F or RF diabetes.

A likely mechanism underlying the relationship between maternal hyperglycemia and infant birth weight was first proposed by Pederson et al. (57) in the 1950s. Maternal transfer of glucose and other substrates across the placenta causes fetal pancreatic hyperplasia and hypersecretion of insulin by fetal β -cells. This results in fetal anabolism and increased fetal adiposity. Hypersecretion of insulin by hyperplastic β -cells after delivery may result in neonatal hypoglycemia (defined as plasma glucose <40 mg/dL) and occurs when the maternal source of glucose to the fetus has been eliminated and relative fetal hyperinsulinemia persists.

NEONATAL HYPOGLYCEMIA

The incidence of neonatal hypoglycemia was approximately 30% in one large study, ranging from 25% in infants of class B mothers to 38% in infants of class D and R mothers (58). Neonates of women who achieve mean preprandial capillary glucose levels of less than 110 mg/dL during the second and third trimesters may have a lower incidence of moderate-to-severe hypoglycemia (<30 mg/dL) than neonates whose mothers have mean capillary glucose levels higher than 110 mg/dL (18.6% vs. 40.6%, respectively) (59). Achieving mean intrapartum glucose levels of less than 100 mg/dL can also decrease the incidence of neonatal hypoglycemia (60).

PREMATURITY AND PERINATAL SURVIVAL

Prematurity occurs with greater frequency in infants of diabetic mothers, especially when diabetes is complicated by renal disease. In most cases, preeclampsia or fetal distress with or without intrauterine growth retardation is present. The incidence of prematurity depends on the definition. Delivery before the 34th week of gestation occurs in approximately 25% of class F or RF pregnancies and before the 37th week of gestation in 50% of pregnancies. Morbidities, including predelivery intrauterine growth retardation and postdelivery respiratory distress syndrome of varying severity, occur in approximately 20% of pregnancies (61).

Variations in the incidence of preeclampsia at different centers arise in part because of the difficulty in distinguishing preeclampsia from the worsening proteinuria and hypertension typical of the late second trimester and the third trimester of pregnancy in patients with chronic diabetic nephropathy. Clinical signs that suggest preeclampsia, such as hemolysis, thrombocytopenia, and transaminase elevations, may not always be present. On the basis of this indistinct clinical picture, the obstetrician is in the difficult position of balancing a poorly defined maternal risk with potential neonatal risks from early delivery.

Most infants of class F and RF pregnancies and many infants of class B through D pregnancies require monitoring in a neonatal intensive care unit. Therefore, these infants should be delivered in tertiary care hospitals where such services are available. Monitoring in neonatal intensive care units is expensive, particularly when infants require lengthy stays, but may be critical to ensure good outcomes for the newborn. Despite the high incidence of short-term morbidity, the overall perinatal survival in class F and RF infants is greater than 95% (21). There are fewer data regarding long-term outcomes for these infants. Pooled data from three separate studies involving 80 children evaluated, on average, at 38 months of age (range, 8 to 78 months) demonstrated psychomotor impairment in 6% (range, 3.7% to 9%) (62).

Maternal Risk

HYPOGLYCEMIA

Hypoglycemia is the most pervasive risk that women with uncomplicated diabetes face during their pregnancies. Severe hypoglycemia occurs in up to 40% of these pregnancies (63). The most severe hypoglycemia occurs during the first half of pregnancy and may be the result of several factors, including emphasis on strict blood glucose control, inconsistent dietary intake associated with morning sickness, and relative insulin sensitivity as compared with that during the second half of pregnancy (64).

Although rats that sustain severe, prolonged hypoglycemia during organogenesis have an increased incidence of congenital malformations, severe hypoglycemia does not seem to be teratogenic in humans. The difference between animal models and humans is not clear but may be related to a dose or duration effect relative to the duration of gestation.

Women whose only symptoms of hypoglycemia are related to neuroglycopenia are at increased risk of severe hypoglycemia. To reduce the risk of severe hypoglycemia, they should assess their blood glucose levels more frequently, including before and after meals, before and after exercise, and before driving. Newer techniques providing continuous glucose sensing may prove to be protective. Hypoglycemia should be treated immediately with 15 g of fast-acting carbohydrate. The finger-stick blood glucose level should be rechecked in 15 minutes and an additional 15 g of carbohydrate given until symptoms have resolved or the blood glucose level is greater than 80 mg/dL. Treating hypoglycemia with unrestricted carbohydrate may result in rebound hyperglycemia. Family and friends should be ready to assist in the case of severe hypoglycemia. Designated family members and friends should be taught how to use the Glucagon Emergency Kit[®].

To improve glycemic control and to ensure the appropriate temporal relationship between caloric ingestion and insulin pharmacokinetics, meals and snack times should be consistent. Many patients use carbohydrate counting in association with short-acting insulin given before meals, with the insulin dose based on a predetermined insulin/carbohydrate ratio and the amount of carbohydrate ingested at a particular meal. This approach allows for flexibility with dietary intake. In the nonpregnant population with diabetes, two insulin analogues, insulin lispro and insulin aspart, have been shown to effectively reduce postprandial hyperglycemia (65-70). Given the shortened duration of action of these insulin analogues, they cause less premeal and nocturnal hypoglycemia than does regular human insulin. Data regarding the use of short-acting insulin analogues in pregnancy are limited, but there are no clear adverse effects (71,72). Because pregnancy is a physiologic state associated with exaggerated postmeal hyperglycemia and premeal hypoglycemia, short-acting insulin analogues may be useful therapeutic agents. The new basal insulin analogue insulin glargine, with its long duration of action, has not been studied in pregnancy. The potential effects on the fetus of its binding to the insulin-like growth factor (IGF) receptor with 6.5 times the avidity of human insulin have not been evaluated (73). Insulin lispro has a Food and Drug Administration pregnancy safety rating of B, whereas insulin aspart and insulin glargine have ratings of C.

HYPERTENSIVE DISORDERS

Patients with preexisting diabetes are at increased risk of hypertensive complications during pregnancy. According to the National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy 2000, hypertensive disorders are classified as (a) chronic hypertension; (b) preeclampsia-eclampsia; (c) preeclampsia-eclampsia superimposed on chronic hypertension; and (d) gestational hypertension (74). Chronic hypertension is defined as a blood pressure greater than 140/90 mm Hg that is noted before pregnancy or up to the 20th week of gestation. The definition also includes hypertension that is diagnosed during pregnancy and persists beyond 12 weeks post partum. Preeclampsia usually occurs after 20 weeks' of gestation and is defined by blood pressure higher than 140/90 mm Hg associated with proteinuria of greater than 0.3 g of protein per 24-hour urine specimen. Preeclampsia-eclampsia may be superimposed on chronic hypertension, as patients with chronic hypertension are at increased risk of preeclampsia. This condition is associated with a sudden increase in blood pressure, new-onset proteinuria, development of HELLP syndrome (hemolytic anemia, elevated liver enzymes, low platelet counts), or a sudden increase in proteinuria if present in early gestation. Gestational hypertension is diagnosed after 20 weeks of gestation when there are no associated signs of preeclampsia in patients without chronic hypertension.

The ADA supports the goal of maintaining blood pressure under 130/80 mm Hg in nonpregnant patients with diabetes (75). Antihypertensive treatment decreases the rate of progression of diabetic nephropathy and reduces both proteinuria and the decline in the glomerular filtration rate (GFR). It reduces mortality from 94% to 45% and the need for dialysis and transplantation from 73% to 31% 16 years after the development of overt nephropathy. No randomized controlled studies have evaluated the effect of antihypertensive therapy during pregnancy on microvascular and macrovascular complications. The effect of antihypertensive therapy on maternal and fetal endpoints in the general pregnant population has been evaluated. Maternal endpoints include the development of proteinuria, cesarean section, and placental abruption. Fetal outcomes include perinatal mortality, prematurity, small for gestational age, and/or admission to special-care nurseries. Two recent meta-analyses suggest that reduction in mean arterial pressure by antihypertensive medications is associated with an increased odds ratio for small-for-gestational age infants (76,77). It is interesting that the risk of respiratory distress syndrome may be decreased in patients receiving antihypertensive therapy. The Working Group Report recommends initiation of antihypertensive therapy for blood pressures exceeding 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic, or lower in the case of risk factors such as renal disease (74).

Because of the lack of supporting data, there are no guidelines regarding initiation of antihypertensive therapy in the hypertensive diabetic gravida. Given the increased risk of endorgan damage in this population, the Joslin Clinic and others recommend initiating therapy when the blood pressure during pregnancy is at or above 130/80 mm Hg, especially if microalbuminuria or diabetic nephropathy is present (62). A broad range of choices of antihypertensive agents are available, including α -methyldopa and labetalol (77); however, it is important to note that angiotensin-converting enzyme inhibitors and angiotensin II–receptor blockers are contraindicated in the second and third trimesters of pregnancy (78).

Complications of Diabetes during Pregnancy

NEPHROPATHY

One third of patients with type 1 diabetes will develop nephropathy during their lifetime (79), with the peak onset 16 to 18 years after the diagnosis of diabetes. Thus, it is not surprising that 5% to 10% of pregnant women with type 1 diabetes have coexistent nephropathy. This complication imparts higher maternal and fetal risk because of the association with hypertensive complications of pregnancy, including chronic hypertension, preeclampsia, and consequent need for early delivery.

Conversely, the physiologic changes of pregnancy may affect renal function. Increases in GFR, urinary albumin excretion, and mean arterial pressure in pregnancies complicated by nephropathy may worsen preexisting nephropathy. Glomerular hyperfiltration is thought to be one of the initial insults to the diabetic kidney, and some studies have demonstrated an association between increased GFR and higher albumin excretion rates (80,81). During normal pregnancy, the GFR increases by 40% to 60%. There is cause for concern that the pregnant state is an intrinsic environmental exposure to hyperfiltration. Furthermore, albumin excretion increases during the last few weeks of normal pregnancy and peaks 1 week post partum. This physiologic response is exaggerated in women with type 1 diabetes, including those who have normal albumin excretion rates at the beginning of pregnancy. Nevertheless, 6 weeks after delivery, urinary excretion returns to normal for both groups of women (82).

Studies involving women with class F diabetes demonstrate that a majority of these patients develop proteinuria in the nephrotic range by the third trimester of pregnancy. Creatinine clearance remains unchanged throughout pregnancy; however, this actually represents abnormal renal function, because GFR normally rises during pregnancy (18,62). A review by Reece et al. (21) demonstrates an overall incidence of maternal complications such as chronic hypertension and preeclampsia in 42% and 41% of these pregnancies, respectively. The frequency of fetal

1040 JOSLIN'S DIABETES MELLITUS

complications in women with class F diabetes is also increased, with intrauterine growth retardation in 15%, preterm delivery in 25%, and neonatal respiratory distress syndrome in 20%. Nevertheless, overall perinatal survival is 95%. Most studies suggest that pregnancy does not alter the natural history of declining renal function with time, particularly in patients with mild nephropathy. However, some studies do suggest that a subgroup of patients with moderate-to-severe nephropathy, as defined by a creatinine clearance of less than 90 mL per minute and 24-hour urinary protein excretion of greater than 1 g, at the beginning of pregnancy may have a more rapid long-term postpartum decline of GFR as a result of pregnancy, but these data are limited by small sample size (18). One small study suggested that treatment with captopril, started 6 months before conception and stopped after a missed menstrual period and positive pregnancy test, resulted in prolonged reduction in proteinuria during all trimesters of pregnancy compared with baseline values (83).

RETINOPATHY

Risk of progression of diabetic retinopathy is increased as a result of pregnancy (84). This risk is influenced by several factors; in particular, the severity of baseline retinopathy and elevation of the HbA_{1c} more than 6 SD above normal at the first prenatal visit contribute to this risk. The Diabetes in Early Pregnancy Study revealed a two-step progression of retinopathy in 10% of patients with no retinopathy, in 20% of patients with mild nonproliferative retinopathy, and in 55% of patients with moderate nonproliferative retinopathy. Risk of progression to proliferative retinopathy occurred in 6% of patients with mild retinopathy and in 30% of those with moderate retinopathy (84). The Diabetes Control and Complications Trial (DCCT) demonstrated a 1.63-fold risk of progression of retinopathy in the pregnant intensively treated group as compared with their risk before pregnancy. In the conventionally treated group, this risk was 2.4 times greater in the pregnant group than in the nonpregnant group (85). At the end of the DCCT, however, there was no difference in level of retinopathy in patients who had become pregnant as compared with patients who never became pregnant, suggesting no long-term risk of pregnancy for retinopathy.

Management of Diabetes in Pregnancy

PRECONCEPTION COUNSELING

All women of childbearing age with preexisting type 1 or type 2 diabetes, whether or not they are planning a pregnancy, should be educated about the importance of achieving near-normal blood glucose control before conception to reduce the risk of congenital anomalies and spontaneous abortions.

Women with preexisting diabetes who express a desire to conceive should be referred, if possible, to a specialized diabetes and pregnancy program. Preconception counseling should include an assessment of maternal and fetal risk and guidance in achieving preconception management goals. Maternal risk assessment also should include a formal dilated funduscopic examination and clearance for pregnancy by an ophthalmologist. Daily folic acid, 1 mg taken orally, or a prenatal vitamin containing folic acid, 1 mg taken orally, to decrease the risk of neural tube defects should be recommended. Folic acid may be started before conception to prevent neural tube defects, although it has not clearly been demonstrated to reduce events associated specifically with diabetes. Metabolic goals should be established prior to conception (86). Self-management skills should be reviewed. Nutrition counseling to establish an individualized meal plan should be provided. Many patients with type 1 diabetes benefit from implementation of carbohydrate counting and the establishment of an empirically deter-

TABLE 61.5. P	Preconception Tre	eatment Goals	
Goal	Plasma (mg/dL)	Whole blood (mg/dL)

mined insulin/carbohydrate ratio. Mental health professionals should be available for consultations or ongoing management. Preconception blood glucose goals are shown in Table 61.5.

ASSESSMENT OF RENAL FUNCTION

A spot urine microalbumin/creatinine ratio and serum creatinine measurement should be obtained. A protein/creatinine ratio should be obtained if the urine microalbumin is elevated.

CARDIAC EVALUATION

Cardiac evaluation should be considered for women 35 years or older who have one or more additional risk factors for coronary artery disease, including hypertension (blood pressure >130/80 mm Hg), smoking, positive family history, hypercholesterolemia (low-density liproprotein \geq 100 mg/dL, high-density lipoprotein \leq 40 mg/dL), or renal disease (microalbuminuria or nephropathy) (87,88). Testing may include one or more of the following: electrocardiogram, echocardiogram, and exercise tolerance testing (89), with the recognition that the resting electrocardiogram is the least sensitive of these tests.

MANAGEMENT OF HYPERTENSION AND/OR MICROALBUMINURIA

Angiotensin-converting enzyme inhibitors and angiotensin II–receptor blockers should be stopped either before pregnancy or early in the first trimester. Alternative antihypertensive agents include α -methyldopa, hydralazine, β -blockers (e.g., metoprolol and labetalol), and calcium channel blockers (e.g., diltiazem and nifedipine), if necessary. Blood pressure should be managed aggressively.

MANAGEMENT OF HYPERLIPIDEMIA

All cholesterol-lowering agents, including statins, are contraindicated during pregnancy. They should be discontinued before conception. Pregnancy is a risk factor for pancreatitis caused by hypertriglyceridemia. Several cases of pancreatitis associated with hypertriglyceridemia are described in the literature, along with approaches for treatment, including caloric restriction, supplementation with medium-chain triglycerides, and use of intravenous heparin (90–92).

Treatment of Diabetes during Pregnancy

Home blood glucose monitoring is a critical component of diabetes management during pregnancy. Home blood glucose monitoring is performed a minimum of four times daily, including before breakfast, 2 hours after meals, before driving, and with signs or symptoms of hypoglycemia. Premeal and middle-of-the-night testing may be necessary in some patients. First-void urine samples are tested for ketones.

TABLE 61.6.	Postconception Treatment Goals
-------------	--------------------------------

Goal	Plasma (mg/dL)	Whole blood (mg/dL)	
Fasting and premeal glucose 1-h postmeal glucose 2-h postmeal glucose Urinary ketones Normalization of hemoglobin A _{1c} Avoidance of severe hypoglycemia Blood sugar goals must be relaxed for patients with hypoglycemia unawareness	70–106 100–155 90–130 Negative	60–95 90–140 80–120

METABOLIC GOALS DURING PREGNANCY

The metabolic goals during pregnancy have received a great deal of attention and most authorities accept the guidelines in Table 61.6 (3).

Multiple daily insulin injections or continuous subcutaneous insulin infusion (CSII) are almost always required during pregnancy in women with type 1 diabetes to achieve therapeutic goals. The therapy for type 2 diabetes associated with pregnancy is more variable and ranges from medical nutrition therapy to intensive insulin therapy. Modern approaches to intensive insulin therapy utilize the so-called basal-bolus approach. This method uses the concept of meeting both resting (basal) insulin needs and meal-time (bolus) insulin needs in the most physiologic manner possible. Intermediate- to long-acting insulin may be used for basal coverage. Premeal short-acting insulin analogues are used for bolus insulin requirements. Alternatively, CSII uses short-acting insulin for both basal and bolus needs. Patients may need to be seen every 1 to 4 weeks for diabetes management, depending on the sophistication of their self-management skills and the complexity of their medical problems. Intensive insulin therapy should be considered the standard of care during pregnancy.

Fetal Monitoring

Evaluations for neural tube defects and other congenital malformations begin with triple-screen testing at approximately 15 to 21 weeks of gestation. A fetal anatomic survey is performed at 18 weeks of gestation. Fetal echocardiography may be performed at 20 to 22 weeks of gestation to screen for cardiac defects that might not be detected on the 18-week ultrasound scan. Ultrasound is used at 28 weeks of gestation to evaluate fetal growth and the quantity of amniotic fluid. Fetal surveillance, including nonstress test and biophysical profile as well as maternal monitoring of fetal activity (2), is initiated in the third trimester to reduce the risk of stillbirth. The timing and frequency of fetal surveillance depend on diabetes control, coexistence of diabetic nephropathy or hypertension, and fetal growth as shown on ultrasound.

Labor and Delivery

The method of delivery is based on the usual obstetric indications, as well as on fetal weight and the presence or absence of active retinal changes. Infants of diabetic mothers are more likely to be macrosomic. Furthermore, the distribution of adiposity is such that, compared with infants of nondiabetic mothers of the same weight, infants of diabetic mothers have a greater shoulder and chest-to-head disproportion, which increases the risk of shoulder dystocia during delivery of the macrosomic infant. Cesarean sections are recommended for fetuses of an estimated weight greater than 4,500 g. This guideline may be individualized to account for prior obstetric history and adequacy of pelvic size. However, ultrasound remains an imprecise measure of fetal weight and can result in cesarean delivery of normalweight infants.

It is important to maintain euglycemia during labor or prior to a scheduled cesarean section. Patients are instructed to take their usual bedtime insulin the night before delivery. A small dose of intermediate-acting insulin, such as one third of the preconception dose, may be given the morning of induction. Alternatively, intermediate-acting insulin can be withheld and an intravenous insulin infusion begun and titrated to achieve and maintain normoglycemia. Patients with insulin pumps may continue their basal infusion if the infusion set is inserted in the thigh or hip. Basal rates are decreased if the glucose levels drop below 80 mg/dL. If the blood glucose levels rise above 110 mg/dL, the pump may be stopped and an intravenous insulin drip initiated and titrated to maintain blood glucose levels in the range of 80 to 110 mg/dL.

For prolonged labor, 5% dextrose administered intravenously at a rate of 100 to 125 mL per hour will prevent starvation ketosis. If there is concern about volume overload in the setting of preeclampsia, a 10% dextrose drip at 50 mL per hour may be started. Boluses of intravenous glucose should never be given unless absolutely necessary to correct severe maternal hypoglycemia because the elevated maternal blood glucose levels increase the risk of neonatal hypoglycemia, hypoxia, and acidosis.

Postpartum Management

Marked insulin sensitivity frequently occurs immediately post partum, and insulin requirements routinely drop to below preconception levels. Patients should be aware that stringent blood glucose control is no longer necessary immediately post partum. To decrease the risk of severe hypoglycemia, one third to one half of the preconception insulin dose is given during the first 24 hours post partum. Insulin dosing should be titrated daily toward the preconception dose as necessary. Patients with thyroid insufficiency should resume preconception doses of L-thyroxine. Because patients are usually discharged before stabilization of blood glucose, frequent communication between the patient and healthcare providers remains necessary. By 2 weeks post partum, insulin requirements have stabilized, making this a good time for a postpartum visit focusing on glucose management. Between 2 and 6 weeks post partum, patients carefully adjust their diabetes regimen. Serial fasts may be necessary to reestablish appropriate basal insulin rates for patients using insulin pumps. Preprandial and postprandial blood glucose readings and carbohydrate records will help determine insulin-to-carbohydrate ratios in some patients. Insulin requirements may remain low in breastfeeding mothers. Access to carbohydrate should be readily available to prevent hypoglycemia during nursing. Glycemic data should be reviewed again at the 6-weeks postpartum visit, at which time management of complications and concurrent medical problems should be addressed. Urine microalbumin, thyroid function, and HbA_{1c} should be reevaluated. The American Academy of Pediatrics considers the angiotensin-converting enzyme inhibitors captopril and enalapril safe for use by the breastfeeding mother and are resumed in patients with nephropathy, microalbuminuria, and hypertension (93). Plans for future medical, diabetes, and

1042 JOSLIN'S DIABETES MELLITUS

ophthalmologic care are discussed with the patient. Both contraception and the importance of planning future pregnancies should also be reviewed during the 6-week postpartum visit. Contraception is particularly important in women with diabetes, who must delay future pregnancies until they are medically stable and have achieved near euglycemia. The choice of contraception is individualized, taking into account desire for additional children, presence or absence of vasculopathy, ease of compliance, inherent failure rates, number of sexual partners, smoking history, and age (94).

GESTATIONAL DIABETES

Definition and Incidence

Gestational diabetes is defined as carbohydrate intolerance of any degree with onset or first recognition during pregnancy (95). This definition does not preclude the possibility that diabetes antedated conception but remained unrecognized until medical visits during pregnancy. Furthermore, the definition applies regardless of whether diet or insulin is used to manage glycemia during pregnancy and whether or not disordered carbohydrate metabolism persists post partum. Diagnosis of gestational diabetes is important to identify both infants at risk of adverse outcomes and women at risk of subsequent development of diabetes. Reports of adverse events date back to at least 1882, when Duncan (96) reported fetal death in 13 of 19 pregnancies in 15 women and maternal death within 1 year of delivery in 9 of the cases. In addition to fetal demise, gestational diabetes has been linked to the complications of large for gestational age; macrosomia; birth trauma, such as increased maternal lacerations and neonatal shoulder dystocia; increased need for cesarean section; and neonatal metabolic disorders such as hypoglycemia, hyperbilirubinemia, and disordered calcium balance. Accurate diagnosis and improved management have favorably altered perinatal outcomes in this condition. For the mother, there is increased risk of subsequent development of diabetes.

The frequency of gestational diabetes depends on both the population studied and the diagnostic criteria used, resulting in a range of prevalence between 1% and 14%. The prevalence of gestational diabetes tends to be higher in populations with high rates of type 2 diabetes. The prevalence in the general U.S. population is about 4% (97), whereas the prevalence in non-Hispanic white women is lower, at about 2% (98).

Pathogenesis

Glucose metabolism deteriorates to some degree in all pregnant women (99), although only a minority of women develop gestational diabetes. In rare circumstances, a woman can develop type 1 diabetes coincident with pregnancy; however, this is uncommon. In populations at greater risk of type 1 diabetes, diabetes of pregnancy may identify risk of development of type 1 disease (100). In most studies, the frequencies of human leukocyte antigens HLA-DR2, DR3, and DR4 that confer risk for type 1 diabetes are similar in women with gestational diabetes and in healthy pregnant women, and the prevalence of autoimmune markers of β -cell destruction in women with gestational diabetes is low. Rather, the pathogenesis of the vast majority of cases of gestational diabetes more closely resembles that of type 2 diabetes.

Fasting plasma insulin levels increase gradually during pregnancy, and during the third trimester, may be double those during the nonpregnant state. Fasting insulin levels are not lower in women with gestational diabetes; however, both the first-phase insulin response and the insulin response to a given glycemic stimulus is lower in women with gestational diabetes than in women with normal glucose tolerance (101,102). Peak plasma insulin levels are achieved later during oral glucose tolerance tests in women with gestational diabetes than in women with normal glucose tolerance. Elevated proinsulin levels are seen early in the gestational diabetic pregnancy (103) and may persist post partum (104), providing further evidence that a defect in β -cell insulin secretion in addition to insulin resistance underlies this disorder.

Screening and Diagnosis

Although the importance of diagnosis and treatment of carbohydrate intolerance during pregnancy is evident, the procedures used to screen pregnant women and the diagnostic criteria are widely disputed. In 1964, O'Sullivan and Mahan (1) evaluated 752 pregnant women with a 3-hour oral glucose tolerance test with 100 g of glucose; 2 SD above the mean threshold for each hour assessed was established to be abnormal based on the future risk of diabetes to the mother in a second group of 1,013 women also tested during pregnancy and followed for a subsequent 5 to 10 years post partum. If two glucose values were exceeded, 22% of women developed diabetes within 7 to 8 years. In the years that followed, the "O'Sullivan and Mahan" criteria became widely accepted for the diagnosis of gestational diabetes. These studies used venous whole blood samples. So when most laboratories shifted to plasma venous samples in 1979 the National Diabetes Data Group (NDDG) recommended conversion by an upward adjustment of 15% to account for the difference in sample measurement (105). Subsequently to account for both changes in laboratory techniques of glucose measurement from the older Somogyi-Nelson assay to the newer enzymatic assays, and the switch from whole blood to plasma venous samples, Carpenter and Coustan (106) again revised the diagnostic criteria in 1982. It is important to note that all of these criteria are based on the original work of O'Sullivan and Mahan and that these were validated on the basis of predictive value of subsequent risk of diabetes in the mother and not specifically to determine maternal or fetal risk during pregnancy.

In much of the world, however, a 75-g 2-hour oral glucose tolerance test is administered, and gestational diabetes is diagnosed according to WHO criteria for the diagnosis of diabetes outside of pregnancy (4). The WHO diagnostic criteria are less stringent than those discussed above. In centers where WHO criteria of impaired glucose tolerance are used to identify women with gestational diabetes, a higher proportion of pregnancies are diagnosed as abnormal than when the other criteria are employed. WHO criteria were not developed specifically for use during pregnancy, nor are thresholds set for detection of either maternal or fetal complications.

Performance of either the 75-g 2-hour or the 100-g 3-hour oral glucose tolerance test evaluates the fasting (between 8 and 14 hours) glucose level and the value at 1 and 2 hours after the glucose load. The 100-g test includes an additional glucose assessment at 3 hours. Normal values based on Carpenter and Coustan criteria include a fasting plasma glucose level of 95 mg/dL or less (5.3 mmol/L); 1 hour, 180 mg/dL or less (10.0 mmol/L); 2 hour, 155 mg/dL or less (8.6 mmol/L); and for the 100-g load 3 hour, 140 mg/dl or less (7.8 mmol/L); (107). Normal values based on NDDG criteria include a fasting plasma glucose level of 105 mg/dL or less (5.8 mmol/L); 1 hour, 190 mg/dL or less (10.6 mmol/L); 2 hour, 165 mg/dL or less (9.2 mmol/L); and 3 hour, 145 g/dL or less (8.0 mol/L). In either test, *two* or more of the venous plasma concentrations must be exceeded to be positive.

In addition to the cost of three or four glucose assessments, the glucose tolerance test is difficult to administer, as it requires women to fast overnight before testing and takes several hours. Screening of women between 24 and 28 weeks of gestation with a plasma or serum glucose level obtained 1 hour following a 50-g glucose load (glucose load test), administered at any time of day without regard to the time since the last meal, has become a well validated and widely applied screening procedure. A value of 140 mg/dL or higher (7.8 mmol/L) identifies 80% of women with gestational diabetes, and a value of 130 mg/dL or higher (7.2 mmol/L) increases sensitivity to 90% (108). Because of the test's high sensitivity (low false-negative rates), women with normal values on this test do not require more extensive testing. However, because of the test's lower specificity (high false-positive rates), between 78% and 87% for the 140 and 130 mg/dL threshold, respectively, women with elevated values require the performance of a diagnostic glucose tolerance test.

Although universal screening of women for gestational diabetes was previously recommended, a series of identifying factors place a woman at lower risk for this complication of pregnancy. These factors include age younger than 25 years, normal body weight, absence of a first-degree relative with diabetes, no history of abnormal glucose metabolism or poor obstetric outcome, *and* not being of a racial or ethnic group with a high prevalence of diabetes. Risk assessment should occur at the first prenatal visit. If a woman meets *all* of these criteria, testing for carbohydrate intolerance during pregnancy may be discretionary (107). Women with multiple risk factors, thus those at high risk, should undergo screening procedures as soon as feasible. If their glucose tolerance is normal early in pregnancy, testing should be repeated between 24 and 28 weeks of gestation, the interval recommended for women at moderate risk.

There is substantial evidence that criteria for diagnosis of gestational diabetes are arbitrary. The relationship between maternal carbohydrate tolerance and rate of macrosomia, need for neonatal special care, and cesarean section may be linear or curvilinear with no threshold value at which a change in risk can be demonstrated (109–111). As such, any abnormal glucose value on diagnostic testing may not be classified as gestational diabetes but may be associated with increased maternal or fetal risk. Threshold values in the future could become subject to evaluation of the cost and effectiveness of intervention.

Management

Although glucose is not the only metabolic fuel that is abnormal during a diabetic pregnancy, because of the ease of assessment, it is the focus of the medical management of the pregnancy. Tight glycemic control can reduce fetal risks (112). However, excessively stringent target levels put the mother at risk of hypoglycemic events, and some evidence suggests that this may also put the infant at risk of being small for gestational age (113). Although glycemic targets have remained somewhat controversial and there have not been universal adjustments of targets for meters that report whole blood levels as compared with plasma glucose levels, current ADA recommendations are to maintain fasting whole blood glucose levels lower than 95 mg/dL (5.3 mmol/L), 1-hour postprandial levels lower than 140 mg/dL (7.8 mmol/L), and/or 2-hour postprandial levels lower than 120 mg/dL (6.7 mmol/L) (6). Glycemic response to the diagnostic carbohydrate load may be abnormal even when the excursions to a mixed meal are maintained. Home glucose monitoring allows for precise assessment of both the need for and the response to more extensive interventions. Despite the emotional burden of increased monitoring, these techniques allow immediate patient feedback of the physiologic response to foods and can be effective in demonstrating the need for dietary compliance. Many women will have improved glucose

profiles when medical nutritional therapy is begun. Although medical nutritional therapy is central in the management of gestational diabetes, the ideal diet remains controversial. Nutritional recommendations are affected by the woman's body habitus, physical activity, and weight gain, but goals are to achieve glycemic targets without being so restrictive as to promote either ketonemia or ketonuria. For patients who are not underweight, modest caloric restriction may be appropriate. A starting plan may provide about 30 kcal per kilogram of actual body weight for the woman who has ideal body weight, 40 kcal/kg for the woman who is less than 80% of ideal body weight, 25 kcal/kg for the woman who is 120% to 150% of ideal body weight, and limited to as low as 12 kcal/kg for the patient who is over 150% ideal body weight (114). In all groups, adjustments are based on assessment of weight gain and the presence of urine ketones. Limiting carbohydrate to 35% to 45% of total calories (with the balance 20% to 25% protein and 35% to 40% fat) can reduce postprandial glucose levels. Interestingly, women with gestational diabetes may demonstrate their greatest carbohydrate intolerance after the breakfast meal and may improve with more strict carbohydrate restriction solely at that meal. The balance between simple carbohydrate foods (high glycemic index) and complex carbohydrates (low glycemic index) is also likely to be important to the maternal glycemic excursions (115). Iron and other nutritional supplements should be administered if necessary.

About 50% of women initially treated with diet alone will require additional therapy, and insulin therapy usually is recommended. Although both insulin-sensitizing agents, biguanide and thiazolidendiones, have been demonstrated to increase rates of ovulation in insulin-resistant women with ovulatory dysfunction, after conception most women are then switched to insulin for glycemic management. Likewise, sulfonylureas rarely are used during pregnancy for concern about teratogenicity and neonatal hypoglycemia. However, in one study of 404 women randomly assigned to glyburide or insulin between 11 and 33 weeks of gestation, use of a sulfonylurea was not associated with any difference in infant rates of large for gestational age, macrosomia, lung complications, hypoglycemia, neonatal intensive care admissions, or fetal anomalies (116).

Insulin management must be individualized, but most pregnant women require about 0.7 units/kg daily, divided into three doses. As in nonpregnant women, about two thirds of the insulin is administered in the morning and one third is administered in the evening, with a 1:2 ratio of short- to intermediate- (or long-) acting insulin. Insulin requirements increase by about 50% from 20 to 24 weeks to around 30 to 32 weeks of gestation, at which time insulin needs often stabilize. The ultra–short-acting insulin analogues insulin lispro and insulin aspart have been reported to improve postprandial glucose in women with type 1 or type 2 diabetes; thus, they could be advantageous during pregnancy and, in limited studies, lispro appears to be safe and effective for the management of gestational diabetes (70,71).

There remains some controversy regarding the current recommendations of strict adherence to glycemic targets for all women with gestational diabetes, as only a minority of the infants are at risk for perinatal morbidity over the range of glycemia commonly encountered during the pregnancy complicated by gestational diabetes. Home glucose monitoring and often insulin use thus could be viewed as being prescribed to many women whose infants are not at risk of complications. Several studies suggest alternate management strategies based on careful assessment of fetal growth using the ultrasound measurement of fetal abdominal circumference to identify those infants at highest risk (117), with intensive intervention reserved for the patient whose fetal abdominal circumference measures greater than the 70th percentile (118). However, until further studies are performed using such treatment decision tools, strict glycemic management for all women with gestational diabetes remains advisable.

Although antenatal care focuses on glycemic management, the woman with gestational diabetes requires close monitoring for the development of hypertension, proteinuria, edema, and preeclampsia or eclampsia, all of which are more common than in the nondiabetic pregnancy. Goals of obstetrical management include the prevention of stillbirth or compromised fetal health at delivery, achievement of lung maturity, and prevention of birth trauma. especially in the macrosomic infant prone to shoulder dystocia. Weekly biophysical profiles are frequently begun at 36 weeks of gestation. A sonographic evaluation is frequently performed at 38 weeks, with induction of labor for the large-for-gestational age infant and cesarean delivery for the macrosomic infant. The infant judged appropriate in size for gestational age may be managed expectantly until 40 weeks, at which time evaluation may include reassessment of size, cervical ripeness, and lung maturity, with induction of labor upon favorable evaluation. Most obstetrical protocols recommend delivery for all women between 40 and 41 weeks (119).

Labor and Delivery

The diagnosis of gestational diabetes impacts not only on the prenatal monitoring of maternal glucose and fetal size and activity but also on the method of delivery. In the Toronto Tri-Hospital Gestational Diabetes Project, women with gestational diabetes with untreated borderline hyperglycemia had a 29% rate of fetal macrosomia, more than double that for the treated women with gestational diabetes (10%) or healthy control subjects (14%). However, despite the smaller birth size in the treated women with gestational diabetes, the rates of cesarean delivery were similar in the group with borderline hyperglycemia and in the treated group (120). The increased cesarean rate in the group with gestational diabetes could be due to the increased likelihood of the physician's performing a cesarean section in a woman diagnosed with gestational diabetes regardless of fetal size.

If the woman does not require insulin during the prenatal period, labor and delivery can likely proceed without special attention to maternal glycemia. If insulin is required, and labor and delivery are to be scheduled, it is preferable to schedule for the morning hours. In this case, the usual insulin dose can be administered the evening before the scheduled delivery, and the morning dose can be held. If the induction procedure is judged likely to be lengthy, a fraction between 25% and 30% of the usual morning insulin dose may be administered, especially if the mother will be allowed meals during early labor. If the maternal glucose rises above 110 mg/dL, an insulin drip should be considered, as maternal hyperglycemia may cause neonatal hyperinsulinemia and hypoglycemia post partum. If the mother took insulin and spontaneous labor ensues, a dextrose infusion with the rate adjusted to a target glucose of 80 to 110 mg/dL may be required to prevent maternal hypoglycemia.

Postpartum

SPECIFIC TO THE MOTHER

In most cases, the glucose intolerance that first arises during pregnancy resolves immediately post partum, and insulin, if required during pregnancy, is no longer required. The earlier in pregnancy the diabetes develops and the more extreme the insulin requirement, the less likely the condition is to resolve post partum. It is prudent to make a single glucose check in the hospital before the patient is discharged to ensure that the glucose level has returned to the normal range. Women who have been performing home glucose monitoring can repeat a measurement after discharge. The most information is gained if this check is performed 1 or 2 hours postprandially. Women with elevated values should present for early postpartum glucose tolerance testing. Otherwise, a 75-g glucose tolerance test performed about 2 months post partum will identify women with persistent diabetes or impaired glucose tolerance. At this time, a test of glycosylated hemoglobin (Hb_{A1} or HbA_{1c}) is not an adequate test, because this value depends both on the level of hyperglycemia and on the life span of red cells. The bleeding associated with delivery produces a reticulocytosis that falsely lowers the glycosylated hemoglobin value during the postpartum period. If glucose levels are elevated, insulin therapy is indicated in the lactating woman, as oral agents may be excreted in the breast milk. Because about 50% of women who have had gestational diabetes will go on to develop diabetes over the next 20 years, an evaluation of glycemia should occur annually. In the woman who develops impaired glucose tolerance or type 2 diabetes, additional cardiac risk factors should be identified and may require treatment. In all women with a history of gestational diabetes, medications that increase insulin resistance should be avoided whenever possible.

Because abnormal glucose levels in early conception are associated with congenital defects, women with a history of gestational diabetes who are planning a future pregnancy should have glucose assessments before conception (121) and should receive counseling regarding this during the postpartum period. If impaired glucose tolerance or type 2 diabetes is found, adequate glycemic control appears more important in prevention of congenital malformations in future pregnancies than is the type of drug used to maintain glucose control (122). Ideally, women on oral medications should be switched to insulin before conception.

In planning postpartum contraception, the estrogen-progesterone combination type of hormonal therapy should be used if this is the contraception method chosen, because in a limited study, progesterone-only therapy was associated with increased rate of development of type 2 diabetes (123). In most cases, the desire to have additional offspring is a very strong and complex one. However, a careful study of the Latino population with previous gestational diabetes indicates an increased risk of progression to type 2 diabetes conferred by additional pregnancies (124).

Given the high risk of future type 2 diabetes in these patients, they would be well served with interventions that delay or prevent diabetes. The Finnish Diabetes Prevention Study Group (125) and the Diabetes Prevention Program (126) demonstrated that aggressive lifestyle management involving nutrition therapy and daily exercise can reduce the onset of type 2 diabetes by nearly 60% as compared with the rates in a nonintervention control group of patients with impaired glucose tolerance, including, but not limited to, patients with previous gestational diabetes. Use of medications has also been demonstrated to reduce the risk of future diabetes in high-risk populations. In the Diabetes Prevention Program, use of metformin reduced the onset of type 2 diabetes by 35% compared with that in the control population (126). Similarly, acarbose resulted in a 25% decrease in conversion of patients with impaired glucose tolerance to type 2 diabetes (127). In women with prior gestational diabetes, use of troglitazone resulted in a more than 50% reduction in the incidence of diabetes in high-risk Hispanic women in the Troglitazone in Prevention of Diabetes (TRIPOD) study (128). Although troglitazone is no longer on the market, pioglitazone and rosiglitazone may have similar protective benefits and need to be studied. However, lifestyle management of diet and exercise offers

the most favorable reduction in progression to diabetes and has no risk of adverse effects that can be associated with medical therapies. These data support the importance of insurance coverage for postpartum nutrition and exercise counseling and monitoring of metabolic status in women who have had gestational diabetes.

SPECIFIC TO THE INFANT

The newborn infant is at greater risk of several metabolic complications, the most frequent of which is hypoglycemia. This likely is due to hyperinsulinemia, which develops in utero in response to the increased maternal fuel. At delivery, the infant's physiology changes from one of continuous feeding to one of fasting and feeding. The infant is at greatest risk of hypoglycemia in the first hours after birth, before the first feeding. The infant should also be assessed for lung maturity and for bilirubin and calcium balance, and a careful physical examination should be performed to assess for birth defects.

The long-term effects of the intrauterine environment on the growth and development of the child have not been exhaustively studied. Clearly, given the genetic predisposition for diabetes, children of diabetic parents are at increased risk of ultimately developing diabetes as compared with children having no family history of diabetes. Few studies have addressed the additional risk of maternal hyperglycemia to the offspring. Careful epidemiologic data have been collected since the mid-1960s among the Pima Indians of Arizona, a group with an increased overall risk of type 2 diabetes. By age 10 to 14 years of age, the 2-hour post-75-g-load glucose level in children was shown to increase based on the 2-hour postload glucose level measured during the mother's pregnancy. In addition, the prevalence of diabetes in the offspring was higher in the cohort born from a diabetic pregnancy than in those who were not (129). Among the Pima, there is a U-shaped distribution of the prevalence of diabetes such that both small- and large-forgestational-age infants are at increased risk of subsequent development of diabetes. Interestingly, there was some protective effect of breastfeeding for 2 months or more, as compared with the prevalence among children who had not been breastfed as infants (130). Although the duration of follow-up evaluation is not as long as in the Pima Indians, similar investigations are ongoing in the largely white cohort in the Northwestern University Diabetes in Pregnancy Study, in which longitudinal studies have been ongoing since the late 1970s. These studies also demonstrate an increased body mass index starting between the ages of 4 and 6 years in the offspring of women with gestational diabetes, as compared with healthy term infants in the Chicago metropolitan area, and an increased risk of impaired glucose tolerance during adolescence (131,132). Additional recommendations for the offspring born from the diabetic pregnancy may evolve as our understanding of the impact of the maternal milieu develops.

OTHER SKIN CONDITIONS STRONGLY ASSOCIATED WITH DIABETES 1056

Diabetic Dermopathy 1056 Diabetic Bullae 1056 Rubeosis 1056 Vitiligo 1056 Acanthosis Nigricans 1057 Finger "Pebbles" 1057 Perforating Disorders 1057 Generalized Pruritus 1057

CUTANEOUS REACTIONS TO THERAPY FOR DIABETES 1057

Insulin-Induced Disorders 1057 Hypoglycemic Agents 1058

Patients with diabetes mellitus commonly suffer from a wide variety of cutaneous maladies. Estimates of the frequency of skin disease in people with diabetes range from 30% overall (1) to 71% of patients with type 1 diabetes mellitus (2). While several skin conditions are specific to diabetes, most of them also occur in individuals without diabetes. The clinical manifestations and complications of skin disease are frequently more severe in the setting of diabetes. The pathophysiology of most cutaneous disorders in the patient with diabetes remains poorly understood. Recent advances in genetic research may soon answer some longstanding questions. For example, results from a recent study indicate that the G82S polymorphism of the *RAGE* gene (receptor for advanced glycosylation end products) is associated with microangiopathic skin conditions in patients with type 2 diabetes (3). In this chapter, we describe the charac-

teristic skin conditions associated with diabetes, incorporating discussion of clinical presentation, pathology, pathogenesis, and treatment (Table 62.1).

CUTANEOUS INFECTIONS IN DIABETES

Candidiasis

Candidal infections of mucosal membranes, genitalia, and nails are more prevalent in patients with poorly controlled diabetes than in the population without diabetes (4–7). Women are more prone to these infections than are men (5). Although yeast infections may be the initial presentation of diabetes, they generally occur in patients already known to have diabetes (6). In indi-

Cutaneous infections Candidiasis Dermatophytosis Phycomycosis Erythrasma Malignant external otitis Neurologic lesions Charcot ioint Compensatory hyperhidrosis Neuropathic ulcer **Disorders of collagen** Necrobiosis lipoidica Granuloma annulare Scleredema diabeticorum Waxy skin Sclerodermalike change of the hand Metabolic diseases Porphyria cutanea tarda Yellow skin Xanthomatosis Hemochromatosis Glucagonoma syndrome Generalized pruritus Skin conditions with strong but unexplained association with diabetes Acquired ichthyosis Diabetic dermopathy Diabetic bullae Rubeosis Vitiligo Acanthosis nigricans Finger "pebbles' Perforating disorders Cutaneous reactions to diabetes therapy Insulin-induced disorders Insulin allergy Insulin lipodystrophy Insulin-induced lipohypertrophy Hypoglycemic agents Hypersensitivity reactions Disulfiram reactions

From Fine JD, Moschella S. Diseases of nutrition and metabolism. In: Moschella SL, Hurley HJ, eds. *Dermatology*. Philadelphia: WB Saunders Company, 1985.

viduals with diabetes, the ratio of epidermal glucose to blood glucose is higher than in persons without diabetes (8), a situation that may produce an environment that is more favorable for the growth of yeast and fungi (9).

ORAL MUCOSAL CANDIDIASIS

Distinctive forms of oral mucosal candidiasis include thrush (curdlike white colonies) over intra-oral surfaces; atrophic candidiasis, which manifests as bright red atrophy of the hard palate or tongue; sore mouth; and angular cheilitis (perlèche), which presents as superficial or deep erosions along the labial commissures. Antifungal creams or troches usually are required to eradicate infection.

CANDIDAL PARONYCHIA

The frequency of candidal paronychia, the inflammation surrounding the nail that is caused by a candidal infection, is increased in persons with diabetes. In one study of 250 women with diabetes, 9.6% had clinical evidence of candidal paronychia as compared with 3.4% of 500 controls without diabetes (10). Typical candidal paronychia begins with erythema,

swelling, and pain at the lateral nail fold, leading to its separation from the nail margin. The proximal nail fold then becomes involved, and the cuticle may separate from the nail plate (11). Purulent drainage may be mistaken for bacterial infection. Candidal paronychia is characterized by intermittent exacerbations with episodic indolent periods, a course that may result in a rippled appearance of the nail plate. Patients with occupations in which the hands are frequently immersed in water are more prone to this condition (12). Practical treatment includes keeping the hands as dry as possible. The wearing of cotton gloves under rubber or vinyl gloves can protect hands during dishwashing. Topical antifungal solutions usually are adequate for treatment; however, patients with refractory cases may require oral therapy with an imidazole.

CANDIDAL VULVITIS

Candidal vulvovaginitis is characterized by pruritus, vulvar erythema, and occasionally fissuring and pustules (11). Glycosuria may promote growth of *Candida* species. Certain case studies have shown that the severity of pruritus is proportional to the degree of glycosuria and hyperglycemia (13). Broad-spectrum antibiotics, birth-control pills, and topical corticosteroids are also common causes of candidal vulvovaginitis. Antifungal vaginal suppositories or oral imidazole antifungal agents are necessary to eradicate infection. Non–*Candida albicans* species of *Candida* are now being recognized as pathogens in vulvovaginitis, particularly in women with diabetes. These organisms are often resistant to standard oral antifungal agents (13). Oral nystatin solution may be beneficial in reducing the reservoir of *Candida* organisms in the gastrointestinal tract.

CANDIDAL BALANITIS

Men with candidal balanitis present with diffuse or focal erythema of the glans penis, often in association with pain or pruritus. White discharge in association with erosions or pustules is commonly seen, particularly under the foreskin of uncircumcised patients. Men with balanitis and phimosis, especially if middle-aged or elderly, should be evaluated for diabetes. In one retrospective study, among 100 men requiring circumcision for phimosis, 35% had diabetes. For most of these patients, diabetes had not been diagnosed previously (7). Administration of topical or oral imidazoles is the treatment of choice. If phimosis is present, a cotton-tipped applicator may be used to gently introduce the anticandidal preparation underneath the foreskin (11).

Dermatophyte Infections

Tinea pedis (athlete's foot) is more prevalent in persons with diabetes than in the general population (4). Although innocuous in most people, tinea can create fissures and portals of entry that may lead to severe bacterial infections in those with diabetes. Web spaces are pruritic, scaly, erythematous, and macerated. Vesicles and pustules may also be present. A "moccasin" distribution of scaling extending from the soles onto the lateral feet is another variant of tinea pedis. Long-standing tinea pedis may involve the nails, which develop a thick, yellowish brown roughened nail plate and subungual debris. Potassium hydroxide (KOH) scraping identifies branching, septate hyphae (12). Patients who have tinea involving their hands or fingernails may inoculate other body sites as well.

Topical antifungal agents are the mainstays of treatment for these infections. For severe fungal infections of skin, hair, or nails, administration of an oral imidazole (such as itraconazole) or an allylamine antifungal agent (such as terbinafine) is the treatment of choice. Blood counts and liver function tests must be monitored during treatment, and drug interactions between imidazole antibiotics and other drugs metabolized by the hepatic cytochrome P450 system must be anticipated. Preventive foot care, including careful drying, wearing of cotton socks, and wearing of sandals in public shower facilities may help prevent infection. Topical ciclopirox administered as a nail lacquer is a welcome recent therapeutic option.

Phycomycetes Infections

The phycomycetes are a group of fungi found on decaying vegetation and foods with a high sugar content. Although rarely pathogenic, the genera most commonly involved in human infection include *Rhizopus*, *Mucor*, and *Absidia* (14). In the clinical setting, all diseases caused by these organisms are referred to as mucormycosis.

Several major clinical syndromes, involving the rhinocerebral, thoracic, gastrointestinal and cutaneous systems are described (15). Of these, rhinocerebral disease is most closely associated with diabetes. The fungal organism colonizes the nasal turbinates and sinuses but can invade the orbit and brain, particularly in the setting of diabetic ketoacidosis. Characteristically black crusty or purulent material is present on the turbinates, septa, or palate, and mucormycosis may initially be mistaken for bacterial sinusitis. Cutaneous mucormycosis occurs when the organism colonizes burned or skin-grafted tissues or nonhealing leg ulcers in patients with diabetes (16).

The diagnosis can be confirmed by skin biopsy or a KOH tissue preparation of sputum or skin, which may demonstrate the large, broad, nonseptate hyphae characteristic of phycomycetes (14). Debridement of necrotic tissue, intravenous administration of amphotericin B, correction of acid–base imbalance, and control of hyperglycemia are the necessary components of treatment (17). The more invasive forms of disease frequently are fatal.

Bacterial Infections

Although patients with well-controlled diabetes do not have increased susceptibility to most bacterial infections, evidence suggests that patients with poorly controlled diabetes may develop more frequent or severe bacterial infections than experienced by the rest of the population (18). Several authors have described abnormalities in leukocyte function associated with diabetes, including diminished chemotaxis (19), depressed phagocytosis (20,21), decreased bacteriocidal activity, (22–25), decreased leukocyte migration (25), and an altered early granulocyte phase of the local cellular inflammatory response (26).

Bacterial infections of the lower extremities are a particular risk for patients with diabetes who have vascular disease or neuropathy (18). Careful foot care and early treatment of dermatophytosis are essential in minimizing potential bacterial portals of entry. A recent review of predisposing factors in hospitalized patients with cellulitis identified diabetes, prior history of cellulitis, edema, dry feet, and evidence of tinea pedis as the most important risk factors (27) (also see Chapter 66).

MALIGNANT EXTERNAL OTITIS

Malignant external otitis is a severe necrotizing bacterial infection that occurs almost exclusively in patients with diabetes (28). Beginning in the external auditory canal, the infection invades local soft tissues and ultimately leads to osteomyelitis of the temporal bone, occasionally progressing to fatal meningitis. *Pseudomonas aeruginosa* is the causative agent in virtually all cases. Symptoms can include unremitting ear pain, purulent otic discharge, and cranial nerve palsies. A tender ear and mastoid area with granulation tissue or polyps in the external auditory canal are typical physical findings. More than 20% of patients have bilateral disease (29). Extended therapy with antipseudomonal agents is necessary, and surgical debridement may also be required.

ERYTHRASMA

Erythrasma is a superficial infection usually affecting intertriginous areas of the skin that is caused by *Corynebacterium minutissimum*. Carriage of fluorescent diphtheroids on clinically normal skin is more common in patients with poorly controlled diabetes than in persons without diabetes. Obesity may be an additional contributing factor, especially in those with adultonset diabetes (30).

Reddish brown, slightly scaly patches typically occur in the intertriginous areas such as the axillae, groin, and web spaces and can be pruritic or asymptomatic. Erythrasma is commonly limited to the toe webs, manifesting with white discoloration and maceration. Frequently, the diagnosis is missed, and not infrequently toe-web involvement is misdiagnosed as tinea pedis. The characteristic coral red fluorescence using a Wood light is diagnostic. The red glow seen is from a porphyrinlike substance produced by the bacteria (31). Gram stain or culture of affected skin scrapings shows gram-positive rods and thread-like filaments traversing the stratum corneum (32). Topical imidazole antifungal agents, topical antibiotics, and systemic erythromycin or tetracycline each provide effective treatment for the disorder. Fusidic acid in a topical preparation is a recent addition to the therapeutic armamentarium (33).

NEUROPATHIC AND ISCHEMIC DIABETIC SKIN DISEASES

Diabetic Polyneuropathy

Diabetic neuropathy is usually bilateral and more severe in the lower extremities than in the upper extremities (34). Dry shiny skin and ulceration on pressure points, particularly on structurally deformed feet, are common. Skin hypoesthesia is one of the most important signs of polyneuritis (34). Lack of thermal sensitivity may lead to burns, calluses, and subsequent ulceration (35). Abnormalities of motor function are much less obvious than sensory defects. Paralysis of the intrinsic muscles of the feet, the most common motor alteration, results in atrophy of the interosseus muscles, which is demonstrated by the "fan sign"-the inability to separate the toes. Such alteration in motor alteration causes the foot to adopt unusual positions, resulting in claw toe or hammer toe deformities or the Charcot joint. In the latter, the tarsal and metatarsal bones are gradually destroyed and joint spaces are obliterated (34,36). As autonomic neuropathy develops and progresses, sweat glands become inactivated. Patients with diabetes may exhibit a compensatory hyperhidrosis of the trunk or face in response to anhidrosis of the lower body (37). Dry and thickened skin of the anhidrotic diabetic foot is prone to fissures, which may serve as portals of entry for bacteria and fungi. Unperceived chronic pressure to the toenails results in thickening, abnormal curvature, and hypertrophy of the nail plate. Ingrown toenails may lead to secondary bacterial infection (12).

Peripheral Vascular Disease

Peripheral vascular disease (PVD) in patients with diabetes can be diffuse and early in onset. The predilection for atherosclerosis and microangiopathy plays a role in the vessel occlusion that occurs in diabetes (38). Some authors consider that microangiopathy plays a part in diabetic vascular disease, while others disagree (38,39). The skin of the lower extremities in patients with diabetes who have PVD is thin, smooth, cold, and often mottled in the dependent position (40,41). Hair is either sparse or absent. Other signs of PVD include pallor or cyanosis with elevation, dependent rubor, and delayed capillary refill.

Diabetic Ulcers

Among the 16 million patients with diabetes in the United States, 1,200 amputations are performed every week (42). This shocking figure indicates the grave importance of identification and treatment of the myriad of causes of cutaneous ulceration in patients with diabetes.

Neuropathic ulcers develop most frequently in areas of high pressure and repeated trauma such as the toes, heels, and metatarsal heads (35) (Fig. 62.1; see also color plate). The patient may present with pain, paresthesia, or anesthesia of the legs and feet. Only occasionally is the ulcer completely asymptomatic in presentation (36).

Venous ulcers tend to occur on the medial malleoli in association with superficial varicosities and yellow–brown discoloration of the skin and are seldom painful. Rest and elevation of the leg ease venous ulcers by controlling edema and reducing venous hypertension.

Arterial ulcers are typically painful (except when accompanied by neuropathy) and occur more distally, on the tips of the toes and on the heel (41). Ulcers of arterial origin may respond to control of hypertension and diabetes as well as to increased exercise, which promotes collateral circulation. Cessation of smoking can be critical. Aggressive treatment of infection, administration of antiplatelet agents or anticoagulants, and surgical revascularization are important treatment modalities in severe cases. Advances in wound healing offer new effective treatments. A recent series of ten patients with diabetic ulcers demonstrated complete healing in seven of ten with the use of sharp debridement and application of a bilayered human-skin equivalent (a construct of live human keratinocytes on a type I collagen dermal matrix, both derived from human fetal foreskin) (42).

A recent study examined the proliferative capacity and ultramicroscopic appearance of fibroblasts taken from leg ulcers of patients with diabetes as compared with fibroblasts taken from nonulcerated skin of patients with diabetes and from control subjects without diabetes (43). Fibroblasts from cutaneous ulcers in individuals with diabetes were found to proliferate at a significantly slower rate than fibroblasts from either control group. Electron microscopic evaluation of fibroblasts from lesional and nonlesional skin in patients with diabetes revealed a large dilated endoplasmic reticulum, a lack of microtubular structures, and multiple lamellar and vesicular bodies. These abnormalities were not seen in the fibroblasts from the control subjects.

DISORDERS OF COLLAGEN

Necrobiosis Lipoidica

Necrobiosis lipoidica is an unusual skin disorder that is strongly associated with diabetes mellitus. The entity was first described in 1929 (44) and was named *necrobiosis lipoidica diabeticorum* (NLD) in 1932 (45). Because of the significant minority of cases of this condition that are associated with diabetes, most investigators now choose to call this condition simply *necrobiosis lipoidica* (NL).

Typical lesions of NL occur on the pretibial skin as irregular ovoid plaques with a violaceous indurated periphery and a yellow central atrophic area (Figs. 62.2 and 62.3; see also color plate). Overlying superficial telangiectasia and scattered hyperkeratotic plugs often are noted (46). The lesions can start as small firm reddish brown papules, which slowly enlarge. They are usually multiple and bilateral, with ulceration seen in approximately 35%. Ulcers often are secondary to minor trauma or are iatrogenically induced by intralesional injection of corticosteroids. It is curious that the ulcers only rarely lead to infection. Patients may complain of pruritus, dysesthesia, or pain at the site of lesions. More frequently, however, the lesions of NL are asymptomatic, and it is the cosmetic disability that is of greatest concern to the patient. Although most commonly found on the lower legs (85% of cases involve only the legs), other locations include the hands, fingers, forearms, face, and scalp (47). Lesions in these locations are often annular, erythematous, or brown and can coalesce to form larger serpiginous plaques, which demonstrate little or no atrophy.

Muller and Winkelmann's classic papers in 1966 (47,48) demonstrate the close association between NL and diabetes. Of their 171 patients with NL, 65% had diabetes. Of the remainder available for study, 42% (8 of 19) demonstrated abnormal glucose tolerance with abnormal oral glucose tolerance tests or cortisone glucose tolerance tests. Among those with normal glucose tolerance, 55% had family histories of glucose intolerance. Despite the high prevalence of diabetes in patients with NL, it is relatively uncommon; the reported prevalence being 3 per

1,000 patients with diabetes. The female-to-male ratio is 3:1, with an average age of onset of 30 years in patients with diabetes. Fifty percent of patients with NL demonstrate other diabetes-related end-organ damage (47).

Despite extensive investigation, the etiology of NL remains largely unknown. Evidence suggests that NL and glycemic control are not related (49) and that genetic factors do not play a large role (50). Vascular etiologies have been entertained; however, vascular changes are absent in one third of biopsy samples. A link with diabetic microangiopathy has been suggested, vet the caliber of the affected vessels in NL is usually larger than the caliber of vessels affected in diabetes. The abnormal collagen found in NL has invited speculation on a direct etiologic relationship of NL to the collagen itself, as a result of accelerated aging of collagen in diabetes, (51) abnormal collagen cross-linking, or overhydrated collagen produced in response to osmotic effects generated by the end products from the aldose reductase (polyol) pathway (52). Abnormal leukocyte mobility has also been implicated (53). Immune-complex disease has been considered as a cause of NL. Ullman and Dahl (54) reported deposition of C3, fibrinogen, and immunoglobulin around dermal blood vessels in nine of 12 patients with NL, but subsequent reports only partially confirm these results. A review of NL addresses these theories in greater detail (55).

Clinically, early NL can be difficult to distinguish from granuloma annulare. As the lesions enlarge, however, NL becomes more distinct, with the epidermal change, atrophy, and yellow color seen developing. Other conditions included in the differential diagnosis for NL are listed in Table 62.2.

A consistently effective treatment for NL has yet to be found. Potent topical corticosteroids applied to the inflammatory rim

TABLE 62.2. Clinical Differential Diagnosis for Necrobiosis Lipoidica

Diabetic dermopathy Rheumatoid nodules Granuloma annulare Stasis dermatitis Morphea Erythema nodosum of lesions are thought to help control disease progression. Other agents used, with variable results, include fibrinolytic agents such as stanozolol, pentoxifylline, and aspirin and dipyridamole, ticlopidine, nicotinamide, and clofazimine, but none have ever been demonstrated to be effective in blinded studies. Ulcerative NL usually responds to routine ulcer treatment, but surgical intervention occasionally becomes necessary. Recent reports described the resolution of extensive ulcerative NL with oral cyclosporine (56) and mycophenolate mofetil (57).

Granuloma Annulare

Granuloma annulare (GA) is characterized by an annular configuration of flesh-colored or pale red papules and plaques that occur in a localized or generalized (disseminated) pattern (Fig. 62.4; see also color plate). Most studies find no association between diabetes and localized GA (58–60) but a link between disseminated GA and diabetes has repeatedly been demonstrated (61,62). In one study, 21% of 100 patients with generalized GA were found to have diabetes (62).

The lesions of GA may vary in size from a few millimeters to 5 cm (64). Localized GA is most characteristically located on the dorsa of the hands and feet. A single lesion is present in one half of patients with GA (65). The papules develop and enlarge slowly in a centrifugal fashion over a period of months to years. Only 15% of patients develop more than ten lesions. Generalized GA is characterized by a symmetrical eruption of hundreds of tiny papules, which can occur all over the body surface. Localized GA eventually undergoes spontaneous resolution—usually within 2 years. Lesions often recur at the same site, however. Resolution in patients with generalized GA is less likely (65). Ulceration and scar formation are rare (64).

Localized GA appears most commonly in children and young adults, affecting twice as many females as males. Generalized GA is, however, more likely to occur in older women (64). The etiology of GA is unknown. Immunoglobin G (IgG) and C3 have been found in blood vessels of involved skin, suggesting an immunologic role. The differential diagnosis includes tinea corporis, sarcoidosis, NL, secondary or tertiary syphilis, annular lichen planus, and insect bites.

Treatment of GA is often unsatisfactory, but fortunately the disease is usually asymptomatic and self-limited. Topical or intralesional corticosteroids are sometimes of benefit in the treatment of localized disease. Treatment of disseminated GA is difficult. Therapy can include the use of systemic corticosteroids, potassium iodide, antimalarials, nicotinic acid, and dapsone, although controversy exists regarding their efficacy (65). One study reported complete clearance of disease in all five patients treated with oral psoralens plus ultraviolet A (PUVA) irradiation (66).

Figure 62.4. (See also color plate.) Disseminated granuloma annulare.

Scleredema Diabeticorum

Scleredema diabeticorum is a diffuse, nonpitting induration of skin characteristically occurring on the upper back, neck, and shoulders. In one study of 484 patients with diabetes, 2.5% were affected (67). Erythema and induration typically begin on the posterior and lateral neck and may extend to the upper back and extremities, including the hands, resulting in extreme limitation of movement. The indurated areas are typically erythematous and finely papular. Patients may perceive decreased light touch and pain in the involved areas. In one report, eight of 13 patients with scleredema diabeticorum had persistent disease lasting up to 20 years (68).

In contrast, another form of scleredema occurs in younger patients without diabetes after streptococcal infection. This subset of scleredema tends to resolve spontaneously within a period of months in 85% of patients (32).

Males are more often affected than are women (ratio 4:1, respectively) (69). Most patients are middle-aged. Both patients with type 1 diabetes and those with type 2 diabetes are affected, but in most instances, diabetes is long-standing. Patients are generally obese, exhibiting a high frequency of diabetic retinopathy, neuropathy, hypertension, and ischemic heart disease. The etiology of scleredema diabeticorum is unknown (70).

The differential diagnosis for scleredema includes scleroderma, eosinophilic fasciitis, eosinophilia myalgia syndrome, and lymphedema. No uniformly effective treatment exists (71). Although scleredema is not generally considered to respond to increased glycemic control (69), a case report documents temporary improvement of rapidly progressive scleredema with improved glycemic control and intravenous prostaglandin E (72). Scleredema associated with paraproteinemia has been treated with photopheresis (73).

Waxy Skin

Persons with juvenile-onset type 1 diabetes can develop waxy, tight skin, also known as diabetic thick skin, in association with limited joint mobility. Rosenbloom et al. (74,75) studied more than 300 patients with type 1 diabetes and found 30% to have elements of this syndrome. Biopsies of wrist skin reveal a markedly thickened dermis, with sparse glands and hair follicles. Increased collagen cross-linking, perhaps related to elevated nonenzymatic glycosylation, has been offered as an explanation (76,77). Some resolution of skin findings has been reported in association with improved glycemic control (78,79).

Plantar Hyperkeratosis

Thickening of scale on the plantar surfaces has been described in association with obesity (80). The prevalence of this skin finding was 35% in 156 obese persons with diabetes and individuals without diabetes whose body mass indices were 27 to 51. The excessive keratin production and retention are theorized to occur in response to direct pressure due to excess weight. This finding may therefore be more likely related to obesity than to diabetes directly.

Acquired Ichthyosis

In a study of 238 people with type 1 diabetes, ichthyosiform skin changes of the skins were noted in 48% of patients (2). Acquired ichthyosis was the most common skin abnormality in the patients described in this report.

METABOLIC DISEASES

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is a disorder of heme synthesis characterized by a sporadic cutaneous eruption and uroporphyrinuria. It is estimated that 25% of men between the ages of 45 and 75 years who have PCT have diabetes (81). Men are more frequently affected than are women. The classic clinical picture includes vesicles, bullae, and erosions over the dorsal hands and arms and other sun-exposed areas. The primary lesions heal slowly, leaving scarring and milia (tiny epidermal inclusion cysts). Patients also are noted to exhibit skin fragility and hypertrichosis. The enzymatic defect, a deficiency of uroporphyrinogen decarboxylase, leads to excessive serum uroporphyrins, which accumulate in tissues. These compounds are excreted in the urine, which fluoresces pink under a Wood light. The iron concentration in serum is frequently increased. Uroporphyrinogen decarboxylase deficiency occurs both in a familial (autosomal dominant) form and a sporadic/induced form, which is triggered by alcohol, estrogens, or any of several hepatotoxic aromatic hydrocarbons. Treatments of choice include avoidance of alcohol, serial phlebotomy, and administration of antimalarial agents (82).

Yellow Skin

As many as 10% of patients with diabetes may have yellow discoloration of the skin. The yellow color may be caused by the concentration of carotene in areas of prominent sebaceous activity (face, forehead, and axilla) and areas of thick stratum corneum (palms, soles, and bony prominences). These patients, unlike those with jaundice of hyperbilirubinemia, do not exhibit scleral icterus (83).

Early reports linked hypercarotenemia with diabetes, citing elevated carotene levels in more than 50% of patients with diabetes (84). These studies may have been conducted at a time when the recommended diabetes diet included large amounts of foods high in carotene. Hoerner et al. (85) used spectrophotometry to compare skin color and levels of serum carotene in individuals with and without diabetes. They found that the skin of the group with diabetes was yellower than the skin of the group without diabetes but found no correlation between skin color and carotene level. The explanation for a higher incidence of yellow skin among patients with diabetes is unclear and remains controversial.

Xanthomatosis

ERUPTIVE XANTHOMA

Eruptive xanthomas occur in one per 1000 patients with diabetes (84). Lesions are small, firm, nontender, pinkish yellow papules, most commonly occurring in crops on the knees, elbows, back, buttocks, and trunk (Fig. 62.5; see also color plate). Persistent papules may coalesce to form larger plaques.

In patients with significant insulin deficiency, decreased lipoprotein lipase activity results in elevated serum triglyceride levels. Cutaneous eruptive xanthomas form when the serum triglyceride level rises above 1000 mg/dL (84). Lipids accumulated in the serum may be deposited extracellularly in the form of cholesterol or triglycerides in the dermis or subcutaneous tissue. This deposition creates a cutaneous xanthoma.

Lesions are indistinguishable from those in other conditions producing hypertriglyceridemia. Chronic biliary cirrhosis, nephrotic syndrome, chronic pancreatitis, and myxedema may

Figure 62.5. (See also color plate.) Eruptive xanthomata of the abdomen in a 45-year-old patient with uncontrolled type 1 diabetes.

cause secondary eruptive xanthomas. Prompt control of hyperlipidemia can result in disappearance of the papules. Weight reduction, carbohydrate restriction, and antilipemic agent therapy may be necessary. Aggressive insulin therapy and good glycemic control are important in patients with diabetes to help resolve the cutaneous manifestations of the hypertriglyceridemia.

XANTHELASMA

Xanthelasma is a distinctive type of xanthoma that occurs on the eyelids. Lesions begin as small yellow–orange macules, which thicken to form oval foamy plaques. Xanthelasma is most common in middle-aged women and is particularly associated with hyperlipoproteinemia, hepatobiliary disorders, and diabetes. Although 50% or more of patients may be normolipemic, it is considered appropriate to obtain serum lipid profiles in these patients. Surgical removal is frequently successful, although recurrences are common. Ablation with cryosurgery (86), laser surgery (87), and bichloracetic acid (88) have been reported as safe and effective. Xanthelasma does not usually regress when diabetes is controlled (18); however, one study documents regression in xanthelasma in 50% of 36 patients treated with the lipid-lowering agent probucol (89).

Hemochromatosis

Hemochromatosis is a disorder of iron storage in which increased gastrointestinal absorption of iron leads to deposition of excessive iron in tissues. The most significant complications result from deposition in the liver, heart, joints, pancreas, and skin. Diabetes is found in 65% of patients, particularly those with family histories of diabetes. In 90% of patients, skin involvement is manifested by diffuse bronzed hyperpigmentation, which is due to cutaneous deposition of melanin and hemosiderin. Therapy includes phlebotomy and use of iron-chelating agents (90). Hematochromatosis is an important secondary cause of diabetes (see Chapter 27).

Lipodystrophy

Progressive lipodystrophy, a rare disorder characterized by complete absence of subcutaneous fat, is associated with diabetes (91). Most cases involve the face, back, upper trunk, and upper extremities. Onset is insidious and discomfort is absent. In the most common partial type, the cheeks are hollowed with prominent malar eminences. Muscles and veins

62: CUTANEOUS MANIFESTATIONS OF DIABETES MELLITUS 1055

are prominent in affected areas (91). Approximately 20% of these patients develop diabetes (92). Generalized lipodystrophy is an autosomal recessive disorder with onset at puberty and results in an acromegalic appearance (93). Decreased binding of insulin to its receptor has been shown (94), but the complete molecular basis for the insulin resistance is unknown and involves insulin resistance of postreceptor signal transduction pathway. Patients with progressive lipodystrophy and diabetes frequently are insulin-resistant or require high doses of insulin. Diabetic control does not improve or alter lipodystrophy. Autologous fat transplantation has been reported to be successful in some cases. Familial partial lipodystrophy of the Dunnigan type (FPLD; Mendelian Inheritance in Man 151660), demonstrates autosomal dominant inheritance. Loss of subcutaneous fat from the extremities and trunk begins in puberty. The predisposition to diabetes and its complications is greater in affected women than in affected men (95).

Glucagonoma Syndrome

In 1942, Becker et al. (96) first described the characteristic eruption of glucagonoma in a patient with an islet-cell type of pancreatic carcinoma. Their report represents the classic clinical presentation of the syndrome with its symmetric confluent areas of macular, erythematous, and vesicular eruptions with exfoliation and superficial necrosis. It was not until 1966 that McGavran et al. (97) documented the hyperglucagonemia and consequent hyperglycemia, resulting from a functioning isletcell tumor. Wilkinson (98) later called the characteristic skin changes of this glucagon secreting α -cell carcinoma "necrolytic migratory erythema." The eruption occurs most severely in intertriginous and periorificial areas. Individual lesions last from 7 to 14 days, heal centrally, and are found in various stages of development. Other associated cutaneous findings include glossitis, conjunctivitis, periorbital crusting, ridging and thickening of nails, and paronychia (99).

Approximately two thirds of patients with glucagonoma have cutaneous abnormalities, and approximately 67% have fasting hyperglycemia. Neither the presence nor the severity of hyperglycemia appears to be related to the degree of skin manifestations. Anemia and weight loss are frequent (100).

The eruption may precede by years all other symptoms of pancreatic islet-cell tumors (101). Removal of the carcinoma prior to metastasis results in complete cure and clearing of cutaneous symptoms (102,103). Unfortunately, most glucagonomas have already metastasized at the time of clinical diagnosis. The cutaneous eruption, which may wax and wane spontaneously, is typically misdiagnosed and resembles many dermatoses, including pemphigus foliaceus, bullous pemphigoid, vasculitis, and psoriasis (100).

Extreme fasting hyperglucagonemia (>500 pg/mL) is present in most cases. Hypoaminoacidemia occurs, in part secondary to the consumption of large quantities of amino acids by enhanced gluconeogenesis. Initial workup includes a determination of fasting plasma glucagon concentration by radioimmunoassay, followed by abdominal imaging. Celiac and hepatic arteriography may also be required (100).

Hyperglucagonemia or the presumed secondary hypoaminoacidemia may be responsible for the skin changes, a possibility suggested by the improvement of cutaneous lesions following systemic administration of amino acids (100,104). Various chemotherapeutic agents have been used when surgery has failed or was not an option; the agents have included streptozotocin and phenoxybenzamine.

OTHER SKIN CONDITIONS STRONGLY ASSOCIATED WITH DIABETES

Diabetic Dermopathy

The lesions of diabetic dermopathy (DD), also known as pigmented pretibial patches or shin spots, are by some reports the most common cutaneous finding in diabetes (105). Early lesions are small, flat-topped, dull, red papules that are typically painless. Over several weeks, the lesions progress to atrophic hyperpigmented irregular patches approximately 5 to 12 mm in diameter. Lesions can be linear, grouped, or individual and frequently appear in crops. Individual lesions resolve over 1 to 2 years, but the emergence of new lesions makes the course appear stationary (18). The lesions are most commonly located on the anterior shins, as well as on the forearms, anterior thighs, and feet, with a propensity to appear over bony prominences (8).

Melin (106) found DD in 50% of male patients and in 29% of female patients with diabetes who were older than 50 years of age. There is controversy as to whether DD is more common with increasing duration and severity of diabetes. The lesions are not specific to diabetes, however. Similar lesions have been noted in 1.5% of medical students and in 30% of randomly selected endocrinology patients (107). The etiology is unknown. Because of the appearance of DD over bony prominences, trauma is thought to play a role. In a study of 19 patients with preexisting DD treated with local heat or cold, 16 developed new lesions (108). Melin could not, however, reproduce the disease with repetitive blows from a rubber mallet. Generally, no treatment other than the protection of susceptible areas from repetitive trauma is indicated.

Diabetic dermopathy has been associated with diabetic retinopathy, neuropathy, and nephropathy (109). A recent study of white subjects with type 2 diabetes and diabetic dermopathy revealed the association of this skin disease with the G82S polymorphism of the gene coding for the receptor for advanced glycosylation end products (the *RAGE* gene) (110).

Diabetic Bullae

Spontaneous bullous formation is a rare but distinct cutaneous sign of diabetes. Known as diabetic bullae, bullous diabeticorum, or idiopathic bullae of diabetes, it is a diagnosis made by exclusion. Kramer (111), in 1930, described asymptomatic blisters on the extremities of patients with diabetes. Diabetic bullae generally are found bilaterally on the extremities of patients with diabetes, particularly those with neuropathy and/or retinopathy (112). The locations of the blisters in a recent series of 12 patients with type 2 diabetes included the toes (5 of 12), heel (2 of 12), and anterior tibial area (2 of 12) (113). The lesions are typically asymptomatic and nonhemorrhagic, ranging in size from vesicles to 3- to 5-cm bullae. Notably, there is no surrounding erythema.

The etiology of diabetic bullae is unclear. Proposed causes include mechanical trauma, ultraviolet light, immune-mediated vasculitis (32), and altered calcium and magnesium levels related to renal failure, changes leading to facilitated epidermal and dermal separation with trauma. The histology of this disorder is not well defined, as both epidermal and subepidermal blistering have been reported. A recent case report documents the presence of hyalinosis of cutaneous blood vessels, which may support an underlying vascular etiology (114). Diabetic bullae may represent more than one entity, a diversity that may explain different histologic presentations.

The differential diagnosis includes localized bullous pemphigoid, porphyria cutanea tarda, drug-induced blistering, and blisters of renal failure. Direct immunofluorescence of perilesional skin is normal in diabetic bullae, distinguishing it from bullous pemphigoid. It is essential to make this distinction to avoid the unnecessary use of glucocorticoids in patients with diabetes (115). Treatment is symptomatic, with compresses or incision and drainage if necessary. Lesions generally resolve spontaneously within several weeks.

Rubeosis

Rubeosis is a descriptive term for the rosy facial coloration found in many patients with diabetes. This appearance tends to be more pronounced in lighter-skinned individuals. The cause remains unknown, but erythema may result from the decreased ability of the thickened dermal vessels to vasoconstrict (116). Some authors believe that improved diabetes control may lessen the erythema. Protection from the sun and avoidance of topical irritants and dietary vasodilators such as alcohol or substances causing facial flushing by their increased temperature, such as coffee or tea, may be helpful.

Vitiligo

Vitiligo is an acquired condition of skin characterized by symmetrical circumscribed macular depigmentation in a localized or generalized pattern. Lesions occur typically around the nostrils, mouth, genitals, and the extensor surface of the hands. Other frequent locations include axillae, nipples, shins, and elbows. Dermatomal patterns occur rarely. Overlying hair can be white or normally pigmented. The amelanotic macules progressively enlarge, and skin depigmentation can be almost complete. In 50% of cases, onset is before the age of 20 years.

Vitiligo is associated with diabetes mellitus. Dawber et al. (117) found vitiligo present in 4.8% of patients with adult-onset diabetes, as compared with 0.7% to 1% of the general population. An increased frequency in patients with type 1 diabetes has been reported as well. Of 2,000 patients with vitiligo, however, 3.1% had diabetes.

The pathogenesis of vitiligo is unclear, but there is substantial evidence implicating an autoimmune process. Vitiligo can occur in association with states of polyglandular hypofunction, including Addison disease, Hashimoto thyroiditis, hypoparathyroidism, gonadal failure, diabetes mellitus, pernicious anemia, celiac sprue, and myasthenia gravis. Elevated titers of antithyroid, antiadrenal, and antigastric antibody activity have been found in children with diabetes and vitiligo (118). It is therefore surprising that the prevalence would be increased in individuals with adult-onset diabetes, which is not thought to be an autoimmune disease, although some patients classified as having type 2 diabetes actually may have slowly progressing autoimmune diabetes.

The condition is asymptomatic but can be very difficult for the patient emotionally. Management includes the use of cosmetics to cover depigmented areas and the avoidance of exposure to the sun, although minimal spontaneous repigmentation in sun-exposed areas has been reported. PUVA therapy has been used successfully for repigmentation, although more than 200 treatments may be needed, for an improvement rate of 50% to 70% (119). In exceptional cases, and only with diffuse involvement, bleaching agents may be applied to surrounding skin. This treatment is irreversible, prolonged, and requires thorough evaluation of potential psychosocial ramifications for the patient. The course of vitiligo associated with diabetes is not affected by glycemic control.

Acanthosis Nigricans

Acanthosis nigricans is a cutaneous condition characterized by the presence of confluent areas of mid- to dark-brown epidermal thickening with a characteristic "velvety" texture. The lesions appear most commonly in the axillae, neck, groin, and intertriginous areas but also may appear over extensor surfaces like the knees, elbows, and knuckles.

In a recent study of 216 patients newly diagnosed with type 2 diabetes (119a), 31% were found to have acanthosis nigricans at the time of presentation. These patients require higher insulin doses than those without this cutaneous finding. A childhood form of the condition, which often occurs during adolescence, usually is benign. In adulthood the condition can be associated with obesity, endocrinopathies, insulin resistance, and malignancy. Acanthosis nigricans associated with obesity is usually benign but indicates the presence of insulin resistance. The lesions may reverse with weight loss. Familial acanthosis nigricans with autosomal dominant inheritance has been reported as well (120). A recent study of 397 people in 33 Mexican-American families demonstrated evidence of very high heritability of acanthosis nigricans. The condition was highly correlated with diabetes mellitus, obesity, and increased fasting insulin levels in patients without diabetes (121). Several endocrine disorders, including Addison disease, polycystic ovarian disease, Cushing disease, acromegaly, and diabetes mellitus are associated with benign acanthosis nigricans. Kahn et al. (122) described two syndromes linking diabetes mellitus, glucose intolerance, and insulin resistance with acanthosis nigricans. In type "A" insulin resistance, the resistance is due to a reduction in the number of cellular insulin receptors, whereas in type "B" insulin resistance, the basis of the resistance is thought to be the presence of antibodies to the insulin receptor. Acanthosis nigricans also occurs in association with certain drugs, including diethylstilbestrol, nicotinic acid, and corticosteroids. When acanthosis nigricans occurs out of the setting of any of the previous conditions, underlying malignancy must be suspected (123). The most commonly associated tumors are adenocarcinoma, particularly of gastric origin. Squamous cell carcinoma, undifferentiated carcinoma, and lymphoma have also been associated with acanthosis nigricans. In two thirds of cases, the lesions of acanthosis nigricans parallel the course of the malignancy.

Treatment of acanthosis nigricans is directed primarily at identification and treatment of the underlying condition, if known. Locally, the lesions can be peeled with 5% to 10% salicylic acid in petrolatum, but no treatments are uniformly effective. A recent review states that metformin, octreotide, retinoids, and topical vitamin D3 analogues can be beneficial (123a).

Figure 62.6. (See also color plate.) Perforating folliculitis in a 50-year-old patient with diabetes with retinopathy and nephropathy.

Figure 62.7. (See also color plate.) Perforating folliculitis in a 50-year-old patient with diabetes with retinopathy and nephropathy.

Finger "Pebbles"

Huntley (124) described distinctive tiny skin-colored grouped papules and thickening over the extensor surfaces of the fingers in 75% of patients with diabetes mellitus, as compared with 21% of control patients without diabetes. The finding was recently reported again (125). Because of the similarity in the appearance of these papules with acanthosis nigricans, some physicians interpret these cutaneous findings as a variant of acanthosis nigricans.

Perforating Disorders

The perforating disorders are a group of diseases in which dermal material perforates through the epidermis out to the surface of the skin. The four classic members of this group are reactive perforating collagenosis, Kyrle disease, perforating folliculitis, and elastosis perforans serpiginosa. All but the last appear to be associated with diabetes, occurring most commonly in patients with coexisting nephropathy. These diseases are occasionally seen in patients with renal disease without diabetes and are rarely noted in healthy individuals.

Reactive perforating collagenosis is characterized by follicular plugs over the extremities, particularly the knees and elbows (126). Kyrle disease affects a similar subpopulation of older patients with severe diabetes and renal disease. Keratin plugs are surrounded by erythema and are found in various stages of development (Figs. 62.6 and 62.7; see also color plate). Lesions preferentially occur on the extremities, buttocks, and sacral region (127). Perforating folliculitis produces similar, but slightly smaller, more numerous lesions, most often on the extremities. Pruritus, the most common complaint, can be extremely resistant to treatment.

Generalized Pruritus

The frequency of generalized pruritus in diabetes is unknown; however, many believe that it is increased in diabetes. Pruritus without primary lesions in a patient with diabetes requires a thorough workup to rule out known causes of pruritus. Patients with systemic disease (renal disease, liver disease, hypo- or hyperthyroidism, iron-deficiency anemia), or lymphoreticular malignancies (e.g., Hodgkin disease) may present initially with pruritus. Each of these, as well as a primary dermatologic cause of itching, should first be ruled out before the pruritus is attributed to diabetes.

CUTANEOUS REACTIONS TO THERAPY **FOR DIABETES**

Insulin-Induced Disorders

The incidence of cutaneous reactions to insulin has diminished considerably since the introduction of recombinant human insulin. Insulin allergy may be secondary to the insulin molecule, additives, or protein contaminants in the commercial preparation (128,129). Local reactions to insulin include erythema, pruritus, induration at the injection site, edema, subcutaneous nodules, or urticaria (130). Serious immediate generalized reactions such as angioedema, serum sickness, bronchial constriction, dyspnea, cardiovascular collapse, and anaphylaxis have occurred but are rare and necessitate discontinuation of insulin therapy in type 2 diabetes and aggressive desensitization techniques in type 1 diabetes (128,131). Delayed reactions, which are usually local at the site of injection, occur approximately 2 weeks after initiation of treatment. Injections that are too superficial may cause cutaneous reactions. Occasional cases of insulin allergy have occurred in association with human (128) and recombinant insulin (132).

Insulin-induced lipoatrophy is now rare (132, 133). Atrophy of subcutaneous fat may occur, resulting in atrophic plaques at insulin injection sites 6 to 24 months after initiation of therapy. Insulin-induced lipohypertrophy is more common in males than in females and is caused by repetitive injections into the same site, a presumed local anabolic effect of insulin (131).

Hypoglycemic Agents

The most common adverse effects of hypoglycemic drugs, which contain sulfa-based components, are gastrointestinal and dermatologic (134). Cutaneous hypersensitivity reactions are similar for the various oral hypoglycemic drugs. Serious cutaneous reactions include a diffuse exfoliative dermatitis; erythema multiforme, which may progress to Stevens-Johnson syndrome; and toxic epidermal necrolysis (135). Cross-reactivity with other sulfonylurea agents may occur, as well as with other sulfa-containing drugs such as thiazides, furosemide, and some antibiotics. Thus, when substitution is necessary, it must be done cautiously. Topically applied preparations may act to sensitize a person to sulfonamides. Fisher (136) reported two cases of a widespread contact dermatitis in patients receiving oral hypoglycemic agents who had previously been sensitized with topical agents containing the para-amino group. A disulfiramlike reaction may result from the ingestion of alcohol in patients receiving a first-generation sulfonylurea agent (134) and occurs in as many as 10% to 30% of patients taking an oral sulfonylurea. Chlorpropamide is the most common offending agent (137.138).

Among the many new oral therapies for diabetes and insulin resistance, most have not yet been reported to cause cutaneous adverse effects. The α -glucosidase inhibitor acarbose, however, was recently reported to cause erythema multiforme after 2 weeks of therapy (139).

As modern therapeutics have helped decrease the mortality and morbidity of diabetes mellitus, increased musculoskeletal symptoms may be discovered as these patients lead longer and more active lives. It is important to recognize the various joint and bone manifestations of diabetes. Although the other complications of diabetes are better recognized as causes of morbidity and mortality, the musculoskeletal syndromes associated with it may be very debilitating. Overall, changes in the connective tissue of patients with diabetes are probably due to disturbances in the structural macromolecules of the extracellular matrix. Many of these rheumatologic manifestations of diabetes mellitus have been reviewed in the last several years (1-3). A wide range of musculoskeletal syndromes have been described in association with diabetes (Table 63.1). In general, these are syndromes commonly or uniquely associated with diabetes mellitus. There are also common rheumatic diseases with an increased incidence in the diabetic population.

RHEUMATIC SYNDROMES UNIQUELY OR COMMONLY ASSOCIATED WITH DIABETES MELLITUS

Adhesive Capsulitis of the Shoulder

Adhesive capsulitis of the shoulder is a common problem manifested by diffuse shoulder pain associated with a loss of motion in all directions and little or no evidence of intraarticular disease (4). The joint capsule is thickened and adherent to the humeral head. Arthroscopy reveals a marked reduction in the volume of the glenohumeral joint. Increased uptake of ^{99m}Tcmethylene diphosphonate by the periarticular tissue has been demonstrated, suggesting the presence of inflammation (5). Bone demineralization follows. Although patients may recover spontaneously within 3 years, the syndrome may recur, and some patients with severe disease may become disabled (3).

The association of adhesive capsulitis and diabetes mellitus has been well documented. Bridgman (6) identified adhesive capsulitis in 11% of 800 diabetic patients as compared with an incidence of 2.5% in 600 control patients. Alternatively, abnormal glucose tolerance tests were seen in 28% of patients with adhesive capsulitis compared with 12% of age- and sexmatched controls attending a rheumatology clinic (6). Arkkila et al. (7) found an overall cumulative prevalence of shoulder capsulitis of 14% in patients with diabetes mellitus. The prevalence was 10% in patients with type 1 diabetes and 22% in patients with type 2 diabetes. Furthermore, adhesive capsulitis is associated with age in patients with type 1 and type 2 diabetes and with duration of diabetes in patients with type 1 diabetes only. Pal et al. (8) found adhesive capsulitis in 20.4% of patients with type 1 diabetes, in 18.3% of patients with type 2 diabetes, and in 5.3% of normal control subjects.

The treatment of patients is directed toward increasing the range of motion of the tightened joint. Early physical therapy, including exercises, heat, and ultrasound, may be helpful. Splinting may lead to further restriction of motion and is contraindicated. Treatment of pain during physical therapy is important. Treatment includes the use of nonsteroidal antiinflammatory drugs (NSAIDs) as both antiinflammatory agents and analgesics. In addition, opioids may occasionally be necessary. Although there are no long-term studies concerning the use of local glucocorticoid injections in this setting, intraarticular injections may occasionally be useful in decreasing pain and increasing motion. In our experience, full recovery of motion may take as long as 6 months. Rarely, patients may require manipulation of the shoulder while they are under

general anesthesia to increase the range of motion. In severe cases of adhesive capsulitis, the patient may not recover full motion and may become disabled.

Shoulder-Hand Syndrome

Shoulder-hand syndrome (SHS) is characterized by adhesive capsulitis of the shoulder associated with pain, swelling, tenderness, dystrophic skin, and vasomotor instability in the hand. It is one of a family of disorders that includes reflex sympathetic dystrophy syndrome, major and minor causalgia, Sudeck atrophy, and algodystrophy. Doury et al. (9) described these syndromes as consisting of severe pain disproportionate to the findings of the physical examination in association with articular or periarticular swelling. Steinbrocker and Argyros (10,11) described three stages of this syndrome. During the first stage, which lasts 3 to 6 months, there is pain, tenderness, swelling, and vasomotor changes, including temperature and color changes in the affected hand. The second stage, which also may last 3 to 6 months, is characterized by trophic skin changes characterized by shiny skin with loss of normal wrinkling. The final stage is characterized by atrophy of skin and subcutaneous tissue, tendon contractures, and progressive osteopenia. Spontaneous improvement may occur, although without treatment the patient may lose function of the affected limb permanently.

Trauma is the most common condition predisposing to SHS, but diabetes; cerebrovascular disease; myocardial infarction; post-thoracotomy state; hyperthyroidism; hyperlipidemia; electrocution; medications, including barbiturates, isoniazid, ethionamide, and cycloserine; and previous exposure to radioiodine, have all been associated with the onset of this syndrome (3). In one study of 108 patients with SHS or related conditions, 7.4% had diabetes (9). The prevalence of diabetes actually may be greater in patients with this syndrome, since glucose tolerance tests were not performed in all cases.

Radiographic findings in SHS typically include a diffuse, patchy osteopenia. Measurements of bone mineral density demonstrate loss of up to one third of the bone mass. Threephase bone scintigraphy reveals asymmetric uptake and increased blood flow and, in most cases, pooling in phases 1 and 2. The phase-3 images are characterized by increased uptake in the periarticular tissues. A small percentage of patients may show decreased uptake on bone scintigraphs.

Treatment of patients with SHS is most effective when begun early in the development of the syndrome. Analgesic medication

and range-of-motion exercises should be prescribed. If these are ineffective, systemic glucocorticoid therapy or sympathetic blockade should be considered. In patients with diabetes, regional sympathetic-ganglion block with a long-acting anesthetic agent, performed by an anesthesiologist, is the preferred treatment method since the use of systemic glucocorticoids may cause difficulties in the maintenance of glucose control. Steinbrocker and Argyros (11) reviewed 146 patients with SHS and found some improvement in up to 80% treated with glucocorticoids or regional sympathetic blockade. Intraarticular steroids may also be used, but no controlled trials exist and experience with this technique is limited. Patients are candidates for surgical sympathectomy if the above approaches provide only temporary relief of symptoms. Recently, interest has increased in the use of α -adrenergic blockade and other vasoactive drugs in the treatment of SHS.

Diabetic Hand Syndrome

Diabetic hand syndrome (DHS), also termed cheiropathy, stiffhand syndrome, diabetic stiff hand, diabetic contractures, or syndrome of limited joint mobility, was first described by Jung et al. (12) in adults with diabetes and by Grgic et al. (13) in a pediatric population with diabetes and short stature (see reference 14 for a comprehensive review of this syndrome). The syndrome has since been described in juveniles with type 1 diabetes and normal stature and in adults with type 1 or type 2 diabetes (15-19). The reported prevalence of DHS in diabetes ranges from 8% to 53% (20–27). Most studies suggest a prevalence of about 35% in patients with diabetes (28–31). It is more common in patients with type 1 diabetes and may be associated with duration of disease. The onset of DHS may not be related to the patient's sex or insulin dosage. It is unclear whether the onset of cheiropathy is related to metabolic control. Silverstein et al. (32) have shown that poor long-term glycemic control, as measured by elevated hemoglobin A1c levels, does increase the risk of earlier onset of hand symptoms in patients with type 1 diabetes. Clinically, patients complain of stiffness, loss of dexterity, and weakness of their hands. The skin on the hands is typically thick, tight, and waxy, and changes may appear compatible with scleredema. There is evidence of recurrent tenosynovitis and decreased range of motion of the small joints of the hands. The patient may exhibit the prayer sign, that is, when asked to hold the palms of the hands together, the patient is unable to bring the fingers and palms together because of flexor tendon contractures. Limitation of flexion and extension occurs predominantly in the proximal interphalangeal and metacarpophalangeal joints. Decreased grip strength results. Sclerodactyly and thick skin may be present.

Much has been reported about the relationship of DHS with the age of the patient, the duration of diabetes, and the presence of diabetic retinopathy (12,29,33,35). In general, DHS is more common in patients with long-standing diabetes and microvascular disease. The presence of DHS may indicate that the patient is at high risk for microvascular disease. In patients with diabetes for 16 years, the prevalence of observed microvascular lesions was three- to fourfold higher in those with hand contractures than in those without contractures (29,33–36). There is some evidence that joint contractures in patients with diabetes are linked with delayed median-nerve conduction and intrinsic hand-muscle wasting (37–39).

In addition, a form of restrictive lung disease has been described in patients with DHS in which total and vital lung capacity is decreased (20,24–26). These patients are usually asymptomatic but may experience dyspnea secondary to

63: JOINT AND BONE MANIFESTATIONS OF DIABETES MELLITUS 1063

hypoxemia. It is likely that in some instances similar abnormalities in connective tissue occur in the hand and the lung.

The limitation of joint movement probably results from dermal and subcutaneous sclerosis (30,40-41). In addition, the fibrous thickening of the flexor tendon sheaths contributes to the loss of mobility. The pathogenesis of these altered connective tissues remains obscure. Pathologically, a biopsy of the thickened skin reveals dermal fibrosis with increased collagen deposition in the dermis and loss of sebaceous glands and other secondary skin appendages (29,31). Raynaud phenomenon, digital ulcers, or other systemic manifestations of scleroderma or other autoimmune diseases are not present. Laboratory evaluation is unrevealing, and radiographs of the hands may be normal or show diffuse osteopenia. Some investigators have documented increased cross-linking of collagen, which leads to increased resistance to collagenase and the resultant decrease in turnover (42-44). Increased nonenzymatic glycosylation of collagen, which might increase intermolecular cross-linking, has also been demonstrated (45-51). Other possible factors include increased hydration of collagen, swelling of the connective tissue through the aldose reductase pathway, and microangiopathy leading to increased collagen synthesis.

Importantly, the role of sorbitol has been hypothesized as possibly contributing to the microvascular complications in patients with diabetes. Hyperglycemia promotes increases in the amount of sorbitol accumulating in cells. In cells, glucose is converted to sorbitol via the enzyme aldose reductase, which may be responsible for an increase in cell osmolality, decreased cell myoinositol, and other factors that may promote collagen and connective tissue abnormalities (52–54). Thus, if sorbitol plays a major role in collagen dysregulation or tissue damage, the use of aldose reductase inhibitors in patients with diabetes may decrease the accumulation of sorbitol and subsequently decrease the microvascular and collagen complications of diabetes. Clinical trials of aldose reductase inhibitors have not shown consistent improvement in the microvascular complications, such as retinopathy, neuropathy, and nephropathy (52–54). There is one report of three patients with contractures who demonstrated a reversal of hand symptoms with aldose reductase inhibitors (55).

Another proposed mechanism is the accumulation of advanced glycosylated end products (AGEs) that may predispose to collagen abnormalities and tissue injury (56,57). Hyperglycemia provides an environment of enhanced glucose availability that accelerates the deposition of AGEs into tissues. This may lead to a stronger cross-linking potential of collagen *in vivo* and vascular injury, as endothelial cells have receptors for AGEs. Clinical trials are now being conducted on aminoguanidine, an agent that prevents the deposition of AGEs in tissue, for the prevention of diabetic nephropathy (58). Perhaps future studies will be undertaken for DHS.

Therapy for the diabetic hand syndrome should include dynamic splinting and an attempt to increase range of motion through exercise. It is unclear without prospective studies whether an increase in exercise will prevent the onset of limited joint mobility or will restore joint mobility that has been lost. Aspirin, NSAIDs, or opiate analgesics for those who are not responding to local modalities may be helpful in controlling pain and stiffness. There are case reports in the literature suggesting that better glycemic control may lead to a decrease in skin thickness (59).

Dupuytren Disease

Dupuytren disease is common in the general population and increases in incidence as the population ages (3,60). It causes a

focal flexion contracture with a thickened band of palmar fascia. Flexion deformities along with tethering of the skin are noted. Knuckle pads (Garrod pads), as well as heel-pad nodules, may be noted (3). Pain and loss of motion result. Dupuytren contracture, in which a low-grade inflammatory reaction producing nodularity may occur, often is associated with diabetes. Contractures may involve the third, fourth, or fifth flexor tendons.

It has been suggested that 25% of patients with Dupuytren contractures have diabetes (2,61). In addition, studies have shown that 21% to 63% of patients with diabetes have the contractures, in contrast to 5% to 22% of the normal population (2). Noble et al. (62) reported the development of this complication in more than 50% of patients with diabetes and an increase in incidence with duration of diabetes and also demonstrated that a high proportion—as high as 16% of adults with diabetes.

The pathogenesis of Dupuytren disease remains unknown. Occasionally, a history of occupational or other trauma may precede its onset. Investigators have described the occurrence of modified fibroblasts (myofibroblasts) that resemble smooth muscle cells and are contractile within tendon nodules (63,64). Proliferation of these cells with subsequent contraction might subject neighboring fascial structures to intermittent tension, resulting in hypertrophy. These same cells have also been reported in the nodules of patients with Ledderhose disease and may be present in the abnormal tissues of patients with Peyronie disease (65,66).

In addition, studies have documented the deposition of increased amounts of type III collagen in the palmar aponeurosis and in diseased fascia. It appears that as more type III collagen is deposited, the disease becomes more severe. The greatest proportion of type III collagen is found in the nodules. It is unknown whether onset is linked to impaired glucose tolerance (67–69) or whether good glucose control in the diabetic patient will limit onset of this problem (70–73). The presence of CD3⁺ lymphocytes in tissue and expression of major histocompatibility complex class II proteins may implicate a T cell–mediated autoimmune disorder (74–76).

Treatment includes aggressive physical therapy, including dynamic splinting and exercises. NSAIDs or other analgesics may be helpful in decreasing pain. Intralesional glucocorticoid injections may provide relief of pain as well as increased range of motion. Occasionally, surgical release of the contracture is necessary.

Neuroarthropathy

Diabetes mellitus is one of the major causes of Charcot joints. The usual presentation is that of a patient with long-standing diabetes, often complicated by hypertension, proteinuria, and retinopathy, who develops joint swelling or deformity after the age of 50. The foot is most commonly involved, followed in frequency by the ankle and knee. Rarely, upper extremity joints are involved. Unilateral painless foot swelling is the most common presentation. Warmth and erythema may be present. When they are present, the differential diagnosis includes gout, pseudo-gout, osteomyelitis, or septic arthritis. Typically, there are few systemic symptoms and no documented fever and leukocytosis. Radiographically, there are destructive changes of the tarsometatarsal and metatarsophalangeal joints. Involvement of the tarsal and proximal metatarsal bones may occur and lead to osteoporosis, osteolysis, and bone fragmentation (77,78).

Another physical examination finding of neuropathic joint is termed "claw toe." This arises as chronic motor neuropathy affects the small intrinsic muscles of the feet. When the larger muscles of the anterior tibial compartment are unopposed, subluxation of the proximal interphalangeal metatarsal joints may result, leading to a claw-toe appearance. This may lead to excessive pressure on the metatarsal heads and thus the tendency to form skin ulcers.

Patients with diabetic peripheral sensory neuropathy have a loss of pain and proprioceptive sensations distally. This loss of the normal afferent signals reduces the protection of the joint from microtrauma, which may result in progressive joint destruction (2,3). In addition, ischemia secondary to both largeand small-vessel disease may play an etiologic role. Whitehouse and Wechstein (77) have suggested that this osteopathy represents a healing phase of local osteomyelitis.

Management of diabetic neuroarthropathy is difficult. Lumbar sympathectomy, arthrodesis, immobilization, and special footwear have been of little value. Minimizing trauma, maintenance of good muscle strength, use of appropriate shoes, and regular inspection of the skin and nails to avoid secondary infection may be helpful. Splinting may exacerbate the problem and may lead to skin ulceration, perforation, and secondary osteomyelitis.

Spinal neuroarthropathy characterized by usually symmetric extensive new bone formation (hyperostosis) also occurs. The vertebral changes include sclerosis and altered bony trabeculae. These changes result in an inability of the vertebrae to withstand normal stresses, with resultant collapse. Typically, local pain and tenderness may occur in association with irritation of the nerve root.

Although not a true neuroarthropathy, the carpal tunnel syndrome (CTS) is a frequent cause of hand pain in patients with diabetes. Entrapment of the median nerve within the carpal tunnel results in hand pain and numbness in the second to fourth fingers, particularly at night. Diabetes mellitus is one of the systemic diseases most frequently associated with CTS. In one study, diabetes was present in 16.6% of patients with CTS (3). Other sensory peripheral neuropathies, such as ulnar neuropathy, may coexist with CTS and may be associated with the diabetic hand syndrome discussed previously. Therapy for CTS includes the use of NSAIDs and splinting. If these are ineffective, local glucocorticoid injection or surgical release of the retinaculum may be indicated.

Hyperostosis

Although patients with type 1 diabetes have a tendency to develop osteopenia (78) (see later section), patients with type 2 diabetes seem to make more bone or to develop hyperostosis. In one study of 428 diabetic patients, 25% had hyperostosis of different areas, including spine involvement, hyperostosis frontalis interna, calcification of the pelvic ligaments, and osteitis condensans ilii (3). New bone formation around the hips, knees, and wrists has also been noted (25,79). In Morgagni syndrome, hyperostosis frontalis interna is accompanied by type 2 diabetes (3).

The most common form of new bone formation in diabetes is disseminated idiopathic skeletal hyperostosis (DISH) or ankylosing hyperostosis of the spine. This syndrome occurs in 2% to 4% of the normal population over the age of 40; in contrast, the prevalence is 13% in patients with diabetes (80,81). In patients with diabetes between the ages of 60 and 69, the prevalence increases to more than 20% (81). The presence of DISH is also associated with obesity, independent of diabetes. No correlation has been found between the degree of diabetic control and the extent of the hyperostosis.

Typically, a patient with DISH may complain of some mild back pain and stiffness, but range of motion is preserved.

Occasionally, the abnormality may be an incidental radiographic finding. Sparing of the posterior spinal joints probably accounts for the preservation of good back motion (82). The syndrome is characterized by asymmetric osteophytes or bony outgrowths that extend vertically along the anterolateral surface of the vertebral bodies, particularly on the right. Anterior bridges between vertebrae and sclerosis of the underlying bony cortex are seen. Unlike patients with ankylosing spondylitis, these patients rarely complain of early-morning stiffness and loss of back motion. In addition, the sacroiliac joints are spared. Radiographically, the vertebral body osteoporosis seen in ankylosing spondylitis is absent. Although early reports suggested an association between DISH and the histocompatibility antigen HLA-B27, this has not been confirmed (2,83,84). The thoracic spine is most commonly involved in DISH, followed by the cervical spine and the lumbar spine. If extensive involvement of the anterior cervical spine occurs, it may result in dysphagia and disturbance of esophageal function.

In addition to the spinal involvement of DISH, widespread osseous changes may be detected elsewhere. These changes are most common around the acetabulum and where fluffy new bone is formed, but similar changes around the knees and wrists have been documented. In addition, some of the changes in the spine can be internal within the canal as well as external. Changes have been noted around the apophyseal joints; these changes may impinge on emerging nerve roots, while the intervertebral discs may be relatively normal. Thus, there may be symptoms of radicular irritation as well as mild localized pain. Degenerative arthritis of the hips has frequently been noted. However, this is a common occurrence in this particular age group with or without DISH. It is unclear whether a progressive degenerative disease of the hip is a unique phenomenon in this syndrome or is just an associated clinical event.

The explanation for the association of diabetes and new bone formation is unclear. Levels of growth hormone are normal in these patients. An abnormal or exaggerated serum insulin response to glucose challenge has been documented in some patients with ankylosing hyperostosis without diabetes (85,86). It is probable that insulin and/or insulin-like growth factors may be important in promoting new bone formation in patients with adult-onset diabetes, obesity, or both of these disorders.

COMMON RHEUMATIC DISEASES ASSOCIATED WITH DIABETES MELLITUS

Osteoarthritis

Osteoarthritis, or degenerative joint disease, is the most common rheumatic disease in the general population. It may be asymptomatic or mild, but severe involvement leads to pain, stiffness, and limitation of motion in the affected joints, most commonly involving the knees, hips, and spine, and may be a source of major disability and morbidity. It is difficult to establish a relationship between common diseases such as osteoarthritis and diabetes, but several studies have documented a positive correlation (3). Several investigators have suggested that the prevalence of osteoarthritis is higher in young and middle-aged diabetic patients and that joint damage starts at an earlier age and is much more severe in diabetic than in control patients (3).

Insulin has been demonstrated to stimulate cartilage growth and proteoglycan biosynthesis. These effects are likely mediated through somatomedin (insulin-like growth factor-1) (87–94). Although insulin may alter the extracellular matrix present in bone and cartilage, the significance of such changes, particularly as a cause of osteoarthritis, has not been determined. Treatment of osteoarthritis is directed toward the control of pain with acetaminophen or NSAIDs, as well as physical therapy–guided exercise programs for the strengthening of muscles and tendons.

Gout and Hyperuricemia

Gout is a heterogeneous disorder characterized by hyperuricemia and arthritis induced by the accumulation of urate crystals. Acute gouty arthritis is characterized by severe joint pain, redness, warmth, and tenderness usually affecting a lower extremity joint. Gout is a recognized but relatively uncommon complication of diabetic ketoacidosis (3). Patients with diabetes who have uncontrolled glucose metabolism associated with ketoacidosis will develop hyperuricemia as a result of competitive inhibition of tubular excretion of urate in the kidney by organic acids. Dehydration and increased protein catabolism also play a role. In addition, many patients with advanced diabetes have nephropathy, which may lead to renal transplantation. Transplant patients require immunosuppressive therapy to prevent rejection of the transplanted kidney. Antirejection drugs such as cyclosporine may increase serum uric acid levels, leading to gouty flares and tophaceous gout.

There is also a possible correlation between chronically stable diabetes and onset of gout symptoms (95,96). Previous studies have demonstrated an increased incidence of hyperuricemia in individuals with stable diabetes and of hyperglycemia in patients with gout. It is likely that a significant proportion of this latter group are patients with gout who are obese with relative states of insulin resistance leading to abnormal glucose tolerance. In addition, many of these studies did not make age correlations. It is now known that glucose tolerance decreases with age. Thus, age may be a link between gout and diabetes. Unfortunately, no prospective studies with age-, sex-, and weight-matched controls have been performed, but it appears that the risk of gout in nonobese patients with diabetes is no greater than that in the normal population (3). Paradoxically, the new onset of frank diabetes has been accompanied by a decrease in serum urate levels and a reduction in the frequency and severity of attacks in patients with preexisting gout (3,97). In general, obesity may be the most important factor linking hyperglycemia with hyperuricemia, as obesity is known to precipitate hyperglycemia, hyperuricemia, and hyperlipidemia (98,99).

Acute gouty attacks may be treated with indomethacin, other NSAIDs, or colchicine. Long-term prophylaxis with allopurinol or a uricosuric agent may be necessary in some clinical settings.

Calcium Pyrophosphate Deposition Disease

Pseudogout is an inflammatory arthritis caused by the deposition of calcium pyrophosphate dihydrate crystals in synovial structures. It may present as an acute monoarticular arthritis, chronic polyarticular inflammatory arthritis, or asymptomatic chondrocalcinosis, defined as linear deposition of calcium pyrophosphate crystals in cartilage, which appear calcified on plain radiographs. Calcium pyrophosphate deposition disease (CPPD) arthropathy is suggested by the radiologic finding of chondrocalcinosis in a patient with acute or chronic inflammatory arthritis and the identification by polarizing light microscopy of weakly positive birefringent rhomboid-shaped crystals in synovial fluid. Acute inflammatory arthritis secondary to CPPD, or pseudogout, without radiographic evidence of chondrocalcinosis, has been reported, particularly in the small joints (2).

63: JOINT AND BONE MANIFESTATIONS OF DIABETES MELLITUS 1065

In 1974, McCarty et al. (101) demonstrated the apparent clinical association of CPPD arthropathy with diabetes. However, this observation has not been confirmed (100). Alexander et al. (100) were unable to document the association in 105 consecutive patients with CPPD arthropathy. The incidence of CPPD arthropathy in diabetic patients has been reported to range between 8% and 73% (3) compared with an incidence of 0.2% in the normal population (101). This discrepancy must be attributable to variations in the diagnostic criteria used in the studies as well as to intervening variables such as age and osteoarthritis.

It is possible that the simultaneous occurrence of CPPD arthropathy and diabetes represents no more than the chance association of two relatively common abnormalities in elderly patients. Alternatively, it is also possible that diabetic patients with chondrocalcinosis are more susceptible than diabetic patients to symptomatic articular disease such as pseudogout. Certainly, an elderly patient presenting with CPPD arthropathy should be tested for subclinical diabetes. The corollary is true as well; pseudogout should be considered in each diabetic patient who presents with articular symptoms.

Symptomatic CPPD arthropathy may be managed with systemic antiinflammatory drugs such as NSAIDs, colchicine, or prednisone. Aspiration of the affected joints alone and/or the intraarticular injection of glucocorticoids may also be effective. McCarty et al. (101,102) suggested that control of hyperglycemia in diabetic patients did not appear to influence the frequency or severity of recurrent attacks of CPPD arthropathy.

Osteopenia

There is controversy about the incidence of osteopenia and osteoporosis in patients with diabetes. Several studies support the relationship between type 1 diabetes and reduced bone mass (103-108). In children, objective measurements of forearm bone mineral density reveal an 8% reduction in cortical bone density and a 14% reduction in trabecular bone density in children with diabetes compared with these values in age- and sex-matched controls (104). A similar reduction in bone mass occurs in adults (106). The decrease in bone density is detectable early in the disease (104). In adults, the rate of bone loss is maximal at or soon after diagnosis of diabetes and is correlated with the serum level of endogenous insulin (109). As insulin levels fall, the incidence of osteopenia increases. However, the relationship between the degree of metabolic control in patients with type 1 diabetes and the degree of osteopenia has not been well documented. In patients with type 2 diabetes, results of forearm bone density studies are conflicting (103,110-112). As discussed previously, hyperostosis, not osteopenia, may occur in this patient population.

Although patients with diabetes may have osteopenia, the evidence regarding the consequences of this osteopenia is confusing. The incidence of diabetes among patients with femoral neck fractures appears to be greater than expected by chance, the relative risk values reported being 1.16 to 3.4 (113–117). However, there is no good evidence about the incidence of vertebral compression fractures in patients with diabetes (118).

The role of insulin in normal bone turnover remains a puzzle. Insulin is an anabolic hormone, and the effects of insulin and insulin-like growth factors have been well documented (119–126). Insulin stimulates nucleotide synthesis by osteoblasts *in vitro*, promotes the intracellular accumulation of amino acids in membranous bone, and can restore levels of circulating somatomedin in experimental diabetes (122–124). Insulin-like growth factors have also been shown to promote synthesis of bone collagen (119,120,123,125) and to increase the deposition of calcium in the skeleton (121,126). These findings suggest that when circulating levels of insulin are decreased, the synthesis of a good bone matrix will be inadequate and the bone will not calcify. It is possible that in type 2 diabetes, with its insulin resistance, hyperinsulinemia will stimulate bony overgrowth. This suggestion is supported by recent data demonstrating that bone mineral density is increased, not decreased, in patients with type 2 diabetes who have increased levels of endogenous insulin but decreased sensitivity to insulin (127).

Osteolysis of Forefoot

A distinct clinical syndrome has been described in patients with diabetes that is characterized by patchy or generalized osteoporosis of the distal metatarsal and proximal phalanges in association with variable amounts of pain and erythema (3,128–130). Because of the appearance of the forefoot, both cellulitis and osteomyelitis need to be considered in the differential diagnosis and excluded by laboratory, radiographic, and microbiologic data. Diabetic patients with this syndrome do not necessarily have small-vessel vascular disease or neuropathy. Osteopenia may be accompanied by juxtaarticular erosions mimicking rheumatoid arthritis or gout (128,129). Articular surfaces are initially spared, but progressive osteolysis may cause disappearance of adjacent bone. At any stage during this process, the syndrome may resolve spontaneously and normal bony architecture may be partially or completely restored. The cause of this condition is unknown. Severe disease with osteoporosis and subsequent fracture or fragmentation of the bone may be confused with neuropathic joint disease. Because the syndrome resolves spontaneously, no specific treatment is recommended.

Migratory Osteolysis of Hip and Knee

The syndrome of migratory osteolysis of the hip and knee is characterized by local areas of decreased bone density or osteopenia associated with significant local pain. The pain may last for up to 1 year and usually resolves without sequelae. Typically, the patient is a woman over 50 years of age who presents with severe pain initially involving one joint in the lower extremity. The painful joint is usually a large weight-bearing joint, but any joint can be affected. The pain is out of proportion to the physical findings. There are few signs of inflammation, although an effusion may be present. However, the joint fluid is usually not inflammatory when aspirated. There may be a recent history of pain similar in type that may have affected a different joint in the lower extremity and resolved spontaneously. Blood tests are usually not helpful. Radiographs of the joint may reveal a small localized area of osteopenia, but the bone scan will show significantly increased uptake over the affected area.

The etiology of this syndrome remains obscure. In a study of 34 patients with involvement of the hip, five were diabetic and all had an exaggerated serum triglyceride response following alcohol ingestion (3). Doury et al. (9) made an association between diabetes and migratory osteolysis of the knee; however, both of these syndromes are typically seen in patients older than 50 years, the age at which the incidence of type 2 diabetes increases. Patients are typically remarkably sensitive to low-dose glucocorticoid treatment, which may exacerbate the insulin resistance and thus worsen the diabetes. In Europe the use of calcitonin has gained popularity. However, because calcitonin induces a decrease in the output of endogenous insulin *in vitro*, this therapy should be used with caution (3).

In 1936, Bargen (1) first described diarrhea and steatorrhea as complications of diabetes. It is now clear that all parts of the digestive system are affected by diabetes, and digestive system dysfunction is an important contributor to the morbidity of this disease (2–4). Digestive symptoms related to diabetes are reported to be common. Feldman and Schiller (3) questioned 136 unselected patients at a hospital diabetes clinic about the presence of gastrointestinal (GI) symptoms. Three fourths of all

⁺Deceased.

patients had digestive symptoms. Frequent GI symptoms were constipation (60%), abdominal pain (34%), nausea and vomiting (29%), diarrhea (22%), and fecal incontinence (20%). Moreover, digestive symptoms in persons with diabetes may lead to clinically significant decreases in quality-of-life scores (5). A more recent U.S. national survey of upper GI symptoms, including heartburn, also showed significantly more upper GI symptoms in persons with diabetes (50% vs. 38% in controls) (6). However, it is unclear whether such GI symptoms are significantly different in the diabetic population than in the nondiabetic population except for decreased heartburn and increased use of laxatives (7). Regardless, asymptomatic abnormalities of gut function frequently occur in these patients.

PATHOGENESIS OF DIGESTIVE SYSTEM DYSFUNCTION

The digestive system dysfunction in diabetes may result from diabetes itself or, more often, from diabetes-associated complications. Diabetic neuropathy plays an important role in motor and secretory abnormalities in the GI tract, in nausea, vomiting, and the syndrome of abdominal pain. Diabetic angiopathy and vascular complications play a role in the pathogenesis of intestinal ischemia, in the severity and outcome of cholecystitis and biliary tract surgery, and in the nerve and muscle dysfunction of diabetic gastroenteropathy. Defects in immune mechanisms in diabetes are related to an increased incidence of esophageal candidiasis, and decreased resistance to infection accounts for the many pyogenic complications in the digestive tracts of these patients.

Some of the digestive system abnormalities in diabetes may not be causally related to diabetes but may reflect a common association of diabetes with these abnormalities. For example, the increased incidence of gallstones and fatty liver is due to associated obesity and hyperlipidemia in patients with type 2 diabetes, and the incidence of celiac disease is increased because of a common gene that predisposes to both conditions. Similarly, gastric parietal cell antibodies are found in human leukocyte antigen (HLA) haplotypes that are prevalent in patients with type 1 diabetes (8).

Hormonal Changes in Diabetes

Other hormonal changes described in patients with diabetes play important roles in the pathogenesis of many digestive disorders. For example, increased postprandial hormone release of glucagon and pancreatic peptide in patients with diabetes may exacerbate the disturbed motility in subjects with type 2 diabetes (9). Amylin, a peptide hormone cosecreted with insulin by the pancreatic β -cells, is deficient in patients with type 1 diabetes and elevated in patients in the early stages of type 2 diabetes. Patients in the later stages of type 2 diabetes have reduced amylin secretion that appears before reduced insulin secretion. Amylin and its analogue pramlintide delay gastric emptying (10). Activity of the gastric inhibitory peptide (GIP) that normally inhibits gastric emptying is almost completely lost in patients with type 2 diabetes, although glucagon-like peptide-1 (GLP-1), expressed mainly by the gut L-cells after feeding, maintains its ability to stimulate insulin secretion in these patients, even long after sulfonylurea secondary failure, and may be an important therapeutic alternative in diabetes (11). Ghrelin, a novel peptide hormone synthesized primarily in the stomach, has potent insulin-releasing, appetite-promoting, and gastric promotility effects. This hormone is decreased in the serum of persons with type 2 diabetes (12).

Enteric Neuropathy in Diabetes

The GI tract is richly innervated by nerves, which can be divided into intrinsic and extrinsic nerves (13). The intrinsic nerves constitute the enteric nervous system (ENS). The extrinsic nerves contain sensory (afferent) and motor (efferent) fibers and are carried along sympathetic, parasympathetic, and somatic pathways to the central nervous system (CNS) (Fig. 64.1). In diabetes, any

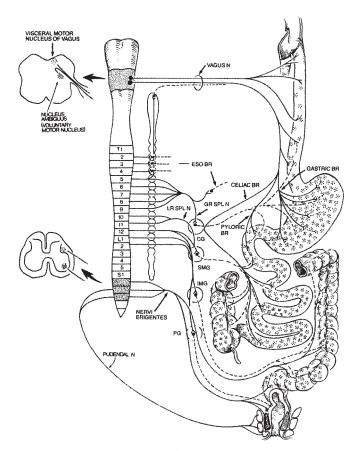

Figure 64.1. Efferent innervation of the gastrointestinal tract. The α motor neurons innervate skeletal muscle at either end of the gut. The α motor neurons to the pharynx and upper esophagus are present in the nucleus ambiguus, and their axons are carried in the vagus nerve. The α motor neurons to the external anal sphincter are present in Onuf's nucleus, and their axons are carried in the pudendal nerve. The sympathetic pathway consists of cell bodies of preganglionic neurons located in spinal cord segments T2 through L2. The preganglionic fibers are carried in the greater splanchnic nerve (GR SPL N), lesser splanchnic nerve (LR SPL N), and smallest splanchnic nerve (not labeled) to terminate in the celiac ganglion (CC), superior mesenteric ganglion (SMG), inferior mesenteric ganglion (IMG), and pelvic ganglion (PC). The postganglionic sympathetic neurons are distributed in a segmental fashion to the gastrointestinal tract. The parasympathetic pathway consists of vagal and sacral outflows. The vagal pathway consists of preganglionic parasympathetic axons whose cell bodies are present in the dorsal motor nucleus of vagus. The vagal parasympathetic fibers supply the gastrointestinal tract up to the right half of the colon. Sacral preganglionic parasympathetic fibers arising from neurons in spinal cord segments S2 to S4 (nervi erigentes) supply the left half of the colon, including the rectum and the internal anal sphincter. The postganglionic parasympathetic nerves and fibers are present intramurally in the gut wall. Sympathetic and parasympathetic nerves make extensive contacts with neurons in the enteric nervous system. In diabetes mellitus one or more components of efferent or afferent innervation (not shown) may be involved (see text). (From Goyal RK, Crist J. Neurology of the gut. In: Sleisenger MH, Fordtran JS, eds. Gastrointestinal disease: pathophysiology, diagnosis, management. Philadelphia: WB Saunders, 1989:21-52, with permission.)

PARASYMPATHETIC INNERVATION

The vagal efferents provide parasympathetic innervation to the entire gut down to the right half of the transverse colon. The left half of the colon and the rectum are innervated by sacral parasympathetic efferents. Parasympathetic preganglionic efferents are thinly myelinated or unmyelinated cholinergic axons. It is now clear that there are two parallel pathway vagal fibers that terminate on excitatory and inhibitory postgan-glionic neurons, respectively, in the enteric plexuses. The parasympathetic influence on the gut includes precise and localized motor and secretory control activity. The vast majority (>80%) of the vagal fibers are low-threshold afferents that are involved in nonnoxious sensations and primarily mediate reflex activities, including nausea, vomiting, and satiety.

Morphologic studies of vagal abnormalities in diabetes have had variable results. Diani et al. (16) reported marked abnormalities in the vagus nerve in nonketonuric and ketonuric diabetic Chinese hamsters. Analysis of axons from the ventral division of the vagus nerve demonstrated that in the diabetic animals the number of nonmyelinated axons and the numerical and volume density of myelinated fibers were markedly decreased. In an autopsy study of patients with diabetes, Smith (17) demonstrated sparse changes in the vagus nerve. Sections obtained at both the cervical and the diaphragmatic levels of the vagus showed that a small number of fibers had undergone segmental demyelination. A larger number of fibers showed wallerian changes of degeneration. Duchen et al. (18) described more severe pathologic changes of the vagus nerve in an autopsy study of four patients with prolonged diabetes. Guy et al. (19) described pathologic changes in a segment of the abdominal vagus removed during gastric surgery from a patient with severe gastroparesis. These changes included a marked reduction in unmyelinated axons; the remaining axons were characterized by a small diameter with an associated increase in surrounding collagen. In contrast to the above findings, Yoshida et al. (20) found no abnormalities on morphologic analysis of sections of the abdominal vagus nerve in five patients with diabetes, two of whom had symptomatic gastroparesis.

Functional studies provide evidence of parasympathetic efferent denervation of the gut in diabetes. Patients with longstanding diabetes have been found to have an impairment of the cephalic phase of gastric acid secretion. In such patients, sham feeding or insulin-induced hypoglycemia is associated with a diminished secretory response, a finding indicative of decreased vagal influence on the stomach. Moreover, the rise in serum levels of pancreatic polypeptide with sham feeding is also impaired in patients with advanced diabetes, indicating deficient parasympathetic innervation of the pancreas (21).

Of note, vagal or autonomic neuropathy does not uniformly affect innervation to all visceral organs. Similarly, there is no direct correlation between the presence of peripheral neuropathy and autonomic neuropathy. Autonomic neuropathy involving the heart is not predictive of GI dysmotility or of its extent (22).

SYMPATHETIC INNERVATION

The preganglionic neurons of sympathetic efferents are located in the spinal cord (T5 to L3), and the corresponding postganglionic neurons are located in the various sympathetic ganglia. The sympathetic efferent fibers entering the gut are postganglion adrenergic fibers that exert most of their actions indirectly via the enteric neurons. The sympathetic efferents exert inhibitory effects on the gut except in the sphincters, which are contracted by the sympathetic nerves.

In a pathologic study of autopsy findings in diabetic patients, Duchen et al. (18) found several abnormalities in the pattern of sympathetic innervation. In the intermediolateral columns of the spinal cord, where the sympathetic neurons arise, cell numbers appeared reduced at several thoracic levels. In addition, in the cervical and celiac sympathetic ganglia, neurons were distended or vacuolated with enlarged club-shaped neural processes. Chang et al. (23) demonstrated that rats with experimentally induced diabetes have a deficiency in adrenergic-mediated absorption of fluid and electrolyte in the ileum and colon, presumably secondary to deficient sympathetic innervation.

Sympathetic afferents carry visceral nociceptive information to the CNS. They also are involved in many sympathetic reflexes, including nausea and vomiting. It is possible that sympathetic afferent stimulation in neuropathy may be involved in the syndrome of abdominal pain, nausea, and vomiting, and the loss of afferent activity may lead to impaired perception of visceral pain.

ENTERIC NERVOUS SYSTEM

The enteric plexus, which consists of the myenteric and submucous plexuses, forms the ENS, which is the "local brain" of the gut. The ENS resembles the CNS in that it contains sensory, motor, and integrating-command interneurons and program generators. Moreover, ENS neurons, like CNS neurons, employ a large variety of neurotransmitters. These include acetylcholine, neuropeptides such as cholecystokinin (CCK), galanin, calcitonin gene-related peptide (CGRP), gastrin-releasing peptide (GRP), enkephalins, somatostatin, substance P, vasoactive intestinal polypeptide (VIP), purines such as adenosine triphosphate (ATP) and adenosine, and possibly amino acids such as γ -aminobutyric acid (GABA), and nitric oxide (NO). The major inhibitory neurotransmitters are VIP and NO, and the main excitatory neurotransmitters are acetylcholine and substance P.

Previous pathologic studies of diabetic patients in which conventional sections were used found the morphology of the myenteric plexus to be normal. More recent pathologic studies that used tangential sections demonstrated mild abnormalities in these patients. Smith (17) described the myenteric plexus of the esophagus as being mostly normal, with only a small number of neurons with swollen irregular processes. She also described the lymphocytic infiltration of a large number of nonneuronal cells in the plexus. Duchen et al. (18) confirmed this finding in sections from a wider distribution of the gut. Duchen also described infiltration of the ganglia with inflammatory cells, especially around unmyelinated axons. In contrast, Yoshida et al. (20), who prepared extensive sections from the stomachs of patients with diabetes, described the myenteric plexus as being completely normal with no evidence of morphologic change or inflammatory infiltrate.

Rats with streptozotocin-induced diabetes show distinctive and contrasting changes in the nerves in the ileum and proximal colon (24–26). In the ileum, immunohistochemical studies show degeneration of adrenergic and serotonin-containing nerves, intact cholinergic nerves, decreased stores of CGRP, increase in VIP and neuropeptide Y, and normal stores of substance P. In contrast, in the proximal colon, the local stores of all these neurotransmitters are either normal or increased. It is noteworthy that the diabetic rats had diarrhea (23). The diminished adrenergic innervation of the ileum might well have contributed to the diarrhea by impairing fluid and electrolyte absorption in this segment. Mouse models of diabetes also show structural changes in the interstitial cells of Cajal, which are thought to generate electrical pacemaker activity and mediate motor neurotransmission in the stomach. These cells were greatly reduced in the distal stomach, and the normally close associations between these cells and enteric nerve terminals were infrequent in nonobese diabetic (NOD) mice. These observations suggest that damage to interstitial cells of Cajal may play a key role in the pathogenesis of diabetic gastropathy (27).

Functional studies also suggest defects in cholinergic innervation in diabetic rats. Nowak et al. (28) measured the contraction of longitudinal and circular strips of intestine in response to electrical field stimulation in rats with streptozotocin-induced diabetes. Among the three groups of rats, significant differences were seen only in strips of longitudinal muscle from the ileum. The amplitude of contraction was highest in control rats, lowest in diabetic rats, and intermediate in insulin-treated diabetic rats. These changes were seen in the atropine-sensitive contractions, suggesting impaired cholinergic neuromuscular transmission in the distal small bowel in diabetic rats. The relaxatory neuropeptide VIP was found to be increased in immunohistochemical studies of a streptozotocin-treated rat model of diabetes, but electron microscopy revealed degeneration of nerve fibers containing this peptide (29,30). Tissue stores of VIP and its basal release were also decreased in the same diabetic rat model and were partly reversible with insulin therapy (31).

Studies have also shown that nitrergic inhibitory neurotransmission is impaired in diabetics. Decrease in neuronal nitric oxide synthase (nNOS), an enzymatic source of NO, was noted in a number of diabetic animal models, including spontaneously diabetic rats and genetic (nonobese diabetic) and toxin-elicited (streptozotocin) models of diabetes in mice (32-34). Watkins et al. (33) demonstrated defects in gastric emptying and nonadrenergic, noncholinergic relaxation of pyloric muscle that resembled defects in mice with a deletion of the nNOS gene. The diabetic mice manifested a pronounced reduction in pyloric nNOS protein and messenger RNA (mRNA). The decline of nNOS in diabetic mice did not result from loss of myenteric neurons. Expression of nNOS and pyloric function were restored to normal levels by insulin treatment. Thus, diabetic gastropathy in mice reflected an insulin-sensitive reversible loss of nNOS. In diabetic animals, delayed gastric emptying could be reversed with a phosphodiesterase inhibitor, sildenafil (33). However, it has also been demonstrated that sildenafil delays gastric emptying of liquids in rats (35). These findings have implications for novel therapeutic approaches and may clarify the etiology of diabetic gastropathy.

SOMATIC INNERVATION

Each end of the GI tube (pharynx, upper esophagus, and external anal sphincter) is composed of striated muscle fibers that are innervated by somatic nerves. Moreover, the parietal peritoneum and abdominal wall receive somatic sensory innervation. Both sensory and motor neuropathies are well-known complications of diabetes. They may cause, on one hand, abnormalities in pharyngeal swallowing and, on the other, external anal sphincter dysfunction during defecation. Sensory neuropathy and radiculopathy may also be responsible for unexplained abdominal pain in patients with diabetes.

The pathogenesis of diabetic neuropathies is not fully understood. Recent revelations of the pathogenesis of diabetic neuropathy may have great bearing on the future prevention of this complication. Biological changes leading to neuropathy that occur with hyperglycemia in patients with diabetes include increased production of advanced glycosylation end products, increased activity of the polyol pathway, disturbance in metabolism of myoinositol and its phospholipid derivatives, elevation of

endothelial angiotensin and abnormal permeability of the small blood vessels, impaired neurotrophic support, and impaired resistance to oxidative stress. Currently, treatment of diabetic neuropathy consists of achievement of better glycemic control and treatment of symptoms related to neuropathy. Specific treatments capable of preventing or curing neuropathy are being studied. With the introduction of potent aldose reductase inhibitors, the role of increased activity of the polyol pathway (and related abnormalities in myoinositol metabolism) in the pathogenesis of diabetes-associated complications may be clarified. Despite interesting results obtained with aldose reductase inhibitors in animal studies, initial results in patients with diabetes are less encouraging (36). Other metabolic approaches, such as antioxidants and y-linolenic acid supplementation, seem promising (37). Clearly, early detection of diabetic neuropathy is required, because at present a preventive approach is the most effective way to avoid or postpone debilitating complications. More research is needed to make effective curative treatments of diabetic neuropathy available.

Gut Smooth Muscle in Diabetes

In general, the intestinal smooth muscle in diabetes is normal and functionally intact. Although the primary disorder of gut motility appears to be one of hypomotility or even atony, experimental observations strongly argue that these changes are the result of deficient innervation. When cholinergic agonists are administered, contractions are of normal amplitude (38). In an extensive review of many sections obtained from all parts of the stomach, Yoshida et al. (20) demonstrated normal smooth muscle without evidence of degeneration or vacuolation. In contrast, Duchen et al. (18) and Guy et al. (19), in a small number of patients, described morphologic abnormality of intestinal smooth muscle. Both groups of investigators observed eosinophilic or hyaline-like bodies (rounded or club shaped) lying in or replacing smooth muscle cells. The extensive autopsy studies of Duchen et al. (18) described the presence of these smooth muscle bodies throughout the GI tract and, in addition, in the smooth muscle of the bladder. The significance of these hyaline bodies is unclear, but the preponderance of clinical data indicates that the intestinal smooth muscle is functionally healthy. Histologic changes in gastric smooth muscle were also reported in overt gastroparetic patients with longstanding type 1 diabetes, including smooth muscle degeneration and fibrosis, with eosinophilic inclusion bodies (Mbodies), which appear to be unique to this condition (39).

There are also electrophysiologic changes in the gut smooth muscle with diabetes. In rat models of type 2 diabetes, for example, the gastric fundus shows functional impairment of neuromuscular transmission, reduced maximum activity of the electrogenic pump, increased sensitivity of muscarinic receptors, reduced sensitivity of adrenoreceptors, and reduced myogenic activity in gastric smooth muscles. These alterations in the properties of smooth muscle may be involved in diabetes-induced gastroparesis (40). The colonic smooth muscle also shows changes, including a more depolarized membrane and a reduction in reactivity of adrenoreceptors to noradrenaline. However, there is also notable attenuation of nonadrenergic noncholinergic inhibitory transmission, suggesting that the constipation appearing with diabetes involves dysfunction of both the enteric autonomic nerves and the smooth muscles in the colon (41).

Microangiopathic Changes in Diabetes

Microangiopathic changes in the GI tract of patients with diabetes are frequently mentioned in the clinical literature. De Las Casas and Finley (42) reported pathologic studies documenting these changes in duodenal biopsies from a patient with longstanding type 1 diabetes and chronic diarrhea. They described striking histopathologic findings of diabetic microangiopathy, including prominent mural thickening and luminal narrowing of blood vessels within the duodenum secondary to accumulation of hyaline material, which was periodic acid–Schiff positive and intensely stained with monoclonal antibodies to type IV collagen. Potential mechanisms for diabetes-specific microvasculature disease, including decreased vasodilators such as NO, increased vasoconstrictors such as angiotensin II and endothelin-1, and increased permeability factors such as vascular endothelial growth factor have recently been reviewed (43).

ABDOMINAL PAIN IN DIABETES

Both acute and chronic abdominal pain can present rather uniquely in patients with diabetes. Syndromes of acute and chronic abdominal pain can masquerade as disorders of intraabdominal or pelvic pathology and must be recognized to permit the institution of appropriate therapy.

Acute Abdominal Pain

Acute abdominal pain, tenderness, and vomiting have long been recognized as frequent in patients presenting with diabetic ketoacidosis (44). Unexplained abdominal pain in the setting of diabetic metabolic decompensation tends to be generalized or epigastric in location. The mechanism of acute abdominal pain is not clear. Hyperamylasemia can occur but is not correlated with the presence of pancreatitis. It has been suggested that abdominal pain and vomiting might be due to the gastric dilatation and intestinal ileus that can occur secondary to the metabolic acidosis. Theoretically, the pain could be due to a stretching of the hepatic capsule in response to hepatic steatosis; abrupt hepatic distention, however, is unlikely to be due to steatosis. Finally, acute pain may simply be due to activation of nociceptors in response to metabolic derangements.

Campbell et al. (44) reviewed the clinical findings and outcome in 211 episodes of metabolic decompensation in 140 patients with diabetes over an 8-year period. Forty-four patients experienced severe abdominal pain and tenderness that necessitated diagnostic evaluation. In 17 patients, the abdominal pain could be attributed to an underlying disorder (e.g., pyelonephritis or appendicitis) considered to have precipitated the metabolic decompensation. In the other 29 patients, the abdominal pain remained unexplained and was attributed to the ongoing ketoacidosis. Patients with unexplained abdominal pain were younger than 40 years of age and, with only three exceptions, had a plasma bicarbonate level of less than 10 mEq/L. The authors suggested that acute abdominal pain in patients with diabetes older than 40 years of age or with plasma bicarbonate levels greater than 10 mEq/L should not be attributed to the metabolic decompensation and that a search should be undertaken for an underlying abdominal or pelvic disorder. In all patients, GI, renal, and pelvic diseases should be excluded, especially in those with fever, localized abdominal pain or tenderness, or abnormal laboratory findings. The acute abdominal pain associated with diabetic ketoacidosis resolves with correction of the metabolic abnormalities. It is important to recognize this entity to avoid unnecessary and harmful exploration laparotomy in these patients.

Chronic Abdominal Pain

Chronic abdominal pain can occur as a result of diabetic sensory neuropathy and can masquerade as serious intraabdominal

pathology, especially when it is associated with weight loss. Thoracic polyradiculopathy is an important cause of chronic pain in patients with diabetes. Longstreth (45) described the syndrome of chronic abdominal pain and weight loss caused by thoracic radiculopathy in 10 middle-aged or elderly patients with type 2 diabetes. Some of these patients initially underwent investigations focused on possible malignancy. Some had even undergone laparotomy in a search for possible carcinoma of the pancreas. In the affected patients, the pain tended to be asymmetric rather than bilateral and most often affected the left upper abdomen and often radiated into or from the lower thoracic spine. At times both the upper abdomen and the lower chest were involved in the pattern of symptoms. The pain was described as a pressure discomfort or sharp pain and at times had neuropathic qualities such as "burning" or "stabbing." The pain was often worse at night and aggravated by light pressure. The onset of the pain was gradual, being at first intermittent, later more frequent, and finally constant. It is especially noteworthy that the pain was not brought on or affected by either eating or defecation, a possible clue that the pain did not originate from the GI tract. Marked weight loss-up to 19 kg-occurred in some of the patients and presumably was caused by pain-induced anorexia. The diagnosis of thoracic radiculopathy secondary to diabetes was confirmed by electromyographic demonstration of either unilateral or bilateral denervation of the paraspinal muscles in the middle thoracic to upper lumbar region in seven of the patients. Nine patients recovered spontaneously, but two had recurrent polyradiculopathy. A combination of nonsteroidal antiinflammatory drugs and tricyclic antidepressants has been used in other syndromes of radiculopathy and/or peripheral neuropathy and is worth a trial in this syndrome.

PHARYNX AND ESOPHAGUS IN DIABETES

Pharyngeal and esophageal motor abnormalities are frequently found in persons with diabetes and are more prevalent in patients with peripheral or autonomic neuropathy. However, these motor abnormalities rarely produce significant symptoms. Thus, dysphagia and chest pain should be thoroughly evaluated and not ascribed to the diabetes. The incidence of reflux esophagitis and candida esophagitis may be increased in patients with diabetes.

Pharyngeal Motility

In barium studies, Borgstrom et al. (46) evaluated "swallowing complaints" in 18 patients with diabetes, 16 of whom had evidence of autonomic neuropathy. Videofluoroscopy of the pharynx demonstrated motor abnormalities in 14 patients. These included defective epiglottic mobility, defective closure of the laryngeal vestibule, and weakness of the pharyngeal musculature. When symptoms of pharyngeal dysphagia are present, swallowing therapy may be helpful in the management of these patients.

Esophageal Motility

Several prospective studies have demonstrated that abnormalities of esophageal motility and transit are quite common among diabetic patients with neuropathy but are usually asymptomatic. Horowitz et al. (47) performed scintigraphic studies of esophageal emptying of a solid bolus and found delayed emptying in 42% of patients with type 1 diabetes and in 30% of patients with type 2 diabetes who were receiving oral hypoglycemic agents. Other groups have reported similar results (48,49).

Manometric studies of esophageal motility are an even more sensitive measure of esophageal motor dysfunction. Hollis et al. (50) studied esophageal motility in patients with diabetes and found that 56% had abnormal esophageal motility. Abnormalities were more common in patients with diabetic neuropathy. Among those with evidence of peripheral sensory neuropathy but not of autonomic neuropathy, 80% had abnormalities in esophageal motility. All four patients in this study who had evidence of autonomic neuropathy showed abnormalities of esophageal motility. In patients with peripheral neuropathy alone, esophageal motility showed (a) contractions of low or normal amplitude, (b) some decrease in velocity of peristalsis, (c) an increased frequency of dropped swallows, and (d) a mild delay of transit. Nevertheless, in patients with peripheral neuropathy alone, the majority of swallows are associated with normal peristalsis. Diabetic patients with autonomic neuropathy have an increased frequency of multipeaked and simultaneous contractions. Huppe et al. (51) and Loo et al. (52) reported similar abnormalities. Correlating scintigraphic studies of esophageal transit to manometric studies, Keshavarzian et al. (53) found that multipeaked contractions usually are associated with normal esophageal transit but that simultaneous contractions are associated with delayed transit. Another group showed that, in type 1 diabetes, retarded esophageal transit usually reflects either peristaltic failure or focal low-amplitude pressure. In these studies, as in others, the overwhelming majority of patients were free of esophageal symptoms. Even patients with motility patterns compatible with diffuse esophageal spasm were usually asymptomatic. Chest pain was a rare symptom (54).

The mechanism of the esophageal motor abnormalities in diabetes remains unclear. Loo et al. (52) reported that the administration of atropine inhibited the development of the second esophageal peak. It has been suggested that the presumed loss of vagal innervation of the esophagus is the mechanism of abnormal peristalsis, although experimental demonstration of this theory has not been documented. In one study, disorder of motor nerve conduction velocity correlated with esophageal motility disorders, but no significant correlation could be found between esophageal dysfunction and diabetic autonomic neuropathy, as measured by coefficient of variation of cardiac R-R intervals (55).

Clouse et al. (56) suggested that the esophageal motor abnormalities observed in patients with diabetes were due to coincident psychiatric disease (depression and anxiety disorders) rather than to neuropathy. Psychiatric illness, as defined by testing, was present in 87% of those diabetic patients with motor abnormalities but in only 21% of those with normal motility. This association was independent of neuropathy. In this study, the vast majority of patients were without esophageal symptoms.

Reflux Esophagitis

In patients without esophageal symptoms, abnormal gastroesophageal reflux on ambulatory pH testing was significantly more prevalent in insulin-dependent diabetics (28% more) compared with healthy persons without diabetes. Moreover, reflux was associated with cardiovascular autonomic neuropathy (abnormal reflux = 38.7% in diabetic patients with cardiovascular autonomic neuropathy and 10.5% in diabetic patients without autonomic neuropathy) (57). In patients with symptomatic diabetic gastroparesis, the combination of gastric distention and increased gastric residual volume may make gastroesophageal reflux a more common occurrence. Jackson et al. (58) compared 24-hour esophageal pH, autonomic function testing, and electrogastrography (EGG) in two patient groups with symptoms of gastroesophageal reflux disease: one group with diabetes and one without diabetes. In this study, those with diabetes frequently had normal 24-hour pH but abnormal autonomic functioning. In contrast, those without diabetes had abnormal 24-hour pH but normal autonomic function. The two groups had identically abnormal mean EGG values. In patients with diabetes, the lower esophageal sphincter generally demonstrates normal pressures and relaxation (50). Therefore, it is unclear whether gastroesophageal reflux is more frequent in diabetic individuals than in normal controls, although the symptom of heartburn is less frequent in the patients with diabetes (7). The decreased symptoms of heartburn may be related to sensory impairment in these patients. The treatment of reflux esophagitis in patients with diabetes is no different from that in patients without diabetes (4).

Candida Esophagitis

An important esophageal complication of diabetes is candida esophagitis. Impaired immunity associated with diabetes is believed to increase susceptibility to this disorder. Moreover, stasis of esophageal contents associated with abnormal motor function could contribute to the susceptibility to candida infection. Extensive esophageal candidiasis may be asymptomatic or may be associated with symptoms of odynophagia (pain on swallowing) or dysphagia. Presence or absence of oral candidiasis has no reliable predictive value for esophageal candidiasis. The technique of barium swallow is relatively insensitive for detecting this disorder; with advanced esophageal candidiasis, a single- or double-contrast barium swallow may demonstrate extensive mucosal abnormalities suggestive of esophagitis. Fiberoptic esophagoscopy is much more sensitive and often demonstrates innumerable scattered white plaques over variable lengths of the esophagus. Esophageal brushings obtained through the endoscope can confirm the diagnosis.

Therapy for affected diabetic persons with otherwise intact immunity most commonly consists of nystatin suspension, 1 to 3 million units administered orally four times per day, or 10 mg of clotrimazole troches given orally five times per day, which are equally effective. More effective is fluconazole, 200 mg on day 1, followed by 100 mg once a day for a minimum of 3 weeks and at least 2 weeks after symptom resolution to prevent recurrence. If the patient is unresponsive, swish and swallow of itraconazole solution, 200 mg per day, for 2 weeks after symptom resolution, for a total of 3 weeks, is often prescribed. Ketoconazole may be somewhat less effective but is only one-third the cost of itraconazole. However, potential for hepatotoxicity has been recognized. The absorption of either itraconazole or ketoconazole is significantly decreased with antacids, and the two should not be administered concomitantly. Relapse is common and often occurs 2 to 4 months after clinical cure. Refractory esophageal candidiasis due to drug resistance may require systemic therapy with amphotericin B. Newer antifungal drugs being developed for fluconazole-resistant Candida include rilopirox (59) and voriconazole (60). Immunologic treatments being developed include vaccines and antibodies to Candida.

Dysphagia in Diabetes

Although minor pharyngeal and esophageal motor abnormalities are quite common in diabetes, they are usually asymptomatic (46). Because this is a disorder associated with few, if any, symptoms, specific therapy is generally not needed. In general, prokinetic agents (metoclopramide or domperidone), which have been shown to enhance esophageal contractions, have not been shown to improve esophageal transit in patients with delayed transit, as demonstrated by scintigraphic techniques. In one study, acute administration of oral cisapride improved esophageal transit in patients with baseline slowing of transit (61). Orally administered erythromycin has also been shown to improve esophageal transit after 2 weeks of therapy (62). After 1 year of treatment with tolrestat, an aldose-reductase inhibitor, patients with type 2 diabetes with asymptomatic diabetic neuropathy showed significant improvement in esophageal transit time on scintigraphy (63).

It is not known if the relative lack of esophageal symptoms in patients with diabetes is due to changes in sensory threshold caused by associated sensory neuropathy involving the esophagus. Feldman and Schiller (3) reported that 27% of unselected patients with diabetes complained of some dysphagia. In general, significant dysphagia in a patient with diabetes should not be explained by the diabetic pharyngeal or esophageal motility abnormalities, and a search for another associated cause of dysphagia should be undertaken.

STOMACH IN DIABETES

Gastric Motor Activity

The stomach normally performs four distinct functional motor activities. It (a) acts as a reservoir to accommodate the volume of solids and liquids of a meal; (b) pulverizes solids and mixes them with gastric acid to reduce the particle size for optimal digestion; (c) empties liquids and pulverized solids into the duodenum during the postprandial digestive period; and (d) empties the remaining food residues, including indigestible material, during the interdigestive period. These actions are achieved in different functional compartments of the stomach, i.e., the proximal stomach, the distal stomach, and the pyloric sphincter region (Fig. 64.2). In diabetes, all of these functions may be impaired (Table 64.1).

PROXIMAL STOMACH

The proximal stomach consists of the fundus and the orad third of the gastric body. The proximal stomach exhibits tonic contractions, producing prolonged elevations in pressure lasting 1 to 6 minutes. These contractions press gastric contents aborally toward the distal stomach and the duodenum and play an

important role in gastric emptying. They are stimulated by excitatory fibers in the vagus and by hormones such as motilin. Normally, the proximal stomach relaxes with each swallow ("receptive relaxation") and also as the volume of swallowed food builds up ("accommodation"). With receptive relaxation and accommodation, the stomach can hold increasing volumes without increasing gastric pressure, which enhances its function as a reservoir. Receptive relaxation is mediated by inhibitory fibers in the vagus nerve, whereas accommodation is mediated by inhibitory neurohormonal influences. The resting tone of the fundus in patients with diabetes is comparable to that in healthy subjects, but fundic contractions, as measured by a motility index, are reduced in patients with diabetes (64). The status of the receptive relaxation or accommodation in patients with diabetes is poorly characterized, but these inhibitory responses are thought to be impaired owing to the loss of inhibitory nerves in patients with diabetes.

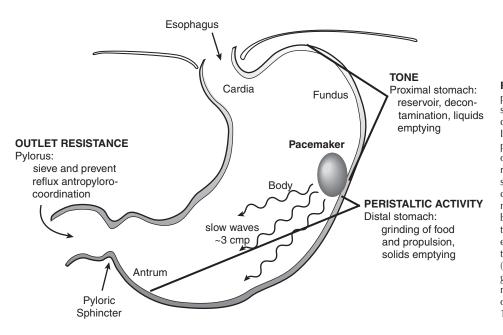

Figure 64.2. Functional integration of different parts of the stomach. The proximal stomach serves as a reservoir that actively accommodates increasing volumes of food during a meal. Its tone creates a pressure gradient to the pylorus, which largely influences the emptying of liquids from the stomach. The more distal regions of the gut actively grind the food into smaller sizes until it can pass through the sieve created by the pylorus. The timing and placement of the contraction waves are determined by "pacemaker" cells scattered in the body of the stomach, which create a rhythmic wave of electrical activity (slow waves) that marches distally to the pylorus at three cycles per minute. (Adapted from Koch KL. Diabetic gastropathy: gastric neuromuscular dysfunction in diabetes mellitus: a review of symptoms, pathophysiology, and treatment [Review]. Dig Dis Sci 1999;44:1061-1075.)

DISTAL STOMACH

In the distal two thirds of the stomach, contraction waves arise proximally and distally to the gastroduodenal junction, carrying part of the gastric contents ahead of the wave. In the interdigestive (fasting) period, four phases of variable motor activity occur in a cyclic fashion (65). During phase I, few, if any, contractions occur in the stomach. During phase II, intermittent random contractions are propagated distally over short distances. This is followed by phase III, which is a brief complex of rhythmic (three cycles per minute), strong propulsive contractions. Phase III originates in the proximal stomach and migrates through the distal stomach. This succession of cycles has been termed the interdigestive migrating motor complex (IMMC), and the period of an entire cycle is approximately 100 minutes. In the digestive (postmeal) period, the phase III activity, if present, is abolished and replaced by the phase II-like activity. The rate of contractions in the distal stomach always occurs at a predictable time that is a multiple of three or four, such that maximal rate of the phasic contractions in the distal stomach is never more than three or four per minute. This rhythm of the peristaltic contractions is paced by the underlying intrinsic electrical waves (called slow waves) that arise from pacemaker cells identified as the interstitial cells of Cajal. These slow waves occur at a rate of about three or four cycles per minute. These cycles originate in a region of the greater curvature of the gastric body (gastric pacemaker) and move distally toward the pylorus at an accelerating rate of 0.5 to 4 cm per second.

Gastric slow waves can be recorded by surface electrodes; this recording is called an electrogastrogram (EGG, Fig. 64.3). When the depolarizations become large, they are superimposed by action potentials, causing gastric contractions (Fig. 64.4). On the other hand, when the amplitude of slow-wave depolarizations decreases, no action potentials are triggered and no contractions occur. The slow-wave rhythm also influences the strength of their depolarizations. The decreased amplitude of depolarization results from abnormal rhythms (dysrhythmia) of gastric slow waves such as tachygastria (increased slowwave frequency), bradygastria (decreased slow-wave frequency), or gastric arrhythmia (irregular slow-wave frequencies) (Fig. 64.5) (66,67). Gastric slow-wave frequencies and amplitude of depolarizations (also described as power of the slow waves) can be monitored with cutaneous EGGs.

Some patients with diabetic gastroparesis have gastric dysrhythmia. In one study, nine of ten patients with diabetic gastroparesis had runs of tachygastria as compared with only one subject from a comparable control group (67). Similarly, in another study of six patients with diabetic gastroparesis, one had tachygastria, two had bradygastria, and the remaining three had flat-line patterns on cutaneous gastrograms (68). In yet another study, patients with diabetic gastroparesis had normal slow-wave cycles but lacked the normal postprandial increase in strength of the slow waves (9). Such electrogastrographic abnormalities could also be demonstrated in a high proportion of children with insulin-dependent diabetes, which correlated with both poor hyperglycemic control and delayed gastric emptying (69). Patients with diabetic gastroparesis may show decreased or normal cycle numbers, decreased or normal amplitudes, and peristaltic or nonperistaltic contractions in any permutation and combination (70,71). The motility index, which is the product of amplitude and number of contractions over time, does not take into account the peristaltic behavior of the contractions. Therefore, the clinical importance of changes in the motility index in diabetes is limited. Fischer et al. (9) observed that the normal postprandial increase in antral motility and myoelectrical activity was missing in patients with diabetes with symptomatic gastroparesis. Malagelada et al. (72) demonstrated that patients with diabetes with symptomatic gastroparesis had no antral IMMCs but had normal IMMCs in the duodenum. In patients with diabetes without symptoms of gastroparesis, IMMC activity was present in both the antrum and the duodenum, whereas symptomatic patients with diabetic gastroparesis had no IMMC activity in the antrum and, for some, in the duodenum (73). In contrast to the general pattern of decreased gastric motor activity, occasional patients with diabetes demonstrate fasting patterns of ectopic and aberrant antral motility. In some patients, episodes of sustained highfrequency activity (three cycles per minute) that is neither propagated nor associated with IMMC activity have been observed in the antrum. These motor abnormalities may also cause gastric stasis. This phenomenon has been related to intestinal motor aberrations created by sympathetic denervation (74).

In diabetes, changes in gastric slow waves and contractions may be due to several factors, including changes in innervation and metabolic abnormalities. Vagal innervation plays a very

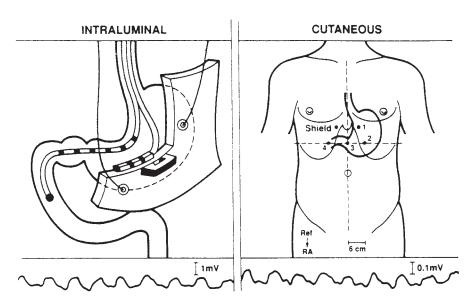

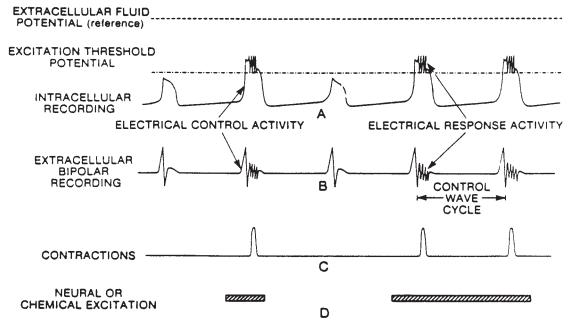

Figure 64.3. Recording of gastric electrical activity by electrographic techniques. Intraluminal electrogastrographic techniques use an internal electrode system that is apposed to the stomach wall by an external magnet placed on the abdominal wall. Cutaneous techniques involve placement of skin electrodes over the region of the stomach. Each technique records a sinusoidal waveform, but the intraluminal signal is ten times stronger than the cutaneous signal. (From Hasler W, Owyang C. Peptide-induced gastric arrhythmias: a new cause of gastroparesis. *Regul Pept Lett* 1990;2:6–12, with permission.)

JOSLIN'S DIABETES

Figure 64.4. Relationship between intracellular and extracellular electrical activities and contractile activity. Resting membrane potential in intracellular recordings is negative with respect to extracellular fluid potential. Intracellularly recorded monophasic depolarizations are recorded as biphasic or triphasic depolarizations by extracellular bipolar electrodes. In intracellular recordings, bursts of electrical response activity appear during depolarization of control potential. However, their temporal relationship to contractile activity is the same in both types of recordings. Membrane potential depolarizations that do not exceed the excitation threshold level are not superimposed with a bout of electrical response activity and are not accompanied by a contraction. Neurochemical stimulation (*rectangles*) increases the amplitude of electrical control activity oscillation and results in a burst of electrical response activity and a contraction during depolarization. An understanding of the electromechanical relationships of the gastrointestinal smooth muscle is necessary for evaluation of the importance of abnormalities in electromyographic studies of the gastrointestinal tract in diabetes mellitus. (From Sarna SK. In vivo myoelectric activity: methods, analysis and interpretation. In: *Handbook of physiology. The gastrointestinal system.* Vol 1. *Motility and circulation.* Bethesda: American Physiological Society, 1989:817–863, with permission.)

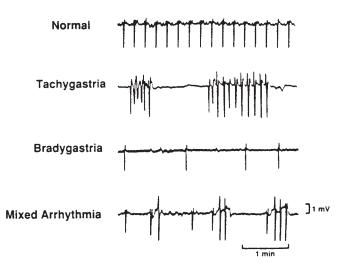

Figure. 64.5. Examples of normal and dysrhythmic slow wave recordings using serosally placed electrodes on canine stomach. Similar patterns of dysrhythmic slow waves are observed on external electrogastrographs in patients with diabetes (see text). (From Hasler W, Owyang C. Peptide-induced gastric arrhythmias: a new cause of gastroparesis. *Regul Pept Lett* 1990;2:6–12, with permission.)

important role in determining the rate, rhythm, and propagation of slow waves and, therefore, in the number, rate, and peristaltic behavior of contractions. Vagal innervation of the stomach is essential for interdigestive cyclic motor activity. With vagotomy, fasting motor activity in the stomach is abolished and the IMMC originates in the duodenum distal to the stomach (65). The cyclic release of motilin from endocrine cells in the duodenum and jejunum plays an important role in initiating IMMCs in the stomach. This cyclic motilin release is mediated by vagal cholinergic influences in the dog but perhaps not in humans. Fox and Behar (38) suggested that this decreased activity in the distal stomach is due to decreased cholinergic transmission; when such patients were treated with parenteral bethanechol, the amplitude and frequency of contractions increased to normal levels.

Acute changes in blood glucose concentration can have major effects on GI motor function. Barnett and Owyang (75) demonstrated that experimentally induced hyperglycemia in normal subjects reduced antral motor activity and abolished the gastric component of the IMMC. With increasing hyperglycemia, levels of serum motilin fell. Because motilin is postulated to be a physiologic regulator of gastric IMMC activity, the authors suggested that the hyperglycemic reduction in motor activity might be due in part to a hyperglycemic reduction in the levels of serum motilin. The investigators noted, however, that gastric IMMC activity was reduced at levels of blood glucose that had no effect on the serum motilin level. Hence they

suggested that hyperglycemia per se might also decrease antral motor activity independent of changes in serum motilin levels. Serum motilin levels were also elevated in patients with diabetes, suggesting therefore that the absence of gastric IMMC activity in these patients was not due to a deficiency of circulating serum motilin (75,76). The group also showed that hyperglycemia causes gastric slow-wave dysrhythmias that could be prevented by administration of indomethacin in healthy volunteers (77). Subsequently, others have shown that hyperglycemia attenuates the stimulation of antral pressures and propagates antral sequences by the motilin receptor agonist erythromycin (78) and attenuates the expected acceleration of both solid and liquid emptying with erythromycin treatment (79,80). Yet others have implicated the role of dopamine stimulation in hyperglycemic disturbance of gastric motility (81,82).

Regardless of the motility changes ascribed to hyperglycemia, the impact of chronically elevated blood glucose concentrations on the rate of gastric emptying remains unclear. An inverse relationship between rate of gastric emptying and blood glucose levels has been reported: Gastric emptying is slower during hyperglycemia and faster during hypoglycemia (83). However, there is also contrary evidence for delayed gastric emptying with hypoglycemia (84). Moreover, Holzapfel et al. (85) reported that there was no relation between emptying and fasting blood glucose concentration, its postprandial increase, or their reduction to euglycemic values in patients with type 2 diabetes. These data did not support a major role of hyperglycemia in gastric stasis.

Fischer et al. (9) proposed that higher-than-normal postprandial blood levels of glucagon may, at least in part, be responsible for disturbed gastric motility in patients with type 2 diabetes. Frank et al. (86) indeed found higher postprandial levels of glucagon and lower insulin concentrations in the nonneuropathic patients with type 2 diabetes in their study. Meanwhile, entry of ingested glucose into the blood and the levels of other various enteropeptides (CCK, glucose-dependent insulinotropic polypeptide, neurotensin, and peptide YY) were similar to that in subjects without diabetes, suggesting that the postprandial hyperglycemia was from hepatic release.

PYLORUS

The gastric pylorus is a narrow channel that can actively change the size of its opening under the influence of excitatory and inhibitory nerves. The pylorus is not a usual sphincter, because under basal conditions its resting pressure is not elevated (65). The opening size of the pylorus determines not only the rate of gastric emptying but also the size of the food particles that are permitted to leave the stomach. Soon after a meal, as the peristaltic waves in the stomach and antrum carry pieces of food toward it, the pylorus opens partially so that only liquids or small particles pass through, and solid chunks of food are trapped in the antrum to be ground by powerful antral contractions. If the pylorus does not open or relax, gastric emptying of liquids, as well as of ground and unground solids, is inhibited and gastric stasis occurs. It has been reported that luminal contents in the small bowel may inhibit gastric emptying by enhancing pyloric closure via neurohormonal reflexes (65). Wider opening of the pylorus is also essential for movement of large pieces of food during the IMMC.

Careful manometric studies have shown that patients with diabetes have increased fasting and postprandial pyloric motor activity. In addition, these patients demonstrate episodes of "pylorospasm" characterized by prolonged periods of increased tonic and phasic motor activity in this region (87). It has been suggested that pyloric motor activity and pylorospasm could act as a "brake" on gastric emptying and hence could contribute to the morbidity and disability of gastroparesis. The increased pyloric motor activity might be due to an increase in cholinergic or noncholinergic excitatory nerve activity or to a decrease in adrenergic or nonadrenergic (VIPergic and nitrergic) activity with resultant decreased pyloric inhibition.

DUODENUM

Normally, duodenal activity is coordinated with antral and pyloric activity. During the period of enhanced gastric emptying, the duodenal and pyloric activities are inhibited with each antral peristalsis. The inhibition is followed by contractions that form a peristaltic sequence with antral contractions. Such a duodenal inhibition can be called receptive relaxation of the duodenum and is due to inhibitory neural influences. Impairment of this duodenal relaxation results in antroduodenal incoordination, and this acts to inhibit gastric emptying. However, the importance of antroduodenal incoordination in diabetic gastroparesis is unclear. Duodenal mucosal afferent nerves also play an important role in reflex modulation of gastric emptying of liquids based on the composition of a liquid meal emptied from the stomach (65). Liquid meals of high caloric densities, high fat content, high osmolality, and acid pH stimulate duodenal receptors to inhibit gastric emptying. No information is available on duodenogastric reflexes in diabetic gastroparesis.

Gastric Emptying

The motor activities of various parts of the stomach are well designed to regulate the emptying of different physical constituents of food, so that the liquid and digestible solid components are emptied in the digestive period (within 2 to 3 hours after ingestion) and indigestible solids are emptied from the stomach during the interdigestive period (2 to 3 hours after a meal). In diabetic gastroparesis, gastric emptying of all these components is affected to varying degrees, depending upon the stage of the disease and the underlying pathophysiologic defects. Figure 64.6 shows patterns of gastric emptying of liquids and solids in one patient with diabetic gastroparesis and in a normal control.

EMPTYING OF LIQUIDS

Gastric emptying of liquids is normally influenced by the composition of the liquid meal, whose characteristics-e.g., acidity, caloric and nutritional content, and osmolality-elicit different responses from duodenal receptors and, in turn, from reflexes responsible for emptying (65). Hence, the liquid emptying varies in different studies because of the use of meals ranging from simple solutions (water, 10% dextrose, and orange juice) to complex nutritional solutions that truly justify the term "liquid meal." However, even with a standardized meal, gastric emptying of liquids in patients with diabetes is variable. Keshavarzian and Iber (88) demonstrated rapid emptying of liquids in patients with diabetes and suggested that it was due to diminished receptive relaxation in the diabetic stomach. In contrast, Loo et al. (89) and Wright et al. (90) demonstrated normal emptying of liquids in patients with diabetes. Others have demonstrated delayed emptying of liquids in patients with diabetes (91-93). The delayed emptying of liquids may be due to reduced fundic motor activity and antral motility. Another factor that could affect liquid gastric emptying is hyperglycemia. Induced hyperglycemia in normal subjects is associated with a slowing of the gastric emptying of liquid meals containing fat and protein; hyperglycemia may cause a reflex decrease in vagal excitatory tone of the stomach with a resulting delay in gastric emptying (94). There was no correlation between the degree of delay of emptying of liquids and the delay in emptying of solids (91).

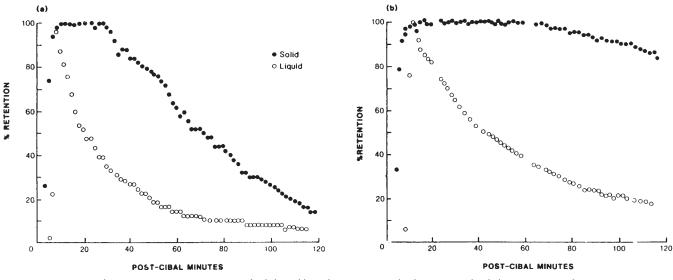

Figure. 64.6. Gastric emptying of solids and liquids in one control subject **(A)** and a diabetic patient with autonomic neuropathy **(B).** Note that emptying of solids is slower than that of liquids and both solid and liquid emptying are slower in the diabetic patient. (From Horowitz M, Harding PE, Chatterton BE, et al. Acute and chronic effects of domperidone on gastric emptying in diabetic autonomic neuropathy. *Dig Dis Sci* 1985;30:1–9, with permission.)

EMPTYING OF DIGESTIBLE SOLIDS

Normally, in the postprandial period, digestible solids are emptied more slowly than liquids because solids must be pulverized to a size (<2 mm) sufficient to pass through the sieve created by the contracted pyloric sphincter. In patients with diabetes, the gastric emptying of solids is frequently delayed. Horowitz et al. (47) studied gastric emptying among unselected patients with diabetes. Emptying of solids was delayed among 58% of patients with type 1 diabetes (61) and 30% of patients with type 2 diabetes.

EMPTYING OF INDIGESTIBLE SOLIDS

Indigestible solids, such as dietary fiber, normally do not empty during the postprandial period of motor activity because of the functional sieving produced by the pyloric sphincter (65). Such ingredients of food are emptied during the interdigestive period by phase III activity of the IMMC. Since gastric IMMC activity is impaired and often absent in symptomatic patients with diabetes, the emptying of indigestible solids from the stomach is delayed in these patients.

Feldman et al. (95) studied the emptying of indigestible solids in normal and diabetic subjects. Normal subjects emptied all of the ingested markers within 6 hours, a rate faster than that of the patients with diabetes (Fig. 64.7). A gastric-emptying study using a radiopaque marker identified patients with diabetes with symptoms of gastroparesis more accurately than did a scintigraphic technique using a meal of ⁹⁹Tc-labeled scrambled eggs. Similar radiopaque markers have been validated by other groups in the diagnosis of diabetic gastroparesis (96,97).

Radiopaque-marker gastric-emptying studies measure both lag time at which the interdigestive motor pattern reappears after a meal and the efficacy with which phase III motor activity empties the indigestible markers. Patients who lack IMMC activity in the stomach and have delayed gastric emptying of radiopaque markers are more likely to have abnormal gastric emptying of dietary fiber and would be more susceptible to the formation of gastric bezoars. If the pyloric sphincter fails to open widely because of either a motility abnormality or partial mechanical stenosis, gastric stasis of indigestible food would occur. However, a recent study cast doubt on the relationship of antral phase III activity in emptying indigestible markers as established from animal studies. Radiopaque markers (1.5-mm, 3-mm, and 7-mm cubes) were given with a test meal and followed by fluoroscopy with simultaneous antral manometry in normal subjects. None of the subjects had an antral phase III before all markers were emptied from the stomach. Instead, the typical irregular postprandial pressure activity was present in all subjects until the emptying was completed, and the highest postprandial motility index during the emptying study was comparable to the motility index during late phase II. Contrary to common opinion, the occurrence of gastric emptying of indigestible solids after a meal can be unrelated to the antral phase III, at least up to a particle size of 3 mm and perhaps even 7 mm (98).

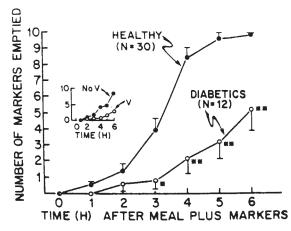

Figure 64.7. Emptying of solid radiopaque markers in 30 healthy subjects and 12 patients with diabetes. Emptying of solid radiopaque markers was significantly delayed in diabetic patients (p < 0.01 vs. controls at 3 hours; p < .001 at 4, 5, and 6 hours). The insert shows that emptying of solid markers was slower in seven patients with diabetes with vomiting (V) than in five patients with diabetes with no vomiting (no V) (p < 0.05 at 6 hours). (From Feldman M, Smith HJ, Simon TR. Gastric emptying of solid radiopaque markers: studies in healthy subjects and patients with diabetes. *Gastroenterology* 1984;87:895–902, with permission.)

Diabetic Gastropathy

Diabetic gastropathy is defined as a symptom complex with functional, contractile, electrical, and sensory dysfunction of the stomach associated with diabetes. In its classical form, called diabetic gastroparesis, it is associated with delayed gastric emptying. However, many patients with dyspeptic symptoms have normal or even enhanced gastric emptying. Thus even the definition of what constitutes a clinically relevant abnormality of gastric motility remains unclear.

DIABETIC GASTROPARESIS

Delayed emptying of solid or nutrient meals is found in up to 50% of patients with type 1 diabetes and in 30% of patients with type 2 diabetes (94). However, the degree of delay for various constituents of food, i.e., liquids, digestible solids, and indigestible solids, is not the same. Simultaneous assessment of gastric emptying of liquids and digestible solids using dual markers (⁹⁹Tc-labeled solid phase and ¹¹¹In-labeled liquid phase) showed that indigestible solids are particularly delayed in persons with diabetes (96,99). Figure. 64.6 shows patterns of gastric emptying of liquids and solids in one patient with diabetic gastroparesis and in a healthy control.

There is a wide range of symptoms in diabetic gastroparesis, and the degree of delayed gastric emptying correlates poorly with severity of symptoms. Many patients with abnormal gastric emptying have no specific symptoms and may be found to have a gastric bezoar or a largely dilated stomach with retained contents. Frequently, however, these patients have symptoms of anorexia, early satiety, and postprandial abdominal fullness and discomfort that resemble simple dyspepsia. Vomiting of old food, however, is indicative of gastroparesis. Nausea and vomiting are common when gastric distention is associated with obstruction and vigorous gastric contractions. In some patients, atonic dilation of the stomach, even when massive, may not be associated with nausea or vomiting. Nausea and reflex vomiting may be elicited by the stimulation of the gastric afferents carried via vagal and sympathetic nerves to the vomiting center in the brainstem. If gastric stasis and distention are primary causes of nausea and vomiting in diabetic gastroparesis, these symptoms should respond to gastric decompression by either vomiting or by insertion of a nasogastric tube.

Severe nausea and vomiting can limit oral nutrition and be a contributor to morbidity. Gastroparesis also may lead to poor glucose control because of both unpredictable oral intake and poor absorption of nutrients from delayed gastric emptying. When nausea and vomiting are prominent symptoms, some determination should be made regarding whether or not gastroparesis is the primary cause of these symptoms. Although some patients may develop vague upper abdominal discomfort from excessive gastric dilation, when patients complain of marked upper abdominal or midabdominal pain, a search should be made for other GI and abdominal diseases.

Kong et al. (100) studied the natural history of diabetic gastroparesis in a cohort of 86 outpatients with diabetes followed 9 to 14 years later. Of the 86 patients, solid gastric emptying was delayed in 56% and liquid emptying was delayed in 28%. At follow-up, the 21 patients who had died had a greater duration of diabetes and a higher score for autonomic neuropathy than did patients who were alive, but there were no differences in gastric emptying or esophageal transit between the two groups and no evidence that gastroparesis was associated with a poor prognosis overall. Autonomic neuropathy rather than myopathy has long been considered the cause of gastroparesis. However, autonomic dysfunction does not necessarily predict the presence of gastroparesis in patients with type 1 diabetes (101).

In some patients with diabetes, gastric emptying may fluctuate between normal and delayed. In some patients, nausea and vomiting are associated with episodes of pyloric spasm (87). These abnormalities may cause gastric stasis and the symptoms of nausea and vomiting intermittently. Such patients would be expected to respond to treatments that inhibit abnormal contractions, such as anticholinergic agents, rather than to prokinetic agents (Fig. 64.8). In still other patients with diabetes, nausea and vomiting may be due to an unknown cause unrelated to gastroparesis, and nausea and vomiting may cause, rather than result from, delayed gastric emptying. The vomiting reflex, regardless of activation by central or peripheral mechanisms, produces dysrhythmia of gastric slow waves and inhibition of antral contractions and characteristic retropropulsive motor activities in the small bowel. It is well known that stimulation of the vestibular system by circular vection involving rotation of a drum with alternating dark and light vertical stripes around a subject placed inside the drum leads to development of symptoms of motor sickness. Such a stimulation also causes tachygastria (68). Tachygastria is associated with weakened contractions and delayed gastric emptying (67). If delayed gastric emptying represents a GI motor response to nausea and vomiting, treatment should be directed toward searching for and treating the underlying cause of nausea and vomiting and primary use of antiemetics (Fig. 64.8).

DIABETIC GASTROPATHY WITHOUT DELAYED GASTRIC EMPTYING

Many patients with diabetes manifest symptoms of gastropathy without associated delayed gastric emptying. The symptoms of

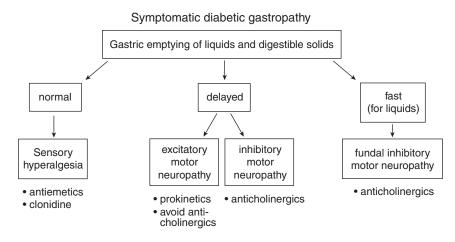

Figure. 64.8. Treatment rationale in symptomatic diabetic gastropathy.

this group of patients do not distinguish them from those with delayed gastric emptying. Some patients with diabetes, and particularly obese patients with type 2 diabetes, may complain of early satiety but have accelerated gastric emptying. These patients show no evidence of autonomic neuropathy (102). However, this symptom complex is thought to be due to loss of nitrergic innervation of the gastric fundus in patients with diabetes, which impairs receptive relaxation and accommodation reflexes. Nausea and vomiting are also common complaints in patients with diabetes, occurring in almost one third (72). Nausea and vomiting are common symptoms during acute ketoacidosis, and in most patients they subside with treatment of the acute metabolic abnormality. Sometimes they occur in a chronic pattern of daily symptoms that wax and wane in severity. In a minority of symptomatic patients with diabetes, the pattern is paroxysmal; such patients may have varying periods with minimal or no symptoms, only to be unexpectedly disabled by the sudden onset of severe nausea and vomiting, necessitating hospitalization for dehydration and ketoacidosis.

Even without ketoacidosis, patients with diabetes experience nausea and vomiting that correlate poorly with delayed gastric emptying (22). Several physiologic factors may play a role, including decreased compliance of the proximal stomach, which may account for an increased perception of gastric distention in patients with type 1 diabetes (103). Moreover, blood glucose concentrations appear to affect the perception of sensations arising from the GI tract; during hyperglycemia, gastric distention in healthy subjects produced more intense nausea and fullness (104,105). However, it is unclear whether physiologic changes in blood glucose levels directly alter sensation.

DIAGNOSIS OF DIABETIC GASTROPATHY

The presenting symptoms of diabetic gastropathy are nonspecific and also could be caused by mechanical obstruction of the gut, peptic ulcer disease, gastroesophageal reflux, chronic cholecystitis, pancreatitis, or metabolic conditions such as uremia, hypercalcemia, hypokalemia, hypocortisolemia, hypothyroidism, or pregnancy. Abdominal pain is generally not considered a significant feature of the clinical presentation of diabetic gastropathy. The relative lack of symptoms in patients with diabetes has been attributed, in part, to afferent neuropathy (106). However, one study showed that abdominal pain was a feature in almost 90% of patients with diabetic gastroparesis. The pain was described as burning, vague, or crampy. Only 36% localized to the upper abdomen. In all, 60% of patients complained of postprandial pain, whereas 80% complained of nocturnal pain that interfered with sleep. Generally, pain responded poorly or not at all to prokinetic agents (107). Nausea or vomiting in the morning, particularly with cranial neurologic symptoms, is an important indicator for considering central nervous system and metabolic disorders. A number of medications, including antidepressants with anticholinergic properties, can also slow gastric emptying. Eating disorders such as anorexia nervosa may be present, particularly in adolescents. Vomiting of old food suggests either gastroparesis or gastric outlet obstruction. An approach to the evaluation of patients with suspected diabetic gastropathy is detailed in Table 64.2.

Delayed gastric emptying is the hallmark test of diabetic gastroparesis. A number of different methods are used for measuring gastric emptying in humans. The method of choice depends on whether solid or liquid meals are to be studied, the level of precision required, the degree of invasiveness that the subject or patient will tolerate, ethical considerations, and the local facilities and expertise available. Simple studies such as a plain abdominal film and an upper GI series help identify patients with gastric bezoar and major problems of gastric stasis. Barium studies and

Besides appropriate blood examination and ruling out obstruction, further investigations are based on the clinical scenario.

esophagogastroduodenoscopy help exclude mechanical causes of gastric outlet obstruction. Gastric emptying of indigestible solids can be determined by studying the emptying of radiopaque markers from the stomach with serial abdominal radiographs (96).

There is no true "gold standard" in this field, but scintigraphy, with appropriate labeling of the test-meal components and appropriate corrections applied to the obtained images, is still the choice and most widely used diagnostic tool in the clinical setting. Emptying of both solid and liquid meals can be assessed simultaneously with the use of dual markers: a ⁹⁹Tc-labeled solid phase and an ¹¹¹In-labeled liquid phase (99). Most other techniques are compared with this method, but its application is limited by the need to restrict exposure to ionizing radiation. Clinically, a variety of different meals are used to measure gastric emptying of solids. Because both the physical state of the labeled meal and its nutritional composition determine the rate of emptying in control subjects, the degree of sensitivity of different test meals in detecting abnormalities in diabetes varies.

The most sensitive technique for the measurement of gastric emptying involves the use of chicken liver labeled with 99Tcsulfur colloid by either in vivo or in vitro methods (61). The labeled liver is then cooked and incorporated into a complex meal. This technique appears to yield the most stable bonding of the radionuclide to solids. In healthy subjects, the labeled meal is emptied in two phases, a lag phase, which appears to correlate with antral grinding of the meal, and a postlag phase of emptying, which represents the passage of the dispersed chyme from the stomach. However, the more involved process of preparing the meal and issues of palatability have perhaps hindered its wide acceptance. More commonly, a less sensitive technique is used that binds the 99Tc-sulfur colloid with cooked eggs, either scrambled or in an egg salad sandwich (70). This test meal usually empties in a single linear phase, because the binding of label to solid is not as stable, and some of the label begins emptying early with the liquid phase.

Gastric emptying is highly variable in patients with diabetes. Some patients with diabetes—particularly those with nausea and vomiting—have evidence of delayed gastric emptying, whereas other patients with diabetes may in fact exhibit accelerated gastric emptying. Presence or absence of symptoms of

upper GI dysfunction correlated poorly with objective measures of gastric emptying in subjects with type 1 diabetes. Nowak et al. (108) studied 21 patients with type 1 diabetes by solid-phase gastric-emptying scintiscan. Thirteen patients had symptoms of GI dysfunction (nausea, vomiting, early satiety, or constipation), and eight patients had no GI symptoms. Eleven patients had orthostatic hypotension. As a group, the patients with diabetes showed gastric emptying that was not significantly different from that of 12 healthy control subjects. Those patients with diabetes without GI symptoms and without orthostatic hypotension, however, showed a gastric emptying half-time that was significantly faster than that of the control subjects. Conversely, those patients with diabetes with nausea, vomiting, and early satiety (or early satiety alone) showed emptying times that were significantly greater than those of the patients with diabetes without these symptoms. No correlation was found between the gastric emptying and the duration of diabetes, the fasting blood glucose at the time of the study, or the respiratory variation in heart rate. These observations indicate that highly variable rates of gastric emptying occur in patients with type 1 diabetes and that accelerated gastric emptying may occur in patients with diabetes who have no symptoms of GI dysfunction.

Alternatives to scintigraphy are tracer methods that indirectly measure gastric emptying by assessing the time it takes for ingested marker substance to appear in either the blood or the breath, such as following the appearance in blood of paracetamol (109) or octanoin (110). These methods assume that there is no barrier either to the absorption of the tracer or to its metabolism and require normal intestinal absorption, liver metabolism, and lung function (for breath testing). Such techniques may be useful for screening in large populations, but they require sampling over several hours, are cumbersome, require complicated calculations, and possibly are too inaccurate for clinical use. However, a simplified nonradioactive assessment of solid gastric emptying has recently been proposed that uses a [¹³C]*Spirulina platensis* breath test that results in a half-life for solids comparable with those obtained by scintigraphy (110).

The double-sampling gastric aspiration technique is used mainly for physiologic investigations in the research laboratory. It allows serial measurements of the composition of the gastric contents and of the volume and composition of gastric secretions but can be used only with liquid meals. Other imaging tools such as ultrasonography and epigastric impedance measurements produce results that correlate well with those obtained by scintigraphy or aspiration. The main advantage of ultrasonography is that it is noninvasive and does not require radioactive isotopes. It can provide information on gastric emptying rate, on antral diameter, and in duplex mode, on motility and transpyloric flow, particularly of liquids. However, it is time consuming, less accurate in obese patients or for solid emptying, and requires a skilled operator. Moreover, the presence of large amounts of gas in the stomach may hinder the study (111). Epigastric impedance to electrical current increases after drinking liquid with low conductance, such as water. Subsequent decline in impedance reflects the duration of gastric emptying. Although electrical impedance measures are noninvasive, they cannot be used for solid or semisolid meals and are sensitive to body movements. Nevertheless, impedance has been applied to documenting improvement in gastric emptying with metoclopramide and may help in confirming or ruling out the presence of gastroparesis (112). Magnetic resonance imaging (MRI) allows the physician to follow the rate of gastric emptying while simultaneously observing any morphologic abnormalities that may contribute to abnormal gastric function. However, this assessment is time consuming and expensive and remains an investigative research tool (113).

Other noninvasive tools include breath hydrogen testing (114) and the potato-lactulose breath test (115), which have been reported to identify patients with diabetic gastroparesis. A metal-detector test has also identified transit disorders in different GI segments of patients with diabetes mellitus. (116).

Regardless of the method used, the clinician must be aware of the intersubject variability for each test in healthy individuals and of the factors known to influence the gastric pattern.

TREATMENT OF DIABETIC GASTROPATHY

Treatment of diabetic gastropathy entails improving gastric emptying, when abnormal, and improving symptoms. The principles of treatment are (a) acute management; (b) dietary adjustments; (c) use of gastric prokinetic agents that enhance gastric emptying; (d) treatment of associated conditions; and in severe cases, possibly (e) feeding jejunostomy or surgery.

Acute Management

In situations in which severe episodes of protracted vomiting are associated with dehydration and diabetic ketoacidosis, hospitalization is mandatory. In such cases, it is essential that the patient be fasted, and the passage of a nasogastric tube may be necessary. Intravenous fluid should be administered, and insulin should be given as indicated by the serum levels of glucose and ketones.

Dietary Adjustments

Dietary adjustments should be made in all patients with symptomatic gastroparesis. A standard American Diabetes Association diet may be poorly tolerated. The recommended diet should be low in fiber and fat and administered in frequent, small feedings (117). It may be necessary to obtain caloric counts to determine the adequacy of nutritional intake. If caloric intake is inadequate, the diet can be supplemented with high-calorie liquid supplements. Because liquids are emptied more easily from the gastroparetic stomach, these will be better tolerated. Some patients may even find it more practical to ingest the majority of their nutrition as liquid supplements. A three-step dietary program has been advocated (Table 64.3) (70).

Gastric Prokinetic Agents

Gastric prokinetic agents are a group of drugs characterized by their ability to enhance gastric emptying and reduce gastric stasis. The pharmacology of these drugs, including the mechanisms of receptor interaction and prokinetic action, is not yet

TABLE 64.3. Three-step Program in Treatment of Severe Gastroparesis

Step 1: Rehydration Day 1–2 Sip Gatorade or salty bouillon solution to ingest goal 1–1.5L over 24 hours, multiple vitamins Avoid citrus or highly sweetened drinks
Step 2: Advance diet to soups
Soups with noodles/rice and crackers, 6 small-volume meals per day, goal 1,500 cal/day and maintain/gain weight Avoid fatty foods
Step 3: Introduction of more solid foods
Starches (require less electrocontractile work), chicken, fish At least 6 small-volume meals/day Multivitamins
Avoid red meat, fresh vegetables, fiber
From Koch KL. Diabetic gastropathy: gastric neuromuscular dysfunction in diabetes mellitus: a review of symptoms, pathophysiology, and treatment [Review]. <i>Dig Dis Sci</i> 1999;44:1061–1075.

fully defined. A variety of pharmacologic agents may have gastric prokinetic effects. For patients with severe acute gastroparesis, the present treatment consists of mainly intravenous erythromycin and oral dopamine antagonists. Substituted benzamides remain the best option for chronic maintenance therapy. Currently under investigation are a number of serotonergic receptor agonists, macrolides devoid of antibiotic activity, and CCK antagonists.

Metoclopramide. Metoclopramide is lipid soluble and readily crosses the blood–brain barrier. It has powerful central antiemetic and peripheral gastric prokinetic actions.

Pharmacology. Metoclopramide is a dopamine D_2 -receptor antagonist, a 5-HT₃ (5-hydroxytryptamine-3) receptor antagonist, an acetylcholine releaser, and a cholinesterase inhibitor. It also has some local anesthetic and antiarrhythmic properties and has direct stimulating action on smooth muscle. Its prokinetic activities in the gut are thought to reflect a combination of an antagonism of the inhibitory effects of dopamine on gastric motility and an enhancement of cholinergic activity in the gastroduodenum that can be blocked by anticholinergic agents (118). When administered parenterally or orally, metoclopramide can increase the amplitude and frequency of fundic and antral contractions (72) and induce associated pyloric and duodenal coordination.

This drug may not initiate gastric IMMC activity. Achem-Karam et al. (73) observed that parenteral administration of metoclopramide initiated gastric IMMC activity in patients with diabetes if it was given more than 30 minutes after the previous cycle of IMMC activity. Malagelada et al. (72) could not induce such activity with metoclopramide in patients with diabetes. Chaussade et al. (119) also failed to initiate such activity with metoclopramide, although they administered metoclopramide less than 30 minutes after the previous cycle of IMMC activity. The IMMC-like activity produced by metoclopramide does not show the full distal migration characteristic of the normal IMMC.

In clinical studies, metoclopramide enhances the rate of gastric emptying of both solids and liquids (89) and reduces symptoms in patients with diabetes. However, there is poor correlation between the reduction of symptoms and enhancement of gastric emptying (70). Even some patients with complete relief of nausea and vomiting may not demonstrate improvement in gastric emptying. For example, Snape et al. (93) reported that with metoclopramide the rate of liquid emptying at 60 minutes in patients with diabetes increased from 32.8% to 56.8%; control subjects emptied 79.4% of the meal in this period. Seventy percent of the patients were symptomatically improved with metoclopramide treatment, and 50% experienced complete relief of symptoms with only minimal changes in the rate of emptying. Moreover, tolerance to stimulation of gastric emptying may develop after a month of therapy, whereas symptomatic relief persists with long-term therapy. This phenomenon may reflect the beneficial antiemetic effects of metoclopramide independent of its prokinetic activity (120).

Pharmacokinetics. The onset of action of metoclopramide is 1 to 30 minutes after intravenous injection, 10 to 15 minutes after intramuscular injection, and 30 to 60 minutes after oral or rectal intake. The duration of action is 1 to 2 hours (120). The bioavailability is not significantly altered in chronic versus acute therapy (121).

Dosage and Administration. Metoclopramide is available as 5and 10-mg tablets, as an injectable solution containing 5 mg/mL, and as rectal suppositories (121). The usual dose is 10 mg taken orally 15 to 30 minutes before meals and at bedtime. It is also available as syrup for use in children. Oral therapy may not be effective in acute stages of the disease. In such circumstances, it can be administered by slow intravenous injection, intramuscularly, subcutaneously, or rectally (122). Higher doses may be used if tolerated. Patients with renal failure require downward adjustment of the dose.

Side Effects and Drug Interactions. As a dopamine antagonist that is capable of crossing into the CNS, metoclopramide is associated with many CNS adverse effects, which are seen in up to 20% of subjects, thus limiting its use. These effects include drowsiness, restlessness, anxiety, and depression. Dystonic symptoms, including tardive dyskinesia, oculogyric crises, opisthotonos, trismus, and torticollis, may occur. Parkinson-like symptoms, including tremor, rigidity, and akinesia, may be produced. Metoclopramide therapy may increase the risk of seizures in patients with underlying seizure disorders. In addition, its antidopaminergic activity enhances the release of prolactin and, in female patients, can lead to breast enlargement, nipple tenderness, galactorrhea, and amenorrhea. It also raises levels of aldosterone and thyrotropin and reduces levels of luteinizing hormone, follicle-stimulating hormone, and growth hormone. This drug should not be used in patients with pheochromocytoma, parkinsonism, or seizure disorder. It should be used with care and in smaller doses in children and the elderly because of the greater incidence of side effects in these patients. Metoclopramide enhances the side effects of other D₂-receptor antagonists, such as the phenothiazines, and its prokinetic effects are annulled by the concomitant use of drugs with antimuscarinic properties. It enhances the effects of monoamine oxidase inhibitors.

Domperidone. Domperidone is a benzimidazole derivative (123). Its use remains investigational in the United States, but it is available for clinical practice in both Canada and Europe.

Pharmacology. Domperidone is a D₂-receptor antagonist, but unlike metoclopramide it may not release acetylcholine from cholinergic nerves. However, it is a cholinesterase inhibitor. It does not cross as readily as metoclopramide into the CNS and hence is associated with a lower incidence of neurologic side effects (124,125). Domperidone enhances the frequency and amplitude of antral and duodenal contractions, improves antroduodenal coordination, and enhances the rate of gastric emptying of both solids and liquids. In clinical studies of patients with diabetes with gastroparesis, treatment with domperidone was associated with an improvement in both the rate of gastric emptying and the severity of clinical symptoms. However, as with metoclopramide, there was no correlation between the degree of improvement in symptoms and the magnitude of enhancement of gastric emptying. Moreover, after 4 weeks of oral administration, domperidone had no significant effect on solid emptying, although improved liquid emptying and decrease in symptoms could still be observed (124). Koch et al. (68) studied the effect of domperidone treatment on symptoms of gastroparesis, the rate of gastric emptying of a radionuclide-labeled solid meal, and gastric electrical activity as assessed by EGG. After 6 months of treatment with domperidone, all six patients studied reported improvement in their symptoms. However, the mean rate of gastric emptying was not significantly improved, and two patients showed no change or even a decrease in the rate. It is interesting that all six patients demonstrated a normalization of the gastric electrical activity on EGG. In some trials, symptomatic improvement and toleration has been observed with domperidone for as long as 12 years (126).

Pharmacokinetics. Peak plasma concentrations of domperidone are reached within 10 to 30 minutes after oral or intramuscular administration and from 1 to 3 hours after insertion of a rectal suppository. The bioavailability of intramuscularly administered domperidone is 90%, in contrast to 15% for the orally administered drug (123).

Dosage and Administration. The recommended dose of domperidone is 20 to 40 mg taken orally 60 minutes before meals and at bedtime. The usual total dose is 40 to 120 mg per day. It is also available as suppositories. However, its intravenous use is not recommended in view of reports of associated cardiac arrhythmias.

Adverse Effects. Because domperidone does not cross the blood-brain barrier and enter the CNS as readily as metoclopramide, the incidence of neurologic side effects is much lower with domperidone than with metoclopramide (124). However, because both the chemoreceptor trigger zone and the site of prolactin release are located outside the blood-brain barrier, it acts as an antiemetic and causes hyperprolactinemia. In 10% to 15% of female patients, it causes breast enlargement, nipple tenderness, galactorrhea, and amenorrhea. Other side effects include dry mouth, skin rash, itching, headache, diarrhea, and nervousness, and neuroleptic malignant syndrome has also been reported in a diabetic patients with gastroparesis. Cardiac arrhythmias have been reported with intravenous administration. Domperidone is useful for the treatment of gastroparesis in patients with coincident Parkinson disease, as it does not exacerbate the extrapyramidal symptoms of Parkinson disease (127).

Other Dopaminergic Drugs. Levosulpiride, which is related to metoclopramide, has been demonstrated to have an accelerating effect on the emptying of solids from the stomach of patients with diabetic gastroparesis. The drug is also effective in relieving upper GI symptoms in patients whose gastric emptying times remain very slow (81). Alizapride, another D₂-receptor antagonist, has been helpful in relieving nausea and vomiting for a variety of causes, but its prokinetic effects in the upper GI tract are uncertain (128).

Cisapride. Cisapride is a benzamide derivative that is chemically distinct from domperidone and metoclopramide. The drug is no longer available in the United States except for investigational or compassionate use but is available for clinical therapy in both Canada and Europe.

Pharmacology. Cisapride has no antidopaminergic properties but enhances the release of acetylcholine in the intestinal myenteric plexus. It also has 5-HT3 receptor antagonistic and 5-HT4 agonistic properties. It enhances the amplitude of contractions throughout the gut, including the stomach and small and large bowels, and therefore its prokinetic effect extends through the entire gut. The increased gastroduodenal activity is associated with enhanced gastroduodenal coordination (129). Rapid MRI studies of patients with diabetic gastroparesis showed that antral contraction frequency, amplitude, and velocity were unchanged after cisapride administration, and cisaprideinduced acceleration of liquid gastric emptying in diabetic gastroparesis may be related to changes in proximal gastric tone or gastric outlet resistance (114). At therapeutic doses, cisapride has no effect on gastric acid secretion. In patients with diabetes, it improves the rate of gastric emptying of both digestible and indigestible solids and liquids (61,130,131). Generally, there is no correlation between the degree of cisapride-mediated improvement in clinical symptoms and the magnitude of enhancement of gastric emptying. In contrast to the time-dependent deterioration of the beneficial effect of metoclopramide and domperidone, chronic therapy with cisapride is associated with continued enhancement of gastric emptying (129). Horowitz and Roberts (132) studied the effects of acute and chronic treatment with cisapride on the rates of gastric emptying of both solids and liquids in patients with diabetes (61). With acute therapy, cisapride not only reduced clinical symptoms but also improved the rate of emptying of both solids and liquids. With chronic therapy with cisapride over 4 weeks, the pattern of symptomatic

improvement continued; moreover, the enhanced rate of gastric emptying persisted even after 14 months of use. Of interest is the inverse relationship of the magnitude of improvement of gastric emptying to the rate of emptying with placebo; i.e., the patients who showed the greatest degree of improvement with cisapride were those with the slowest rate of emptying at baseline.

Side Effects and Drug Interactions. Cisapride is associated with a low incidence of side effects. Because this drug lacks antidopaminergic properties, it does not have neurologic side effects. Infrequently reported side effects include headache, abdominal cramps, and diarrhea, reflecting effects on the distal bowel (120). Prokinetic effects on the gut are blocked by agents with antimuscarinic properties. Cisapride is associated in a dose-dependent manner with prolongation of QT interval (133) and cardiac arrhythmias. Patients with recurrent severe hypoglycemia or renal impairment may be at increased risk of cisapride-related cardiotoxicity.

Pharmacokinetics. The half-life of cisapride after intravenous administration is 19.4 hours. Bioavailability after oral administration is 35% to 40%. Plasma levels after ingestion of a 10-mg tablet peak at 1.5 to 2.0 hours (120).

Dosage and Administration. Cisapride is available in Europe and Canada as 10-mg tablets for oral use. It is not available as suppositories or for parenteral use. The recommended dosage is 10 to 20 mg three times a day taken 30 to 60 minutes before meals (120).

Motilin Agonists and Erythromycin (Motilides). Erythromycin is a macrolide antibiotic.

Pharmacology. Erythromycin is known to have many GI side effects. Itoh et al. (134) observed that in the dog stomach, erythromycin in doses 2,000 times smaller than the usual antibacterial doses induced typical phase II and phase III contractions that migrated to the duodenum and upper jejunum. The contractile pattern induced by erythromycin was similar to a spontaneous or motilin-induced migrating motor-activity front. Erythromycin also caused endogenous release of motilin in the dog; therefore, the authors suggested that the action of erythromycin in inducing IMMCs is mediated indirectly by release of motilin. Subsequent studies of isolated rabbit duodenum showed that erythromycin is a motilin agonist, interacting directly with motilin receptors (135). Moreover, Lin et al. (136) observed that when dogs were treated with intravenous erythromycin, there was an increase in inadequately triturated food particles (>0.5 mm) in the duodenum. Whether this abnormality in gastric emptying affects digestion and absorption remains unknown. Sato et al. (137) have identified erythromycin derivatives, EM523, EM536, and EM574, that have no antibiotic activity but are up to 3,000 times more potent than erythromycin in inducing IMMCs in the dog.

Erythromycin and various macrolide derivatives have been found to induce migrating motor complexes in humans (138). Otterson and Sarna (139) further found that erythromycin initiated IMMCs only when administered in very small doses (1 mg/kg intravenously) and not with larger doses. Larger doses (up to 25 mg/kg intravenously) initiated retrograde giant contractions and "vomiting complexes," periods of generalized inhibition of all activity, and giant peristaltic contractions. These higher doses also produced increased coordinated antroduodenal activity. Cineradiography confirmed this enhanced antrobulbar activity (140). Various other groups have shown improved gastric emptying in patients with diabetes treated with erythromycin (62,141-144). Petrakis et al. (79,80) and others (78) showed that intravenous erythromycin-induced acceleration of gastric emptying in patients with diabetes was related to the plasma glucose level. The induced hyperglycemia

reduced the erythromycin-induced acceleration of both solidand liquid-phase gastric emptying. In spite of the inhibitory effect of induced hyperglycemia on gastric emptying, erythromycin was still able to accelerate the emptying rate.

DiBaise et al. (145) studied the role of prolonged intravenous erythromycin in the ambulatory setting as a treatment for severe gastroparesis in 11 patients; one received no benefit, two had complete responses, and all others reported some benefit. Antibiotic resistance or secondary infections were not encountered. Intravenous motilin is also able to increase gastric emptying in patients with diabetes with gastroparesis (146).

To date, there are no controlled studies documenting a beneficial effect of intravenous or oral erythromycin therapy on symptoms of gastroparesis. Only a few anecdotal reports attest to possible beneficial activity. It is not clear if the lack of efficacy of oral therapy is related to the failure of absorption of erythromycin because of gastroparesis or to the occurrence of tachyphylaxis with chronic therapy.

Pharmacokinetics. After intravenous administration of erythromycin lactobionate, peak serum levels are reached 15 to 30 minutes after initiation of the infusion. The peak action following intravenous administration lasts for about 1 hour. Oral erythromycin succinate does not achieve as high a serum level as erythromycin stearate.

Dosage and Administration. Erythromycin is available for oral use as erythromycin stearate and erythromycin ethylsuccinate and for intravenous use as erythromycin lactobionate. The lactobionate is administered as an infusion over a 30-minute period as a dose of 200 mg diluted in normal saline. Lower doses (60 to 100 mg) may be effective. For oral use, erythromycin stearate is used at dosages of 250 mg administered three times a day 30 to 60 minutes before each meal.

Adverse Effects. Erythromycin administration has been associated with nausea, vomiting, and abdominal cramping in 80% to 95% of healthy subjects.

New Serotonergic Agonists. Tegaserod, a 5-HT₄ receptor partial agonist (Novartis) (147), and prucalopride, a 5-HT₄ receptor complete agonist (Janssen) (148), have been introduced for human use as potent promotility agents with significant pharmacologic effects on the mid and distal gut. Their potential use in delayed gastric emptying is being evaluated.

Cholecystokinin Receptor Agonists. The effect of recently developed CCK-A-specific receptor antagonists—namely, lox-iglumide and its dextroisomer—dexloxiglumide—on improving gastric emptying was studied in the rat (149). This has become available for human use and is currently under study (150).

TREATMENT OF BEZOARS

If gastric bezoar is present, it can be disrupted with a forceful pulsating jet of water during endoscopy (151). Alternatively, the patient is instructed to consume 1 to 2 L of clear liquids or a cellulase solution (0.5 g/dL of water) over a 24-hour period for 2 days or is administered an infusion of metoclopramide, 40 mg, over a 24-hour period for 3 days (152, 153).

FEEDING JEJUNOSTOMY

The endoscopic placement of both percutaneous gastrostomies and jejunostomies may be useful in some patients with diabetes with gastroparesis and malnutrition. These procedures are successful if the tubes are carefully placed and maintained. It should be recognized that feeding jejunostomies, whether surgically or endoscopically placed, are useful palliative measures that can greatly improve hydration and nutrition. These devices relieve the patient of the need to eat and drink and thereby reduce the clinical symptoms of gastroparesis (154).

SURGERY

In general, surgery is of no proven benefit in diabetic gastroparesis. The reported conservative gastric operations, such as loop gastroenterostomy and vagotomy and pyloroplasty, have been unsuccessful. Guy et al. (19), who reported on two patients with gastroparesis, stressed that these patients were the only patients with diabetes to have undergone elective surgery for gastroparesis in a 10-year period at their institution. In these two patients, clinical improvement, but not complete relief of symptoms, was observed only after extensive operations resulting in subtotal gastrectomy, truncal vagotomy, and Roux-en-Y gastrojejunostomy. Reardon et al. (155) reported their experience with surgery in a single patient This individual failed to respond to a pyloroplasty but did seem to benefit from the placement of both a surgical gastrostomy, which aided in decompressing the stomach, and a jejunostomy, which was successfully employed for enteral feedings. These experiences coincide with the observations of others who suggest that the surgical management of states of gastric retention (postsurgical, idiopathic, and diabetic) likely require a subtotal or near-total gastrectomy with Roux-en-Y gastrojejunostomy (39,156). In general, such surgery for diabetic gastroparesis should be avoided.

TREATMENT OF SYMPTOMS ASSOCIATED WITH DIABETIC GASTROPATHY

Most of the symptoms of diabetic gastropathy that do not resolve with the improvement of gastric emptying with prokinetic agents or those that occur without delayed gastric emptying require consideration of following approaches.

Antidepressants

Some patients with diabetic gastroparesis have associated depression. These patients need sympathetic support, psychotherapy, and, if appropriate, antidepressant therapy. Because of the negative effects of drugs with anticholinergic properties on both gastroparesis and the action of prokinetic agents, antidepressive agents should be carefully selected and should include agents with minimal anticholinergic properties, such as desipramine (Norpramin), trazodone (Desyrel), and serotonergic reuptake inhibitors such as fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), and citalopram (Celexa).

Anticholinergic Agents

Anticholinergic agents worsen delayed gastric emptying and are contraindicated in patients with overt gastroparesis. However, in certain patients having diabetic gastropathy without delayed gastric emptying with selective deficiency of the inhibitory innervation and unopposed excitatory cholinergic innervation, a therapeutic trial of short-acting anticholinergics may be indicated (Fig. 64.8).

Clonidine

Clonidine, an α_2 -adrenergic receptor agonist and antihypertensive agent, reduces perception of gastric distention in normal volunteers. No dose effect of clonidine was observed on gastric emptying. Clonidine relaxes the stomach and reduces gastric sensation without inhibiting accommodation or emptying (157). In a small uncontrolled study involving patients with diabetic gastroparesis, subjects showed improvement in both gastric emptying and symptom scores while taking clonidine, and this effect was maintained for 6 to 56 weeks of follow-up (158). These findings suggest that adrenergic influences play a role in the pathophysiology of diabetic gastroparesis and that clonidine may be a useful alternative for treating patients with this condition.

Behavioral Therapy

In an analysis by Soykan et al. (159) of patients with gastroparesis, 26% of whom had diabetes, the majority of diabetic patients responded well to pharmacologic agents; however, patients with predominant abdominal pain and also a history of physical and sexual abuse had poorer outcome with prokinetic agents. Such patients may benefit from behavioral therapy.

Accustimulation and Gastric Electrical Stimulation

Nondrug treatments of the nausea and vomiting related to gastroparesis have included accustimulation and direct gastric electrical stimulation. The accustimulation at P6 Neiguan point, a traditional Chinese acupuncture site, has been reported to reduce nausea in the first trimester of pregnancy, after surgery, and after chemotherapy (160). The mechanism of this action is unknown, and physiologic studies are necessary. A portable stimulation wristband has been introduced (ReliefBand, Woodside Biomedical, Carlsbad, CA), which is intended to stimulate this accustimulation site (161).

Direct electrical stimulation of the stomach using a surgically implantable stimulator (Enterra therapy, Medtronic, Minneapolis, MN) is being used experimentally, particularly in patients who are refractory to drug treatments and have lost weight despite nutritional support (162). Preliminary evidence supports the conclusion that the stimulators improve nausea, without consistent improvement in gastric emptying. In contrast to gastric electrical stimulation, gastric pacing of the human stomach has been evaluated only for short intervals, and no clear-cut therapeutic applications have been established (163).

HELICOBACTER PYLORI IN DIABETES

From the pediatric literature, there appears to be increased incidence of *Helicobacter pylori* in persons with diabetes compared with those without diabetes. In one study of 88 children with type 1 diabetes and 42 healthy control children, 55.6% of the children with diabetes and 30.9% of the control children were positive for anti-H. pylori immunoglobulin G (IgG). H. pylori status was not related to gastric emptying time (164). The literature about adults is conflicting. Some studies report a higher frequency of *H. pylori* infection in adult patients affected with type 2 diabetes than in subjects without diabetes (165) and a nearly twofold higher frequency of nonulcer, nongastritis dyspepsia in those with diabetes as compared with those without diabetes (166). Autonomic neuropathy was associated with increased occurrence and recurrence of H. pylori infection (167). In contrast, another study consisting of a validated questionnaire for GI symptoms and blood enzyme-linked immunosorbent assay (ELISA) for *H. pylori* showed that the seroprevalence of *H. pylori* was 33% and 32%, respectively, in patients with diabetes and in controls. Although patients with diabetes had a significantly higher prevalence of early satiety, fullness, and bloating than did controls, none of these symptoms correlated with presence or absence of H. pylori. Thus, H. pylori infection appeared not to be associated with diabetes or upper GI symptoms in diabetes (168). From a practical standpoint, patients with diabetic gastropathy should be evaluated and treated if *H. pylori* is present.

SMALL BOWEL IN DIABETES

Motor and Electrical Activity

Normally, the fasting pattern of small-bowel motility is characterized by the presence of the cyclic IMMC. In the small bowel, as in the stomach, the IMMC is characterized by periods of motor silence (phase I), random motor activity (phase II), and intense motor activity (phase III). In the small bowel, phase III activity consists of high-frequency (10 to 12 contractions per minute) complexes that are propagated distally through the entire small intestine. The highest frequency of contractions is determined by the rate of slow waves (pace-setter potential) in the small bowel. In healthy subjects approximately 80% of phase III activity originates in the stomach, whereas 10% to 20% originates in the duodenum. In each case the initiated complex then travels distally. After a meal, small-bowel motility consists of randomly occurring nonpropulsive or segmental contractions. Interspersed among the segmental contractions are some peristaltic contractions that propagate aborally for several centimeters and cause periodic slow shifts of intestinal contents distally. Another type of small-bowel contraction is called a "giant contraction," as it is 1.5 to 2 times the amplitude and 4 to 6 times the duration of a normal contraction of the small bowel. The giant contractions occur without regard to the intestinal slow waves. Normally, these giant contractions are present only in the distal small bowel. Abnormally, retrogradely propagated giant contractions occur during nausea and vomiting, and antegradely propagated giant contractions occur with a variety of pharmacologic manipulations that cause diarrhea (169)

Camilleri and Malagelada (74) analyzed GI motility by manometric studies in 14 patients with diabetes with gastroparesis but no diarrhea. All of the patients had long histories of type 1 diabetes. The following abnormalities of both fasting and fed motor activity in the small bowel were observed. (a) Migrating motor complexes were noted in the small bowel in most of the patients, although 60% of the observed phase III complexes did not have an antral component; among control subjects, only 8% of phase III complexes failed to originate in the antrum. (b) In 28% of the patients, the amplitude and frequency of duodenal and jejunal contractions were decreased. (c) In addition, 64% of the patients had striking periods of marked phasic pressure activity that were not propagated; these complexes consisted of both short bursts and long periods of high-frequency (10 to 12 contractions per minute) activity that were often isolated and not propagated distally as is characteristic of phase III activity. (d) After the test meal, 50% of the patients failed to develop the typical fed motor pattern; instead, the long and short bursts of high-frequency activity persisted. The appearance of abnormal complexes was thought to be due to sympathetic denervation that might result in the loss of an inhibitory "brake," thus allowing the appearance of ectopic and uncoordinated high-frequency motor activity. The small-bowel motor patterns observed in the patients with diabetes were similar to those observed in dogs following experimental ganglionectomy of the celiac and superior mesenteric plexuses (170).

Dooley et al. (171) studied fasting GI motility in 12 patients with diabetes who had unexplained diarrhea and evidence of autonomic neuropathy. In 16%, phase III activity was completely absent at all levels of the antrum, duodenum, and jejunum. In 81%, phase III activity had no antral component, whereas in 62.5% the proximal duodenum was not involved by the complex. In 12.5% of the patients, the observed phase III activity originated in the jejunum without antral or duodenal components. Furthermore, in three patients, phase III activity was abnormally propagated; in one, phase III activity appeared simultaneously in the small-bowel leads, and in the other two, the complex was conducted at an excessively rapid rate.

There is no adequate functional test of the small bowel that is analogous to solid-phase gastric emptying studies of the stomach. A diagnosis of intestinal dysmotility generally relies on symptoms, plain abdominal radiographs, barium studies, and intestinal manometry. Studies using hydrogen or hydrogen-lactulose breath tests to measure oral-cecal transit time cannot distinguish the contribution of delayed gastric emptying unless the latter is measured independently (98), and an early increase in exhaled hydrogen can result from bacterial overgrowth. A noninvasive metal-detector test to study intestinal transit has been described (118). As in gastric dysmotility, mechanical obstruction must be ruled out in the evaluation of patients with symptoms of intestinal dysmotility.

Small-Bowel Transit and Bacterial Overgrowth

Bacterial overgrowth in the small intestine and autonomic neuropathy seem to play a major role in the genesis of chronic diarrhea in patients with diabetes. Dooley et al. (171), using the lactulose-hydrogen breath test, studied oral-cecal transit times. Transit was prolonged in patients with diabetes (173 \pm 20 minutes) compared with the time in control subjects (93 \pm 10 minutes), but it is unclear how much of the prolonged transit reflected delayed gastric emptying as opposed to delayed smallbowel transit. In patients with diabetes with delayed transit, there was no correlation between abnormal motility and individual transit times. Twenty-five percent of the patients with diabetes who had diarrhea had evidence of bacterial overgrowth of the small bowel and improved clinically with antibiotic therapy. Two of the three patients who had bacterial overgrowth did have phase III activity. However, conduction of the complexes through the entire jejunum and ileum was not studied.

Wegener et al. (172) incorporated lactulose into a radionuclide-labeled meal so that they could measure gastric emptying and small-bowel transit simultaneously. Of the 43 patients with type 1 diabetes who had been hospitalized for various diabetic complications, 60% had clinical evidence of autonomic neuropathy, 30% had vomiting, and 14% complained of diarrhea. The oral-cecal transit times of the patients with diabetes were not significantly different from those of a large number of control subjects. However, more patients with diabetes than control subjects had delayed small-bowel transit (23% vs. 3.6%), and even when patients with delayed gastric emptying were excluded, this trend among patients with diabetes persisted. Although all six patients with diarrhea had delayed gastric emptying and evidence of autonomic neuropathy, there was no consistent pattern of rapid or delayed transit in these patients. Keshavarzian and Iber (88) examined oral-cecal transit by the hydrogen breath-test technique in patients with diabetes with and without peripheral neuropathy and autonomic neuropathy. Of the 25 patients studied, 12% had diarrhea and 16% had nausea without vomiting. In both the diabetic and control subjects, the transit of a liquid meal to the cecum was more rapid than that of a solid meal. There was no significant difference between the transit times in controls and patients with diabetes for either meal. No significant differences in transit times were seen in patients with diabetes with and without autonomic neuropathy and peripheral neuropathy. Sixteen percent of patients demonstrated rapid transit and 16% demonstrated slow transit, and there was no striking correlation between the clinical complaint of diarrhea and abnormal transit.

Virally-Monod et al. (173) demonstrated the high prevalence of small intestinal bacterial overgrowth by glucose-hydrogen breath testing and the success of antibiotic treatment in a population of patients with diabetes with chronic diarrhea. In the 35 patients with diabetes studied, 15 (43%) had small-intestinal bacterial overgrowth syndrome and 20 had no bacterial overgrowth. Age, duration of diabetes, level of glycosylated hemoglobin A_{1c} , and presence of autonomic neuropathy did not differ between the patients with and without bacterial overgrowth. However, those identified with bacterial overgrowth had longer duration of diarrhea, higher number of stools, and more frequent GI symptoms. There was dramatic clinical improvement in most patients with bacterial overgrowth treated with antibiotics.

Gluten-sensitive Enteropathy

Diabetes per se has no demonstrable effect on mucosal morphology or absorption in the small bowel. However, glutensensitive enteropathy (GSE) can coexist with diabetes and may be a cause of or contributor to diarrhea in such patients. Shanahan et al. (174) undertook HLA subtyping in patients with type 1 diabetes, GSE, and both disorders. HLA haplotypes B8 and DR3 were more prevalent in patients with GSE alone and in patients with both diabetes and GSE. Therefore, some patients are at increased risk for developing both type 1 diabetes and GSE as a result of autoimmune features associated with their HLA status. In this study of 24 patients with both disorders, the diagnosis of GSE was made after the onset of clinical diabetes in more than one half of the patients.

A Swedish study tested children and adolescents with a new diagnosis of type 1 diabetes for prevalence of IgA-antiendomysial and IgA-antigliadin autoantibodies. They found that in this population, prevalence of GSE at diagnosis of type 1 diabetes was 6% to 8% and suggest that screening for celiac disease is justified among patients with newly diagnosed type 1 diabetes (175).

Various serologic markers can be used to screen for GSE. Immunoglobulin A antiendomysial antibody (IgA-EMA) has been shown in North American children with type 1 diabetes to have a sensitivity of 94% and specificity of 91% for IgA-sufficient patients (176). The recent discovery that the autoantigen responsible for the endomysial pattern is tissue transglutaminase has led to the development of automated enzyme immunoassays for autoantibody quantitation. These commercial tests for tissue transglutaminases are simpler to perform and also comparably sensitive. In either test, positive results should be confirmed by intestinal biopsy, and false-positive results require serial follow-up. Symptomatic children require biopsy regardless of their serology.

Intestinal Fluid Secretion

In streptozotocin-treated diabetic rats, net secretion of fluid and electrolytes by the intestine is increased. This increase is thought to be due to sympathetic denervation (23). Sympathetic nerves release norepinephrine, which acts on α_2 -adrenergic receptors present on the enterocytes. The villous enterocyte responds to stimulation of the α_2 -adrenergic receptor by stimulating intracellular calcium-mediated electroneutral NaCl absorption, and the crypt enterocyte responds to stimulation of the α_2 -adrenergic receptor by stimulating intracellular calcium-mediated chloride secretion. However, the adrenergic influences cause net fluid absorption. In the absence of adrenergic influence, a net secretion of fluid and electrolytes occurs in the small bowel, particularly in the postprandial state. In some patients with diabetic diarrhea, this secretory defect may be corrected by an agonist receptor α_2 -adrenergic such as clonidine (177).

Treatment of Intestinal Dysmotility

Treatment of intestinal dysmotility includes a low-fat diet, antibiotics, and prokinetic agents. Although clinical trials have not been done, it is common practice to use a different antibiotic for 7 to 10 days each month to avoid drug resistance. Typically, doxycycline, 100 mg twice a day, metronidazole, 500 mg three

times a day, ciprofloxacin, 500 mg twice a day, or doublestrength trimethoprim-sulfamethoxazole twice a day is used. In general, prokinetic agents such as cisapride and erythromycin are less effective in treating intestinal dysmotility than gastroparesis (178). In refractory or intermittent but severe intestinal dysmotility, a venting jejunostomy is helpful. However, attempts should first be made to use the small bowel for nutrition. Trial infusions of liquid formulas, including elemental preparations, are warranted. Octreotide was initially shown to inhibit intestinal secretion and induce small-bowel activity similar to the interdigestive motor complex. Patients given the drug for up to 15 days seemed to improve (179). However, further studies suggest that the induced contractile activity is not well coordinated and is often simultaneous or very rapidly propagating. In healthy individuals, low doses (50 µg three times a day) inhibit small-bowel transit and ileocolonic bolus transfers, suggesting that octreotide may be helpful in treating diarrheal states but not conditions that cause small-bowel stasis and bacterial overgrowth (180). The role of octreotide in treatment of diabetic intestinal dysmotility needs further studies. Total parenteral nutrition may be required with bowel failure. Intestinal transplantation and pacing are still experimental.

COLON IN DIABETES

Colonic involvement in diabetes usually causes constipation but may sometimes also cause diarrhea.

Colonic Motility

Normal colonic motor activity consists of short-duration contractions (<10 seconds), long-duration contractions (>1 minute), and peristaltic contractions (duration >1 minute and amplitude two to three times larger than other colonic contractions). The short-duration contractions occur as a result of spikes associated with colonic slow waves. They occur irregularly at a frequency of 3 to 12 per minute, corresponding to the frequency of colonic slow waves. Long-duration contractions and giant contractions occur without regard to slow waves or spikes. The short- and the long-duration contractions occur singly or in trains and may be propagated or nonpropagated (segmental). The propagated wave may be propagated antegrade (peristaltic) or retrograde (retroperistaltic). Segmental and retropulsive contractions form the main activity of the right colon. An increase in segmental contractions in the left side of the colon is associated with constipation, and a decrease is associated with diarrhea. Peristaltic short-and long-duration contractions are responsible for slow caudal shifts of colonic contents. Giant peristaltic contractions propagate at velocities of 2 to 3 cm per second and are responsible for rapid shifts of large volumes of colonic contents. These movements are called "mass movements." Giant peristaltic contractions occur that sweep over the entire colon during defecation, but they also occur without associated defecation when they travel over a small segment of the colon. Mass movements are induced in the left side of the colon as a reflex response to stimulation such as eating (gastrocolonic reflex). These reflexes, mediated by neurohormonal influences and parasympathetic nerves, play an important role in giant peristaltic contractions and associated mass movements (181).

Information available on colonic electrical activity and motility in diabetics is limited. Battle et al. (182) studied colonic myoelectric and motor activity in the sigmoid colon in 12 patients with type 1 diabetes; although 11 of the patients had clinical evidence of autonomic neuropathy, 6 had no or mild constipation

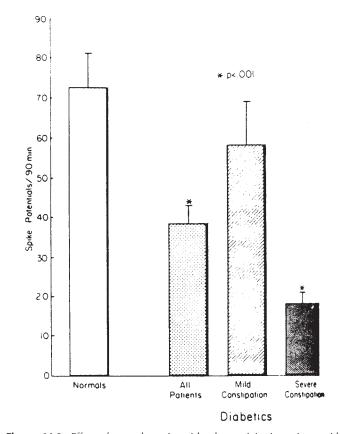

Figure. 64.9. Effect of a meal on sigmoid colon activity in patients with diabetes. Note that the cumulative spike potential response after ingestion of a 1,000-calorie meal is decreased in patients with diabetes mellitus. This decrease is most marked in patients who have severe constipation. Asterisk indicates significant (p < 0.001) decrease in response in various patient groups as compared with healthy controls. (From Battle WM, Snape WI Jr, Alavi A, et al. Colonic dysfunction in diabetes mellitus. *Gastroenterology* 1980;79:1217–1221, with permission.)

and 6 patients had severe constipation as defined by a stool frequency of two or fewer stools per week. After subjects consumed a standardized meal, both the myoelectric spike activity and the motor response were greater in the control than in the diabetic subjects (Fig. 64.9). Those patients with severe constipation had no postprandial response, whereas the six patients with mild constipation had a distinct but reduced postprandial response. In these latter patients with diabetes, the myoelectric response was delayed until 60 to 90 minutes after the meal, in contrast to the physiologic response, which occurred during the first 30 minutes after the meal. Wegener et al. (172) report delayed whole-gut transit in 26% of diabetics; they used a carmine red method, but this assay cannot distinguish the contributions of different segments of the gut. Metal detectors have also been used to assess colonic transit, showing normal or prolonged transit, which did not necessarily correlate to complaint of constipation, in both in type 1 and type 2 diabetic patients compared with controls (116).

Constipation and Colonic Dilation

Constipation is a symptom, rather than a disease, and is characterized by decreased frequency of defecation, increased stool hardness, and/or difficulty passing fecal matter. Constipation is common in the diabetic population (183) and is considered to be a complication of autonomic dysfunction of the gut. A sweat test devised to detect autonomic neuropathy in patients with diabetes has been shown to correlate with the presence of chronic constipation (184). Overall, persons with diabetes had slower colonic transit than did those without diabetes, and those with diabetes who experience constipation or use laxatives have a greater prevalence of delayed colonic transit or evacuatory dysfunction than do community controls (185).

The treatment of constipation in patients with diabetes is similar to that for the general population. In clinical practice, constipation in a diabetic patient is treated conservatively with the usual methods using bulking agents (such as psyllium) and stool softeners. If these agents fail, laxatives used prudently can be quite helpful (182).

There are anecdotal reports of roles for additional agents in patients with diabetes who do not respond to conventional treatments. Intramuscular administration of the cholinesterase inhibitor neostigmine has been shown to stimulate colonic myoelectric activity to a normal level in patients with diabetes. Whereas the administration of neostigmine and metoclopramide is associated with increased colonic motor activity, neither agent has been shown to consistently improve the clinical pattern of constipation, probably because they increase the frequency of segmental contractions but do not promote overall colonic transit. Some patients with diabetes with both gastroparesis and constipation may experience an improvement in constipation during treatment with metoclopramide. Whether this beneficial effect reflects a direct action of metoclopramide on the colon or an indirect effect by increasing oral intake and promoting colonic bulk remains unclear (182). Cisapride was shown to have prokinetic properties in some, but not all, patients with idiopathic or diabetic constipation (186) but currently is limited to investigational and compassionate use. Tegaserod, a 5-HT₄ receptor agonist, increases colonic transit in animals and healthy subjects and is being introduced for the treatment of constipation-predominant irritable bowel syndrome (187). It may soon find a place as a prokinetic agent in the future treatment of constipation associated with diabetes. Domperidone and alizapride are D₂-receptor antagonists, which antagonize the constipatory effects of opiates in rats (128). Promotility effects on human colon have yet to be established. There are also anecdotal reports of improved chronic constipation in patients with diabetes taking the aldose reductase inhibitor epalrestat (188). This and other members of its class hold promise in reversing some of the complications of autonomic neuropathy.

Infrequently, colonic dysfunction in patients with diabetes may lead to more severe colonic disorders. Berenyi and Schwarz (189) described 13 patients with autonomic dysfunction and marked sigmoid dilation. Surprisingly, the majority of these patients experienced diarrhea. Diabetes was present in 9 of the 13 patients and was thought to be the underlying cause of the observed autonomic dysfunction.

Diabetes and Colon Cancer

A number of studies have suggested a potential modest increase in colorectal cancer risk in patients with type 2 diabetes (190–193), even though these patients may be less likely to be screened for colorectal cancer (194). Among proposed biological mechanisms to account for this epidemiologic correlation are the observations that higher levels of insulin in patient with type 2 diabetes, analogous to insulin-like growth factor (as in acromegaly) (195), may influence cell proliferation and apoptosis (196) and thus play a role in carcinogenesis (197). Delayed stool transit and elevated fecal bile acid concentrations, associated with hyperglycemia and diabetic neuropathy, have also been suggested as factors contributing to the development of colon cancer. Earlier studies of the contribution of diabetes to colorectal cancer incidence and mortality are compromised by small sample sizes and failure to adjust for covariates. The 1959 to 1972 Cancer Prevention Study, with more than 1 million respondents, showed that persons with diabetes were indeed more likely to develop colorectal cancer during the 13-year follow-up period than were persons without diabetes. After adjustment for colorectal cancer risk factors, such as race, educational level, body mass index, smoking, alcohol use, dietary intake, aspirin use, physical activity, and family history of colorectal cancer, the incidence density ratio comparing colorectal cancer in those with diabetes was 1.30 (95% confidence interval, 1.03 to 1.65) for men and 1.16 (95% confidence interval, 0.87 to 1.53) for women. However, diabetes was not associated with a greater case-fatality rate (198).

DIABETIC DIARRHEA

Clinical Features

By definition, "diabetic diarrhea" is a clinical syndrome that occurs in patients with diabetes without an identifiable underlying GI disorder and is therefore a diagnosis of exclusion (199). The clinical characteristics vary in different patients, presumably because the underlying pathogenetic mechanisms are numerous and heterogeneous. Hence not all patients respond to a common treatment. Most patients with this disorder have longstanding diabetes with its associated complications (200). Almost all have evidence of both peripheral and autonomic neuropathy, and autonomic neuropathy is thought to be an underlying mechanism. Examination of the rectal mucosa from symptomatic patients showed a significant decrease in substance P, but not in VIP or somatostatin, compared with that in diabetic patients with normal bowel habits or in nondiabetic controls (201). In the majority of affected patients, the pattern of diarrhea is intermittent, lasting weeks to months, with intervening periods of either normal stool frequency or constipation. Although early reports emphasized a predominantly nocturnal pattern of diarrhea, later series described a variable pattern, with the majority of patients experiencing a persistent or predominantly daytime pattern commonly associated with fecal incontinence (200). In diabetic diarrhea, stool weight can vary from 200 to 1,600 g per day. Coincident steatorrhea can occur in 40% to 50% of patients, is usually mild, and generally does not cause progressive weight loss. In a diabetic patient, the documentation of steatorrhea does not exclude the diagnosis of diabetic diarrhea but should prompt a careful exclusion of underlying jejunal and pancreatic disease (202).

Pathogenesis

Proposed mechanisms of diabetic diarrhea include pancreatic exocrine insufficiency, altered intestinal motility, bacterial overgrowth, altered composition of the bile-salt pool and bile-salt excretion, and increased intestinal secretion as a result of autonomic neuropathy. A review of medical records of patients with diabetes and diarrhea seen at a tertiary referral practice revealed that diarrhea was often due to celiac sprue, bacterial overgrowth in the small bowel, or fecal incontinence in conjunction with anorectal dysfunction. However, these causes could be excluded in about half of the patients, and abnormal intestinal motility or secretion was deemed to be the likely cause of diarrhea in these patients (203). Oral hypoglycemic agents have been associated with chronic diarrhea, and one report suggested that metformin but not sulfonylurea was independently associated with chronic diarrhea and with fecal incontinence (204).

ROLE OF EXOCRINE PANCREATIC INSUFFICIENCY

Given the high incidence of impaired pancreatic exocrine function in patients with type 1 diabetes, exocrine insufficiency in steatorrhea would seem to be a possible mechanism of diabetic diarrhea. Because of the high capacity for enzyme secretion of the exocrine pancreas, however, the observed 50% to 60% reduction in bicarbonate and enzyme secretion does not impair luminal digestion and hence does not result in steatorrhea (205). In patients with diabetic diarrhea, duodenal intubation studies have demonstrated little or no reduction in exocrine function (200). Furthermore, empiric trials of pancreatic enzyme supplements have routinely been ineffective in reducing the volume of diarrhea in these patients.

ROLE OF ABNORMAL SMALL-BOWEL MOTILITY AND BACTERIAL OVERGROWTH

Abnormal small-bowel motility in diabetes may be associated with bowel stasis and bacterial overgrowth (173). Clearance of luminal bacteria by normal small-bowel motility generally prevents the development of pathologic concentrations of bacteria. Normally, bacteria are present in the proximal small bowel in very low concentrations, but the concentration increases with the stasis caused by obstruction or motility disorders. The IMMC is absent in the intestine of some patients with diabetic diarrhea.

In clinical studies, the prevalence of bacterial overgrowth in patients with diabetes with diarrhea has ranged from 20% to 43% (202,206). In one study, however, none of 11 patients had clinically significant bacterial overgrowth (207). In patients with bacterial overgrowth, steatorrhea often is present as a result of impaired micelle formation caused by bacterial deconjugation and hydroxylation of bile salts (207). The presence of bacterial overgrowth can be documented by (a) culture of jejunal contents (206), (b) [¹⁴C]glycocholate (208) or [¹⁴C]xylose breath tests (207), or (c) glucose- or lactulose-hydrogen breath tests (207). In clinical practice, one may alternatively observe the effect of an empiric trial of antibiotics (tetracycline or metronidazole). In patients with bacterial overgrowth resistant to empiric antibiotic therapy, jejunal intubation studies may be performed so that accurate antibiotic sensitivity determinations can be done.

Autonomic neuropathy, by causing alterations in small-bowel motility, might result in rapid intestinal transit, which in turn may lead to diarrhea in affected patients with diabetes. However, careful studies suggest that transit through the small intestine in patients with diabetic diarrhea is delayed—not accelerated (171). This slowing of transit has been documented both by breath tests (171) and by luminal sampling via multilumen tubes (202). Although small-bowel motility is abnormal in patients with diabetes with diarrhea, no specific pattern of abnormal motility was found to correlate with rapid or delayed transit (171). It seems unlikely that diabetic diarrhea is due to rapid intestinal transit, and presumably slow intestinal transit in this population is the likely basis for the increased incidence of bacterial overgrowth.

BILE-SALT MALABSORPTION

Altered bile-salt circulation and kinetics through the gut have been suggested as possible factors in diabetic diarrhea (209). Bile salts usually are absorbed efficiently in the terminal ileum, and the passage of increased amounts of bile salts into the colon results in increased colonic secretion of fluid and electrolytes. Observations in diabetic subjects suggest that increased amounts of bile salts escape ileal absorption and pass into the colon. Studies of kinetics and turnover of the bile-salt pool in patients with diabetes with diarrhea indicate that metabolism of endogenous bile salts by intestinal bacteria is increased (209). Although these results could be caused by abnormal contact between the bile salts and bacteria in the small bowel as a result of overgrowth, they more likely reflect the action of colonic bacteria on bile salts. In addition, the size of the bile-salt pool has been described as reduced, and the fraction of the bile-salt pool that is excreted has been found to be increased (208). Although bile-salt malabsorption does occur in diabetic patients with diarrhea, this phenomenon does not appear to be the mechanism of the diarrhea. For example, Schiller et al. (209) found that increased fecal excretion of bile salts is a nonspecific finding in several forms of both clinical and experimental diarrhea and does not prove a pathogenetic basis of the bile-salt excretion in the diarrhea. Indeed, there are no clinical data attesting to the efficacy of agents that bind bile salts (e.g., cholestyramine) in halting diabetic diarrhea.

IMPAIRED INTESTINAL ABSORPTION OF FLUID

Diarrhea in patients with diabetes might also result from impaired intestinal absorption of fluid and electrolytes secondary to autonomic neuropathy. In experimental studies, Chang et al. (177) demonstrated that a component of fluid and electrolyte absorption in the ileum and colon is mediated by α_2 -adrenergic receptors. Adrenergic-mediated fluid and electrolyte transport does not play a physiologic role in jejunal absorption. Studying the pathogenesis of diarrhea in rats with streptozotocin-induced chronic diabetes, Chang et al. (23) demonstrated a decrease in sympathetic tone in the ileal and colonic mucosa that was presumably secondary to sympathetic denervation caused by autonomic neuropathy. The resulting reduction in absorption of fluid and electrolytes in these segments of the intestine produced clinical diarrhea. In vitro studies also demonstrated that the impaired sympathetic tone in the ileum and colon was accompanied by adrenergic-denervation hypersensitivity, presumably as a result of an increase in the number of α_2 -adrenergic receptors. In the diabetic rat, administration of clonidine, an α_2 -adrenergic agonist, can correct this defect in ileal and colonic absorption (23).

Few clinical studies have directly examined intestinal fluid and electrolyte absorption in patients with diabetes. Whalen et al. (203) studied fluid and electrolyte absorption in the jejunum and ileum of 13 patients with diabetes with unexplained diarrhea. Under fasting conditions, the absorption of fluid and electrolytes in the jejunum and ileum of these patients was comparable to that of controls. Following the administration of a test meal, however, the volume of the test meal in the ileum was greater in diabetic than control subjects, suggesting that the ileal absorption of the fluid from the test meal was impaired. Indirect evidence of impaired sympathetic innervation of the gut in diabetic subjects with diarrhea also comes from the observation that therapy with clonidine strikingly reduced the volume of diarrhea, presumably by stimulating intestinal adrenergic receptors (210). The prevalence of these different pathogenetic disorders (including impaired absorption) in a population of patients with diabetes with diarrhea is not known. However, at least some fraction of patients with diabetes appear to experience diarrhea related to the impaired fluid and electrolyte absorption in the ileum and colon caused by sympathetic denervation.

Diagnostic Studies

Patients with diabetes with chronic intermittent or persistent diarrhea should undergo a careful evaluation. Investigators at the Mayo Clinic suggest three sequential assessments. First, blood tests should assess glucose control, electrolyte balance, evidence of malabsorption or anemia, thyroid status, antinuclear antibody, and possible drug levels. Stool specimens should be sent for culture and, in the appropriate setting, for parasitology. Flexible sigmoidoscopy should also be part of the initial workup to rule out mucosal disease in the distal colon. In the second step, small-bowel aspirate and biopsy are advocated if the results of initial blood or stool tests are abnormal. Patients with steatorrhea need to have disorders of jejunal malabsorption and pancreatic insufficiency carefully excluded. Anorectal function tests are suggested if initial blood and stool tests are normal. In the third step, if the outlined evaluation fails to identify a definite source of diarrhea, it is likely that increased fecal-fluid excretion is due to impaired intestinal absorption of fluid and electrolytes. In these patients, measurement of GI transit or therapeutic trials with opioids, clonidine hydrochloride, and, rarely, cholestyramine resin or octreotide acetate (or both methods) are recommended (202).

Therapy

If the evaluation identifies a specific cause of the diarrhea, directed therapy should be undertaken. If diagnostic studies for the presence of bacterial overgrowth are not available, it is reasonable to undertake an empiric trial of antibiotics. In patients for whom diagnostic studies are unrevealing and antibiotic therapy is unhelpful, trials of symptomatic therapy with diphenoxylate/atropine or loperamide are reasonable. Because diarrhea in these patients is episodic, symptomatic therapy can be used during periods of symptoms and later discontinued. In patients for whom symptomatic therapy is unsuccessful, a trial of clonidine is reasonable (210,212,213). However, there are few data to suggest the proper dosage and schedule of clonidine. Moreover, no data exist on the rate of success of clonidine therapy in patients with diabetes with unexplained diarrhea. Fedorak et al. (210) reported good results with high doses of clonidine (0.5 to 0.6 mg) administered every 12 hours, but these were associated with increased risk for excessive sedation. Experimental studies suggest that a state of adrenergic hypersensitivity may exist. As such, lower doses may be effective and better tolerated. In patients with diabetes with coincident diarrhea, autonomic neuropathy, and orthostatic hypotension, clonidine therapy does not appear to exacerbate the orthostatic hypotension, presumably because of the underlying neuropathy. There are also reports of topical administration of clonidine with a transdermal preparation (215).

If diarrhea is severe and unresponsive to clonidine, the somatostatin analogue octreotide should be considered. Although the specific mechanism of somatostatin action in diabetic diarrhea is unknown, this drug may reduce intestinal mucosal secretion and enhance mucosal absorption under physiologic conditions and, anecdotally, in diabetic diarrhea (216-219). Octreotide must be administered parenterally, either subcutaneously in divided doses or intravenously through a constant infusion pump. When administered in this fashion, octreotide has been demonstrated to produce striking reductions in the volume of diabetic diarrhea in a small number of patients (220,221). Of interest, in this setting octreotide was also helpful in the management of refractory orthostatic hypotension. There have been anecdotal reports of successful treatment of severe diabetic diarrhea with octreotide (216) and with ondansetron, a selective 5-HT₃ antagonist (222).

ANORECTAL FUNCTION IN DIABETES

Fecal Incontinence

CLINICAL FEATURES

Fecal incontinence denotes the inability to retain stool and prevent its involuntary passage, which can occur with or without the patient's knowledge. Although a small percentage of patients experience incontinence even with solid stool, the majority of affected individuals suffer this problem with liquid stool. The prevalence of fecal incontinence among patients with diabetes is approximately 20% (3), and the incidence and severity appear to correlate with duration of diabetes and with evi-

dence of microangiopathy or neuropathy (223). This is likely an underestimate, because many embarrassed patients complain of diarrhea rather than incontinence. Patients with diabetes frequently have both diarrhea and fecal incontinence. Almost one third of affected patients have mild steatorrhea, which does not correlate with the volume of the diarrhea. Most patients with diabetes with fecal incontinence have normal or only moderately increased daily stool volumes but also exhibit multiple abnormalities of anorectal sensory and motor functions that are not present in continent patients with diabetes (252). Among patients with diabetes, the frequency of incontinence varies from several episodes daily to a few episodes yearly and worsens during periods of diarrhea. On physical examination, both continent and incontinent patients with diabetes appear to have reduced resting and squeeze pressures in the anal canal. It should be recognized that the subjective assessment of sphincter function on rectal examination correlates poorly with actual manometric measurements of sphincter pressure (224).

QUANTIFICATION

Schiller et al. (225) assessed the anal continence mechanism for liquids and solids in diabetes. The continence mechanism for liquids was assessed by determining the volume of saline infused into the rectum that a person could hold without leaking. Both the intrarectal saline volume at which the first leak occurred and the total volume retained were much lower in incontinent patients with diabetes than in continent patients with diabetes or in control subjects. Moreover, the volume at first leak showed a better correlation with clinical continence than did the strength of anal sphincter squeeze measured manometrically. The anal continence mechanism for solids was determined by measuring the applied weight required to pull a solid sphere through the contracted sphincter. Patients with diabetes with fecal incontinence expelled the spheres at lower applied weights than did control subjects (Table 64.4).

PATHOGENESIS

At the junction of the distal rectum and the pelvic floor, the anal canal extends as a slit-like lumen 2.5 to 5.0 cm through the diaphragm of the pelvis musculature. One of the muscles of the diaphragm, the puborectalis, forms a sling of fibers that originates from both sides of the pubis symphysis and passes backward to the posterior wall of the anorectal junction. This sling of voluntary striated muscle is innervated by branches of the sacral nerve (S3, S4), and its tonic contraction creates a relatively acute angle of 80 to 100 degrees at the anorectal junction (anorectal angle) that is thought to be a major contributor to the continence of solid stool.

The internal anal sphincter consists of a thickening of the rectal circular muscle that extends the length of the anal canal. It is composed of involuntary smooth muscle whose tonic contraction is due to intrinsic myogenic activity and a variety of neurohormonal influences. Sympathetic innervation via the hypogastric nerve (L5) results in contraction of the sphincter. Parasympathetic innervation via the pelvic nerves (S1, S2, and S3) exerts both excitatory and inhibiting influences. The excitatory neurons are both cholinergic and noncholinergic. The inhibitory neurons are nonadrenergic and noncholinergic, and possibly involve NO and vasoactive intestinal peptide as neurotransmitters. It is estimated that the tonic contraction of the internal anal sphincter results in approximately 80% of the resting closure of the anal canal. With rectal distention the sphincter relaxes transiently (anorectal inhibitory reflex). Although the inhibitory reflex could "allow" incontinence of stool, sensation mediated by rectal distention results in both reflex and voluntary contraction of the external anal sphincter, resulting in closure of the anal canal.

Squeeze-pressure Increment, and Marked Incontinence of Liquids			
	Nondiabetic controls (n = 35)	Incontinent diabetics (n = 16)	Continent diabetics (n = 14)
Basal pressure (mm Hg)	63 ± 4	37 ± 4	54 ± 5
Squeeze increment (mm Hg)	111 ± 13	75 ± 10	99 ± 18
Continence of solid sphere			
Weight held with sphincter relaxed (g)	685 ± 32	532 ± 52	624 ± 48
Weight held with sphincter contracted (g)	1065 ± 37	799 ± 64	951 ± 55
Continence of infused saline			
Saline infused before first leak (mL)	1253 ± 71	410 ± 107	1222 ± 424
Total saline held (ml)	1423 ± 39	715 ± 115	1328 ± 86

TABLE 64.4. Effect of Diabetes on Anal Sphincter Pressure and Anal Continence: Incontinent Diabetic Patients Have Sphincter Hypotension, Decreased Squeeze-pressure Increment, and Marked Incontinence of Liquids

Data from Schiller LR, Santa Ana CA, Schmulen AC, et al. Pathogenesis of fecal incontinence in diabetes mellitus: evidence for internal-anal-sphincter dysfunction. *N Engl J Med* 1982;307:1666–1671.

The external anal sphincter consists of at least three bundles of striated muscle that surround the anal canal and act as a single unit. It is a voluntary muscle with innervation by the pudendal nerve (S2, S3, S4). Whereas the external sphincter demonstrates some tonic activity at rest (contributing to closure), its voluntary contraction is a major mechanism for continence of stool and flatus. The fibers of the pudendal nerve are cholinergic and exert their effect at the motor end plate via nicotinic receptors. With rectal distention, the external anal sphincter contracts reflexively to close the anal canal (sphincteric reflex). Rectal sensation is mediated by afferent pelvic splanchnic fibers passing to the sacral cord (S2, S3) and alerts the subject to rectal distention produced by stool or flatus. The stimulus of rectal distention causes conscious or reflexive contraction of the external anal sphincter and puborectalis.

Under physiologic conditions, the internal anal sphincter provides resting closure of the anal canal and some protection against rectal leakage and fecal stress incontinence. As stool passes into the rectum, distention of the rectum alerts one to contract both the external anal sphincter, which tightens the closure of the anal canal, and the puborectalis, which further closes the anorectal angle. Contractions of the external anal sphincter and puborectalis nullify the relaxation of the internal sphincter associated with rectal distention. These mechanisms maintain continence until defecation is appropriate.

In various patients with diabetes with fecal incontinence, anorectal testing has demonstrated (a) decreased resting and squeeze anal pressures, (b) decreased sensation to rectal distention, (c) an elevated threshold for the external anal sphincteric reflex, and (d) impaired anocutaneous reflex. Decreased threshold of sensation to distention and to electrical stimulation noted particularly in the upper anal canal has been suggested as an early abnormality in the development of diabetic incontinence (226). The rectoanal inhibitory reflex involving the internal anal sphincter has been described as normal by some groups (227,228) but diminished in patients with longstanding diabetes and fecal incontinence (223,225) (Fig. 64.10). Prolonged pudendal nerve terminal latency has also been correlated with diabetic patients having fecal incontinence (229) and may explain the decreased squeeze pressure, because this is generated by the skeletal external anal sphincter muscle, which is indirectly innervated by the pudendal nerve.

At least in some patients with diabetes, instability of the internal anal sphincter plays a major role in fecal incontinence. During basal recording, some patients with diabetes demonstrated oscillations in anal electrical activity and pressure. Some patients also exhibited spontaneous transient anal relaxations, and fecal leakage occurred as the anal pressure fell below the rectal pressure (230).

The observed basal hypotonia of the anal canal is presumably caused by dysfunction of the internal anal sphincter secondary to diabetic autonomic neuropathy. Patients with diabetes with fecal incontinence not only show evidence of autonomic neuropathy but also suffer from diarrhea, suggesting a distinctive pattern of sympathetic denervation of the gut that results in both impaired fluid absorption and dysfunction of the internal sphincter.

Altered rectal sensation in patients with diabetes is presumably a manifestation of sensory neuropathy and is not observed in patients with fecal incontinence related to other disorders. Because rectal sensation mediates the afferent limb of the sphincteric reflex, it is not surprising that the threshold for reflex contraction of the external anal sphincter is also elevated. In patients with diabetes, however, the threshold for anorectal inhibitory reflex is comparable to that for control subjects (227). In this setting, fecal incontinence can occur because an amount of rectal distention that will induce relaxation of the internal sphincter may fail either to initiate reflex contraction of the external sphincter or to alert the subject to contract the sphincter voluntarily.

The etiology of fecal incontinence in diabetes is multifactorial, including dysfunction of the internal anal sphincter, decreased sensation of the rectal vault, impaired fluid absorption, dysfunction of the external anal sphincter, and impaired "sampling" function of the anal canal. As in other regions of the upper GI tract, these physiologic measures correlate poorly with the extent of autonomic neuropathy.

TREATMENT

In patients with diabetes, fecal incontinence usually occurs in relation to liquid stool. Because the success of attempts to develop continence is much greater if the patient has solid stools, every effort should be made to identify and treat the underlying cause of diarrhea. In some patients, trials of clonidine can be undertaken to control so-called diabetic diarrhea. In patients with functional diarrhea, the use of antidiarrheal agents, such as loperamide and diphenoxylate/atropine, is

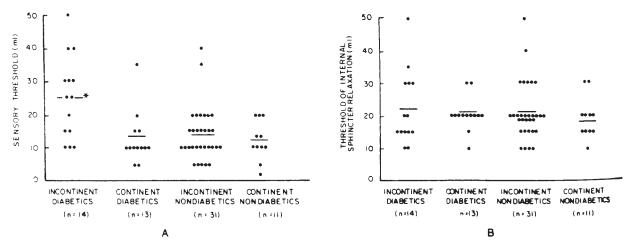

Figure 64.10. Anorectal sensory thresholds and thresholds of internal anal sphincter relaxation in four groups of subjects. The mean threshold of rectal sensation (**A**) was significantly higher in the incontinent patients with diabetes than in the other three groups of patients (p < 0.02), as indicated by the asterisk. There were no significant differences in thresholds of internal sphincter relaxation (**B**). Note that in all groups except the incontinent patients with diabetes the sensory threshold was lower than the threshold for internal anal sphincter relaxation. These observations suggest that fecal incontinence in patients with diabetes may be due to an increase in the sensory threshold above that for internal anal sphincter relaxation. (From Wald A, Tunuguntla AK. Anorectal sensorimotor dysfunction in fecal incontinence and diabetes mellitus: modification with biofeedback therapy. *N Engl J Med* 1984;310:1282–1287, with permission. helpful. If these measures are unsuccessful in achieving fecal continence, the performance of anorectal manometry is recommended. Basal anal canal pressure, sensory threshold pressure for rectal distention, and internal anal sphincter relaxation and external anal sphincter contraction responses to rectal distention should be studied. If manometric studies demonstrate an elevated sensory threshold for rectal distention, biofeedback training can be helpful in obtaining symptomatic relief (228).

Biofeedback training in incontinent patients with diabetes employs a balloon catheter to achieve both rectal sensory and external sphincter conditioning (Fig. 64.11). Using this technique, Wald and Tunuguntla (228) noted improvement in 73% of

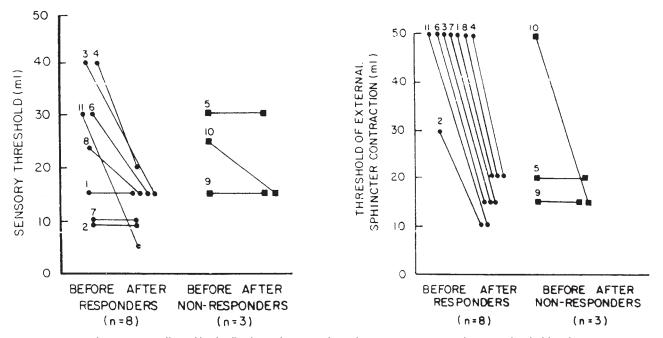

Figure 64.11. Effect of biofeedback conditioning of rectal sensation on anorectal sensory threshold and threshold of external anal sphincter contraction in eight responders (decreased frequency of fecal continence) and three nonresponder patients with diabetes. **Left:** Normalization of rectal sensory thresholds to less than 20 mL occurred in all but one patient with thresholds above 20 mL. No improvement in the sensory threshold was noted in patient 5. **Right:** Thresholds of external sphincter contraction showing strong association between improvement of the external sphincter response and reestablishment of bowel control. (Reprinted from Wald A, Tunuguntla AK. Anorectal sensorimotor dysfunction in fecal incontinence and diabetes mellitus: modification with biofeedback therapy. *N Engl J Med* 1984;310:1282–1287, with permission. patients with diabetes, who achieved a reduction in fecal soiling without any striking change in stool frequency. Improvement in fecal control correlated with the ability to improve both the sensory threshold and the threshold for phasic external sphincter contraction. Most important, the manometric improvements did result in clinically meaningful enhancements in lifestyle, as patients experienced a greater freedom of activity once the risk and frequency of rectal incontinence were reduced. Long-term testing demonstrated that the improvements in sensory and sphincter thresholds were sustained during periods of follow-up exceeding 1 year. Presumably, enhancement of sensory perception results from recruitment of adjacent neurons that mediate rectal sensation. By relearning the appropriate physiologic response to rectal distention, patients thereby regain improved control over rectal function.

BILIARY SYSTEM IN DIABETES

Cholelithiasis is common in patients with diabetes, especially in women with type 2 diabetes (231,232). Patients with diabetes may have physiologic reasons for being at increased risk for the formation of cholesterol gallstones. First, in these patients, total body cholesterol synthesis is increased independently of obesity, which may lead to more lithogenic bile. Second, patients with diabetes have larger gallbladders (233) and possibly diminished gallbladder motility, which could result in enhanced formation of cholesterol crystals. Despite these physiologic factors, recent studies suggest that diabetes alone may not significantly increase the risk for gallstones. Earlier studies did not differentiate the effects of obesity, hypertriglyceridemia, and other cofactors known to contribute to increased risk of gallstones.

Lithogenic Bile

Under physiologic conditions, the liver secretes bile that is unsaturated with respect to cholesterol, and the relative amounts of bile salts and lecithin in the bile are capable of maintaining cholesterol in a stable solution (234). Pathologic disorders that result in either a decrease in bile-salt secretion or an increase in cholesterol secretion will result in the formation of bile that is supersaturated with respect to cholesterol. Cholesterol crystals and eventually gallstones can develop from such lithogenic bile. Risk factors leading to the secretion of lithogenic bile include (a) increasing age, (b) obesity, (c) hypertriglyceridemia, and (d) decreased size of the bile-salt pool (235).

Haber and Heaton (236) examined the lipid composition of bile in patients with diabetes and in controls matched for obesity. Patients with type 1 or type 2 diabetes were matched to nondiabetic control subjects by age, gender, and obesity index. The analyses demonstrated no significant difference between the cholesterol saturation of bile in patients with diabetes and that of appropriately matched control subjects. The bile of patients with type 1 diabetes was unsaturated with respect to cholesterol. Patients with type 2 diabetes had a higher body mass index and more saturated bile than did patients with type 1 diabetes. Thus, the risk of lithogenic bile is greater in patients with type 2 diabetes than in those with type 1 diabetes and is related to concurrent obesity rather than to diabetes itself. Other studies have also suggested that diabetes per se does not predispose to secretion of abnormal bile (235). Similarly, there was no significant correlation of diabetes with type of stone, i.e., pigment or cholesterol, when corrected for other variables such as age and presence of cirrhosis (237).

Gallbladder Emptying

Studies using radiographic cholecystography have suggested that the emptying of the gallbladder is delayed or impaired in patients with diabetes. Other studies using ultrasonography and scintigraphy have yielded contradictory results. Stone et al. (238) used radionuclide cholescintigraphy to analyze gallbladder emptying in response to intravenous cholecystokinin octapeptide. Stimulated gallbladder emptying was lower in patients with diabetes than in controls (55% vs. 74%). Furthermore, the most severe impairment of gallbladder emptying occurred in patients with diabetes with associated autonomic neuropathy. Similar results were described by other groups using ultrasonography (239). With ultrasonography, Keshavarzian et al. (240) found contrasting results in an examination of fasting gallbladder volume and postprandial emptying. Among patients with diabetes, both fasting and postprandial gallbladder volumes were comparable to the respective values in controls. No effect of autonomic neuropathy on gallbladder emptying could be demonstrated. In patients with type 1 diabetes of less than 10 years' duration, no differences in emptying could be discerned, although the authors suggested that a dilated gallbladder at rest may correlate with autonomic neuropathy and the increased likelihood of stone formation (241). It is difficult to reconcile the differences in gallbladder motor function reported in these studies. Although differences in methodology may be a factor, a consistent pattern of gallbladder motor dysfunction has not been established in patients with diabetes.

Gallstones

PREVALENCE

In keeping with these contrasting observations about gallbladder function among patients with diabetes, studies on the prevalence of gallstones in this population have also yielded contradictory results. The findings of both autopsy studies (242,243) and epidemiologic studies (244) have conflicted. A large case-control study from Canada failed to find any association between cholesterol cholelithiasis and clinical diabetes (245). Epidemiologic studies based in Italy showed that multiple risk factors, including hyperinsulinemia, are associated with the formation of gallstones (246). More recent studies suggested that diabetes is associated with gallstones on univariate analysis but not on multivariate analysis (247) and that obesity and age, which are associated with type 2 diabetes, are stronger risk factors for the development of gallstones than is the presence of type 2 diabetes (248). Hence, if diabetes does affect the prevalence of gallstones, the effect is small.

TREATMENT

The surgical approach to the management of asymptomatic gallstones has been changing. As pointed out by Pellegrini (249), several observations have discouraged the routine use of surgery in patients without diabetes with asymptomatic gallstones. Among such patients, relatively few develop symptoms during periods of follow-up as long as 20 years. In addition, life-threatening complications of gallstone disease are rarely the first manifestation. Milder symptoms of biliary colic usually arise first and prompt a timely surgical referral before the appearance of acute cholecystitis and cholangitis. Furthermore, long-term follow-up of many patients with mild symptoms indicates that the majority remain free of serious complications. Finally, autopsy studies indicate that more than 90% of patients with gallstone disease die of an unrelated cause.

The role of surgery in patients with diabetes with asymptomatic gallstones has been controversial. In the past, it was believed that patients with diabetes with cholelithiasis should undergo surgery, even if asymptomatic, to avoid the increased morbidity and mortality presumed to occur in patients with diabetes. This aggressive perspective perhaps originated with Rabinowitch in 1932, who suggested that patients with diabetes and cholecystitis fared worse than patients without diabetes (250). In 1961, Turrill et al. (251) reported that the mortality rate after surgery for gallstones was fivefold higher in patients with diabetes. Deaths in that series occurred primarily in patients with diabetes who were undergoing emergency surgery. When the analysis was limited to patients in the fifth and sixth decades of life who underwent emergency cholecystectomy, the mortality among patients with diabetes was reported to be 20-fold higher than that among patients without diabetes. Others have also reported increased morbidity and mortality associated with emergency surgery for gallstones among patients with diabetes and recommended elective surgery for gallstones when possible, because the mortality among patients with diabetes with elective surgery was comparable to that among patients without diabetes (78,86,250). Both Turrill et al. (251) and Mundth (252) even recommended that all patients with diabetes undergo screening with oral cholecystography and that all with gallstones undergo elective surgery. Yet other authors report similar increases in morbidity and mortality for acute cholecystitis and suggest early surgery but believe that this is not necessarily an indication for cholecystectomy in asymptomatic patients (75,253).

Further analyses of the morbidity and mortality of gallstone surgery among patients with diabetes criticized the conclusions of earlier studies with respect to several issues: First, modern morbidity and mortality rates are much lower as a result of the use of antibiotics and improvements in medical and surgical care; second, earlier studies did not report the prevalence of concurrent medical disorders among the patients with diabetes (e.g., atherosclerosis) that might affect the rate of postoperative complications independent of diabetes; and finally, studies, including that of Mundth (252), did not include a contemporary control group that was analyzed over a comparable period (254). Several retrospective studies more critically examined the morbidity and mortality among patients with diabetes with surgical gallstone disease (255). Patients with diabetes undergoing surgery tended to be older than patients without diabetes and to have more concurrent medical disorders, especially cardiovascular disease. There was a trend toward increased surgical mortality among the patients with diabetes, but this difference was statistically significant in only one study. It is interesting that in a review of a 21-year period at one institution, the case-fatality rate among patients with diabetes with surgical gallstone disease decreased over the course of the study, presumably as a result of improvements in medical and surgical care (256).

In both patients with diabetes and those without diabetes, morbidity and mortality were increased in the setting of emergency cholecystectomy and with preoperative evidence of cardiovascular and renal disease. In none of the studies was diabetes per se a risk factor for increased operative mortality. Analyses indicated that the presence of preoperative concurrent medical disorders predicted postoperative morbidity and mortality more accurately than did the presence of diabetes. In reviewing earlier surgical studies, Walsh et al. (257) suggested that 50% to 80% of the patients with diabetes in those studies showed evidence of occlusive vascular disease, which might have accounted for the observed increase in morbidity and mortality independent of diabetes.

64: EFFECTS OF DIABETES ON THE DIGESTIVE SYSTEM 1095

There was a trend toward increased postoperative complications among patients with diabetes, but it is unclear whether this risk is related to diabetes or to concurrent medical disorder. Hickman et al. (255) observed that with emergency cholecystectomy the incidence of postoperative infectious complications was higher in patients with diabetes, an increase that could not be explained by any pattern of concurrent medical disorders. In contrast, Sandler et al. (258), applying regression analysis, demonstrated that the twofold higher rate of postoperative complications in patients with diabetes was related to coincident medical problems rather than to diabetes per se (80). Furthermore, the increased incidence of postoperative complications among patients with diabetes occurred with both emergency and elective cholecystectomy (38).

In summary, the current data do not support elective cholecystectomy in patients with diabetes with asymptomatic gallstones. Nevertheless, because emergency cholecystectomy for acute cholecystitis is associated with increased morbidity and possibly increased mortality, one should consider elective surgery in those patients with diabetes with concurrent biliary symptoms, especially if serious medical disorders do not coexist. Laparoscopic cholecystectomy may provide a safer and preferable alternative to abdominal cholecystectomy (259).

EXOCRINE PANCREAS AND DIABETES

Diabetes in Pancreatic Disease

Primary disorders of the exocrine pancreas can affect islet cell function and result in states of glucose intolerance or in overt diabetes. For example, with acute pancreatitis of any etiology, hyperglycemia can result and is recognized as a prognostic sign of severity of pancreatitis (260). In this setting, hyperglycemia is thought to be secondary to increased circulating levels of glucagon and epinephrine rather than to islet destruction with actual insulin deficiency. Indeed, individuals who are not diabetic before an episode of acute pancreatitis will again achieve normal glucose control after resolution of the episode. In contrast, both diabetes and glucose intolerance are recognized complications of advanced chronic pancreatitis. The advanced stages of pancreatic injury and fibrosis result in damage to the islets, with resulting insulin deficiency and chronic diabetes (261).

Exocrine Pancreas in Diabetes

Well-recognized changes in pancreatic exocrine morphology and function have been identified in idiopathic diabetes mellitus. In type 1 diabetes, there is widespread islet atrophy and fibrosis with associated atrophy and fibrosis in the surrounding exocrine tissue (262). Careful studies of pancreatic histology in patients who died shortly after initial presentation of type 1 diabetes showed that the effects of diabetes on the endocrine and exocrine pancreas are halted at a relatively early stage. In parts of the diabetic pancreas where the islets remain intact and concentrations of insulin in β-cells determined immunohistochemically are normal, the surrounding exocrine tissue appears normal. In contrast, in those areas where the islets have atrophied, the surrounding acinar tissue also is atrophied. These observations support the hypothesis that insulin and other islet cell peptides have trophic effects on the surrounding acinar cells and are consistent with a microcirculatory architecture of the pancreas (263). Blood traveling through islet capillaries supplies surrounding exocrine tissue and exposes the acinar cells to high concentrations of islet cell

peptides. Both insulin and pancreatic polypeptide appear to have trophic effects on acinar glands, whereas glucagon and somatostatin may have inhibitory effects. By this theory, islet dysfunction resulting in either decreased levels of trophic hormones or increased levels of inhibitory peptides could result in exocrine dysfunction (264).

In type 2 diabetes, the changes in the islets are less extensive, with variable reduction of the β -cells; there is hyalinosis of the islets of varying extent and severity. The associated changes in the surrounding exocrine tissue are less extensive than those seen in type 1 diabetes but are easily demonstrated nevertheless. As indicated by ultrasound examination, the overall size of the pancreas is smaller than in control subjects (264). On histologic study, the reduction in gland size correlates with atrophy and fibrosis of exocrine tissue.

Careful studies of pancreatic exocrine function in diabetes have demonstrated a surprisingly high prevalence of dysfunction (203,265). Vagal cholinergic and peptidergic neurons are involved in stimulating exocrine secretion. VIP increases water and bicarbonate secretion, whereas acetylcholine and GRP increase enzyme secretion. However, the role of diabetic autonomic neuropathy in pancreatic exocrine dysfunction remains unclear. Exocrine function has traditionally been measured by duodenal intubation and collection of pancreatic secretions following stimulation of the gland with both cholecystokinin and secretin. Exocrine function can also be measured indirectly by assessing serum levels of immunoreactive trypsin, which were shown to correspond to exocrine secretions into the duodenal lumen (266). Both direct (203,265) and indirect (266) measures of exocrine function identify moderate degrees of exocrine deficiency in 65% to 80% of patients with type 1 diabetes. With direct studies, both amylase secretion and bicarbonate secretion were found to be reduced 55% to 65% (203,265). Despite the marked reduction in exocrine function in a large fraction of the diabetic population, steatorrhea caused by exocrine insufficiency is quite rare owing to the large secretory capacity of the exocrine pancreas. Both direct and indirect studies of exocrine function found a significant correlation between the declining endogenous insulin secretion, as measured by C-peptide concentration, and amylase and bicarbonate output (265,266). In some studies the reduction in exocrine function worsened with time and corresponded to the progressive decline in concentrations of C-peptide (265). This correlation is thought to represent the causal effect of insulin deficiency on exocrine function and would support the hypothesis of the trophic effects of insulin on exocrine function. Hence, with a decline in the release of endogenous insulin in type 1 diabetes, the surrounding acinar cells atrophy, with resulting exocrine dysfunction. In type 2 diabetes for which insulin therapy is not required, there is also a demonstrable decrease in exocrine secretion but of a magnitude smaller than that observed in type 1 diabetes and insulindependent type 2 diabetes (265).

Although the presence of autonomic neuropathy could reduce pancreatic exocrine secretion as a result of reduced secretomotor action, careful secretory studies have suggested that this is not the case (203). In diabetic patients requiring insulin, the decreased exocrine secretion cannot be corrected with supramaximal concentrations of cholecystokinin and secretin. In addition, when bethanechol was administered simultaneously with cholecystokinin and secretin, the additional cholinergic stimulation also failed to correct the decrease in exocrine secretion. These data are seen to indicate a reduction in or atrophy of the acinar cell mass rather than an alteration in the secretomotor activity of the nerves or hormones on the pancreas.

Hyperamylasemia and Pancreatitis

Hyperamylasemia has been reported in 46% to 79% of patients with diabetic ketoacidosis (267). Abdominal pain and tenderness occur in up to 45%, and a history of vomiting exists in up to 73% (267). In the past, this constellation of symptoms and findings was attributed to acute pancreatitis. However, more recent careful analyses have indicated that acute pancreatitis is rarely present in diabetic ketoacidosis and hence is not a common cause of the abdominal symptoms and hyperamylasemia (268). Hyperamylasemia is often not present at the initial presentation with ketoacidosis but can develop later during hospitalization (267). The magnitude of serum amylase elevation is variable, but the level reaches up to six times higher than normal, which is an elevation often considered specific for acute pancreatitis. However, there is no correlation between hyperamylasemia and the abdominal symptoms, and hyperamylasemia occurs with equal frequency in patients with and without these symptoms. In the vast majority of patients with ketoacidosis and hyperamylasemia, isoamylase testing has demonstrated that the major contributor to the elevation is a salivary-type, rather than a pancreatic, isoamylase. Simultaneous lipase levels are usually normal. The source of the salivarytype isoamylase is unclear, because all forms of isoamylase other than pancreatic isoamylase are assayed as the salivarytype isoenzyme. Hyperamylasemia may be a consequence of acidemia and serum hyperosmolality per se rather than a specific consequence of diabetic acidosis. Eckfeldt et al. (269) collected serum from 33 patients with metabolic or respiratory acidosis in the absence of diabetic acidosis or renal failure. The total serum amylase level was elevated in 36% of these patients, and five patients had marked elevations in a range usually considered diagnostic of acute pancreatitis. There was a trend toward a greater prevalence of hyperamylasemia with worsening acidosis, but the difference was not statistically significant. As in other studies of hyperamylasemia, the majority of patients had a salivary-type isoamylase of unknown origin, and almost all affected patients had normal lipase levels. More recent studies showed that nonspecific hyperamylasemia and hyperlipasemia in diabetic ketoacidosis are common, occurring in 16% to 25% of cases, and elevations of amylase correlated with pH and serum osmolality, but lipase elevation correlated with serum osmolality alone (270,271). From such studies, diagnosis of acute pancreatitis, based solely on elevated amylase or lipase, even if more than three times normal, does not seem justifiable.

The cause of the abdominal symptoms in diabetic ketoacidosis remains uncertain but is likely not related to pancreatitis. Alternate explanations for the pain have included intestinal ileus or gastric dilatation caused by the underlying acidosis. In patients presenting with diabetic ketoacidosis and hyperamylasemia for whom a reasonable question exists regarding the presence of pancreatitis, examination of the lipase level and studies of pancreatic morphology by abdominal imaging should be helpful.

Although there is no known association between diabetes mellitus and pancreatitis, two important associations should be recognized. First, the incidence of gallstones may be increased in type 2 diabetes because of coincident obesity. In this setting, acute pancreatitis secondary to the passage of gallstones can occur (235). Second, type IV hyperlipoproteinemia occurs more frequently in type 2 diabetes. In susceptible patients, high dietary fat intake might turn type IV hyperlipoproteinemia into type V hyperlipoproteinemia, which is associated with an increased risk of acute pancreatitis.

Pancreatic Cancer and Diabetes

In population-based case-control studies of pancreatic cancer conducted in the United States, diabetes was a risk factor for pancreatic cancer (272,273), as well as a possible complication of the tumor (273). A significant positive trend in risk with increasing years prior to diagnosis of pancreatic cancer was apparent, with persons with diabetes diagnosed at least 10 years prior to diagnosis having a significant 50% increased risk. Use of insulin or duration of insulin use did not correlate with risk of developing pancreatic cancer. However, increased insulin level has been proposed as a possible "unifying concept" in the increased risk of various cancers seen in persons with diabetes (274). Patients with abnormal glucose metabolism, as determined by elevated serum glucose levels 1 hour after an oral glucose challenge, were found to have an increased risk of developing pancreatic carcinoma even if patients who died of that disease during the first 5 years of follow-up were excluded from consideration (275).

LIVER IN DIABETES

Increased Hepatic Glycogen

It is surprising that hepatic glycogen is increased in some patients with diabetes, because adequate serum levels of insulin are necessary to stimulate glycogen synthesis. Nevertheless, in some patients with type 1 diabetes, increased hepatic glycogen does occur and results in or contributes to clinical hepatomegaly (276). Among these patients, the disorder is observed with increased frequency in patients with "brittle" diabetes who are prone to hypoglycemia. In these patients, intermittent excesses in insulin therapy appear to achieve the serum levels necessary to stimulate glycogen synthesis in the liver. Although increased hepatic glycogen can cause hepatomegaly, it does not produce clinical liver dysfunction as typified by abnormal laboratory testing or clinical symptoms (15,277).

Diabetic Fatty Liver

Hepatic steatosis is defined as the accumulation of lipid by the liver, usually in the form of triglyceride, such that the weight of lipid exceeds 5% of the total weight of the liver (278,279). Histologic studies indicate that diabetic hepatic steatosis can produce either microvesicular or macrovesicular deposition of fat. In general, with marked fatty infiltration, there is macrovesicular fatty deposition with some hepatocellular destruction. Hepatocyte necrosis is usually mild and is not associated with an inflammatory infiltrate.

It is difficult to estimate accurately the incidence of this lesion in diabetes because a percutaneous liver biopsy is necessary for proper identification. The medical literature reports a wide range in incidence, differences that are probably due to the large variation in body weight of patients, as well as to the effect of the type of diabetes on this disorder. In type 1 diabetes the incidence of hepatic steatosis is low (4% to 17%) (279). In these patients, hepatic steatosis is related to inadequate serum levels of insulin and hence to poor diabetic control. Increased mobilization of fatty acids from peripheral adipose tissue results in an increased hepatic concentration of fatty acids and enhanced hepatic synthesis of triglyceride and very-lowdensity lipoprotein (VLDL) (278). Both hyperlipidemia and hepatic steatosis are readily reversible with appropriate insulin therapy. Because of this reversibility, the incidence of hepatic steatosis in type 1 diabetes remains relatively low.

In type 2 diabetes, the incidence of hepatic steatosis is high (21% to 78%) and is related primarily to concurrent obesity rather than to the duration of the diabetes or the adequacy of control (279). It is difficult to differentiate the effect of diabetes from that of obesity in the pathogenesis of fatty liver in this setting. In patients with morbid obesity, without coincident diabetes, the incidence of fatty liver can be as high as 94% (281).

In type 2 diabetes, the pathogenesis of hepatic steatosis is multifactorial (279,282). Increased serum and hepatic fatty acids found in these patients result in an increased rate of hepatic triglyceride synthesis that exceeds a relatively normal rate of hepatic secretion of VLDL. In type 2 diabetes, hepatic steatosis is less readily reversible and is managed more effectively by the introduction of a low-calorie, low-carbohydrate diet with achievement of weight loss.

The role of peroxisome proliferator-activated receptor γ (PPAR γ), which is an important regulator of genes involved in glucose and lipid metabolism, in the liver has generally not been appreciated because, in contrast to PPAR α or PPAR δ , PPAR γ is not abundantly expressed in the liver under normal conditions. However, in several murine models of obesity and type 2 diabetes mellitus, there is increased expression of PPAR γ in the liver. Moreover, treatment of diabetic mice with selective PPAR γ ligands and with the activators thiazolidinediones resulted in the development of severe hepatic centrilobular steatosis. In light of reports that troglitazone has been associated with rare but serious hepatotoxicity in patients, further insight into PPAR γ -mediated versus non–PPAR γ -mediated effects of thiazolidinediones in humans is needed (283).

In general, the hepatic steatosis of diabetes produces asymptomatic hepatomegaly and few, if any, clinical symptoms. The results of laboratory studies of hepatic function and injury tend to be normal. Mild elevations of these test values have been documented in up to 18% of unselected patients with either type 1 or type 2 diabetes, particularly of alkaline phosphatase and γ -glutamyltranspeptidase (284,285). Diagnostic imaging studies can document the presence of hepatic steatosis; an abdominal computed tomographic (CT) scan can show decreased hepatic density caused by fatty infiltration, and abdominal ultrasonography demonstrated a reflective or "bright" pattern in 23% of unselected patients in one series (286).

The natural history of hepatic steatosis of diabetes is controversial. In general, this lesion is benign and not prone to progression to a more severe hepatic injury. Indeed, it is rare to document actual cirrhosis as a consequence of hepatic steatosis, although epidemiologically there is a correlation between diabetes and hepatitis C infection, which is the leading cause of chronic liver disease in the United States (277).

Diabetic Steatonecrosis

A more severe histologic lesion has been described in some patients with diabetic fatty liver. Steatonecrosis ("nonalcoholic steatohepatitis" or "fatty liver hepatitis") produces histologic changes similar to those seen in alcoholic hepatitis or following ileojejunal bypass in obese patients (279,282,287), consisting of moderate steatosis with macrovesicular fatty change. Fibrosis may be both periportal and pericentral. Hepatocellular degeneration and necrosis may occur, with intracellular hyaline bodies identical to Mallory bodies. Although chronic inflammatory cells may infiltrate the portal areas, there is no infiltration by polymorphonuclear cells, a finding that may distinguish this lesion from that of alcoholic hepatitis. Infiltration by polymorphonuclear cells is common and almost pathognomonic for alcoholic hepatitis in the setting of the other histologic findings. In some patients with diabetic steatonecrosis, bridging fibrosis between portal tracts and central veins may exist.

As might be expected, steatonecrosis is more common in patients with type 2 diabetes, particularly in middle-aged, obese women (277). Although it usually presents as asymptomatic hepatomegaly with abnormal values in liver function tests, rarely the patient presents with complaints of fatigue and with ascites. Laboratory studies may demonstrate marked elevations of the sedimentation rate, as well as mild-to-moderate elevations in alkaline phosphatase and γ -glutamyltranspeptidase levels; elevations of transaminases tend to be mild. In general, the levels of bilirubin, albumin, and globulin are normal.

The finding of pericentral fibrosis raised concerns in the past regarding the progression of this lesion to more severe liver disease. In other disorders, sclerosis of the terminal hepatic venules suggests progressive liver injury that may be a harbinger of eventual cirrhosis (284). In steatonecrosis, however, progression to more severe liver disease seems less common. In one study, bridging fibrosis was found in those patients with diabetes of longer duration (282), but actual cirrhosis proved to be rare. In a study that provided long-term follow-up of 35 patients with nonalcoholic steatohepatitis, the hepatic histology in 91% of the patients remained stable or changed only slowly (288). Only 9% of the patients demonstrated deterioration of the histologic lesion, and cirrhosis was found in only two patients.

Steatonecrosis in a patient with type 1 diabetes has been reported (287). Although this patient presented with mild jaundice and hepatosplenomegaly, liver biopsy did not demonstrate cirrhosis. With improved diabetic control, the liver function test became normal, hepatosplenomegaly resolved, and serial imaging studies by abdominal CT scan demonstrated a return of hepatic density to near-normal values.

Primary Liver Cancer

A Swedish population-based study showed increased risk of developing primary liver cancer and biliary tract cancers among patients with diabetes (273). Selection bias was minimized by excluding patients in whom liver and biliary tract cancers were diagnosed during the first year of follow-up. Overall standardized incidence ratios (SIRs) adjusted for age, sex, and calendar year for comparison during the 1 to 24 years of follow-up was 2.5. The risk was higher in men (SIR = 3.2) than in women (SIR = 2.0), and the incidence of primary liver cancer alone was increased fourfold (SIR = 4.1). After exclusion of patients with diabetes with concomitant diseases that predispose to primary liver cancer, such as alcoholism, cirrhosis, and hepatitis, the persistence of an approximately threefold excess risk was observed. Similar increased association of liver cancer and diabetes has been noted in Japan (289), Italy (290), and the United States (291), although the latter did not show increased risk in the absence of viral or alcoholic cirrhosis.

CONSIDERATIONS IN CLINICAL DECISION MAKING 1104

Risks of Oral Agents in the Hospitalized Patient 1105

Diabetes-related hospitalizations in the United States totaled 13.9 million days in 1997 (1). The advances made in anesthesia and perioperative cardiovascular monitoring in recent years have led to a dramatic improvement in the outcome following major surgery in patients with diabetes (2). Too often, however, inattention to the metabolic management of the patient with diabetes will lead to complications in the hospital course and prolong hospital stay. Illness and surgery trigger counterregulatory hormone responses that counteract insulin action and can lead to metabolic instability and decompensation. In the hospitalized patient, host defenses against infection are compromised by disruption of the mucocutaneous barriers by endotracheal tubes, catheters, and surgical procedures. Furthermore, hyperglycemia directly inhibits immune function, adding to the risk for nosocomial infection. It is hoped that current trends toward the use of standardized treatment protocols to improve and expedite hospital care will have a positive impact on inpatient diabetes management.

TREATMENT CONSIDERATIONS: GOALS

Prevention of Metabolic Decompensation

The prevention of metabolic decompensation from the "stress" of illness and surgery is a key goal in the management of diabetes in the hospitalized patient. Surgery and illness induce a metabolic response that is characterized by increased secretion of epinephrine, glucagon, cortisol, and growth hormone (3,4). These counterregulatory hormones lead to a state of insulin resistance, with accelerated lipolysis and protein catabolism (5).

Type of Diabetes 1105 Metabolic Response to Hospitalization 1105 Other Considerations 1106

TREATMENT GUIDELINES 1106

CONCLUSION 1108

In nondiabetic patients, there is a compensatory increase in insulin secretion that, in addition to maintaining glucose homeostasis, will counteract the catabolism and tissue breakdown. In the patient with diabetes, these counterregulatory changes can lead to metabolic decompensation with severe hyperglycemia and osmotic diuresis accompanied by dehydration and electrolyte disturbances. In patients with marked insulin deficiency, the increased levels of epinephrine and glucagon will trigger a state of accelerated lipolysis and ketogenesis that can culminate in diabetic ketoacidosis. The fundamental goal in the management of diabetes in the hospitalized patient is to ensure that there is sufficient circulating insulin to counteract this catabolic state.

Promotion of Wound Healing

The catabolic state that develops during injury and surgery can compromise the nutritional state of the patient and delay wound healing (6). Insulin has a key anabolic role in the physiologic responses that restrain tissue catabolism during injury. Studies in animal models of diabetes indicate that hyperglycemia and insulin deficiency attenuate the process of wound healing (7). The administration of insulin to injured nondiabetic patients markedly attenuates protein breakdown and urea generation (8,9). In addition, insulin therapy in the injured patient reduces the efflux of amino acids from skeletal muscle (10). Although there are no definitive data demonstrating that tight glycemic control improves wound healing in patients with diabetes, the weight of evidence showing that insulin blunts protein catabolism provides a strong physiologic rationale for ensuring that the hospitalized diabetic patient has adequate insulin (11).

Minimizing Infection Risk

The answer to the question of how tightly to control hyperglycemia in the hospitalized patient depends on several considerations. Hyperglycemia has direct effects on immune function that can increase susceptibility to infection (12). Furthermore, the impaired phagocytic and bactericidal function of neutrophils from patients with poorly controlled diabetes is reversed with intensive glycemic control (13,14). Data from the Beth Israel Deaconess Medical Center, affiliated with the Joslin Clinic, clearly indicate that early postoperative glucose control is an important predictor of serious nosocomial infections such as bacteremia, pneumonia, and surgical wound infections (15). One hundred consecutive diabetic patients undergoing elective surgery over a 4-month period were prospectively followed for the development of postoperative infections. Patients with hyperglycemia (defined as at least one serum glucose measurement > 220 mg/dL) on postoperative day 1 had an infection rate 2.7 times that noted in diabetic patients whose serum glucose measurements were all $\leq 220 \text{ mg/dL}$. Remarkably, when urinary tract infections were excluded from the analysis, hyperglycemia on postoperative day 1 was associated with a 5.8-fold increase in rates of nosocomial infection. These findings have been confirmed in an analysis from the Johns Hopkins institutions of postoperative infection rates in diabetic patients undergoing coronary bypass grafting (16). Postoperative glucose levels in the cohort were divided into quartiles and, independent of other factors, including underlying comorbidity and the severity of illness during the recovery, the patients in the lowest quartile (mean glucose level, 121 to 206 mg/dL) had lower infection rates.

Evidence from the Bypass Angioplasty Revascularization Investigation (BARI) (17) that patients with diabetes and multivessel coronary artery disease who receive internal mammary grafts have superior long-term survival compared with those who receive saphenous vein grafts or percutaneous transluminal coronary angioplasty has important implications with respect to perioperative diabetes management. Coronary bypass with internal mammary grafts has become the procedure of choice in patients with diabetes and multivessel coronary artery disease; however, this surgery is associated with a markedly higher incidence of postoperative deep sternal wound infections compared with saphenous vein grafting. In patients undergoing internal mammary grafting, the incidence approaches 11.5% to 14.3% (18,19), and there is a significant correlation between postoperative blood glucose levels and infection rates (20,21). Retrospective data from the St. Vincent Medical Center in Portland, Oregon, show that the implementation of a perioperative insulin infusion protocol in 1991 resulted in more than a 50% reduction in deep sternal wound infections (21). Mean blood glucose levels with the continuous insulin infusion protocol were significantly lower than those achieved prior to 1991 with subcutaneous insulin (199 \pm 1.4 vs. 241 \pm 1.9 mg/dL on the operative day; 176 \pm 0.8 vs. 206 ± 1.2 mg/dL on postoperative day 1). During the period of analysis, the rate of deep sternal wound infections in the nondiabetic patient population remained constant, suggesting a causal link between the improved perioperative glucose control and reduced infection risk.

There is no definitive evidence from randomized controlled clinical trials demonstrating that tight glycemic control reduces rates of perioperative infection. However, the evidence that hyperglycemia directly impairs immune function and the weight of the empiric data showing a link between perioperative glycemic control and risk of infection provide support for a policy of aiming for blood glucose levels of less than 200 to 220 mg/dL in the surgical patient.

Risks of Hypoglycemia

The goal of avoiding hyperglycemia needs to be balanced against the increased risk of hypoglycemia associated with tight glycemic control. In the hospitalized patient with diabetes, the major concern related to hypoglycemia is the potential triggering of ventricular arrhythmias. Circumstantial evidence links hypoglycemia with sudden death in patients with diabetes, and experimental clamp studies have demonstrated that the epinephrine surges that occur with hypoglycemia can be accompanied by alterations in ventricular repolarization and ectopy (22,23). However, data from the Diabetes Mellitus Insulin Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study suggest that the risks from hypoglycemia in the hospitalized diabetic patient are minimal. In this study, 306 patients with type 2 diabetes presenting with myocardial infarction (MI) were randomized to an intensive treatment protocol with an intravenous insulin-glucose infusion. Fifteen percent of these patients had at least one episode of hypoglycemia [predefined as a blood glucose level <3 mmol/L (54 mg/dL)], and none of these episodes were associated with any direct harmful effects (24).

Outcome Following Myocardial Infarction

The importance of intensive glycemic control in improving outcome following MI remains controversial. Patients with diabetes who have blood glucose concentrations ≥11 mmol/L at presentation of MI are at greater risk for in-hospital mortality (25). Although stress hyperglycemia may simply be a marker of the severity of illness, several plausible biologic mechanisms could account for this association. The relative insulin deficiency underlying the hyperglycemia will limit myocardial glucose uptake, and energy generation becomes increasingly dependent on free fatty acids, which are toxic to the ischemic myocardium (26). Moreover, the insulin deficiency will trigger lipolysis, thereby increasing circulating levels of free fatty acids. In addition, insulin deficiency leads to increased activity of plasminogen activator inhibitor type-1 (PAI-1), with a resultant impairment in fibrinolysis (27). In the DIGAMI study, the patients presenting with MI randomized to the intensive-treatment protocol with intravenous insulin had an improved outcome. However the subset analysis revealed that only those patients in the intensivetreatment arm who were categorized as low risk and who were not receiving insulin at presentation demonstrated this benefit (28). This raises the possibility that it was not the intensive management but rather the withdrawal of other diabetes therapies (such as sulfonylureas) that led to the improved survival after MI (29). Although the DIGAMI data do not unequivocally demonstrate that the tight peri-MI glycemic control per se accounted for the improved outcome, the intensive treatment regimen did not lead to any harmful complications in the study (24). The physician should consider use of an intravenous insulin infusion to maintain tight glycemic control if the MI patient is in a coronary care unit where intense monitoring allows the safe implementation of this regimen.

CONSIDERATIONS IN CLINICAL DECISION MAKING

Clinical decisions about how to manage diabetes in the hospitalized patient rest on several considerations.

Risks of Oral Agents in the Hospitalized Patient

Lactic acidosis is a rare, but serious, complication of metformin therapy, and this agent should be withheld from at-risk patients (30). The recommendation to withhold metformin includes the following conditions: radiologic procedures with dye loads (risk of renal impairment with delayed drug clearance), major surgery (risk of hypoperfusion with anaerobic metabolism and lactate generation), general anesthesia in patients with autonomic neuropathy (high risk of hypotension) (31), ischemic limbs (anaerobic metabolism and lactate generation), hepatic disease (impaired lactate metabolism), and cardiorespiratory failure with hypoxia.

Sulfonylureas are associated with an increased risk for prolonged drug-induced hypoglycemia in the patient with reduced caloric intake, renal disease, and a previous history of hypoglycemia (32), and these agents should be used judiciously in the hospitalized patient with these characteristics.

The use of sulfonylurea agents to manage diabetes in the patient presenting with acute MI is controversial. Sulfonylureas block the adenosine triphosphate (ATP)–sensitive potassium channels present in the myocardium and coronary vasculature, and this action impairs ischemic preconditioning and the coronary vasodilatory response to ischemia (33). Retrospective data from the Mayo Clinic showed a significantly higher in-hospital mortality following coronary angioplasty treatment for acute MI in those patients with diabetes treated with sulfonylurea agents (34). Subset analysis from the DIGAMI study also points to a possible deleterious effect of sulfonylurea therapy on post-MI outcome (28). However, no relationship between treatment with sulfonylureas and adverse outcome following MI was noted in a recent analysis of the Health Care Financing Administration database of 64,171 elderly patients with diabetes (35).

Type of Diabetes

In patients with type 2 diabetes controlled with oral agents, the major consideration of the physician deciding on initial therapy is whether the patient is likely to have sufficient β -cell insulin secretory capacity to counteract the insulin resistance that develops with hospitalization. In the absence of adequate β -cell reserve, insulin therapy is necessary. The patient with well-controlled diabetes receiving submaximal dosages of oral agents usually will manage to maintain satisfactory perioperative glycemic control without the medications when taking no calories in orally. In contrast, the patient with poorly controlled diabetes receiving maximal oral therapy will probably not have sufficient β -cell reserve to compensate for the insulin resistance and will need to have insulin therapy initiated.

Despite the insulin resistance associated with illness/injury, the obese patient with insulin-requiring type 2 diabetes often will need considerably less insulin when placed on a controlled diet during hospitalization. The initial response to insulin administered in the hospital often predicts whether the patient is likely to require a reduction in insulin dosage.

Metabolic Response to Hospitalization

Several potential factors and mechanisms contribute to the development of insulin resistance in the hospitalized patient. This includes inactivity, starvation, use of medications such as steroids and dobutamine (36), and the release of counterregulatory hormones triggered by the stress of illness, surgery, and anesthesia. Consideration of all of these factors will help the physician decide whether the patient with type 2 diabetes is likely to need insulin therapy and to anticipate changes in insulin requirements during the hospital course.

65: TREATMENT OF DIABETES IN THE HOSPITALIZED PATIENT 1105

Metabolic and hormonal responses will vary depending on the type of anesthesia and surgery. Barker et al. (37) compared the impact of local versus general anesthesia in patients with type 2 diabetes controlled with diet and oral agents who were undergoing cataract extraction. The patients who received local anesthesia had stable perioperative glucose levels despite omission of the diabetes medications on the morning of surgery. In contrast, the patients who had general anesthesia had significant increases in both the blood glucose and serum cortisol levels, with the glucose rising from a fasting level of 6.6 mmol/L to 8.6 mmol/L 2 hours after the procedure. Thomas et al. (38) have noted that patients with type 1 diabetes undergoing coronary artery bypass grafting require considerably higher rates of intravenous insulin infusion to maintain stable glycemic control than those required by similar patients undergoing general surgery.

The glucose infusion rates typically used in clinical practice do not cover basal energy requirements and are insufficient to suppress starvation ketosis. An infusion of 10% dextrose at 100 cc per hour would provide only 2.2 mg·kg⁻¹·min⁻¹ for a 70-kg person, whereas Wolfe and Peters (39) have demonstrated that fasting normal volunteers require infusions of 4 mg·kg⁻¹·min⁻¹ to suppress lipolysis. Although most fasting patients have reduced insulin requirements, the catabolic state induced by fasting can lead to insulin resistance. Ljungqvist et al. (40) pretreated a cohort of nondiabetic patients with a high-dose glucose infusion (5 mg·kg⁻¹·min⁻¹) overnight before abdominal surgery. Compared with control patients who underwent the same operation in the fasted state, the fed patients had a substantial improvement in insulin sensitivity during the 24-hour period following the abdominal surgery. This catabolismrelated insulin resistance is a major factor underlying the marked glucose elevations that often will develop in the hospitalized diabetic patient with relatively modest intravenous glucose loads.

The administration of Ringer lactate to the patient with diabetes undergoing surgery can markedly increase glucose levels. Lactate is a gluconeogenic precursor, and in situations of stress such as surgery the rate of gluconeogenesis may be enhanced. Thomas and Alberti (41) noted that the mean plasma glucose concentration in a group of patients with type 2 diabetes undergoing major surgery who received 1 to 1.5 L of Ringer lactate increased from 8.5 to 16.0 mmol/L, whereas the glucose concentration in the diabetic control group who did not receive intravenous fluids perioperatively increased only by 2.1 mmol/L.

The importance of the perioperative metabolic state of the patient on the postoperative course has received little attention in clinical care. Nygren et al. (42) subjected a cohort of nondiabetic patients scheduled for elective hip replacement to euglycemic hyperinsulinemic clamps [to induce a state of physiologic hyperinsulemia (serum insulin levels 58 ± 3 to 64 ± 4 μ U/mL)] for 4 to 5 hours before the surgery and throughout the operation. The perioperative insulin and glucose infusion blunted the normal stress response to surgery, as reflected by significant attenuation of postoperative changes in plasma levels of free fatty acid, serum cortisol levels, and fat oxidation, and there was an associated normalization of postoperative insulin sensitivity. In addition to blunting the catabolic response to surgery, the insulin-glucose infusion may have a positive impact on anabolic changes during the recovery from surgery. Levels of insulin-like growth factor 1 (IGF-1) declined less after surgery in the subjects receiving the infusion than in the control subjects. In addition, levels of IGF-binding protein-1 more than halved following the infusion, whereas levels in the control subjects more than doubled. Although IGF-1 activity was not measured directly, these contrasting changes in the two study groups would lead to a marked difference in the bioavailability of IGF-1 that could have an impact on healing and recovery following surgery. Further studies are required to determine whether implementation of this treatment protocol would lead to improved clinical endpoints and shorter hospital stays.

The insulin clamp studies of Nygren et al. (42) suggest that the postoperative deterioration in glucose tolerance is related primarily to a decrease in glucose uptake by the insulin-sensitive tissues rather than to an impairment in insulin-mediated suppression of endogenous glucose production. This has relevance to clinical decision making: When adjusting insulin replacement regimens in the postoperative patient who is hyperglycemic, the physician should give initial consideration to increasing insulin coverage during the day to enhance disposal of consumed glucose by the insulin-sensitive tissues rather than to increasing overnight insulin coverage.

Other Considerations

When making insulin adjustments for the patient receiving glucocorticoid therapy, the physician needs to consider the pharmacokinetic action and dosage schedule of the steroid. For example, prednisone taken at breakfast will lead to insulin resistance in the afternoon that can usually be covered by prebreakfast intermediate insulin. Patients receiving high-dose prednisone will require proportionately larger insulin doses, and some patients will develop late-morning hypoglycemia due to the onset of the intermediate insulin, an effect that can be obviated by having the patient take this insulin midmorning. Patients receiving prednisone in the morning will often have relative adrenal insufficiency overnight, and bedtime insulin coverage will need to be reduced accordingly.

Nutritional supplements given to the hospitalized will often contain substantial amounts of carbohydrate despite their being labeled "no added sugar." For the hospitalized diabetic patient with marked glycemic excursions, the physician needs to exclude carbohydrate-containing nutritional supplements as a contributing factor.

The accuracy of bedside glucose monitors will be affected by the hematocrit level. Anemia (with hematocrits in the range of 20%) will result in an overestimation of the glucose level, and this can mask the diagnosis of true hypoglycemia (43). Consumption of high doses of ascorbic acid by the patient will lead to the overestimation of glucose levels by the Accu-Chek and Precision devices. Therapeutic acetaminophen and dopamine concentrations will also interfere with the accuracy of some bedside glucose monitors (44).

TREATMENT GUIDELINES

Several comprehensive reviews (3,45–47) present specific guidelines for inpatient diabetes management. Figure 65.1 shows an algorithm commonly used by staff at the Joslin Clinic in the care of the diabetic surgical patient. Tracer studies have shown that major surgery has no effect on the absorption rates of subcutaneously injected neutral protamine Hagedorn (NPH) insulin (48). It is our practice to give intravenous glucose from midnight onward to patients who are in the hospital the evening before surgery. These patients generally receive their usual evening dose of intermediate insulin. For patients admitted to the hospital the morning of surgery, we recommend that the dose of intermediate insulin in the preceding evening be reduced by 10% to 20%. This minimizes the risk for hypoglycemia during the early morning activity involved in coming

to the hospital. Previous recommendations (3) that the evening intermediate insulin be withheld were based on the use of animal insulins that have a longer duration of action than biosynthetic human insulin.

Insulin sliding scales have an important role in the inpatient management of diabetes. The assertion by Queale et al. (49) that sliding scales are of no benefit in this setting is not valid because this conclusion was based on a retrospective analysis of severely ill patients whose sliding-scale dosages were not appropriately individualized. Moreover, many patients examined did not have basal insulin coverage. "Corrective" sliding scales that start at glucose levels greater than 175 to 200 mg/dL have an important role in preventing severe hyperglycemia in the hospitalized patient. However, with the exception of patients whose diabetes is readily controlled by diet or modest dosages of oral agents, sliding scales alone usually do not provide adequate diabetes control for the hospitalized patient. Patients whose diabetes is well controlled out of the hospital with submaximal doses of oral agents usually will require corrective sliding-scale insulin coverage in addition to their usual diabetes medications when hospitalized with a medical illness. In contrast, patients whose diabetes is poorly controlled with maximal oral therapy usually do not have the β -cell reserve to compensate for the insulin resistance associated with illness; these patients, like patients with type 1 diabetes, will require basal coverage with intermediate- or long-acting insulin formulations in addition to the sliding scale.

In writing insulin orders for the hospitalized patient, the physician should make a distinction between sliding scales used to "correct" hyperglycemia and "anticipatory" premeal sliding scales required in patients with absent or markedly impaired β-cell function to provide fast-acting insulin to cover anticipated carbohydrate intake. Anticipatory sliding scales should provide premeal insulin coverage even if the premeal glucose level is in the desired physiologic range. Typically, the patient who receives morning and bedtime intermediate insulin will require anticipatory prebreakfast and predinner slidingscale insulin and compensatory coverage before lunch and at bedtime. The patient whose basal insulin requirements are covered by ultralente or insulin glargine will lack the lunchtime insulin coverage provided by the morning intermediate insulin and will require anticipatory insulin coverage before breakfast, lunch, and dinner with compensatory coverage at bedtime. The physician will need to review the patient's response to administered insulin to assess if dosages require adjustment: the initial sliding scale written usually provides for additive increases in the insulin dosages as the glucose level increases; however, because of hyperglycemia-induced insulin resistance, many patients will require relatively greater insulin dosages at high glucose levels and the sliding scale coverage in the upper range will need to be disproportionately greater.

Although there have been no comprehensive studies of continuous subcutaneous insulin infusion (CSII) during surgery, in our experience CSII provides good metabolic control perioperatively. At our institution most patients receiving CSII continue it during surgery. Patients receiving CSII who are undergoing major surgery for which there may be hemodynamic instability and concern about potential problems with absorption of subcutaneous insulin will usually be given CSII perioperatively. Basal CSII rates are generally left unchanged from usual settings. Provided that the glucose level before the surgical procedure level is in the target range, the levels after the procedure are generally within acceptable limits. During the preoperative period, the patient should go through the formal process of ensuring that the basal-rate settings are correct by skipping meals. The patient should change the infusion catheter the day

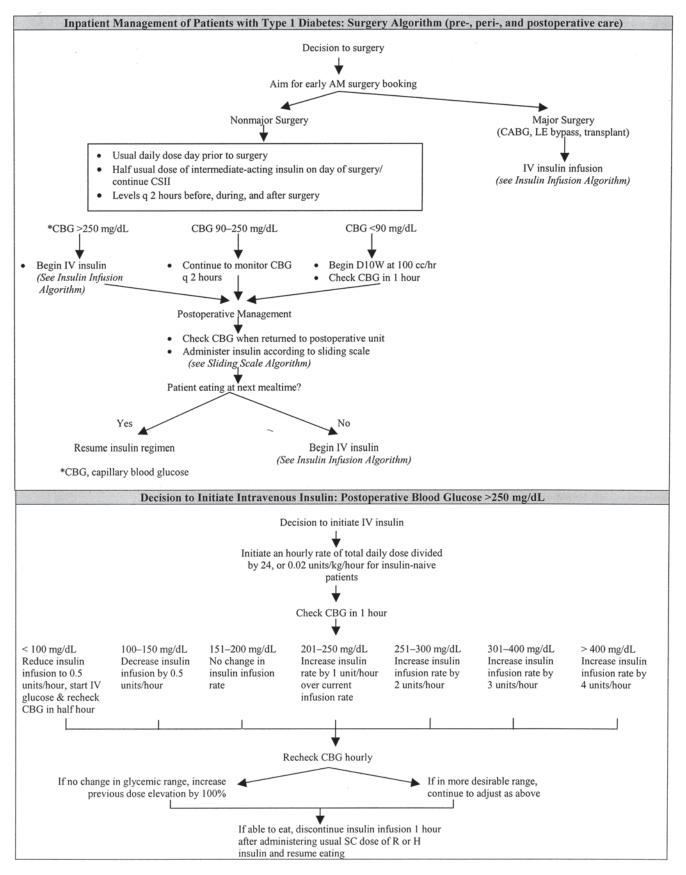

Figure 65.1. Inpatient management of patients with type 1 diabetes: surgery algorithm (pre-, peri-, and postoperative care).

before, and it is important to ensure that the catheter is placed in a site that does not interfere with the surgical field and that the cannula and tubing are securely fastened.

Intravenous insulin is the most precise means of managing diabetes perioperatively, and several different regimens have been recommended. Alberti has been a proponent of the use of glucose-insulin-potassium infusion (45,50). With this regimen, fixed concentrations of glucose, insulin, and potassium are mixed up in a single bag and the infusion rate is adjusted according to the perioperative blood glucose measurements. The proportion of insulin to glucose (expressed as units per g) in the infusate mixture prepared before surgery will be varied depending on the patient's condition and the planned procedure: liver disease, 0.5–0.6; obesity, 0.4–0.6; severe infection 0.6–0.8; steroid therapy, 0.5–0.8; cardiopulmonary bypass, 0.8–1.2; and other circumstances, 0.3–0.4.

Although studies have established the efficacy of the glucose-insulin-potassium infusion in perioperative diabetes management (51,52), this approach is limited by the need to mix up a new bag with a different proportion of insulin and glucose every time the glucose level is out of the target range. The use of a separate glucose infusion and a variable-rate insulin infusion gets around this problem. The starting insulin infusion rate will need to be individualized depending on several considerations, including the patient's usual insulin requirements, the blood glucose level, and identifiable factors that affect insulin sensitivity.

Because of the short half-life of intravenous insulin, interruption of the infusion rapidly leads to metabolic decompensation. Some authors (48) have suggested that this problem might be prevented by also giving a subcutaneous depot of intermediate insulin to patients receiving continuous intravenous insulin. Patients who are sedated or under anesthesia are at particular risk for developing unrecognized hypoglycemia, and the patient receiving CSII to maintain tight glycemic control requires frequent glucose monitoring.

CONCLUSION

Improvements in anesthesia and perioperative care have markedly improved the outlook for the patient with diabetes. There are no definitive data from randomized clinical trials indicating that tight glycemic control will shorten hospital stays or improve wound healing and the outcome for the hospitalized patient. However, the weight of evidence indicates that the metabolic state of the patient is an important determinant of prognosis and that risks from hypoglycemia in the hospitalized patient are minimal. Treatment plans and goals will obviously need to be individualized. However, if available resources permit, the physician should strive to ensure tight metabolic control in the hospitalized patient.

Diabetic foot disease affects nearly 2 million patients with diabetes in the United States annually (1). This places an inordinate social and economic burden not only on the United States healthcare system but also on the families of these patients. It is estimated that almost \$200 million is spent annually strictly for the care of the diabetic foot (2). This represents only the direct costs of hospitalization, medications, and surgery. Indirect costs such as lost employment, disability, and stress on the family unit cannot even be estimated. More amputations are performed in patients with diabetes than any other group of patients.

The management of diabetic foot disease is focused primarily on avoiding amputation of lower extremities. This goal is carried out through three main strategies: identification of the "at-risk" foot, treatment of the acutely diseased foot, and prevention of further problems. Vital to the success of any program is education of the patient and family members. A comprehensive program of diabetic foot management must include each of these aspects for successful salvage of limbs.

These goals are best met by the establishment of a dedicated limb-salvage team. The members of this team must be dedicated to meeting the challenge of the patient with diabetes whose fears of limb loss are rivaled by fears of blindness and kidney failure (3,4). Members of this team most commonly include a podiatrist, an endocrinologist, a vascular surgeon, and a pedorthist. The team also may include plastic surgeons, infectious disease specialists, orthopedic surgeons, and diabetes teaching nurses. All players must know their role and be available in a timely fashion for consultation.

Several systems exist for grading the at-risk foot (5–7). The main purpose of any classification system is to standardize descriptions of lesions and to formulate algorithms for treat-

ment. While each system claims to be complete, all have pitfalls. Identifying the patient with diabetes at risk for ulceration requires examination of the feet, including the vascular and neurologic systems, skin condition, and foot structure.

IDENTIFICATION OF RISK FACTORS

While certain clinical features are known to increase the risk for lower-extremity amputation, peripheral sensory neuropathy has been identified as the major risk for diabetic foot ulceration (8). Pecoraro et al. (9) placed peripheral sensory neuropathy in the face of unperceived trauma at the entrance to the pathway to ulceration and amputation (Fig. 66.1). The inability of a patient with diabetes to feel pain places him or her at significant risk for future foot problems. Knowledge of this condition and education on preventive measures are critical to the patient's ability to avoid ulcerations. However, even with appropriate preventive measures, ulcerations will develop. Unperceived or unintentional trauma occurs that results in breaks in the skin and inoculation by bacteria.

Clinically significant peripheral sensory neuropathy can be detected by using a 128-millihertz (mHz) tuning fork and a 5.07 Semmes–Weinstein monofilament wire as screening tools to identify at-risk patients (10–12). While loss of vibratory sensation is the initial step in the development of clinically significant neuropathy, grading with a tuning fork is often a subjective exercise without scientifically established norms. A biothesiometer provides more objective documentation of a patient's ability to perceive vibratory sensation. Clinical studies have determined a vibratory perception threshold of 25 mHz as identifying patients at risk for ulceration (13). This instrument, how-

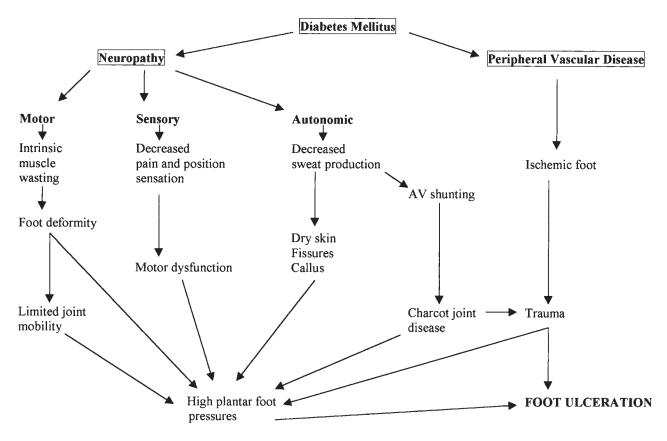

Figure 66.1. Clinical pathways leading to foot ulceration.

ever, is not readily available to the practicing clinician. It is used primarily in clinical trials where documentation of the degree of sensory neuropathy is important in stratifying groups.

The 5.07 (10 g) Semmes–Weinstein monofilament wire is an effective and inexpensive device to identify the patient at risk for foot ulceration. Several clinical trials have demonstrated that patients with diabetes who are unable to perceive this gauge of monofilament wire are at a statistically significant higher risk for development of ulceration than are patients who are able to detect the wire (12). Proper use of the wire requires application of the wire against the foot with enough force to gently bend the wire (Fig. 66.2). Inability to feel the wire implies lack of adequate protective sensation. By testing different sites

on the foot, areas of insensitivity can be mapped and identified to the patient. These patients then must be educated on the significance of sensory neuropathy and the steps to preventing foot ulcerations. Regular evaluation by a foot care specialist is recommended for these individuals.

Formal nerve conduction studies in patients with diabetes have not been shown to alter treatment planning. Nerve conduction studies are rarely helpful or necessary for the evaluation of neuropathy. Many patients with type 2 diabetes have clinically significant neuropathy at the time of diagnosis, and nerve conduction studies will be abnormal in the majority of these patients.

Motor neuropathy can produce foot deformities that put the foot at risk for ulceration (Fig. 66.3). Loss of innervation of the

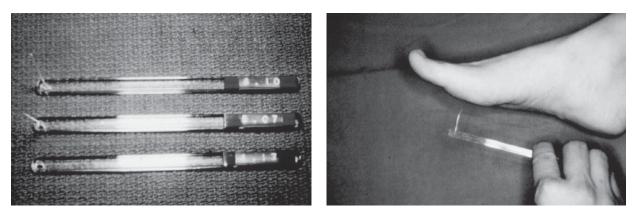

Figure 66.2. Proper use of the monofilament wire requires application of just enough pressure to bend the monofilament.

Figure 66.3. The intrinsic minus foot is particularly vulnerable to ulceration as a result of the digital and plantarflexion deformities that may occur.

intrinsic musculature of the foot can lead to common foot deformities such as hammer toes, claw toes, and plantar-flexed metatarsals. Plantarly prominent metatarsal heads result in areas of high focal pressures that have been shown to increase risk for foot ulceration. Digital deformities can be irritated dorsally by shoe gear, resulting in corns or even ulcerations.

Autonomic neuropathy, although less common than peripheral sensory neuropathy, can also affect the feet. Most commonly, autonomic neuropathy affects local temperature regulation and the function of sweat glands. Loss of sweat production can lead to dry skin (14). Untreated this can lead to cracking and fissuring, especially in the heel, creating a portal of entry for bacteria.

Peripheral vascular disease by itself is responsible for only a small percentage of diabetic foot ulcerations. Only 15% of all diabetic foot ulcers are purely ischemic (15). However, arterial insufficiency can lead to nonhealing of ulcerations once they have developed. The single most important indicator of adequate perfusion is the presence of palpable pedal pulses. Additional clinical maneuvers to assess vascular status should include measurement of the venous filling time and evaluation for dependent rubor and pallor on elevation. The presence of a slowly or nonhealing ulceration in the face of absent pulses warrants further evaluation. This may be in the form of noninvasive arterial studies. Pulse volume recordings and the character of the distal pulses on Doppler evaluation (monophasic vs. triphasic) can provide valuable information on the patient's ability to heal the ulceration. Although ankle-brachial indices (ABIs) are measured, they are of limited usefulness in the patient with diabetes. The ABIs often are artifactually elevated due to medial calcinosis of pedal vessels. Assessment of a patient's ability to heal should not be based solely on this measurement. The presence of a nonhealing ulceration with clinical or objective evidence of arterial insufficiency warrants a prompt referral to a vascular surgeon (16).

The areas under the metatarsal heads are the most vulnerable areas for plantar ulcerations. These areas have been identified as having high focal pressures in patients with diabetes (17–19). A symptom of these high pressures is the presence of callus tissue under a metatarsal head. This most commonly results from plantarly prominent metatarsal heads, as occurs in the intrinsic minus foot and when the plantar fat pad atrophies (20,21). More recently, an association between limited joint mobility and high plantar foot pressures has been discussed as a risk factor for foot ulcerations (22,23). Other causes of high foot pressures include developmental foot deformities such as bunions, hammer toes, or rocker-bottom deformities from Charcot joint disease.

Quantitation of plantar foot pressures in the form of vertical load is possible with various computerized pressure-sensing equipment (24). These devices are expensive for most private practitioners and are most useful as a research tool. A Harris mat (ink-impregnated foil that demonstrates pressure points in static stance), however, is a simple, inexpensive tool that can be helpful in identifying areas of high plantar foot pressures.

CLASSIFICATION OF ULCERATIONS

As previously noted, several classification systems for grading ulcerations exist (6). Classification systems have two primary purposes: (a) to provide healthcare professionals with a common language to describe and understand common conditions, in this case diabetic ulcerations; and (b) to help direct the management and treatment of these conditions. While these are noble and useful purposes, there are also notable deficiencies in each of these grading systems. Some neglect the importance of ischemia, others are too complex to remember, and others are not completely applicable to diabetic ulcers but are more appropriate to pressure or decubitus ulcers. Nevertheless, for the purposes of this book, the Wagner classification has been selected for the discussion of ulcerations and their management, as it is the simplest, best known, and most widely used system. One should, however, by aware of its shortcomings. The Wagner classification system is based strictly on ulcer description and depth. It ignores the importance of ischemia and infection in determining the severity of the ulceration. In other words, although a Wagner grade 1 or 2 ulceration in a patient with adequate blood flow can often be managed with little to no complications, a similar condition in patients with poor perfusion can be a limb-threatening condition.

Grade 0 Foot

The Wagner grade 0 foot is the diabetic foot without ulceration but with one or more risk factors. Clinically significant sensory neuropathy as described above is one such risk factor. Other risk factors include bony deformities, atrophic fat pad, plantarflexed metatarsals, peripheral vascular disease, and Charcot joint disease. Dermatologic conditions also may pose risks to the grade 0 foot. Such conditions include dry, scaly skin with fissures, or thickened, discolored nail plates as seen in chronic onychomycosis. Although peripheral sensory neuropathy is the primary component cause for ulceration, the predictive index for ulceration increases significantly with each additional component cause identified (25). This constellation or grouping of risk factors is referred to as sufficient causes for ulceration (i.e., two or more component causes equal a sufficient cause for ulceration) (25).

Appropriate evaluation of this foot should include a careful neurologic examination using the 5.07 Semmes–Weinstein monofilament wire (26). Mapping of insensate areas helps the patient and the physician identify vulnerable areas. The foot should be closely inspected for corns or calluses, because these areas will identify focal pressures or irritation that may lead to ulceration. The vascular examination should include palpation of pedal pulses and observation for pallor with elevation or rubor on dependency. The physician should inspect for fissures either on the heels or in the interdigital spaces.

Management of the grade 0 foot centers on a program of education and prevention. Patients should be educated about the risks associated with the neuropathic foot and instructed on the early signs of inflammation, irritation, and infection and the initial treatment of these conditions. They should also be edu-

TABLE 66.1. Advantages of Changing Shoes

Prevents accumulation of pressure in any one area Maintains support from the upper Maintains shock absorption from the outer sole Allows inspection of the foot

cated on the importance of good glycemic control in the management of foot disease.

Disease prevention in this patient population may include shoe-gear modification to decrease plantar foot pressures and to accommodate foot deformities and the use of orthotic devices and padded hosiery to further decrease plantar foot pressures (27,28). The simple habit of changing shoes every 4 hours can also help modify plantar foot pressures. This simple technique has several advantages in ulcer prevention: (a) it prevents the accumulation of pressure over any one area of the foot for extended periods; (b) it reduces loss of shock absorption and support functions of the outer soles and leather uppers, which occur the longer a shoe is worn; (c) it provides the patient with the opportunity to inspect his or feet frequently, allowing earlier detection of potential foot lesions (Table 66.1).

Regular visits to the foot specialist are recommended as part of a program of education and prevention. Depending on the patient's risk category, these visits should be scheduled annually, semiannually, or more frequently. Pulses should be palpated and any lesion should be noted at each visit. Corns and calluses should be debrided (29–31). The patient should be instructed on the proper care of the nails and skin. Moisturizing creams should be prescribed for application to the bottom of the foot for dry, scaly skin to avoid fissures. The interdigital spaces should also be inspected for fissures or evidence of tinea pedis.

The single most important aspect of preventive self-care is for the patient to inspect his or her feet daily. In those situations in which patients are unable to perform this function themselves, a family member should receive instruction on how to do this properly. Proper inspection involves inspecting the bottom of the foot visually and feeling it for lesions such as blisters, loose skin, or open sores. Patients also should note any areas of unexplained swelling or redness. The interdigital spaces are particularly problematic areas. They should be inspected and kept dry to prevent maceration, which may lead to athlete's foot and secondary bacterial infection.

Grade 1 Foot

The grade 1 ulceration implies the presence of two or more risk factors: peripheral sensory neuropathy and at least one other risk factor, such as bony deformities, plantarly prominent metatarsal heads with distally displaced fat pad, limited joint mobility, or ill-fitting shoes. The grade 1 ulceration extends to the dermis but not beyond (5). The evaluation of ulcerations should include a search for risk factors and an underlying cause. Ulcerations themselves should be evaluated for size, depth, and location. Knowledge of the anatomic structures involved, as well as the presence of any infection, will help direct treatment. The presence and type of drainage should also be noted. Cultures are of limited usefulness at this stage as the ulceration likely will be colonized with multiple organisms representing primarily skin flora (32).

Treatment most commonly requires soft-tissue debridement and elimination of all pressure from the site of ulcerations (8). Ulcerations most commonly will have some degree of hyperkeratosis surrounding the ulcer bed. In many cases, this callus tissue will overhang the margins of the ulcer, thus preventing ulcer healing from the "inside out." Therefore, all exuberant hyperkeratotic tissue must be debrided to a healthy granular bed that will support further granulation. Debridement has the added advantage of promoting dependent drainage and perhaps stimulating growth factors. Studies have suggested that ulcers that have undergone aggressive debridement may heal faster (33).

The second important concept of wound healing is off-loading, the technique by which pressure at the site of the ulceration is eliminated or reduced. There are various means of accomplishing this. The most effective is total non–weight-bearing on the affected extremity by means of crutches or a walker. This is often impractical for most patients, making compliance a serious issue. Therefore, techniques such as the total-contact cast and felted foam dressings have been devised as a compromise to relieve pressure, increase compliance, and improve the chances for healing (34–37).

Dressings are changed daily to provide a moist wound environment, which has been shown to be conducive to wound healing. Normal saline, hydrogels, and growth factors are acceptable choices for superficial ulcerations without active drainage or infection. Harsh, undiluted chemicals should be avoided, as they can be toxic to granulation tissue (38). Topical antibiotics have limited usefulness in this setting (39). If an infection is suspected, it is best treated with systemic antibiotics. Oral antibiotics are recommended only when clinical signs of infection are present (i.e., erythema, purulent drainage). Overuse of oral antibiotics may lead to superinfection or development of resistant strains. Exceptions to this rule include patients with severe peripheral vascular disease, in whom development of infection may be limb-threatening, or in patients receiving immunosuppressive medications, as in kidney or kidney/pancreas transplant recipients.

Repeated ulcerations may warrant consideration of surgical correction of any underlying structural deformity. Metatarsal osteotomies, digital arthroplasties, and metatarsal-head resections have all proven useful in the prevention of recurrent ulcerations (40–45).

Grade 2 Foot

Failure to adequately off-load grade 1 lesions likely will lead to deepening ulcerations beyond the level of the dermis (5). Deeper structures such as tendons or joint capsule may often be involved (grade 2). Appropriate management of these ulcerations depends on the accurate assessment of ulcer depth and the structures involved.

The most accurate and cost-effective method for assessing ulcer depth is to probe the ulcer base gently with a stainlesssteel blunt probe. This technique can detect undermining of the ulceration, presence of any penetrating sinus tract, and involvement of deeper structures (Fig. 66.4). The ability to probe bone with this simple technique has an 89% specificity for the diagnosis of osteomyelitis. This compares favorably with more expensive and invasive tests such as labeled white blood cell (WBC) scans and magnetic resonance imaging (MRI) (46). Bone, joint, or tendon involvement should alert the clinician to the possible need for hospitalization, complete bed rest, surgical debridement, and broad-spectrum intravenous antibiotics (47).

Areas of undrained infection should be opened and drained dependently. Although most of these debridements can be performed at the bedside in severely neuropathic patients, if the infection is expected to be extensive, the patient should be brought to the operating room for a thorough debridement. The wound is then packed open (47). All nonviable, necrotic tissue

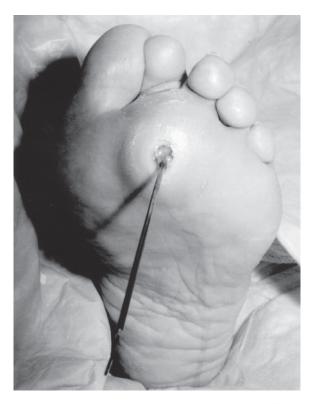

Figure 66.4. A blunt stainless steel probe is a clinically cost-effective tool for diagnosing osteomyelitis.

should be sharply debrided. This may often require the removal of infected tendon and/or bone. Antibiotics are adjusted to cover the offending organisms. The choice of antibiotics should be based on deep cultures taken at the time of surgery (48).

The clinician often may delay or avoid the aggressive debridement of the infected foot in patients with ischemia. Such delay may actually lead to further tissue loss and potential limb loss. The infection should be controlled first by debridement. Once this is accomplished, an arteriogram and lower extremity revascularization should be performed in the patient with an ischemic limb to prevent further tissue loss and to salvage the limb (49). Recent advances in vascular surgery and anesthesia have made this option safe and successful in patients with diabetes (49).

Although radiographs are not always sensitive enough to make the diagnosis of osteomyelitis, they should be performed on all long-standing, full-thickness ulcerations to evaluate for osteomyelitis. Bone scans, labeled WBC scans, MRIs, and bone biopsies have been recommended as more sensitive studies for diagnosing osteomyelitis (50–54). However, any of these modalities can result in false-positive and false-negative diagnoses. Once again, the ability to probe bone with a blunt, sterile probe is both reliable and cost-effective in diagnosing osteomyelitis (46).

Not all patients with grade 2 ulcerations require hospitalization (16). Outpatient treatment of these lesions must follow the same principles as those applied to treating grade 1 ulcerations, namely strict adherence to non-weight-bearing if healing is expected to occur. Although rare, ulcerations over exposed tendon and capsule have the ability to granulate. The same strategies to off-load grade 1 ulcerations (e.g., felted foam dressings, total-contact cast) should be applied to grade 2 ulcerations. Dressings typically are changed twice daily because of the increased drainage that commonly occurs with these ulcerations. It is best if dressings are changed by a healthcare professional, such as a visiting nurse, trained in recognition of early signs of infection. Oral antibiotics, while often not necessary in grade 1 ulcerations, are more commonly prescribed in grade 2 ulcerations because of the depth of the ulcerations, the vital structures involved, and the presence of drainage, creating an ideal environment for bacterial growth. First-generation cephalosporins are often a good initial choice as they provide broad-spectrum coverage and good coverage of staphylococci (55,56). Any changes in antibiotics should be based on deep wound cultures and sensitivity as well as the clinical response of the wound.

The care of the foot following complete healing is just as important as the care provided to rid the foot of infection. Regular patient follow-up is essential to ensure proper wound healing and assess the effectiveness of any orthotic device and shoegear modification. This is especially important in cases in which metatarsal heads have been resected, either single or multiple. One can expect that additional pressure will be transferred to adjacent metatarsal heads (57). It is therefore important for the foot to be protected with an appropriate orthotic device. These patients will also require education on selection of appropriate shoe gear. Conventional jogging shoes fitted with an orthotic device are appropriate for most patients with diabetes. However, patients with more severe foot deformities need specialized shoe gear. Extra-depth shoes that have a deep toe box may be required (Fig. 66.5). In some cases custom-molded shoes may be necessary. Patients also need to be educated on the care of the foot. Daily care should consist of daily inspection, especially between the toes, and the daily use of an appropriate moisturizing cream on the heel and the sole of the foot to avoid fissures. Both the inside and the outside of the shoes should also be

Figure 66.5. The rounded, deeper toe box of an extra-depth shoe is helpful in accommodating deformities such as bunions and hammer toes.

inspected every day. The patient should understand the need for regular visits to a foot specialist for continued monitoring.

Grade 3 Foot

Grade 3 ulcerations typically result from grade 2 ulcerations that have not responded to local care or have been neglected. Less common causes include particularly aggressive bacteria that result in early and rapid tissue necrosis and puncture wounds that lead to direct inoculation of underlying bony structures. Invariably, these ulcerations involve bone. Therefore, hospitalization and surgical debridement often is necessary.

The key to managing grade 3 ulcerations is to perform an adequate incision and drainage procedure of any underlying infection (47). Any sinus tract discovered must be explored. Any abscess must be drained, and all devitalized tissue must be debrided. In some cases, open amputations may be required to control the spread of infection and achieve limb salvage. This should be performed initially without regard to the vascular status of the limb.

After the infection has been cleared and healthy granulation tissue is seen, thought can be given to surgical reconstruction of the wound and foot. This may involve simple delayed primary closure or more complicated reconstructive surgery, including additional bone resections, tissue flaps, or skin grafts (58). No single technique can be applied to all wounds. A flexible approach to wound closure will maximize limb salvage. These lesions will make maximum use of all members of the diabetic foot team (49,59).

Because ablative surgery is common in the grade 3 foot, pressure is often transferred to adjacent areas of the foot, increasing the risk of chronic ulcerations. The long-term management of the grade 3 foot must emphasize prevention of transfer ulcerations. Prevention of recurrent ulcerations requires knowledge of orthoses and footwear. These at-risk patients should be encouraged to schedule regular visits to their podiatrist for the purpose of preventive diabetic foot care, education, and evaluation of orthoses and footwear. When orthoses and shoe gear are worn out, they should be replaced immediately. The goal of these interventions is to distribute plantar foot pressure evenly and avoid concentrating pressure in any one area.

Grade 4 Foot

Diabetic patients with grade 4 lesions may pose several challenges, including a variety of underlying risk factors. The cooperation and involvement of a dedicated limb-salvage team will often be required to help manage the various issues encountered in this particular group of patients. The team may include vascular surgeons, podiatrists, plastic and reconstructive surgeons, and orthopedic surgeons. The primary goal is to limit the amount of tissue loss and maintain a functional extremity.

Gangrenous changes in the lower extremity can commonly occur in one of two ways. Minor injury to the foot can result in gangrenous changes of the skin when severe arterial insufficiency is present (9). Injuries such as puncture wounds, superficial abrasions, or heel fissures may appear minor. Yet, they can have devastating consequences in the patient with arterial insufficiency. The arteries below the level of the popliteal artery are most commonly affected. This results in lack of adequate perfusion and oxygenation. Initially, there may be a focal area of necrosis. If not corrected, tissue loss will increase, leading to dry gangrene. The second potential cause of gangrene is overwhelming infection. In this case, occlusion of digital arteries can occur as a result of marked edema of the local tissue or an infective vasculitis (60). The clinical findings described as "wet gangrene" result from infective vasculitis. It is therefore imperative to identify the underlying cause in the hope of minimizing further tissue loss. When gangrene results from arterial insufficiency, an immediate vascular assessment should be instituted and lower-extremity revascularization performed where possible (61). If infection is the primary cause, selection of an appropriate antibiotic and aggressive debridement with adequate incision and drainage is the treatment of choice.

The vessels most commonly affected by diabetic vascular disease are the anterior and posterior tibial arteries. A significant clinical feature of the diabetic foot is that the foot vessels (i.e., dorsalis pedis) are often spared (62,63). This is significant because it makes distal arterial bypass procedures possible and effective. This contradicts the concept of "small-vessel disease," which has been associated with the diabetic foot since the late 1950s. It previously was believed that lack of healing of diabetic foot ulcers was due to occlusive disease of the digital arteries (64). Several investigators have shown that this does not occur (65). Most vascular surgeons and individuals who deal with the diabetic foot on a regular basis believe that small-vessel disease is not a major issue in the diabetic foot.

Adequate preoperative evaluation for arterial insufficiency requires visualization of the pedal arteries. The current standard of care dictates the use of digital subtraction angiography (DSA) to assess the level of revascularization accurately (49). Once revascularization has been performed, an amputation at the most distal level that will support healing should be performed with consideration to preserving as much of the weightbearing surface of the foot as possible. This will allow more efficient ambulation, better distribution of plantar pressures, and easier shoeing of the foot.

When gangrene results from extensive or overwhelming infection, immediate incision and drainage must be performed, because any delay in treatment may lead to systemic toxicity, including a substantial risk of mortality. This may necessitate open amputation and should be performed even in the face of arterial insufficiency. Once control of the infection has been established and the patient is stable, thought should turn to foot salvage. This may require revascularization or reconstructive surgery of the foot and ankle.

Grade 5 Foot

The only treatment for extensive necrosis of the foot is primary amputation. Arterial occlusion and lack of arterial inflow are the main causes of gangrene. Even in these advanced cases, patients should undergo vascular assessment in the form of DSA and, if possible, revascularization so that the most distal level of amputation that will support healing is performed. It should be remembered that oxygen consumption increases dramatically with more-proximal amputations, increasing work and energy expenditure by the patient during ambulation. Because many of these patients already have some compromise of cardiac function, this becomes an important factor in their postoperative recuperation and in their ability to function independently (66).

CARE OF THE AMPUTATED FOOT

One of the risk factors for recurrent ulcerations is prior foot surgery, either reconstructive or ablative. The partially amputated foot poses special problems due to the loss of the weightbearing surface (67). In basic terms, the same weight-bearing forces that acted before the amputation are at work after the amputation. However, those forces are now distributed over a

TABLE 66.2. Preferred Characteristics of a Shoe

Soft leather upper for accommodation Rigid heel counter for support Cushioned outer sole such as crepe or Vibram for shock absorption Laces rather than slip-ons Change shoes every 4 hours

smaller area. Consequently, the pressure over any one area is increased. In addition, certain types of amputations may lead to muscle imbalances and contractures (68). This can lead to an abnormal gait and further changes in plantar pressures.

Proper protection of these feet requires the use of orthotic devices and, very often, specially designed therapeutic shoes. Custom-molded orthoses should be made of a soft, closedcelled material that will allow for good shock absorption and accommodation of any lesions or deformities. These must be inspected regularly, because they do fatigue and collapse, thus losing their accommodative properties. Shoe-gear modification is almost always necessary for these at-risk feet. Basic recommendations for shoe gear should include a soft upper with a deep or rounded toe box to accommodate deformities such as bunions or hammer toes. The outer sole should be made of a soft shock-absorbing material such as EVA (ethylvinylacetate), crepe, or Vibram. These typically wear well and are the best shock absorbers. Patients should also be encouraged to wear shoes with laces as opposed to loafers, because a better, more supportive fit is provided by a laced shoe. Finally, patients should be encouraged to change their shoes every 3 to 4 hours to avoid pressure points, to maintain the support and stability of the shoe, and to allow patients the opportunity to inspect their feet during the course of the day (Table 66.2). When the patient has severe foot deformities, as those seen with Charcot joint disease, a custom-molded shoe may be the patient's best alternative.

Regular examination by a podiatrist is an important part of preventive care. The role of the podiatrist is to detect early warning signs of impending trouble. The presence of corns or calluses is a sign of focal pressure, from either weight-bearing forces or shoe irritation. The myth that calluses are protective and should not be trimmed has proven to be false (29-31). Any corn or callus should be trimmed by a podiatrist. Nails should be inspected for proper growth and care. Patients with diabetes should be instructed on the importance of avoiding "bathroom surgery" for the self-care of ingrown nails. While cutting nails straight across may be desired, few patients' nails allow this. Current convention dictates that nails should be trimmed according to the contour of the nail. Diabetic patients with profound sensory neuropathy or evidence of peripheral vascular disease should not be allowed to trim their own nails and should seek professional care. Diabetic patients should have their orthoses and shoes evaluated regularly for increased wear and loss of support. When this occurs they should be replaced immediately.

FOOT SURGERY FOR THE DIABETIC PATIENT

Not so long ago, patients with diabetes were advised to avoid foot surgery at all cost. Small-vessel disease and the risk of infections were cited as factors that impaired healing. This misinformation and misconception prevented many patients with diabetes from undergoing potentially limb-sparing foot procedures. Today, a more aggressive approach to the diabetic foot, including earlier surgical intervention, to prevent major amputations has been advocated by various centers (40–45,49,69).

Local surgical intervention may be advised where bony deformities exist, which are known to pose risk for ulceration, or where chronically recurrent ulcerations have failed to heal. Hammer toes and plantar-flexed metatarsals are known risks for ulceration, as they are often areas of high focal pressures. Arthroplasties and metatarsal osteotomies have been shown to be effective surgical treatments to allow primary healing of the ulcer and to decrease the risk of recurrence (41,65). Local surgical procedures such as metatarsal head resections can be performed to resect localized osteomyelitic bone (70,71). Multiple metatarsal head resections can be performed as an alternative to distal amputation and still leave a functional foot capable of efficient ambulation (42,43). Furthermore, maintaining as much of the plantar weight-bearing surface as possible allows better weight distribution.

In recent years, there has been increased discussion on the role of prophylactic surgery in the diabetic patient. Some groups define prophylactic surgery as surgery performed to correct an underlying deformity even in the absence of a history of ulceration (40,69). Other groups subscribe to a narrower definition of prophylactic surgery: surgery performed on those deformities that have a history of ulceration to prevent further ulceration and possible amputation (44).

When surgery is being considered, proper patient selection and preoperative evaluation are tantamount to success. A thorough history and physical examination should be performed, with special emphasis on the cardiac and vascular examination. Whenever possible, surgery should be performed with the patient under local anesthesia with mild sedation to minimize stress on the heart. Many of these surgical procedures are amenable to this type of anesthesia because of the patients' sensory neuropathy (72).

CHARCOT JOINT DISEASE

It is estimated that one in 680 patients with diabetes have Charcot joint disease (73). However, this may be an underestimate, as many cases go undetected until the late stages. Classically, Charcot joint disease presents as unexplained swelling and erythema of the foot. Although there is often a history of trauma prior to the development of the Charcot joint, the trauma may be so insignificant that patients are unable to recall a specific injury. It is often believed that profound sensory neuropathy makes this a painless process. In fact, patients may complain of mild to moderate discomfort. The pain, however, is not in proportion to the degree of bone and joint destruction seen on radiographs (74). Charcot joint disease is one of the most misdiagnosed entities involving the diabetic foot. Common misdiagnoses include osteomyelitis, tendinitis, gout, or acute sprain. It is important to maintain a high index of suspicion when encountering diabetic patients with unexplained painless swelling. In these patients, in the absence of a portal of entry, a diagnosis of Charcot joint disease should be considered until proven otherwise.

Initial evaluation of a suspected Charcot joint should begin with plain radiographs. In most circumstances, no further diagnostic studies are necessary, as the bone destruction is often quite obvious. Computed tomography (CT) scans and MRIs are rarely necessary to make the diagnosis of Charcot joint. CT scans may be useful for preoperative planning if surgical correction of the deformity is being contemplated. Although any joint of the foot can be affected, the most common location is the tarsometatarsal articulations (Lisfranc joint) (73). Charcot joint

1118 JOSLIN'S DIABETES MELLITUS

disease is characterized by three clinical phases: acute, coalescence, and reconstruction or remodeling. The acute phase is characterized by edema, localized warmth, erythema, and joint crepitus with range-of-motion examination. Radiographically, this phase is characterized by osseous debris, fragmentation, and possible subluxations of joints. The degree of fragmentation is variable and most often is related to the particular joints involved and continued ambulation on the fractures.

Once appropriate treatment is instituted, edema and erythema reduce rapidly. As the Charcot joint progresses to the next phase of coalescence, skin temperature begins to equilibrate and joint crepitus diminishes. Plain radiographs will show resorption of osseous fragments and the laying down of new bone. The reconstructive or remodeling phase occurs over a period of months and years. During this phase, the joints further stabilize and remodel by way of increased trabeculations and new bone growth. This can eventually lead to a stable foot devoid of significant motion. Unfortunately, in many cases, the foot can be severely deformed, with obvious bony prominences susceptible to ulceration (e.g., the rocker-bottom foot) (74) (Fig. 66.6).

Treatment for the acute Charcot foot is directed at eliminating weight-bearing forces that may lead to further destruction and deformity. This is best achieved by the use of crutches, a walker, or in the event of bilateral involvement, a wheelchair. A walking cast in acute Charcot joint disease is not appropriate treatment. Noncompliance with non-weight-bearing in the early stages of this disease will cause further fragmentation of bone, resulting eventually in greater deformity (Fig. 67.6). Casts, splints, or braces may be used for immobilization and to provide stability to the involved joints but not for weight-bearing initially (75). Our preference is the use of a removable bivalved cast brace that will allow regular inspection of the insensate skin (Fig. 66.7). Adjunctive therapies, such as biphosphonates or electrical bone stimulation, have been discussed as means to enhance healing (76,77). While isolated reports appear to favor these modalities, further clinical trials are needed for objective documentation of their effectiveness.

No weight-bearing is allowed as long as crepitus across joints and elevated skin temperature persist. Lack of attention to these clinical parameters will result in reexacerbation of the disease. Protected weight-bearing can be instituted when the clinical examination and serial radiographs show gradual resolution of the inflammatory process and healing of the involved joints. When appropriate, weight-bearing is instituted in a gradual manner and with protection. Weight-bearing is begun with a protective brace and with 15 to 20 lb of pressure. This can be increased in 10-lb increments per week as long as there are no signs of reactivation. Should reactivation occur, the patient should be returned to non–weight-bearing until resolution of these symptoms. As weight-bearing progresses, the patient is eventually allowed to ambulate short distances without assistive devices.

Long-term management of chronic Charcot joint often involves accommodation of any resultant foot deformity to avoid ulceration. Whenever possible, conventional shoe gear is preferred over custom-molded shoes. All shoes should be fitted with a well-molded Plastizote orthotic device that will support and cushion the foot. If severe foot deformity develops, there may be no alternative to a custom-molded shoe that matches the shape of the foot (78).

There has been much recent discussion in the surgical literature of surgical reconstruction foot rendered deformed or unstable by Charcot joint disease (79–81). Severe deformity and instability is not uncommon when destruction involves the

Figure 66.6. Photograph and radiograph showing the rocker-bottom deformity of advanced Charcot joint disease.

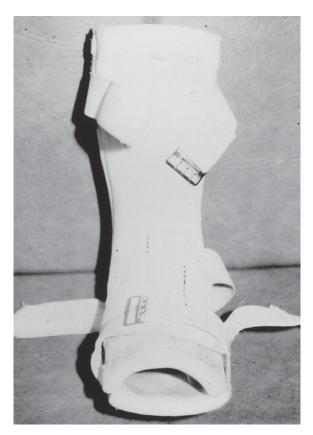

Figure 66.7. A lined bivalved fiberglass cast brace for the treatment of Charcot joint disease.

midtarsal, subtalar, or ankle joints. This can lead to a high likelihood for ulceration or difficulty with ambulation. Arthrodesis of the involved joints can provide a stable platform for ambulation and resistance to further ulcerations. Patients who elect to undergo these procedures must be advised as to the need for prolonged immobilization and non-weight-bearing—in some cases as long as 6 months. Strict adherence to the principles of internal fixation is required if success and limb salvage is expected.

FUTURE OF DIABETIC FOOT MANAGEMENT

The amount of interest in the diabetic foot has increased tremendously over the past 5 years. One only has to look at the numbers of wound-care centers that have sprouted up nation-wide as evidence (82,83). The major impetus for this interest is the financial burden of caring for the diabetic foot. In 1980, more than \$200 million was spent in direct hospital costs alone for the treatment of diabetic-foot complications and amputations (2). While current cost estimates for the United States are not available, one can only assume that they are significantly higher and will only get higher as the population continues to age and the incidence of diabetes continues to increase.

Most research has centered on treatment of foot ulcers and identification of those factors important in wound healing. Such research has increased our knowledge of the mechanism of wound healing and the identification of various growth factors and their roles in wound healing (84,85) From this research, autologous platelet-derived wound healing factor was introduced as a topical dressing to help promote wound healing. State-of-the-art research has recently made platelet-derived growth factor available as a topical gel for use on diabetic foot ulcerations (86). Recombinant DNA technology is used to produce this factor in the laboratory. Early experience with this product has been favorable. Other factors potentially conducive to wound healing are currently being developed in the laboratory using similar technology and should be available for clinical trials within the next 5 years.

The newest area of promise involves the use of bioengineered living-skin equivalents. These products have previously been approved for use in venous stasis ulcerations. Recently, one product, Apligraf, received US Food and Drug Administration approval for use in diabetic foot ulcerations. This product is a dermal/epidermal composite graft grown from neonatal foreskin. It is grown into large sheets on mesh in culture media. It is applied to a properly prepared ulcer bed in the same way that a skin graft is applied. The clinical trials that led to the approval of this product showed a higher percentage of healed ulcerations and a faster healing rate compared with controls (87).

There continues to be great interest in the treatment and prevention of sensory neuropathy. Earlier studies involving aldose reductase inhibitors had to be suspended before any useful clinical results could be evaluated because of a high incidence of adverse effects. However, the available data suggested that these agents might have some usefulness. Controversy exists concerning the potential role of these agents in the management of diabetic peripheral neuropathy. Recently, there has been renewed interest in these agents, which have been modified to reduce the risk of adverse effects. Tolrestat and γ -linoleic acid have been studied intensively, with promising, but inconclusive, results (88–90).

Diabetic neuritis or painful neuropathy remains one of the most frustrating conditions for the patient and for the clinician. The cause of this condition is not well understood. It is often believed that poor glycemic control may be responsible for exacerbations of this condition, although this is not universally accepted. Treatment often consists of trial and error using various agents. Most commonly, the combination of an analgesic with a tricyclic antidepressant has proven most effective, albeit not universally successful (91). Gabapentin is being used with increasing frequency. While it appears to be relatively safe, there have been conflicting reports on its efficacy (92–94).

Diabetic neuroarthropathy (Charcot joint) is another area fertile for investigation. The underlying cause of Charcot joint has not been clearly elucidated. Further, medications that may modulate the Charcot process have been studied on a small scale (77). Prospective, randomized trials are needed to determine whether these medications have any role in the treatment of Charcot joint disease. Anecdotal reports have claimed a role for the use of electrical bone stimulation to achieve more rapid consolidation (76,95). These studies have looked at small numbers of patients and have suffered from being neither randomized nor blinded trials. A large, randomized, double-blinded multicenter trial is needed to determine the efficacy of this modality of treatment.

SUMMARY

The impact of sensory neuropathy and vascular insufficiency of the foot in patients with diabetes can be reduced by frequent surveillance, patient education, and aggressive early intervention for addressing foot lesions. The coordination of care between physicians and podiatrists in dealing with the diabetic foot has the potential to save limbs and improve the quality of life for patients with diabetes.

Vascular Disease of the Lower Extremities in Diabetes Mellitus: Etiology and Management

Cameron M. Akbari and Frank W. LoGerfo

THE DIABETIC FOOT: FUNDAMENTAL CONSIDERATIONS 1123

PATHOPHYSIOLOGY OF VASCULAR DISEASE IN DIABETES MELLITUS 1124

Microvascular Abnormalities 1124 Macrovascular Abnormalities 1125

DIAGNOSIS 1126

Problems of the diabetic foot are the most common causes of hospitalization in patients with diabetes, with an annual health care cost of more than \$1 billion (1). The prospect of possible amputation terrifies patients with diabetes and justifiably so: diabetes mellitus is a contributing factor in half of all lower extremity amputations in the United States, and the relative risk for leg amputation is 40 times greater among persons with diabetes than among those without diabetes (1,2). Moreover, up to 50% of diabetic amputees will undergo a second leg amputation within 5 years of the initial amputation. Foot ulceration will affect 15% of all individuals with diabetes during their lifetime, with an annual incidence of 3% in patients with diabetes, and is clearly a significant risk factor in the pathway to limb loss (3).

THE DIABETIC FOOT: FUNDAMENTAL CONSIDERATIONS

The principal pathogenic mechanisms in diabetic foot disease are ischemia, neuropathy, and infection; acting together they contribute to the sequence of tissue necrosis, ulceration, and gangrene. Fundamentally, limb salvage strategies are focused on a clear understanding of these abnormalities in patients with diabetes, which subsequently allows for improved prevention and treatment in this population.

Although discussed in greater detail elsewhere in this book, a brief discussion of neuropathy is warranted here, since it afflicts as many as 50% to 60% of all patients (4,5) and is present

PRINCIPLES OF ARTERIAL RECONSTRUCTION IN THE DIABETIC FOOT 1129

ADJUNCTIVE PROCEDURES IN THE DIABETIC FOOT 1130

CONCLUSION 1131

in more than 80% of diabetic patients with foot lesions (6). Broadly classified as focal and diffuse neuropathies, the latter are more common and include the autonomic and chronic sensorimotor polyneuropathies, which both contribute to foot ulceration.

Sensorimotor neuropathy initially involves the distal lower extremities, progresses centrally, and is typically symmetric. Sensory nerve-fiber involvement leads to loss of the protective sensation of pain, whereas motor-fiber destruction results in small-muscle atrophy in the foot. Consequently, the metatarsals are flexed with metatarsal head prominence and "clawing" of the toes. This causes abnormal pressure points to develop on the bony prominences without sensation, with subsequent erosion and ulceration. Meanwhile, autonomic neuropathy in the foot causes loss of sympathetic tone, which results in increased arteriovenous shunting and inefficient nutrient flow. Autonomic denervation of oil and sweat glands leads to cracking of dry skin, which further predisposes the diabetic foot to skin breakdown and ulceration (7).

The spectrum of infection in diabetic foot disease ranges from superficial ulceration to extensive gangrene with fulminant sepsis. The majority of infections are polymicrobic, with the most common pathogens being staphylococci and streptococci. The more complicated wounds, such as deep ulcers or those with associated abscesses, may harbor anaerobes and gram-negative bacilli. Potential sources of diabetic foot infection include a simple puncture wound or ulcer, the nail plate, and the interdigital web space. Untreated cellulitis can lead to the spread of bacteria along tendon sheaths and to deep-space plantar infection, with eventual destruction of the interosseous

Figure 67.1. This 57-year-old man with diabetes and significant sensorimotor neuropathy underwent a metatarsal head resection for a "neuropathic" ulcer. Pedal pulses were not palpable. Subsequent appearance of the wound is shown, with clearly ischemic edges and complete failure of healing.

fascia and spread to the foot dorsum. With worsening infection, edema is also commonly seen, which leads to elevated compartmental pressures, with resultant capillary thrombosis and further impairment of nutrient blood flow.

Evaluation for ischemia may begin once the infection has begun to resolve and signs of systemic toxicity have disappeared. The decision to perform arteriography and vascular reconstruction should be made during this waiting period, which is usually no longer than 5 days. Further delays may lead to loss of opportunity to salvage the foot (8). A proper evaluation for underlying vascular disease is essential for limb salvage in patients with diabetic foot ulceration, even when neuropathy and infection are present. *All* limb salvage efforts will fail unless ischemia has been recognized and corrected (Fig. 67.1). Most important, consideration should be given to the unique pathophysiology of diabetes and vascular disease and the need to tailor treatment decisions in diabetic patients with lower extremity vascular disease.

PATHOPHYSIOLOGY OF VASCULAR DISEASE IN DIABETES MELLITUS

Microvascular Abnormalities

Many of the complications of diabetes may best be characterized as alterations in vascular structure and function, with subsequent end-organ damage and death (9). Specifically, two types of vascular disease are observed in patients with diabetes, a nonocclusive microcirculatory impairment involving the capillaries and arterioles of the kidneys, retina, and peripheral nerves and a macroangiopathy characterized by atherosclerotic lesions of the coronary and peripheral arterial circulation (10–13). The former is relatively unique to diabetes, whereas the latter lesions are morphologically and functionally similar in nondiabetic and diabetic patients.

One of the greatest impediments to understanding and treating vascular disease in patients with diabetes is the misconception that they have an untreatable occlusive lesion in the microcirculation, which has fostered the belief that arterial reconstruction is futile. This idea originated from an uncontrolled histologic study demonstrating the presence of periodic acid-Schiff-positive material occluding the arterioles in amputated limb specimens from diabetic patients (14). However, subsequent prospective anatomic staining and arterial casting studies (15) have demonstrated the *absence* of an arteriolar occlusive lesion (16). Further evidence comes from physiologic studies of femoro-popliteal bypass grafts in diabetic and nondiabetic patients in which direct vasodilator administration into these grafts demonstrates a comparable fall in peripheral resistance between the two groups (17), again supporting the absence of a distal occlusive arteriolar lesion. Dispelling the notion of "small-vessel disease" is fundamental to the principles of limb salvage in patients with diabetes, since arterial reconstruction is almost always possible and successful in these patients.

While there is no occlusive lesion in the diabetic microcirculation, other structural changes do exist, most notably thickening of the capillary basement membrane. However, these changes do not lead to narrowing of the capillary lumen, and arteriolar blood flow may be normal or even increased despite these changes (18). Thickening of the capillary basement membrane is a structural change observed in both diabetic retinopathy and nephropathy.

In the diabetic foot, thickening of the basement membrane theoretically may impair the migration of leukocytes and the hyperemic response following injury and thus may increase the susceptibility of the diabetic foot to infection (19,20). Although resting total skin microcirculatory flow is similar in diabetic and nondiabetic patients, the capillary blood flow is reduced in patients with diabetes, indicating a maldistribution and functional ischemia of the skin (21). Moreover, studies of skin microvascular flow have demonstrated a reduced maximal hyperemic response in patients with diabetes, suggesting that a *functional* microvascular impairment is a major contributing factor to diabetic foot problems (22). All of these changes result in an inability to vasodilate and achieve maximal blood flow following injury.

Diabetes also affects the axon reflex (23). Normally, injury directly stimulates nociceptive C fibers, which results in both orthodromic conduction to the spinal cord and antidromic conduction to adjacent C fibers and other axon branches. One function of this axon reflex is neuropeptide secretion, such as substance P and calcitonin gene–related peptide, which directly and indirectly (through release of histamine by mast cells) causes vasodilation and increased permeability. This neurogenic vasodilatory response is impaired in diabetes, further reducing the hyperemic response when it is most needed—under conditions of injury and inflammation (24).

Endothelial dysfunction is seen in the earliest stages of atherogenesis and is characterized *in vivo* by an impaired endothelium-dependent vasodilatory response. Normally, endothelium-derived nitric oxide allows for arterial vasodilation in response to either a pharmacologic (e.g., acetylcholine) or a physiologic (e.g., increased shear stress) stimulus. Both type 1 and type 2 diabetes are characterized by an abnormal endothelium-dependent vasodilation (25,26), possibly due to the effects of prolonged hyperglycemia or insulin resistance on both the micro- and macrocirculation (27).

Macrovascular Abnormalities

Lower extremity arterial disease is more common among patients with diabetes than among those without diabetes. The presence of diabetes is associated with a two- to threefold excess risk of intermittent claudication compared with its absence (28). Despite significant advances in the prevention and treatment of peripheral vascular disease, diabetes continues to be the single strongest cardiovascular risk factor for the development of critical leg ischemia and limb loss (29).

Unlike microvascular disease, which is unique to diabetes and its metabolic alterations, the cause of lower extremity ischemia is similar in diabetic and nondiabetic patients and is due to accelerated atherosclerosis. One notable difference between these populations is the pattern and location of the occlusive atherosclerotic lesion. As noted earlier, there is no evidence for an occlusive lesion at the arteriolar level ("smallvessel disease") in patients with diabetes. However, patients with diabetes are more likely to have atherosclerotic disease affecting the infrapopliteal (tibial) arteries, with *sparing* of the foot arteries (30), which allows for successful arterial reconstruction to these distal vessels. Conversely, the superficial femoral or popliteal artery is less likely to be affected by the occlusive process, allowing these vessels to serve as a possible inflow source for bypass grafting (Fig. 67.2).

Because the foot vessels are often patent in the patient with diabetes and because of the success of bypass grafting to these vessels, an appropriate evaluation for ischemia is essential in patients with diabetes. The complex milieu of motor and sensory neuropathy, thickening of the capillary basement membrane, loss of the neurogenic inflammatory response, and the wide spectrum of microcirculatory and endothelial abnormalities all result in a biologically compromised foot. Unless ischemia is recognized and corrected, limb salvage efforts with the diabetic foot will fail, even if infection and neuropathy have been appropriately treated.

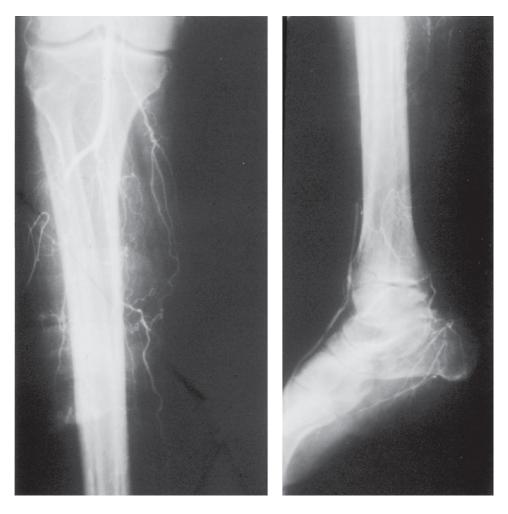

Figure 67.2. Angiogram demonstrating the characteristic pattern of lower extremity vascular disease in diabetes, with atherosclerotic occlusion of the tibial arteries and sparing of the foot vessels. Note the normal appearance of the popliteal artery, another characteristic finding.

DIAGNOSIS

As with any other disease process, evaluation should begin with a detailed history and physical examination. In the patient with a diabetic foot ulcer, it is helpful to consider the duration of the ulcer, the type of treatments used, and any past history of foot ulceration and treatment. Although nocturnal rest pain in the foot is strongly suggestive of lower extremity arterial disease in the nondiabetic patient, the variable effects of neuropathy make pain more difficult to evaluate in the diabetic limb. Similarly, claudication symptoms may be entirely absent in the patient with an ischemic diabetic foot ulcer. Long-standing foot ulceration, coexisting cardiac disease (such as angina or heart failure), and sensorimotor neuropathy may all limit the ability to ambulate sufficiently to manifest claudication symptoms.

Physical examination should be directed toward the underlying pathophysiology of foot ulceration. Neuropathy may easily be evaluated: observation may reveal the morphologic motor abnormalities such as "claw foot" or Charcot's osteoarthropathy, while monofilament testing will assess the degree of sensory neuropathy. Noting the location of the ulcer may also be helpful, since purely ischemic lesions typically occur in the most distal parts of the foot, such as the toes, forefoot, or heel, in contrast to the neuropathic ulcers seen on weight-bearing areas.

All ulcers, including those with a significant neuropathic component, should be assessed for an ischemic component. The peripheral pulses at all levels should be palpated. Although patients with diabetes have a propensity for development of atherosclerotic occlusion of the tibial arteries, it is not unusual to encounter atherosclerosis of the aortoiliac region (evidenced by diminished femoral pulses) or other vessels of the lower extremity. Similarly, the examination should not end with the popliteal pulse: 40% of diabetic patients presenting with ischemic ulceration or gangrene of the lower extremity have palpable popliteal pulses. In fact, recognition of the anatomic pattern of diabetic vascular disease leads to the single most important aspect of the physical examination: the presence or absence of a palpable foot pulse. In simplest terms, if the foot pulses are not palpable, the presence of occlusive vascular disease can be assumed.

A variety of noninvasive arterial tests may be ordered in an effort to quantify the degree of ischemia. However, in the presence of diabetes, *all* of these tests have significant limitations. Although Doppler-derived pressure measurements have proved to be reliable in localizing the degree and level of arterial occlusive disease in nondiabetic patients, their use is limited in the presence of diabetes. Medial arterial calcinosis occurs frequently in patients with diabetes and is characterized by a *nonobstructive* calcification of the vessel wall at the media layer; its presence can result in noncompressible arteries with artifactually high segmental systolic pressures and ankle-brachial indices. Medial calcification should be suspected whenever the ankle pressure greatly exceeds arm pressure or when the Doppler signal at the ankle cannot be obliterated with greater than 250 mm Hg pressure. Lower levels of calcification in the toe vessels support the use of toe systolic pressure measurements as a more reliable indicator of arterial flow to the foot (31). However, the use of toe pressures is often limited by the proximity of the foot ulcer to the cuff site, the size of the cuff itself, and other extrinsic variables.

Segmental Doppler waveforms and pulse volume recordings are unaffected by medial calcification. A normal Doppler waveform is triphasic; with proximal obstruction, the waveform becomes monophasic (Fig. 67.3). Pulse volume recordings rely on plethysmographic recordings of the change in volume that occurs with each pulsation. A sharp upstoke, narrow peak, and dicrotic notch characterize a normal recording. With increasing levels of arterial insufficiency, the waveform loses the dicrotic notch, followed by loss of amplitude and blunting of the waveform (Fig. 67.4). Since neither of these tests relies on obliterating flow within a vessel (unlike Doppler-derived pressures), they may prove useful in the diabetic patient with suspected arterial insufficiency. However, significant limitations exist in their use, and caution should be exercised when interpreting their results. Evaluation of these waveforms is primarily qualitative and not quantitative. A flat forefoot tracing is a convincing demonstration of ischemia, but it is difficult to make clinical decisions based on the magnitude of the waveform. Similarly, severity of arterial insufficiency cannot be accurately interpreted, since no reliable quantitative scoring exists (Fig. 67.5). In addition, the quality of the waveforms is affected by peripheral edema, cuff size, and motion artifact. Finally, the presence of ulceration, especially at the forefoot level, often precludes accurate cuff placement.

Regional transcutaneous oximetry (TcPo₂) measurements are also unaffected by medial calcinosis, and recent studies have noted its reliability in predicting healing of ulcers and amputation levels (32). Limitations, including a lack of equipment standardization, user variability, and a large "gray area" of values, preclude its applicability. Furthermore, TcPO₂ measurements are

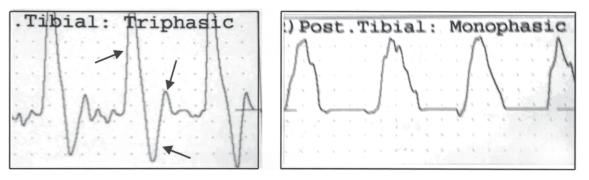

Figure 67.3. Left, The normal Doppler tracing illustrates a triphasic flow pattern, with forward flow in systole (*first arrow*), a reversal of flow in early diastole (*second arrow*), and a secondary forward flow in late diastole (*third arrow*). **Right**, With proximal arterial obstruction, the waveform becomes monophasic with loss of the reverse flow component and blunting of the systolic peak.

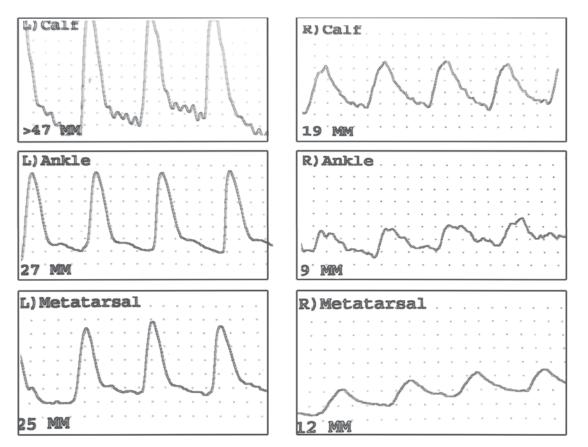

Figure 67.4. Left, Normal pulse volume recordings (PVRs) illustrate a brisk, sharp rise to the systolic peak, with a dicrotic notch. **Right**, With increasing levels of proximal arterial obstruction, the waveform loses the dicrotic notch, the peak becomes more rounded, and the downslope is prolonged. Severe occlusive disease produces a flattened waveform with a slow upstroke and downstroke.

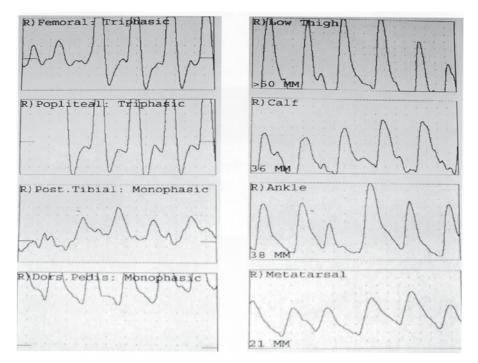

Figure 67.5. Noninvasive lower extremity arterial studies of the patient shown in Figure 67.1. On the basis of the ankle and metatarsal pulse volume recording waveforms, these results were interpreted as "mild tibial disease."

1128 JOSLIN'S DIABETES MELLITUS

higher in diabetic patients with foot ulcers than in the nondiabetic population, which further limits the ability of this test to predict ischemia (33).

The limitations of noninvasive vascular testing in diabetic patients with foot ulceration emphasize the continued importance of a thorough bedside evaluation and clinical judgment. To reiterate, the status of the foot pulse is the most important aspect of the physical examination. In simplest terms, it can be assumed that occlusive disease is present if the foot pulses are not palpable. This finding alone is an indication for contrast arteriography in the clinical setting of tissue loss, poor healing, or gangrene, even if neuropathy may have been the antecedent cause of skin breakdown or ulceration.

Concern for contrast-induced renal failure should not mitigate against a high-quality angiogram of the circulation in the entire lower extremity. The incidence of contrast nephropathy is not higher in the diabetic patient without preexisting renal disease, even with the use of ionic contrast (34,35). The more costly nonionic agents should be reserved for the diabetic patient with compromised renal function. Even in this group, the concern for contrast nephropathy should not delay arteriography, as it seldom requires dialysis for treatment. More recently, attention has focused on the roles of magnetic resonance angiography, carbon dioxide angiography, and duplex scanning as replacements for contrast arteriography. However, each has its limitations, and although we have selectively used these modalities, we continue to rely heavily on a high-quality contrast arteriogram for most of our patients requiring distal arterial reconstruction.

Whatever preoperative imaging modality is chosen prior to arterial reconstruction, it is mandatory that consideration be given to the pattern of lower extremity vascular disease in patients with diabetes. Because the foot vessels are often spared by the atherosclerotic occlusive process, even when the tibial arteries are occluded, it is essential that arteriograms not be terminated at the midtibial level. The complete infrapopliteal circulation should be incorporated, including the foot vessels (Fig. 67.6). The advent of digital subtraction angiography, which allows for subtraction of the bones from the final images, has greatly helped in visualizing these distal vessels (Fig. 67.7). These principles, namely preangiographic hydration, the use of selective femoral and/or digital subtraction arteriography, and demonstration of the foot arteries even when the leg arteries are occluded, are fundamental considerations for lower extremity arteriography in patients with diabetes.

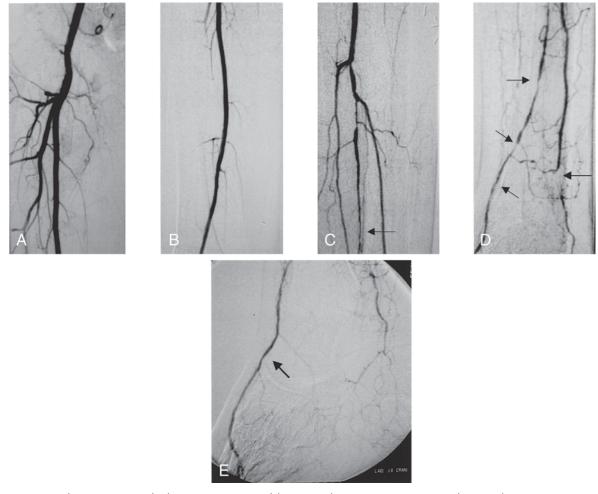

Figure 67.6. Digital subtraction angiogram of the patient shown in Figure 67.1. Note the normal appearance of the femoral and popliteal arteries (**A** and **B**). At the tibial level, however, there are occlusions of the peroneal (**C**, *arrow*), anterior tibial (**D**, *multiple arrows*), and posterior tibial (**D**, *single arrow*) arteries. **E**, Demonstration of the importance of visualization of the foot arteries, showing a patent dorsalis pedis artery (*arrow*). A popliteal-to-dorsalis pedis bypass was subsequently performed which allowed for successful limb and foot salvage.

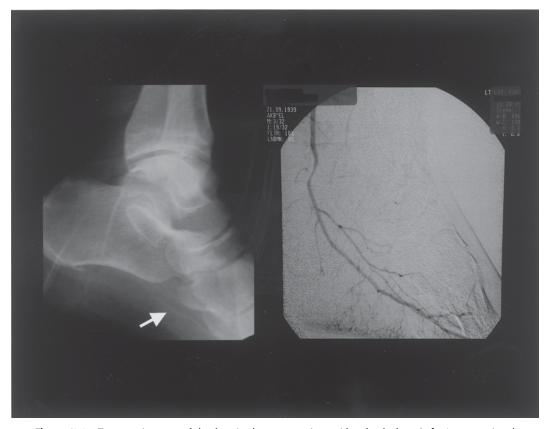

Figure 67.7. Two arteriograms of the foot in the same patient with a heel ulcer. **Left:** A conventional angiogram showing only a minimally opacified plantar artery (*white arrow*). The posterior tibial artery is not well visualized due to overlying bony structures. Because no target outflow artery was available, amputation was recommended. **Right:** Repeat arteriogram using digital subtraction techniques, illustrating a patent distal posterior tibial artery. Successful bypass was performed.

PRINCIPLES OF ARTERIAL RECONSTRUCTION IN THE DIABETIC FOOT

The concept of ischemia must be modified in making decisions about arterial reconstruction in the diabetic foot, since the biologically compromised foot requires *maximal* circulation to heal an ulcer. This leads to three significant principles: (a) all diabetic foot ulcers should be evaluated for an ischemic component; (b) correction of a moderate degree of ischemia will improve healing in the biologically compromised diabetic foot; and (c) whenever possible, the arterial reconstruction should be designed to restore normal arterial pressure to the target area. These three concepts form the basis of a critical difference in the approach to arterial reconstruction in diabetic and nondiabetic patients. In patients without diabetes, more proximal arterial reconstructions to the profunda or popliteal artery may restore perfusion adequate to obtain wound healing, in contrast to the diabetic patient, who mandates normal pulsatile pressure to the foot ulcer.

A complete arteriogram facilitates choosing an outflow artery that will restore a palpable foot pulse. Proximal bypass to the popliteal or tibioperoneal arteries may restore foot pulses. More often, however, because of the pattern of occlusive disease in the diabetic patient, bypass grafting to the popliteal or even tibial arteries cannot accomplish this goal because of more distal obstruction. Similarly, although excellent results have been reported with peroneal artery bypass (36), the peroneal artery is not in continuity with the foot vessels and may not achieve maximal flow, particularly to the forefoot, to achieve healing.

Restoration of the foot pulse is a fundamental goal of revascularization in the diabetic foot. Specifically, autogenous vein grafting to the dorsalis pedis, distal posterior tibial, and plantar arteries incorporates our knowledge of the anatomic pattern of diabetic vascular disease and provides durable and effective limb salvage. The choice of outflow artery should be based on availability of conduit, the location of the foot ulcer, and the quality of the outflow vessel.

The dorsalis pedis bypass represents the single most important advance in our management plan for diabetic limb salvage (37,38). Fundamental to the success of the dorsalis pedis bypass is meticulous technique and its appropriate use. The principal indication for the pedal graft is the absence of any other vessel that has continuity with the foot, particularly in cases with tissue loss. Dorsalis pedis bypass is unnecessary when a more proximal bypass will restore foot pulses and should not be done if there is an inadequate length of autogenous vein. In addition, if the dorsum of the foot is extensively infected and the peroneal artery is of good quality on the preoperative arteriogram, preference should be given to peroneal artery bypass.

Our initial report of dorsalis pedis arterial bypass demonstrated technical feasibility and short-term durability of the procedure, with patency and limb salvage rates approaching 90% at 3 years (39). We subsequently reported on a more extensive 8-year experience encompassing 384 vein grafts to the dorsalis pedis artery in 367 patients (40). Ninety-five percent of the patients had diabetes, and all procedures were performed for limb-threatening ischemia. Twenty-nine grafts (7.5%) failed within the first 30 days, but 19 were successfully revised when a correctable technical problem was found at reoperation. The perioperative in-hospital mortality rate was 1.8%, and the actuarial primary and secondary patency rates were 68% and 82% at 5 years' follow-up. Furthermore, the limb salvage rate was 87% at 5 years, again attesting to the durability of the dorsalis pedis graft.

The distal location of the dorsalis pedis artery theoretically necessitates a long venous conduit, which is often not attainable. However, by using the popliteal or distal superficial femoral artery as an inflow site, a shorter length of vein may be used, with excellent long-term patency (41). This is particularly true in the patient with diabetes, again due to the pattern of atherosclerotic disease. In the authors' institutional experience of 384 pedal bypasses over a 7-year period, 60% of grafts used the more distal inflow site, usually the popliteal artery. This avoids dissection in the groin and upper thigh, a common location for wound complications, and also obviates the need for foot extension of the vein harvest incision. The approach is flexible, in that the vein graft to the dorsalis pedis artery can be prepared as an in situ, reversed, or nonreversed vein graft, without any significant difference in outcome (42). With the *in situ* or nonreversed graft, the valves may be lysed blindly, or preferably, cut under direct vision with an angioscope. This also allows for concomitant angioscopic assessment of the vein to detect any intraluminal abnormalities (43).

Active infection in the foot is commonly encountered in the complicated ischemic diabetic foot. However, it is not a contraindication to dorsalis pedis bypass, as long as the infectious process is controlled and located remotely from the proposed incision. Adequate control implies resolution of cellulitis, lymphangitis, and edema, especially in areas of proposed incisions required to expose the distal artery or saphenous vein. At the authors' institution, the results of 56 vein bypasses to the dorsal pedal artery in patients with ischemic foot lesions complicated by infection were recently reviewed (44). This included 15 patients with severe gangrene, osteomyelitis, and/or deepspace abscess. The average duration between admission and bypass was 10 days. Although there was a 12% wound infection rate, the primary graft patency was 92% at 36 months' followup. This aggressive approach to revascularization in the ischemic and infected foot resulted in a rate of limb salvage of 98% at the end of 3 years.

In the patient with an ischemic heel ulcer or gangrene, first consideration should be given to the posterior tibial or plantar arteries if they are patent by preoperative imaging. However, the absence of a patent posterior tibial artery is not a contraindication to arterial bypass and limb salvage. Our large experience with dorsalis pedis artery bypass has allowed us to examine its role and efficacy in the treatment of ischemic heel lesions (45). Over a 6-year period at our institution, 96 patients underwent pedal bypass for heel ulceration. When compared with a similar cohort of 336 patients with forefoot lesions undergoing dorsalis pedis bypass, there were no differences at 5 years with respect to primary patency, secondary patency, or limb salvage. More important, dorsalis pedis bypass accomplished complete healing in 87% (84 of 96) of heel lesions, with healing rates being independent of the presence or absence of an intact pedal arch, and it allowed for a limb salvage rate of almost 90% at 5 years.

Despite the technical success of lower extremity bypass in patients with diabetes, there continues to be a guarded

optimism about long-term patient function and survival. In an effort to dispel concerns regarding late graft patency, limb salvage, and survival among patients with diabetes, we recently reviewed our experience with lower extremity revascularization in a largely diabetic population of almost 1,000 patients followed 5 years or longer (46). A total of 962 vein grafts were performed on 843 patients, of which 83% (795 grafts) were in patients with diabetes. Minimum follow-up was 5 years and extended up to 9 years. The dorsalis pedis or plantar/tarsal arteries served as the outflow artery in 271 (35%) of the patients with diabetes. Cumulative 5-year primary graft patency was 74.7% overall, with no difference among patients with and without diabetes (diabetic, 75.6% vs. nondiabetic, 71.9%). The secondary graft patency rate was 76.2% for the entire cohort and was also similar in the diabetic and nondiabetic groups (diabetic, 77% vs. nondiabetic, 73.6%). Most important, 5-year limb salvage and survival rates were virtually identical in diabetic and nondiabetic patients. The overall limb salvage rate was 87.1% (diabetic, 87.3% vs. nondiabetic, 85.4%). Survival at 5 years was 58.1% in the entire cohort (diabetic, 58.2% vs. nondiabetic, 58.0%). These data strongly emphasize that concern for long-term mortality, limb loss, and graft patency in diabetic patients is unwarranted and should not prevent aggressive attempts at distal bypass required for limb salvage.

ADJUNCTIVE PROCEDURES IN THE DIABETIC FOOT

It must be remembered that ischemia is only one component of the total problem. Prompt recognition and control of infection assumes first priority in the consideration of any diabetic foot problem. Recognizing that a benign-appearing superficial ulcer may rapidly progress to a potentially fatal infection underscores the importance of a thorough evaluation for infection in these patients. Therefore a complete examination of the infected areas is mandatory, and the wound should be thoroughly inspected, including unroofing of all encrusted areas, to determine the extent of involvement. Immediate incision and drainage of all infected tissue planes and abscesses is mandatory. The incision must be long enough, wide enough, and deep enough to ensure complete drainage of pus or débridement of necrotic tissue. Drains and small stab incisions do not provide dependent drainage and are not used. Dressings should consist of gauze sponges moistened with normal saline or 0.25% povidone-iodine solution. Full-strength astringents, hot compresses, and whirlpools lead to more harm than good.

Following successful revascularization, secondary procedures may be performed for both limb *and* foot salvage. Previous surgical débridements or amputations may be revised, and chronic ulcerations may be treated by ulcer excision, arthroplasty, or hemiphalangectomy. In the patient with extensive tissue loss, both local flaps and free flaps may be used. Due to the architecture of the diabetic foot, underlying bony structural abnormalities are often the cause of ulceration and may be corrected by metatarsal head resection or osteotomy. Heel ulcers may be treated by partial calcanectomy and local (e.g., flexor tendon) or even free-flap coverage.

Once the diabetic foot has healed, attention should be turned to lifelong foot care and preventive maintenance. While daily bathing and inspection should be emphasized, soaking should be discouraged. Because of sensory neuropathy, water should always be hand-tested for temperature to avoid scalding. Liberal use of moisturizer is encouraged to prevent calluses and cracks in dry skin. Self-treatment of calluses and corns, or so-called bathroom surgery, is never permitted, and in most instances, the

diabetic individual should seek a qualified podiatrist for foot and nail maintenance. Footwear and stockings should fit well (without folds, wrinkles, or seams), be comfortable, and, to avoid pressure points, be changed daily. Again, the advice and care of a qualified podiatrist is indispensable for the diabetic individual who is prone to developing foot problems (47).

CONCLUSION

Our knowledge of the pathophysiology of lower extremity vascular disease in patients with diabetes has allowed us to incorporate it into our overall treatment plan of the diabetic foot, with improved limb and foot salvage. This is reflected in a recent report from our institution, which has seen a significant reduction in every category of lower limb amputation since 1984 (38). For the primary physician caring for the diabetic patient, limb salvage should be the rule rather than the exception. This can only be possible with a thorough understanding of diabetic peripheral vascular disease, an awareness of the complex physiology of the diabetic foot, and a logical treatment plan based on our current knowledge of the disease process.

NEUROPATHY 1133

ISCHEMIA 1136

INFECTION AND INFLAMMATION 1138

TREATMENT 1139

Diabetes mellitus, the most common endocrine disease, is a complex systemic disorder with a broad range of effects on nearly every organ system. It ranks in the top ten causes of death in the United States and encompasses a heterogeneous and progressive group of abnormalities with a wide spectrum of severity (1). Although difficult to determine precisely because of inconsistent standards of diagnosis, the prevalence of diabetes in the United States is probably between 1% and 2%, with a range as high as 11% (2). Generally, it is clear that both morbidity and mortality are increased in this population. However, the effects of diabetes on wound healing remain controversial and the mechanism underlying altered wound healing is poorly understood.

Diabetes itself is one of the earliest described diseases. The Ebers Papyrus dating back to 1500 B.C. lists some of the symptoms and possible treatments for this ailment (3). The gangrenous foot wound is clearly described in biblical writings, although its association with diabetes was likely unknown. In 1887, Pryce describes the chronic painless foot ulcer associated with diabetic neuropathy (4). The diabetic foot ulcer continues to be a significant healthcare problem and a major source of morbidity for the diabetic patient. In fact, ulcers of the leg and foot are the most common complications of diabetes (5). Furthermore, there are estimates that diabetic ulcers will increase by 14% per year (6). Fifteen percent of all patients with diabetes will develop a nonhealing foot wound during their lifetime despite meticulous glucose and dietary control (7,8). Diabetic patients have a 15-fold higher risk of lower-extremity amputation and account for at least 50% of the more than 50,000 nontraumatic amputations performed in the United States each year (9,10). The financial cost of the diabetic foot wound to society is formidable. An estimated \$500 million is spent annually, with amputations costing about \$25,000 in the United States (11). In one study, successful conservative management of a diabetic foot ulcer led to a savings of 80% compared with the cost of amputation (12). Furthermore, these estimates do not include financial and psychological losses incurred by the diabetic patient, his or her family, and society as a result of the limitations imposed by the amputation.

The cliché that postoperative wound complications are increased in patients with diabetes is not entirely supported by the literature (13). If patients are matched for age, sex, weight, and comorbidities, several studies show that diabetic patients have no significant increase in postoperative wound complications as compared with nondiabetic patients (14,15). In fact, no increase has been found in postoperative cardiopulmonary, vascular, or infectious wound complications after major vascular or abdominal surgery (16–20). This is in sharp contrast to a number of animal and *in vitro* studies that clearly document that optimal glycemic control leads to optimal wound healing in diabetes (21–25). Hyperglycemia and insulin deficiency are linked to decreased formation of granulation tissue and collagen, poor deep-wound tensile strength, deficient capillary ingrowth, and defective immune function, among other deficiencies (22,26–32). Whether these laboratory findings have clinical significance remains to be shown.

The wound classically associated with diabetes is the nonhealing foot ulcer (Fig. 68.1). Wounds in other locations are rarely as challenging clinically, and few data exist to support an association between diabetes and wounds other than the foot ulcer. Elimination of the diabetic foot ulcer would reduce the number of in-hospital days for the diabetic patient more than the elimination of any other problem associated with diabetes. It is one of the most common and morbid complications of diabetes, and a great deal of literature has been written on this subject. To review the effects of diabetes on clinically relevant derangements in wound healing, we will examine the pathophysiology of the foot ulcer. Specifically, we will review the triad of neuropathy, ischemia, and infection, all common complications of diabetes and all culprits in the pathogenesis of the nonhealing foot ulcer.

NEUROPATHY

Neuropathy in the diabetic patient can take many forms. They range from the "classic" chronic progressive distal symmetric neuropathies to the acute mononeuropathies to the pressure palsies most often affecting the median and ulnar nerves (33,34). The distal symmetric neuropathy is the most common symptomatic neuropathy associated with diabetes mellitus (35). It is a diffuse neuropathy with sensory loss predominating over motor deficits. The symptoms start distally and progress proximally in a stocking distribution, with the longest nerves affected first (36,37). Pathologically, there is a distal dying back of the axons (33,36). Mainly large myelinated fibers are lost,

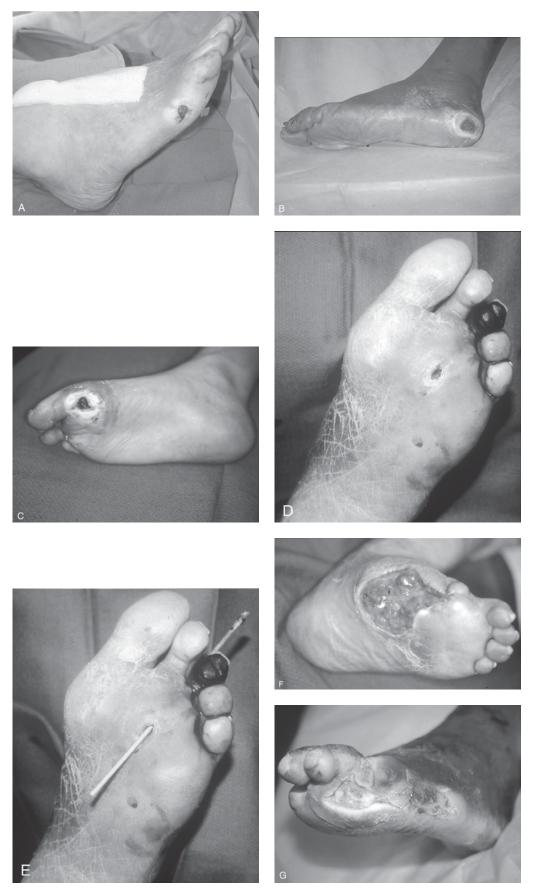

Figure 68.1. Typical diabetic foot ulcers. **A:** Early neuropathic ulcer over fifth metatarsal prominence. **B:** Chronic heel ulcer. **C:** Neuropathic forefoot ulcer over first metatarsal head with callus formation. **D, E:** Deceptively small metatarsal head ulcer with necrotic toe. Note true extent of ulcer, penetrating the foot to the dorsum. **F, G:** Advanced diabetic ulcers with extensive soft tissue and bone loss. Note clawing of toes.

with variable loss of small unmyelinated fibers (38–40). There is focal demyelination and regeneration with slowing of conduction velocities, elevation in sensory thresholds, and slowing of axonal transport (33,41–43). Signs and symptoms vary with the nerve fibers involved (44). Loss of large sensory fibers can lead to diminished light touch and proprioception, and damage to large motor fibers, though less common, may result in unsteadiness and weakness of the intrinsic muscles of the foot. Injury to small fibers results in increased pain thresholds and an inability to recognize temperature changes. These abnormalities predispose to repeated foot injuries and eventually to ulceration.

The prevalence of neuropathy in the diabetic population has been difficult to determine, with estimates ranging from 10% to 90% (45-49). The Diabetes Control and Complications Trial (DCCT) quoted a 50% prevalence of significant neuropathy among their population, although a range of 20% to 30% represents more closely those patients who have symptoms or findings on examination (45,50). Generally, the incidence of neuropathy seems to increase with duration of disease and severity of hyperglycemia (51–53). One large study found an incidence of neuropathy of 8% at diagnosis of diabetes that increased to 50% at 25 years after diagnosis (54). However, this association is far from perfect. Many studies have shown a correlation between neuropathy and height, age independent of duration of diabetes, and smoking (45,51,54,55). Furthermore, the DCCT failed to find a correlation between neuropathy and levels of glycosylated hemoglobin (45).

Autonomic neuropathy also plays a role in diabetic foot ulceration and closely parallels the incidence of somatic neuropathy. Like somatic neuropathy, the incidence of autonomic neuropathy seems to increase with duration of disease. One study found a 4% incidence at the time of diagnosis of diabetes. This increased to 28% after 5 years (56). Others have shown a prevalence of 50% in unselected diabetic populations (57). Abnormal autonomic function tests were shown in 20% to 40% of various groups of patients with diabetes, with up to 20% having cardiovascular abnormalities and 12% having postural hypotension (58–60). However, although almost all patients with sensory neuropathy have an associated autonomic neuropathy, the autonomic abnormality is rarely symptomatic.

Many studies show a clear correlation between diabetic neuropathy and foot ulceration, with up to 80% of patients with foot ulcers having a clinically significant neuropathy (61–64). The positive predictive value of a clinically detectable neuropathy was shown in a prospective study, in which an increased vibration perception threshold was associated with a sevenfold increased risk of ulceration over 4 years (65). A more clinically useful examination, the Semmes-Weinstein nylon monofilament test, has also been shown to identify those at increased risk for ulceration (61,66–68). The inability to feel the 10-g filament greatly increases the patient's risk of developing an ulcer. Undoubtedly, neuropathy plays a considerable role in the development of diabetic foot ulcers.

Sensory neuropathy is by far the major contributor to ulcer formation. Specifically, loss of pain sensation typically leads to repetitive trauma from walking, usually with poorly fitting shoes or from a foreign body in the patient's shoe that the patient does not feel. This is compounded by loss of proprioception, which can lead to abnormal foot posture and amplified trauma from walking. Additionally, autonomic neuropathy can lead to sudomotor abnormalities, resulting in decreased sweating and dry skin that is prone to cracking. These breaks in the skin are portals for infection and further ulcer formation.

As autonomic neuropathy progresses, there is sympathetic denervation of the foot, resulting in loss of vasoconstrictor tone and peripheral vasodilation. As arteriovenous shunts open, there is, on average, a fivefold increase in blood flow to the skin, even in the absence of other signs of neuropathy (69–72). Clinically, the skin is deceptively warm and healthy appearing, with bounding pulses, marked venous distention, and an elevated venous PO₂ secondary to shunting of blood (73). Increased capillary pressure may result in neuropathic edema that can further compromise tissue integrity (74). It has been suggested that shunting may bypass capillary beds, resulting in compromised flow of nutrients and oxygen to the bypassed tissues (75). However, it has been shown that nutritive capillary flow is not only normal but often increased (71). Blood flow to bone is also increased and may be responsible for the osteopenia of advanced disease, predisposing the patient to the development of Charcot neuroarthropathy (76).

Neuropathy alone is not sufficient to cause ulceration. Clearly trauma of some form is necessary. With time, loss of pain sensation in the foot can be compounded by structural abnormalities (34). Damage to motor nerves, specifically the tibial nerve, can lead to weakness and wasting of the intrinsic muscles of the foot. This leads to an imbalance between the flexor and extensor forces, deforming the shape of the foot itself. The metatarsal heads become more prominent, with unopposed dorsiflexion of the metatarsophalangeal joints; exaggerated interphalangeal joint plantarflexion results in clawing of the toes. The weight of the body is shifted onto a smaller surface, mainly the metatarsal heads and heel. In the early phases, the patient has a red, swollen foot with a clear sensory deficit on examination. As the neuropathy progresses, daily activities in the absence of adequate protective proprioceptive and nociceptive function lead to joint erosions, unrecognized fractures, and demineralization and devitalization of bones. Neuroarthropathy or Charcot joints develop as the foot collapses, the longitudinal arch flattens, and a rocker bottom deformity with weight bearing on the distal tarsal row develops, leaving the patient with an insensate misshapen foot (Fig. 68.2). Deformity becomes a constant source of abnormal pressure that in synergy with sensory dysfunction leads to ulceration. In one study, neuropathic feet with abnormally distributed pressures resulted in a 28% ulceration rate over 2.5 years as compared with no ulcers in neuropathic feet with normal pressures (77).

Sites of high pressure loading, such as the metatarsal heads and heel, are prone to callus formation as exuberant keratin production is stimulated by high shear forces (Fig. 68.1B,C) (78). Callus buildup itself leads to further increases in pressure loading, which eventually results in foci of hemorrhage, liquefaction necrosis, and ulcer formation. Callus over a weight-bearing area is strongly predictive of ulcer formation, whereas callus removal decreases local pressures and the risk of ulceration (79,80). Clearly, the combination of neuropathy and altered pressure loading is a major risk factor for foot ulceration in the patient with diabetes. Deformity leads to altered pressure loading, which leads to callus formation and ultimately to ulceration. Repeated and continuous trauma disrupts the orderly sequence of cellular events necessary for wound healing and results in a nonhealing wound. Unchecked, these processes can result in a vicious cycle of further deformity, abnormal pressure loading, and progression of tissue breakdown.

The etiology of neuropathy in the patient with diabetes is complex and likely multifactorial. The ravages of neuropathy begin distally and are most likely to affect longer nerves first, such as those in the feet. This may be the result of the cumulative effect of multiple insults, both biochemical and vascular in nature, or increased capillary hydrostatic pressure, which is relatively unique to the feet and lower extremities (33,53). The association between hyperglycemia and worsening neuropathy is convincing and has been demonstrated by several groups (51–54). Furthermore, strict glucose control using continuous subcutaneous insulin infusion or pancreas transplantation can

Figure 68.2. A, B: Charcot foot. Note ulcer forming over area of abnormally high pressure in this misshapen foot.

slow or even halt the progression of neuropathic changes (45,81,82). The DCCT showed that intense glucose control led to a 69% reduction in subclinical neuropathy and a 57% reduction in clinically evident neuropathy (83). Some of the more convincing data regarding the pathogenesis of diabetic neuropathy implicate activation of the sorbitol pathway, the formation of advanced glycation end products, and increased oxidative stress (84–93). Animal models show that hyperglycemia can augment the sorbitol pathway in peripheral nerves. The products of this pathway can either directly or indirectly lead to nerve damage. Unfortunately, these animal data are not easily reproduced in human studies (94–97).

Glucose uptake in peripheral nerves occurs independently of insulin. As a result, serum hyperglycemia leads to intracellular hyperglycemia and activation of the enzyme aldose reductase, stimulating the production of sorbitol (33,98). The concentrations of the intracellular osmolytes sorbitol, myoinositol, and taurine normally respond to changes in extracellular osmolality, buffering the intracellular environment (99-101). However, as hyperglycemia artificially drives the sorbitol pathway, intracellular accumulation of the osmolyte sorbitol leads to compensatory depletion of myoinositol and taurine (84,85,102,103). Initially, nerve damage was attributed to the intracellular accumulation of sorbitol and the resultant increased influx of water. This increased water content was shown in both diabetic animal and human nerves and was found to be reversible with aldose reductase inhibitors (104). However, the magnitude of the osmotic change was believed to be too small to account for significant peripheral neuropathy. Alternatively, the depletion of myoinositol, a significant component of phosphoinositide metabolism and a key determinant in the Na+-K+-ATPase that maintains nerve membrane potential, may become limiting for phosphoinositide signaling. Taurine depletion can exacerbate oxidative stress and lead to dysregulation of neuronal hyperexcitability and neurotransmitter release (85,102,105-110). The nerves of diabetic rats were found to have decreased myoinositol levels. The severity of myoinositol depletion correlated with decreased Na+-K+-ATPase activity and slowing of nerve conduction velocity. Furthermore, both defects were corrected with myoinositol supplementation or aldose reductase inhibitors (111-116). Although these data are intriguing, not all the evidence is supportive (117-120).

Activation of the sorbitol pathway consumes NADPH (reduced form of nicotinamide adenine dinucleotide phosphate), a cofactor necessary for the function of glutathione

reductase and nitric oxide synthase activity, leading to depletion of both reduced glutathione and nitric oxide (92,121–125). Glutathione is a potent antioxidant and a critical element in the cellular defense against oxidative stress. Although direct evidence is lacking, oxidative tissue damage in diabetes has been attributed to NADPH consumption and the resultant depletion of reduced glutathione (121,126). Nitric oxide is a potent endothelium-derived mediator of vasodilation and neurotransmission (122,127). Aldose reductase–mediated depletion of NADPH can hinder nitric oxide synthase activity, which is NADPH dependent. Decreased nitric oxide production by the endothelial cells of the vasa nervorum can lead to limited vasodilation and impaired blood flow in the endoneurium of peripheral nerves, leading to local ischemia and neuronal dysfunction (92,98,121,123–125,128,129).

Activity of the sorbitol pathway can generate highly reactive sugar moieties that can glycate proteins, forming advanced glycation end products (AGE) (33,130). In general, high glucose concentrations can lead to the nonspecific glycation of both intracellular and extracellular proteins. Insulin-independent tissues such as peripheral nerves are particularly prone to hyperglycemia-induced glycation of intracellular proteins. Glycation of tubulin, a component of microtubules in nerves, can interfere with axonal transport, and AGE can nonspecifically consume nitric oxide, quenching its local vasodilatory effects and predisposing to neural ischemia (121,131). Aminoguanidine, an inhibitor of AGE formation, can reverse nerve conduction and blood flow abnormalities in diabetic rats (130,132,133). Finally, extracellular AGE are felt to play a role in the development of large-vessel atherosclerosis and ischemia in the patient with diabetes. AGE-induced abnormalities in the extracellular matrix have been shown to alter the structure and function of the vasculature, decreasing elasticity in large vessels and increasing permeability across the carotid artery in rats (130). By blocking the cytostatic effect of nitric oxide on vascular smooth muscle, accumulation of AGE is thought to contribute to the premature and accelerated evolution of atherosclerosis and large-vessel occlusive disease in the diabetic patient (130).

ISCHEMIA

Ischemia and its complications are responsible for some of the most devastating ravages of diabetes mellitus. Patients with

diabetes are at an increased risk of developing atherosclerotic disease of both large and small vessels and do so at an earlier age and at an accelerated rate (134,135). More than 80% have vascular disease 20 years after diagnosis of their diabetes, and 75% of patients with diabetes die of vascular disease or its complications (136). Ischemia clearly plays a role in diabetic foot ulcers as well. Tissue hypoxia as measured by a reduction in dorsal foot transcutaneous oxygen tension has been shown to be an independent predictor of foot ulceration in the diabetic patient (137). However, purely ischemic ulcers are relatively uncommon, representing only 10% to 15% of diabetic foot ulcers (63,138,139). Most of these ulcers are neuropathic or neuroischemic in nature (54,75,134,140,141). Certainly, the metabolic requirements of a wound are greater than those of uninjured tissues (142). Therefore, a diabetic foot with adequate tissue perfusion may become ischemic once it is wounded if it is unable to augment blood flow to the injured tissues. Vascular occlusive disease in combination with an abnormal autonomic response secondary to neuropathy may limit the ability to augment flow. This creates the vicious cycle of a wound leading to ischemia, leading to a larger wound, which, if uninterrupted, often leads to amputation.

The patient with diabetes has a 20-fold increased risk of developing atherosclerosis of the lower extremities (134). The

68: DIABETES MELLITUS AND WOUND HEALING 1137

process starts at a younger age, is accelerated, and has less male bias than in the nondiabetic patient. The risk of developing an occluded artery in the lower extremity is almost twice as high in the diabetic than in the nondiabetic patient, and the distribution of disease tends to be more diffuse (143). Vascular occlusive disease is associated with almost two thirds of nonhealing diabetic foot ulcers and is an etiologic factor in almost half of all amputations (62). The Framingham Study showed a 50% higher incidence of nonpalpable pedal pulses in women with diabetes and a 25% higher rate in men with diabetes compared with their nondiabetic counterparts (135). Although the frequency of proximal disease involving the iliac and femoral vessels tends to parallel that of the general population, patients with diabetes have a unique tendency for significant involvement of the tibial and peroneal vessels between the knee and ankle (Fig. 68.3) (1,3,144–146). It is interesting that the vessels in the foot tend to be spared. In fact, the vessels in the feet of diabetic patients may be less involved with atherosclerosis than are the pedal vessels in nondiabetic patients (147,148). As a result, patients with diabetes are often good candidates for bypass surgery, with the vast majority having surgically correctable disease with excellent long-term results (149–152).

One of the impediments to aggressive revascularization of the diabetic foot had been the myth of small-vessel disease. This

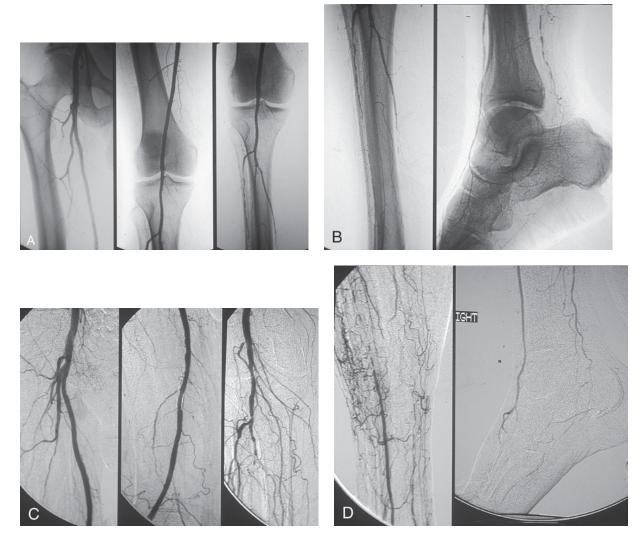

Figure 68.3. Two patients (A, B and C, D) with typical diabetic lower extremity vascular occlusive disease. Note predominantly infrapopliteal involvement with relative sparing of the foot.

myth was promoted to explain the apparent dilemma of the nonhealing diabetic foot ulcer in the presence of palpable pedal pulses. Unfortunately, this was given some credibility by a retrospective, unblinded study of amputation specimens in 1959 (153). Periodic acid-Schiff-positive staining material seen in small vessels on histologic sections was interpreted as proof of small-vessel occlusive disease specific to the diabetic foot. However, since then, multiple studies have failed to confirm these findings. No difference in occlusive disease was found in arterial casts of amputation specimens of diabetic and nondiabetic patients (147). Strandness and colleagues (148) repeated the 1959 study of Goldenberg et al. (153) and were unable to confirm their findings. A study of diabetic and nondiabetic patients after femoropopliteal bypass surgery showed no difference in arteriolar resistance or reactivity to papaverine treatment (154). Wyss et al. (155) were unable to show a significant difference in transcutaneous oxygen tension in the extremities of patients with peripheral vascular disease with and without diabetes. Finally, there was no difference in the oxygen gradient between arterial blood and pedal skin in diabetic patients with ulcers compared with those without ulcers and those without diabetes (156). Although it has been shown that the basement membrane of muscle capillaries in diabetic feet is thickened, there is little evidence that microvascular disease contributes to ischemia or foot ulceration (157).

Abnormal hemorheology is one factor that can contribute to localized microvascular occlusion and ischemia. The combination of increased plasma viscosity, increased aggregability, and reduced red blood cell deformability in the diabetic patient can lead to stagnation of blood flow, hypoxia, and ischemia (158,159). The red blood cell is stiff and unable to deform to pass through the small capillary channels. This stiffness occurs during the hyperglycemic state and is a result of nonenzymatic glycation of the red blood cell membrane protein spectrin (160-162). This process not only renders the red blood cell stiff but also increases aggregability, which leads to increased blood viscosity (163). Increased viscosity leads to increased resistance and, in order to maintain flow, to increased perfusion pressures. This increased pressure leads to increased transudation and, paradoxically, higher viscosity. Because of the thixotropic nature of blood, as flow slows, it becomes more and more resistant to acceleration of flow (163). This increases shear stress to the microvascular wall, leading to increased permeability and extravasation of plasma proteins. The resultant stagnation within the microcirculation leads to occlusion, hypoxia, and finally ischemia (163,164). Interestingly, the stiffness of the red blood cell membrane can be reversed within 24 hours if normoglycemia is maintained (165,166).

Another functional defect in oxygen delivery involves hemoglobin itself. Under hyperglycemic conditions, hemoglobin is glycosylated, resulting in a shift in the oxygen-hemoglobin dissociation curve to the left (15,167). Glycosylated hemoglobin has a higher affinity for oxygen and releases less oxygen to tissues (15,168). As a result, under hyperglycemic conditions, oxygen delivery is hampered in two ways. The red blood cell is rendered stiff and more likely to aggregate, resulting in increased blood viscosity and poor microperfusion, and hemoglobin is glycosylated, preventing the efficient release of oxygen at the tissue level. However, it is notable that both conditions are reversed with good glucose control. A diabetic foot wound clearly has higher metabolic needs and oxygen requirements than unwounded skin (142,169,170). Baseline ischemia is therefore amplified in the face of a healing wound. Thus, it is critical to optimize blood flow and oxygen delivery to the foot. In the patient with nonpalpable pedal pulses, a vascular workup is a must. Most occlusive lesions in this population are amenable to surgical bypass with excellent

long-term results. Although not yet shown in clinical studies, optimizing blood glucose control may improve the local microvascular hemorheology and allow for better oxygen release by hemoglobin at the tissue level. Furthermore, minimizing edema with leg elevation and wrapping is also beneficial to local nutrient delivery and wound healing.

INFECTION AND INFLAMMATION

Although infection is not the instigator of ulceration in the diabetic foot, it can clearly be a major impediment to healing. Once an ulcer is established through a combination of neuropathy, ischemia, and repetitive trauma, it can become chronic and unable to heal secondary to superimposed infection. In fact, infection complicating ischemia often leads to amputation in the patient with diabetes, with infection playing a significant role in two thirds of lower-extremity amputations in this population (9,62,171). In general, patients with diabetes are at an increased risk of acquiring an infection and of developing a more severe variant when compared with their nondiabetic counterparts (172,173). Several studies have showed an increased risk of postoperative wound infections in patients with diabetes (134,174-180). Diabetes is an independent risk factor for postoperative wound infection in patients undergoing cardiac surgery, cholecystectomy, vascular surgery, and hip arthroplasty (174-177,181-185). Glucose control may lower this risk after open-heart surgery (178). However, many of the early studies showing increased postoperative morbidity in patients with diabetes have not stood up to the scrutiny of correcting for age, weight, sex, and comorbid conditions (17-20,174-180). These conflicting results stand in sharp contrast to the clearly hostile environment of the diabetic foot in wound healing. Surgical and traumatic wounds in other locations may or may not be at increased risk of developing complications. There is no doubt, however, that wound healing in the diabetic foot is often highly compromised. Some of the factors that hinder wound healing in the foot include lack of prompt and appropriate wound care secondary to the patient's inability to feel (neuropathy) or see (retinopathy) an early ulcer, abnormally high pressures and continued trauma to a deformed foot, ischemia as a result of large-vessel occlusive disease or abnormal hemorheology, or more likely, a combination of the above.

Breaks in the skin, whether they are imperceptible cracks, fissures in calluses, or large wounds, are portals of entry for bacteria. In the diabetic foot wound, this initial bacterial inoculum is not eliminated efficiently. As a result, the normal repair processes are delayed or halted altogether. The most common aerobe in diabetic foot wounds is Staphylococcus aureus, followed by streptococci and gram-negative bacilli such as Escherichia coli. Almost all infected diabetic foot wounds also harbor anaerobes and are polymicrobial in nature (152,186-189). Unlike the patient without diabetes, the patient with diabetes is often unable to respond to infection with increased blood flow. Rather, vascular occlusive disease impairs the delivery of much-needed oxygen and antibiotics. Autonomic neurogenic vascular responses are rendered ineffective by neuropathy. Microthrombi form in small arterioles, compounding any existing ischemia (3). The increased oxygen and nutrient requirements of an infected open wound, together with the inability to meet these requirements, result in a vicious cycle that can ultimately lead to massive tissue necrosis and sepsis.

Many studies have documented immune deficiencies directly related to the metabolic derangements caused by poorly controlled diabetes. As a result, the World Health Organization has classified diabetes as a secondary immunodeficiency disease (190). Specifically, a great deal of research on wound healing in diabetes has focused on leukocyte function. In the early inflammatory phase of wound healing, the neutrophil is a critical line of defense against bacteria and debris and is necessary to the orderly progression of the healing cascade. In the patient with diabetes, deep wounds were found to be relatively deficient in neutrophils (24,191,192). This may explain the failure of these wounds to progress and heal.

Although it is assumed that individuals with diabetes are more prone to infection than are those without diabetes, most of the data documenting immune dysfunction in the presence of hyperglycemia are based on in vitro models. In vitro studies of neutrophils from subjects with poorly controlled diabetes have revealed defects in chemotaxis, adherence, phagocytosis, diapedesis, intracellular killing, and complement function (28-32,193-203). It appears that most of these defects are corrected when normoglycemia is attained. However, this is somewhat controversial, with some studies suggesting a defect in the patient's serum and not in the neutrophil itself (29,201,204,205). Others note that although phagocytosis and intracellular killing are improved with normoglycemia, overall granulocyte function remains abnormal, suggesting additional defects (206,207). The thickened capillary basement membrane of patients with diabetes may act as yet another impediment to the migration of activated leukocytes. Granulocytes accumulate in the microvasculature, further impairing the passage of red blood cells already compromised by abnormal hemorheology and macrovascular occlusive disease. There is increased edema and local ischemia is accentuated, leading to further deterioration. Although there appears to be clear *in vitro* evidence for immune dysfunction in the patient with diabetes, the clinical significance of these findings and the benefits of normoglycemia to wound healing in the diabetic patient remain unclear.

Multiple groups have shown deficient wound healing in diabetic animal models. Hyperglycemic obese mice have delayed wound closure as compared with normoglycemic controls (169). There is decreased accumulation of collagen and fewer myofibroblasts in these wounds, delaying closure by contraction. Slow or inadequate granulocyte influx into diabetic wounds has been associated with deficient protocollagen and collagen synthesis in deep surgical wounds (24,191,192,201,208). These wounds have poor tensile strength (22,25). Experiments with subcutaneous cylinders have shown decreased production of hydroxyproline, a key component of collagen (23). Other findings include poor capillary ingrowth and inadequate fibroblast proliferation (208,209). Most of these defects are corrected with insulin administration or reduction in glucose concentrations or both.

In sharp contrast to the abnormalities encountered with deep surgical wounds, healing of superficial corneal wounds in diabetic rats and humans was equivalent to that in their nondiabetic counterparts (210,211). Both groups showed minimal leukocyte infiltration, suggesting that granulocytes are not an important part of epithelialization. Rather, granulocyte function seems to be intimately related to the healing of deep wounds, whereas collagen formation is critical to tissue restoration. Other studies have shown that wound healing in experimental diabetes is improved with zinc supplementation or with large doses of vitamin A (212,213). Insulin administration, independent of glucose concentrations, was found to be necessary for satisfactory capillary ingrowth into healing wounds in diabetic animals (208). Poor intracellular glucose levels correlated with fewer granulocytes and fibroblasts in the early phases of wound healing, leading to deficient collagen deposition and poor tensile strength. Interestingly, the timing of insulin administration also was found to be important. Only if insulin was given immediately after wounding did the formation of granulation tissue return to normal, suggesting compromise of an early event in wound healing (191,214). This corresponds to the phase when neutrophil function is crucial to wound healing. On the other hand, others report that insulin neither prevents nor corrects the multiple tissue defects associated with diabetes (215,216).

TREATMENT

Diabetic foot ulcers, like all chronic wounds, will heal only if the underlying pathology is corrected (217). Most of these chronic wounds will heal with proper local care. However, the recurrence rates are quite high. Furthermore, patients who suffer recurrent ulcers are those at highest risk for amputation (62). Unlike acute wounds that sustain a transient external insult, chronic wounds are exposed to both physical and biochemical stressors for a prolonged period. This leads to a sustained inflammatory state, with increased local tissue damage and ineffective healing. In the patient with diabetes, the typical foot ulcer is a result of chronic recurrent trauma resulting from a combination of neuropathy and a misshapen foot. This can be aggravated by ischemia and superimposed infection.

The key to the management of diabetic foot ulcer is early, aggressive care (218,219). This has been shown to improve prognosis and reduce the risk of amputation. There are some basic guidelines for managing the chronic diabetic foot ulcer. Initially, it is important to establish the true extent of the wound. Often, the external appearance of the ulcer does not betray the true severity of the injury (Fig. 68.1D,E). Therefore, a close examination is critical. Any necrotic or marginally viable tissues, including bone, should be débrided until only healthy tissues are left (188). There is nothing more expedient, effective, and cost-effective as sharp surgical débridement for cleaning a wound. The goal is to remove all necrotic tissues and foreign bodies from the wound, drain abscesses or deep infections, and keep the bacterial count to a minimum. For deep wounds, a radiograph of the foot can be helpful in determining the extent of bony involvement. Deep infections should be treated with broad-spectrum antibiotics initially. Most infections in this population are polymicrobial, involving gram-positive, gramnegative, and anaerobic organisms (152,186-189). An abscess or contained deep infection can be cultured and the antibiotic coverage tailored to the culture results. Cultures of superficial open wounds are rarely helpful, as most of these wounds are colonized with a multitude of organisms. Antibiotic use in these superficial open wounds is usually unnecessary.

For the most part, topical treatments are of little benefit to the management of diabetic foot ulcers. The long and growing list of topical agents is a testament to their lack of efficacy. No topical débriding agent can substitute for surgical débridement. Topical antimicrobials such as povidone-iodine (Betadine), acetic acid, Dakin solution, and hydrogen peroxide not only destroy surface bacteria but also destroy cellular elements critical to wound healing (3,220,221). Antibiotic ointments are safe and effective at reducing surface bacteria and should be used as an adjunct to and not a substitute for surgical débridement. They also maintain a moist environment, which promotes wound healing (222,223). Recent experimental studies with wound chambers have demonstrated accelerated wound healing in a wet environment (222). The potential benefits of wet treatments in diabetic wounds still remain to be explored. One of the only topical agents shown to be of any benefit in treating diabetic foot ulcers is platelet-derived growth factor (224–229). Once again, this growth factor accelerates healing in a clean wound and is not a substitute for adequate surgical débridement.

Once the wound itself has been optimized with débridement, drainage, and appropriate antibiotics, local conditions must be enhanced for healing to occur (203). First and foremost, tissue oxygenation must be adequate for wound healing to take place. Diabetic foot ulcers are most commonly found on the forefoot overlying the metatarsal heads or the interphalangeal joint of the great toe. Approximately 30% of these plantar forefoot ulcers are associated with significant atherosclerosis of the tibioperoneal vessels, which contribute to their poor healing (Fig. 69.3) (1,3,144–146). A pulse examination is a must in all patients with wounds in the foot. In the absence of palpable pedal pulses, a vascular workup is obligatory. Segmental pressure measurements, pulse volume recordings, transcutaneous oxygen pressures, and various diffusion clearing techniques can be used to assess the blood supply to the foot (3,230,231). It has been noted that successful treatment of an ulcer is better predicted by the degree of ischemia than by the extent of the ulcer itself (231). Another group looked at a number of variables and concluded that the local transcutaneous PO2 is the critical physiologic determinant of healing in a diabetic ulcer (230). Furthermore, although atherosclerotic occlusive disease of the lower extremities is quite common in patients with diabetes, it is usually very amenable to reconstructive bypass surgery. Once the diagnosis is made, a vascular surgery consultation should be obtained (149-152).

Other local impediments to wound healing include edema and dry, inelastic skin. Edema is usually at its peak when the patient presents with an acutely inflamed, often infected, wound. Simple elevation and gentle compression will minimize edema and facilitate the diffusion of oxygen, nutrients, antibiotics, leukocytes, and fibroblasts to the healing wound. Elevation and compression should be gently balanced in the patient with occlusive vascular disease, as too much of either can further limit perfusion to an already ischemic wound. Optimizing cardiac and renal function, strict glucose control, eliminating infection, and maximizing nutrition will all aid in minimizing edema (152). Nutrition is often overlooked. A serum albumin of less than 3.0 g/dL is a poor prognostic sign and should be treated appropriately (232). Soaking the feet has been taught traditionally but has been shown to be of little benefit (233). In fact, soaking can lead to maceration of previously healthy tissues with progression of infection. In the insensate foot of the neuropathic patient, hot water may lead to further tissue damage. Instead, moisturizers are a safe alternative and can be used to keep the skin more pliable and, therefore, more resistant to cracking. Calluses should be removed proactively to minimize local pressure and shear (79,80).

Abnormally high local pressures are one of the main sources of diabetic foot ulcers. The insensate, misshapen diabetic foot is subjected to poorly distributed pressures without effective feedback. The result is chronic repetitive trauma, which culminates in an ulcer. Once the ulcer has been débrided, infections drained, and adequate blood supply confirmed, the patient must not bear weight on the wound for it to heal. Because these ulcers do not hurt, most patients continue to walk on them. The result is progression of the ulcer, not healing. Some have advocated the use of crutches and wheelchairs. However, most diabetic patients with significant neuropathy are somewhat ataxic, and the use of crutches can be dangerous (3,234).

One of the best techniques for optimizing conditions for wound healing, minimizing pressure on the ulcer, and allowing the patient to remain somewhat ambulatory is the total contact cast (3,75,234–239). The bony prominences of the foot are gently padded, a hydrocolloid or similar dressing is applied to the wound, and a below-knee plaster cast is applied. This redistributes pressures across the foot, minimizing point loading. Extending the cast to below the knee also minimizes shear, translating it into forward motion instead. A rocker bottom reduces forefoot loading on toe-off. A relatively occlusive environment is maintained to augment wound healing. The total contact cast is most effective in patients with adequate blood supply; an open, well-drained wound; no systemic signs of infection; and close follow-up (3,235–237,240). It has been shown that even locally infected wounds, including localized osteomyelitis, can be effectively treated with the occlusive cast (238,239). Excellent results have been reported with the total contact cast (241–246). Generally, 80% to 90% of ulcers are healed within 1 to 2 months. Smaller forefoot ulcers usually heal within 1 month. Larger ulcers and more posterior plantar ulcers tend to take longer. Even with the cast in place, weight bearing should be limited in this latter subgroup.

Once an ulcer has healed, the challenge of preventing a recurrence remains. Most recurrences happen in the first month, when the newly formed scar is most tenuous (237). Often this is attributed to infection, but usually the real culprit is shear. Careful examination will reveal the early preulcerative changes, including blistering, petechiae, erythema, and localized warmth. Protection from repeated stress is the key to prevention. Edmonds et al. (139,141) demonstrated how important proper footwear can be in preventing recurrence. Patients who returned to wearing their own shoes after an ulcer had healed had a recurrence rate of 83% as compared with a recurrence rate of 26% for those who were given specially designed protective shoes. The goal is to distribute the stresses of walking evenly over the entire plantar surface of the foot. This can be accomplished with a soft insole, a molded insole, or a rigid-soled rocker bottom shoe. Patients must be educated so that they understand the problem and will make a real attempt to alter their lifestyles. Walking habits need to be altered to minimize shear stress. Shear is greatest during fast walking, quick starts and stops, and with long strides (247).

Areas that cannot be addressed with a well-designed shoe need to be addressed surgically. It is almost impossible to maintain a healed ulcer in the face of a persistent bony deformity. Correction of clawing at the metatarsophalangeal joints and interphalangeal joints, arthrodesis of the interphalangeal joint of the great toe, resection of prominent metatarsal heads, and even lengthening of the Achilles tendon may all be necessary to maintain a healed ulcer (3,237). Interestingly, percutaneous lengthening of the Achilles tendon may be the single best treatment for a recurrent plantar forefoot ulcer in the face of an adequate blood supply. This improves ankle dorsiflexion, minimizing abnormal pressure on the forefoot during walking. Along with proper shoes or braces, significant decreases in recurrence are noted. The callus is another benign-appearing fixed deformity that must be dealt with aggressively in this population (3,217,234,237). All calluses should be viewed as preulcerative lesions, especially in the neuropathic foot with altered sympathetic function. These hyperkeratotic deformities in the context of a dry, insensate foot create severe localized shear and compressive stresses, creating the perfect milieu for ulcer formation. Calluses and unvielding bony prominences should be removed, the foot should be padded with custom-designed shoes and insoles, and skin cleansing and care with moisturizers should be emphasized. The patient must have a good appreciation of the problem and, together with an experienced and diligent clinician, work toward preventing these highly morbid wounds.

Acknowledgments

We would like to thank Dr. Julian Pribaz, Dr. Michael Conte, Ann Crowley, RNC, Christine Gallagher, Leyla Ganchi, and Guyon Ganchi for their contributions to this work.

Hypoglycemia, simply defined as a low blood glucose level, is a laboratory finding that may or may not be associated with significant pathology. Pathologic hypoglycemia may be caused by a large spectrum of entities, which vary depending on the age at onset and the presence of other, related symptoms. In this chapter we will provide a systematic approach to the diagnosis and treatment of hypoglycemic disorders in adults and children.

REGULATION OF GLUCOSE LEVELS (GLUCOSE HOMEOSTASIS)

The central nervous system (CNS) is dependent on the oxidation of glucose as its primary source of energy. Lack of an adequate glucose supply results in brain dysfunction (neuroglycopenia) and, if prolonged, in irreversible neuronal damage and death. In the healthy adult, the glucose requirements of the brain have been estimated at about 1 mg/(kg · min), corresponding to about 100 g/day in a 70-kg man. Uptake of glucose by the CNS is facilitated by two glucose transporters, GLUT1 and GLUT3, neither of which is regulated by insulin. During hypoglycemia, this glucose transport system is rate-limiting. Chronic hypoglycemia is associated with upregulation of glucose transport, a phenomenon that may be important in the development of hypoglycemia unawareness (see below).

In the fasting state, the brain can utilize ketone bodies (β -hydroxybutyrate and acetoacetate) as alternate energy sources. The uptake of ketone bodies by the brain is proportional to their concentration in the blood. Oxidation of ketone bodies can provide a significant energy source only when circulating levels are elevated, as in the case of a prolonged fast. Therefore, when glucose levels are low, but ketone levels are very high, the brain is partially protected from the deleterious effects of hypoglycemia. However, when both glucose and ketone levels are low, as in insulin-induced hypoglycemia and disorders of fatty acid oxidation, the brain is particularly vulnerable to metabolic damage.

Given the importance of glucose for neural function, it is not surprising that redundant mechanisms have evolved to prevent hypoglycemia. The circulating glucose concentration is determined by the balance between glucose input (absorption plus production) and glucose utilization. During fasting, glucose production is dependent on the availability of the substrates and the metabolic machinery required for glycogenolysis and gluconeogenesis. Glucose utilization is determined by insulin-

stimulated glucose uptake as well as by the availability of alternative energy sources, particularly for muscle (1).

The major mechanisms responsible for prevention of hypoglycemia are shown in Figure 69.1. In the postabsorptive state, insulin levels fall, resulting in decreased uptake of glucose by the liver, muscle, and fat and relieving the insulin-mediated suppression of glycogenolysis, gluconeogenesis, and lipolysis. Hepatic glycogenolysis provides most of the glucose requirements during the first 12 to 24 hours of fasting (2), provided that the glycogen stores are adequate and that the uptake of glucose by muscle and fat is not excessive. During more prolonged fasting, after liver glycogen stores are depleted, lipolysis and protein breakdown supply a steady stream of fatty acids, glycerol, and amino acids. The fatty acids are used by muscle as an energy source and by the liver to produce ketone bodies, which can then be used as an energy source by most tissues of the body. Glycerol and amino acids are taken up by the liver and kidney and used as substrates for gluconeogenesis. A recent study demonstrated that net glucose production in healthy males was about 1.8 mg/(kg \cdot min) during a fast lasting up to 40 hours. The contribution of gluconeogenesis to this basal glucose production increased from 41%

after 12 hours to 92% after 40 hours of fasting (3). In prolonged fasting, the kidney produces 25% or more of the total glucose requirement, achieved primarily through gluconeogenesis from glutamine, lactate, and glycerol (4). The importance of renal glucose production is emphasized by the finding that severe chronic renal insufficiency may be associated with fasting hypoglycemia (see below).

If glucose levels dip below the threshold of hypoglycemia, counterregulatory hormones are released, resulting in a further increase in glucose production (see below). This threshold has been estimated at 67 mg/dL (i.e., just below the normal glucose level in the postabsorptive state and above the level at which neuroglycopenic symptoms usually occur) (5). The ventromedial hypothalamus appears to be of primary importance in initiating the counterregulatory response (6). The counterregulatory hormones can be divided into two major groups: the rapid-acting hormones (catecholamines and glucagon) and the slow-acting hormones (growth hormone and cortisol).

The catecholamines (epinephrine and norepinephrine) act by further suppressing insulin release while directly stimulating hepatic and renal gluconeogenesis, inhibiting peripheral utiliza-

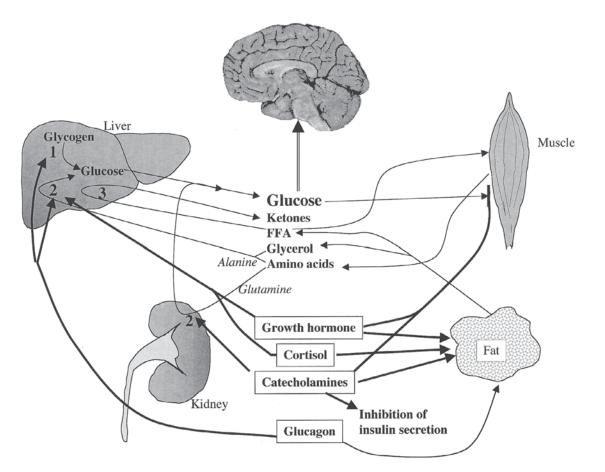

Figure 69.1. Schematic diagram showing the major pathways by which plasma glucose concentrations are maintained in the fasting state. Glucose uptake by the brain is obligatory and constant and is not dependent on hormonal action. During short-term fasting, hepatic glycogen is broken down to glucose by the glycogenolysis pathway (1). During longer fasts, the breakdown of muscle and fat provides the liver with the necessary substrates for gluconeogenesis (2) and ketogenesis (3). Hepatic gluconeogenesis (2) depends primarily on the availability of alanine, whereas renal gluconeogenesis uses glutamine as its primary substrate. Glucogon prevents hypoglycemia, primarily by stimulating hepatic glycogenolysis and gluconeogenesis. Catecholamines stimulate both hepatic and renal gluconeogenesis, while stimulating lipolysis, inhibiting glucose uptake by muscle, and directly inhibiting insulin secretion. Cortisol and growth hormone stimulate both hepatic gluconeogenesis and lipolysis, whereas growth hormone also suppresses peripheral utilization of glucose.

tion of glucose, and stimulating lipolysis. The latter provides both substrate for glyconeogenesis (glycerol) and an alternative energy source for muscle (fatty acids and ketone bodies). Glucagon acts primarily by stimulating hepatic glucose production, having little or no effect on peripheral glucose utilization or renal glucose production. Although glucagon stimulates lipolysis and thus ketogenesis, it appears to have a minimal net effect on the mobilization of gluconeogenic precursors from fat (7). Catecholamines and glucagon act independently, and both are required for an adequate glycemic response. Failure of either will significantly impair the glycemic response to hypoglycemia (8).

The counterregulatory effects of cortisol and growth hormone take several hours to become evident. Therefore, these hormones play a small role in the prevention of acute hypoglycemia but are important in the prevention of hypoglycemia during prolonged fasting. Cortisol stimulates both hepatic gluconeogenesis and lipolysis, resulting in increased levels of free fatty acids and glycerol. Growth hormone has a similar effect on lipolysis and gluconeogenesis, while simultaneously suppressing peripheral utilization of glucose. Both of these hormones rely on increased lipolysis to provide substrates for gluconeogenesis, as well as free fatty acids and ketone bodies, which are used as alternative energy sources. These are in effect glucose sparing in that they decrease the dependence of muscle and other non-neural tissues on glucose. This emphasizes the importance of the lipolytic and ketogenic pathways in the prevention of hypoglycemia. If levels of fatty acids or ketone bodies fail to increase, either because of inadequate fat stores or because of metabolic defects that prevent their production, utilization of glucose by muscle will increase, as will the risk of hypoglycemia, even if the remaining counterregulatory mechanisms function normally.

Therefore, despite the multiple redundant mechanisms that have evolved to prevent hypoglycemia, malfunction of any one of them will place the patient at risk of developing hypoglycemia. The specific nature of the malfunction will determine the associated clinical syndrome, with some defects resulting in profound, treatment-resistant hypoglycemia and others causing only mild hypoglycemia during prolonged fasting. In this chapter we review the common and rare causes of hypoglycemia. Because of the complexity of this problem in the developing child, and because of recent major advances in this field, a separate section is devoted to causes and treatment of hypoglycemia in the newborn and infant.

MEASUREMENT OF CIRCULATING GLUCOSE LEVELS

Accurate measurement of the circulating concentration of glucose is crucial to making the diagnosis of hypoglycemia. Appropriate reference standards must be used, because levels differ depending on whether whole blood or plasma is measured and if the sample is obtained from an artery, vein, or capillary. Most reference ranges are based on venous plasma samples. Arterial glucose concentrations are higher than venous glucose concentrations because of substantial glucose extraction across the forearm during hyperinsulinemic conditions. Glucose concentrations in whole blood are lower than those in plasma because glucose is metabolized by the glycolytic pathway in red blood cells and leukocytes, resulting in unequal distribution of glucose between intracellular and extracellular fluid. Whole-blood glucose measurements may be spuriously high in severe anemia and low in polycythemia vera or in the presence of excessive leukocytosis. Spuriously low glucose measurements due to glycolysis in blood cells in vitro (pseudohypoglycemia) should be avoided by transferring plasma rapidly to the laboratory for

centrifugation. If delay is anticipated, chilling on ice will decrease the rate of *in vitro* glycolysis. Alternatively, this artifact can be minimized by collecting the blood in a tube containing inhibitors of glycolysis, such as oxalate and fluoride.

Glucose values frequently are measured in capillary blood obtained by a fingerstick and applied to a reagent strip for analysis by visual inspection or by a glucose meter. Visual inspection of a reagent strip to which blood has been applied is not a reliable way to distinguish normal from low glucose values. Glucose-meter measurements may be subject to artifacts resulting from poor technique of the patient or the medical staff performing the test or from technical problems with the glucose meter. Moreover, most glucose meters are calibrated to measure high glucose values and thus may be inaccurate in the hypoglycemic range. Therefore, although glucose meters may be very useful for screening patients to determine if symptoms correlate with low glucose measurements, thus excluding hypoglycemia when levels are high, the definitive diagnosis of hypoglycemia must always be based on an appropriately calibrated, standard chemical test in the laboratory.

DEFINITION OF HYPOGLYCEMIA

The diagnosis of hypoglycemia is most convincingly based on the Whipple triad: symptoms consistent with hypoglycemia, a low plasma glucose concentration, and relief of symptoms after the plasma glucose level is raised to normal by administration of exogenous glucose (9). However, the cutoff glucose concentration for defining hypoglycemia is controversial. A review of the literature reveals that glucose concentrations that have been proposed range from 45 to 75 mg/dL (2.5 to 4.2 mmol/L). This controversy stems from the fact that hypoglycemia can be defined in several ways, including the normal response to fasting, the level at which clinical neuroglycopenic symptoms appear, and the level at which a physiologic counterregulation response is triggered. Thus, the glucose level at which hypoglycemia is diagnosed depends primarily on the definition used. According to the first criterion, glucose concentrations in venous plasma obtained after an overnight fast are considered abnormal if they are lower than 60 mg/dL (3.3 mmol/L). However, if hypoglycemia is defined as the clinical pathophysiologic state characterized by autonomic and neuroglycopenic symptoms, then glucose concentrations below 54 mg/dL (3.0 mmol/L) should be defined as pathologic (10).

Defining hypoglycemia is further complicated by the fact that the normal plasma glucose response to prolonged fasting is different in adult men and women. In adult men, the normal fasting plasma glucose level is above 55 mg/dL (3.1 mmol/L) at 24 hours and 50 mg/dL (2.8 mmol/L) at 48 and 72 hours. In normal premenopausal women, fasting plasma glucose levels may dip as low as 35 mg/dL (1.9 mmol/L) at 24 hours, whereas more prolonged fasts may drive glucose levels to as low as 30 mg/dL (1.7 mmol/L) and, rarely, even below this (Fig. 69.2) (11). Responses of counterregulatory hormones to lowered blood glucose are reduced in healthy young women, which may explain these low fasting plasma glucose levels (12). Because the normal glucose response to fasting may vary according to the age and gender of the patient, the appearance of neuroglycopenic symptoms is an important indication that the measurement of a low plasma glucose concentration is indeed true hypoglycemia. In the healthy adult, prolonged fasting results in the formation of ketone bodies that can be used as an alternative fuel for brain metabolism; therefore, neuroglycopenia may not occur at glucose levels that under other conditions would cause severe symptoms. In contrast, hypoglycemia induced by insulin or insulin-like factors is associated with sup-

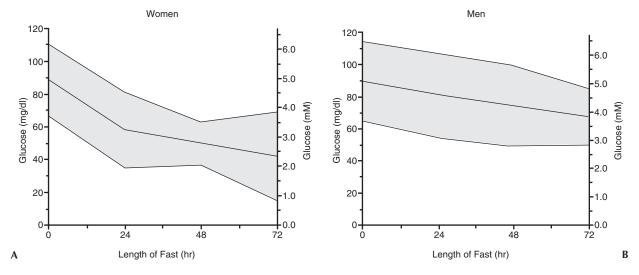

Figure 69.2. Glycemic response to a 72-hour fast in nonobese adult women (**A**) and men (**B**). Plasma glucose levels were measured by the glucose oxidase method and are presented as the mean \pm 2 standard deviations. (Data from Merimee TJ, Tyson JE. Stabilization of plasma glucose during fasting: normal variations in two separate studies. *N Engl J Med* 1974;291:1275–1278.)

pression of ketosis, and the brain may therefore be sensitive to moderate reductions in glucose levels.

An alternative approach is to define hypoglycemia on the basis of the physiologic counterregulatory hormone response to lowering of plasma glucose. Insulin secretion is suppressed at glucose levels of 76 to 72 mg/dL (4.2 to 4.0 mmol/L), and glucose-counterregulatory hormones are released at glucose levels of 70 to 65 mg/dL (3.9 to 3.6 mmol/L) (1).

In practice, the definition of hypoglycemia should be adjusted to the clinical situation. Although there is no well-defined glucose concentration for defining hypoglycemia, venous glucose concentrations between 45 and 60 mg/dL (2.5 and 3.3 mmol/L) strongly suggest hypoglycemia, and those below 45 mg/dL (2.5 mmol/L) are usually indicative of important pathology. If the low glucose level is associated with neurologic symptoms, the clinical suspicion for hypoglycemia is high and prompt evaluation to identify the cause is required. In patients with diabetes treated with insulin, glucose levels should be maintained above 75 mg/dL (4.2 mmol/L) to prevent symptomatic hypoglycemia and hypoglycemia unawareness (see Chapter 40).

SIGNS AND SYMPTOMS OF HYPOGLYCEMIA

Signs and symptoms of hypoglycemia result from neuronal glucose deprivation and can be divided into two categories: autonomic and neuroglycopenic (Table 69.1). The former result from the activation of the autonomic nervous system, with release of epinephrine from the adrenal medulla into the circulation and of norepinephrine from sympathetic postganglionic nerve terminals within the target tissues. Under normal circumstances, the glycemic threshold for catecholamine release is higher than that for induction of neuroglycopenic symptoms. Therefore, the autonomic symptoms precede the neuroglycopenic symptoms. Symptoms and signs related to catecholamine release include tremulousness, pallor, palpitations, tachycardia, widened pulse pressure, and anxiety. Sweating, hunger, and paresthesias are also common and are mediated by acetylcholine. In adults, sweating is often very prominent and is thought to be mediated by sympathetic cholinergic postganglionic neurons (13).

Neuroglycopenic symptoms are the result of glucose deprivation in the brain. Because glucose is the main fuel of metabolism in brain tissue, reduced levels of glucose may be insufficient to supply the brain with its energy requirements. Thus, the symptoms of neuroglycopenia and those of hypoxia are virtually indistinguishable. They include nonspecific complaints, such as weakness, fatigue and dizziness, headache, behavioral changes, and confusion. Affected persons often show poor judgment, perform their activities in an automatic, repetitive manner, and become uncooperative. They may become lethargic, irritable, and occasionally even aggressive. There is variable impairment of cognitive functions, including difficulty in think-

TABLE 69.1. Signs and Symptoms of Hypoglycemia in the Adult						
Autonomic		Neuroglycopenic				
Symptoms	Signs	Symptoms	Signs			
Hunger Sweating Anxiety Paresthesias Palpitations Tremulousness	Pallor Tachycardia Widened pulse pressure	Weakness, fatigue Dizziness Headache Confusion Behavioral changes Cognitive dysfunction Blurred vision, diplopia	Cortical blindness Hypothermia Seizures Coma			

ing and concentration, aphasia, and slurred speech. In addition, hypoglycemia may cause blurred vision, cortical blindness, paresthesias, hemiplegia, hypothermia, and eventually coma, seizures, and death. Symptoms are less specific in the neonate than in the older child and adult and may include irritability, jitteriness, changes in tone, cyanosis, tachypnea, lethargy, and frank coma or seizures (see section on neonatal hypoglycemia).

The glycemic threshold for the appearance of counterregulatory hormone response and for neuroglycopenic symptoms is dynamic. It shifts to higher glucose concentrations following sustained hyperglycemia in patients with poorly controlled diabetes (14) and to lower glucose concentrations in patients with recurrent episodes of hypoglycemia (15). Even a single episode of hypoglycemia can blunt catecholamine response to subsequent hypoglycemia (16). The shift in glycemic thresholds following recurrent hypoglycemia results from an adaptive increase in uptake of glucose by the brain, probably due to increased cerebral blood flow (17) and enhanced extraction of glucose induced by upregulation of the brain glucose transporters GLUT1 and GLUT3 (18). In addition to depending on the previous glycemic environment, the response to hypoglycemia depends on the availability of alternative fuels for the brain, such as ketone bodies and lactate (19).

Cerebral energy requirements, the adaptive changes in glucose extraction, and the ability to utilize alternative fuels are not uniform in all the regions of the brain. Thus, enhanced uptake of glucose in response to recurrent hypoglycemia can maintain normal metabolism and function in some regions of the brain, while other regions may remain susceptible to hypoglycemiainduced dysfunction. From the clinical standpoint, a patient with recurrent hypoglycemia may fail to develop warning symptoms of hypoglycemia and may not be able to react quickly enough to avert severe neuroglycopenia and coma when the glucose concentration reaches a critical threshold. Therefore, enhanced uptake of glucose by the brain following recurrent hypoglycemia is potentially dangerous and should be considered maladaptive (18).

Severe and prolonged hypoglycemic episodes may cause neuronal cell death, resulting in permanent impairment of brain function. However, if the hypoglycemia is treated effectively, apparent full recovery is the rule even after severe episodes of hypoglycemia. There are concerns that recurrent hypoglycemia may result in permanent damage to intellectual capacity, although in adults there is no conclusive evidence to support this notion. Prospective studies of patients with diabetes at risk for recurrent severe hypoglycemia show no effect on long-term cognitive function (20,21). In contrast, children younger than 5 years of age do show a permanent impairment in IQ after recurrent events of hypoglycemia (22). Thus, hypoglycemia is harmful to the developing brain during the first years of life.

CLASSIFICATION OF HYPOGLYCEMIC DISORDERS

The differential diagnosis of hypoglycemia is broad (Fig.69.3). The various hypoglycemic disorders can be classified on the basis of glucose kinetics (increased glucose utilization vs. defi-

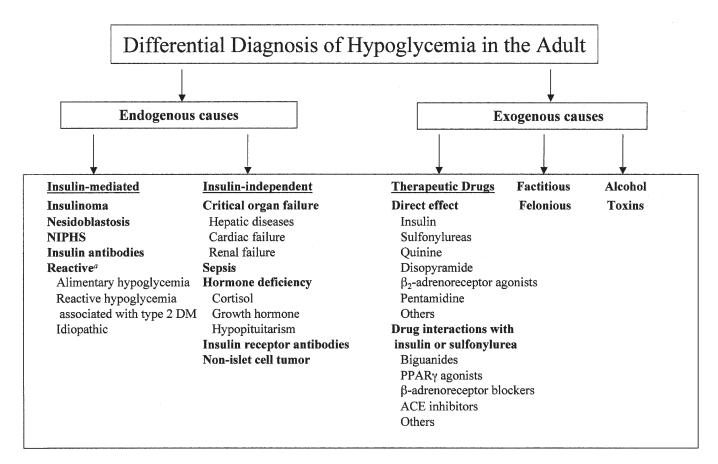

Figure 69.3. The major causes of hypoglycemia in the adult are grouped according to mechanism. NIPHS, noninsulinoma pancreatogenous hypoglycemia; PPAR-γ, peroxisome proliferator-activated receptor-γ; ACE, angiotensin-converting enzyme. ^aPostprandial symptoms are common but usually not associated with hypoglycemia.

cient glucose production), insulin mediation (hyperinsulinemic vs. hypoinsulinemic), etiology (endogenous vs. exogenous causes), age (adults vs. infants and children), and the clinical characteristics of the patient (appears healthy or ill) (23).

From a clinical standpoint, it is common to classify hypoglycemic disorders as fasting or reactive. Reactive hypoglycemia refers to the occurrence of hypoglycemia in the postprandial state, not during fasting, and usually does not imply a serious underlying disorder. However, this term describes the timing of hypoglycemia and has no implication regarding mechanism or etiology. For example, postprandial hypoglycemia may be the predominant finding in some patients with insulinoma (23). Moreover, the majority of patients referred for evaluation of postprandial symptoms do not have low plasma glucose levels at all. Therefore, true functional/ reactive hypoglycemia is not common (24,25).

In this chapter, we refer to hypoglycemic disorders based on the age group of the patients. In adults, hypoglycemia may be caused by drugs, systemic disease, abnormalities in counterregulatory hormones, or tumors. Hypoglycemia arising as a consequence of the therapeutic use of insulin or oral hypoglycemic agents in patients with diabetes, the most common exogenous cause of hypoglycemia, is considered elsewhere in this volume (see Chapters 40 and 41). In infants and nondiabetic children, hypoglycemia often results from inborn genetic defects in proteins important for regulating insulin secretion or substrate metabolism. In recent years, there has been an explosion of information on the human genome, leading to better classification and characterization of different hypoglycemic disorders. Thus, the etiologies of hypoglycemia in this age group are discussed separately.

EXOGENOUS CAUSES OF HYPOGLYCEMIA

Drug-Induced Hypoglycemia

Many drugs have been associated with hypoglycemia (Table 69.2); however, a cause-and-effect relationship has not been

established for many of these agents. Factors predisposing to drug-induced hypoglycemia include very young and very old age, impaired renal and liver functions, and poor nutrition (26). Drugs may cause hypoglycemia by several mechanisms: (a) by increasing release of insulin secondary to activation of the insulin secretion machinery or secondary to a direct toxic effect to pancreatic islets resulting in nonregulated insulin release; (b) by increasing uptake and utilization of glucose in the peripheral tissue; and (c) by decreasing production of glucose by the liver. In addition, drugs may interact with sulfonylurea agents and insulin and potentiate their hypoglycemic effects. In these cases it may be difficult to assess the role of the individual drugs in the development of hypoglycemia.

Many of the drugs that have been associated with hypoglycemia are in very common use, and patients, particularly the elderly, are frequently receiving multiple drugs. Therefore, iatrogenic hypoglycemia should always be included in the differential diagnosis. Doing so may facilitate diagnosis and treatment and prevent unnecessary diagnostic and therapeutic procedures. The most common causes of drug-induced hypoglycemia are alcohol and treatment with a sulfonylurea or insulin in patients with diabetes. The latter is discussed in Chapter 41.

DRUGS AND TOXINS THAT INCREASE INSULIN RELEASE

Quinine and Related Drugs

The antimalarial drug quinine and its antiarrhythmic derivative quinidine have been shown to induce hyperinsulinemic hypoglycemia. Quinine-related substances stimulate insulin secretion from pancreatic β -cells and cause a mild decrease in blood glucose levels that is usually not sufficient to induce symptoms of hypoglycemia in healthy subjects. The hypoglycemic effect of quinine may become more prominent in the presence of renal failure, since drug clearance is reduced and the concentration of quinine in the blood is higher. In addition to quinine-induced hyperinsulinemia, acutely ill patients with malaria are prone to development of hypoglycemia because of consumption of glucose by the malarial parasites. In patients with malaria falci-

ACE, angiotensin-converting enzyme; PPARy, peroxisome proliferator-activated receptor-y.

These drugs very rarely cause hypoglycemia by themselves but may exacerbate hypoglycemia in patients treated with oral

hypoglycemic agents or insulin.

^bMost of these drugs are in very common use and only rarely have been reported to be associated with hypoglycemia. Furthermore, in many cases, the direct cause-and-effect relationship was not proven.

^cAppear to cause hypoglycemia by decreasing insulin clearance.

parum who are treated with quinine, hypoglycemia may be overlooked because the neurologic symptoms may be attributed to cerebral malaria. Therefore, blood glucose should be carefully monitored and a glucose supplement administered to prevent dangerous hypoglycemia (27,28).

Disopyramide

Disopyramide, used clinically as an antiarrhythmic agent, has been shown to increase insulin secretion from pancreatic β cells, resulting in hyperinsulinemic hypoglycemia. The drug causes closure of the β -cell K_{ATP} channel, binding to the channel at a site distinct from the sulfonylurea binding site (29). Disopyramide often is used in elderly patients, who may also suffer from impaired renal function and who appear to be particularly susceptible to the glucose-lowering effect of the drug (30). A recent study found that the use of disopyramide did not affect the risk of hypoglycemia in an ambulatory patient population, suggesting that this side effect may be minor in the general population and may be of clinical importance only in selected patients at particular risk (31). It has been claimed that, although rare in absolute terms, disopyramide is one of the most common causes of drug-induced hypoglycemia in nondiabetic patients (32).

β₂-Adrenoreceptor Agonists

Ritodrine therapy to delay premature delivery during pregnancy can stimulate insulin secretion and cause hypoglycemia in the newborn and rarely in the mother (33). Therapeutic doses of β_2 -adrenoreceptor agonists administered to patients with bronchial asthma were not reported to induce hypoglycemia; however, albuterol overdose was reported to cause hypoglycemia in a young child (34).

Pentamidine

Pentamidine is used for the treatment of *Pneumocystis carinii* pneumonia in patients with AIDS and for parasitic infections, including trypanosomiasis and leishmaniasis. The drug is toxic to pancreatic β -cells, resulting in unregulated release of insulin from the damaged β -cells and leading to hypoglycemia followed by hyperglycemia and even permanent diabetes mellitus. The toxicity to the β -cells is more common and severe following systemic administration and is related to the cumulative dose of the drug (35,36).

DRUGS THAT INCREASE INSULIN SENSITIVITY

Biguanides and Peroxisome Proliferator-Activated Receptor-γ Agonists

Metformin and the glitazones do not usually cause hypoglycemia when taken alone. Over 10 years of follow-up among patients with type 2 diabetes taking metformin in the UK Prospective Diabetes Study (UKPDS), the proportion of patients per year who had one or more episodes of hypoglycemia was 4.2%, none of whom developed severe hypoglycemia (37). The biguanides and glitazones may augment hypoglycemia caused by sulfonylureas and insulin by increasing the uptake and utilization of glucose (38). Metformin also decreases hepatic production of glucose and decreases intestinal absorption of glucose.

Angiotensin-Converting Enzyme Inhibitors

The association between angiotensin-converting enzyme (ACE) inhibitors and hypoglycemia in patients with diabetes treated with sulfonylureas or insulin is controversial. One study reported that 14% of all hospital admissions for hypoglycemia might be attributable to ACE inhibitors (39). The association between ACE inhibitors and hypoglycemia was not explained

by potential confounding factors, such as the type of diabetes treatment and congestive heart failure (40). ACE inhibitors can intensify the glucose-lowering effect of insulin or sulfonylureas. A study using a hyperinsulinemic euglycemic clamp protocol found that captopril improved sensitivity to insulin in healthy volunteers with normal blood pressure. With enalapril, however, the increase in insulin sensitivity was less pronounced and did not achieve statistical significance (41,42). ACE inhibitors may indirectly increase insulin sensitivity by increasing circulating kinins, leading to vasodilatation and increased uptake of glucose in muscle tissue. Nevertheless, large series of patients with diabetes treated with ACE inhibitors, including the UKPDS, show that these are safe and that the risk of hypoglycemia is very low (43).

β-Adrenergic Receptor Blocking Agents

Nonselective β -adrenergic receptor blocking agents, such as propranolol, have been associated with hypoglycemia in otherwise healthy children but not in healthy adults (44). Most of the cases of hypoglycemia associated with these agents were in patients with diabetes receiving insulin or sulfonylureas. Thus, it is difficult to prove a cause-and-effect relationship between therapy with β -blockers and hypoglycemia (45). β -Blockers can increase glucose uptake in skeletal muscle by antagonizing the effects of catecholamines on glucose uptake and lipolysis (46). Suppression of lipolysis with reduction of nonesterified free fatty acids in plasma improves insulin sensitivity and indirectly reduces gluconeogenesis. β-Blockers decrease insulin secretion from pancreatic β -cells. Therefore, insulin-treated patients with diabetes may be more susceptible to the glucose-lowering effects of β -blockers, whereas patients with type 2 diabetes treated with oral medications or diet may have exacerbations of hyperglycemia rather than hypoglycemia. Similar to ACE inhibitors, β-blockers were not associated with a higher frequency of hypoglycemic episodes in large series of patients with type 2 diabetes, including the UKPDS (43). β-Blockers may block the adrenergic response to hypoglycemia, leading to hypoglycemia unawareness and a predominance of the neuroglycopenic symptoms. Moreover, β -blockers may delay the recovery from hypoglycemia because of inhibition of catecholamine-mediated glucose counterregulation. Catecholamines are not required for prompt recovery from hypoglycemia in patients with intact islet-cell function; however, β -blockade may become critical in glucagon-deficient patients with type 1 diabetes. The risk for severe hypoglycemia in insulin-treated patients with diabetes can be reduced by using one of the relatively selective β_1 -adrenergic antagonists (47).

DRUGS THAT DECREASE HEPATIC GLUCOSE PRODUCTION

Hypoglycemia resulting from suppressed hepatic production of glucose may occur in the setting of acute drug intoxication, which may result in metabolic inhibition of gluconeogenesis, such as with alcohol or in hepatic necrosis, as may occur after paracetamol poisoning. Hypoglycemia may be exacerbated if acute renal failure occurs concomitantly with hepatic toxicity.

Alcohol-Induced Hypoglycemia

The most common cause of drug-induced hypoglycemia secondary to suppressed gluconeogenesis is alcohol overdose. Alcohol-induced hypoglycemia may occur in persons of all ages and in all classes of society. It is more common in men than in women and in malnourished persons on a low-calorie diet. Young children are especially susceptible to the hypoglycemic effects of alcohol. Therefore, accidental consumption of even modest amounts of alcohol may result in hypoglycemia in infants and young children (48). Fewer than 1% of patients with

alcohol intoxication presenting to the emergency room have hypoglycemia. However, because of the very high incidence of alcohol intoxication relative to the incidence of all other causes of hypoglycemia, alcohol can be implicated in 18% to 52% of patients admitted to the emergency department because of sustained hypoglycemia (26). This variation in the incidence of alcohol-induced hypoglycemia in different series probably reflects social, ethnic, and cultural differences in alcohol consumption among the populations studied. Symptoms of alcohol intoxication may be very similar to those of neuroglycopenia, making clinical differentiation difficult. Thus, immediate routine determination of blood glucose is recommended for all intoxicated patients in the emergency department to guarantee rapid identification of those with significant hypoglycemia. A delay in the diagnosis may result in permanent brain damage and death. The mortality rate among hospitalized patients with alcohol-induced hypoglycemia may be as high as 10% (26).

Ethanol is usually still detectable in the blood at the time the patient presents with hypoglycemia but may not be markedly elevated and may correlate poorly with the glucose concentration. Characteristically, the patient with alcohol-induced hypoglycemia is an alcoholic with a history of moderate to excessive consumption of alcohol and little or no protein or carbohydrate intake during the preceding hours or days. The patient often is referred to the hospital in a comatose state and also may suffer from hypothermia. Most patients do not experience autonomic response to alcohol-induced hypoglycemia, and some chronic alcoholics can tolerate low blood glucose levels without symptomatic neuroglycopenia. The diminished neuronal response to hypoglycemia may result from recurrent subclinical episodes of hypoglycemia that reduce the glycemic threshold for the appearance of counterregulatory hormone response and for neuroglycopenic symptoms. There may also be a direct effect of alcohol on the activation of the hypothalamic-adrenal axis in response to hypoglycemia. In addition, plasma ketone bodies are often high and can be used as an alternative fuel for brain metabolism. Some patients present with alcoholic ketoacidosis, which may occur several days following alcohol ingestion and resembles diabetic ketoacidosis. In these patients, plasma glucose levels are usually normal or high; however, some patients may present with severe hypoglycemia. Both the pathogenesis of this condition and the reason certain patients develop hypoglycemia while others become hyperglycemic are unknown. This medical emergency should be treated with intravenous glucose injection preceded by thiamine injection to prevent the development of Wernicke encephalopathy.

Alcohol causes hypoglycemia by inhibiting gluconeogenesis. Ethanol is metabolized in the liver by alcohol dehydrogenase to acetaldehyde and then to acetic acid by aldehyde dehydrogenase. The enzymatic reactions generate free hydrogen ions, with subsequent reduction of nicotinamide dinucleotide (NAD) to NADH. The depletion of hepatic NAD stores inhibits the metabolism of precursors in the gluconeogenic pathway, including the conversion of lactate to pyruvate, several steps in the tricarboxylic acid cycle, and the conversion of glycerol to glucose (49). Ethanol does not inhibit glycogenolysis. Thus, well-nourished obese patients and those who have had significant carbohydrate intake within 12 to 24 hours are likely to have adequate hepatic glycogen stores, which partially protect them from hypoglycemia.

Ethanol also inhibits the release of corticotropin, cortisol, and growth hormone in response to hypoglycemia. The glucagon and epinephrine responses to hypoglycemia may also be delayed, although this is controversial. The failure to activate a counterregulatory hormone response may contribute to the development of fasting hypoglycemia (50). In addition to inducing fasting hypoglycemia, alcohol may increase the risk for reactive hypoglycemia. Moderate alcohol consumption was shown to increase insulin secretion in response to glucose stimulation. Thus, a mixture of alcohol and sucrose may induce postprandial reactive hypoglycemia due to insulin excess. For example, 10% to 20% of healthy volunteers who consumed a gin and tonic (a sucrose-rich alcoholic beverage) on an empty stomach and did not eat for several hours afterwards developed symptomatic reactive hypoglycemia (51).

Interaction Between Alcohol and Antidiabetic Drugs

The effect of alcohol on insulin-induced hypoglycemia is controversial. In one study, blood glucose levels were similar after administration of insulin and ethanol together or insulin alone (52). However, alcohol does inhibit gluconeogenesis (see above) and has been reported to be commonly involved in admissions to the hospital for hypoglycemia resulting from insulin overdose (53). Furthermore, there are concerns that alcohol consumption may exacerbate the brain-damaging effects of hypoglycemia. There is very limited information on the interaction between sulfonylureas and the hypoglycemic effects of alcohol. In one large series of patients with drug-induced hypoglycemia, a few patients with diabetes developed hypoglycemia following administration of both sulfonylureas and alcohol (54).

Hypoglycin A

Hypoglycemia may occur after the ingestion of the unripe akee fruit. The akee fruit is commonly consumed in Jamaica, and if eaten unripe may cause severe weakness, vomiting, convulsions, coma, and eventually death. The symptoms are associated with severe hypoglycemia resulting from the toxin hypoglycin A, which inhibits fatty acid oxidation and thus causes a metabolic syndrome very similar to that caused by inborn errors of fatty acid metabolism (see section on hypoglycemia in the neonate) (55). Both ketogenesis and hepatic gluconeogenesis are inhibited, causing both hypoglycemia and lowered ketone bodies, a combination that may be particularly neurotoxic.

OTHER DRUGS

Many drugs cause hypoglycemia by various mechanisms, some of which have not yet been completely defined. Some drugs, such as sulfonamide, dicumarol, and phenylbutazone, interact with sulfonylureas to enhance their hypoglycemic activity. Other drugs, including isoniazid and synthetic antimalarial drugs such as chloroquine, may rarely induce hypoglycemia in patients with diabetes by reducing the clearance of insulin from the blood. A large dose of salicylates may induce hypoglycemia in young children, but rarely in adults. The mechanism of salicylate-induced hypoglycemia is unknown but may be related to increased peripheral utilization of glucose, suppression of hepatic gluconeogenesis, or augmentation of insulin release (26). Recent studies have shown that salicylates can enhance insulin sensitivity by inhibiting the IkB kinase (56).

Factitious Hypoglycemia

Most cases of factitious hypoglycemia are caused by the deliberate administration of insulin or oral hypoglycemic agents by the patient, although accidental administration or administration by a caregiver may occur as well. The prevalence of factitious hypoglycemia is unknown. It was suggested that it is more common in women than in men, although this has not been confirmed (57). The typical patient is young, aged 15 to 40 years, and has access to insulin or oral hypoglycemic agents such as sulfonylureas. The patient may be a medical or para-

medical worker or a family member of a person with diabetes treated with oral hypoglycemic agents or insulin and may know the effects of the abused medication and the symptoms of hypoglycemia. Most patients seem to be "mentally healthy" and provide detailed description of their "illness," obviously omitting the fact that hypoglycemic drugs were abused. Similar to other factitious diseases, use of hypoglycemic drugs is usually denied. When confronted with this possibility, the patient may respond in an aggressive manner, blaming the physician for not trusting him or her. These patients may be very sophisticated in concealing self-administration of hypoglycemic drugs, and episodes of hypoglycemia may occur even during close supervision in the hospital. The history of episodes of hypoglycemia may extend over periods of many years, sometimes with intervals of remission explained by irregular administration of the drugs. The history may suggest the presence of an insulinoma, and failure to diagnose the cause of hyperinsulinism may result in an unnecessary laparotomy and even pancreatectomy.

Accidental administration of insulin or oral hypoglycemic agents may produce "factitious" hypoglycemia. Inadvertent administration of insulin to the wrong patient in a hospital is a rare cause of hypoglycemia. Unintended use of oral hypoglycemic agents may result from a prescribing error by a physician or a pharmacist or by substitution of an oral hypoglycemic for another medication by the patient or by a family member. Insulin and drug-induced factitious hypoglycemia may also be the result of attempted suicide or homicide.

The diagnosis of factitious hypoglycemia should be considered in all patients with hyperinsulinemic hypoglycemia. The initial history may provide clues suggesting the presence or absence of factitious hypoglycemia; however, each patient must be fully evaluated regardless of initial impression. We recently evaluated a young soldier with a highly suggestive history of insulinoma, no apparent access to insulin or drugs, and no suggestion of secondary gain, who was subsequently proven to have ingested glibenclamide. Another patient, with a clinical history highly suspicious of factitious hypoglycemia and easy access to medical personnel and medication, was subsequently proven to have a benign insulinoma.

The biochemical diagnosis of insulin-induced factitious hypoglycemia is relatively simple if blood is collected during an episode of hypoglycemia for glucose, insulin, and C-peptide measurement. Plasma insulin is high, with discordant low levels of C-peptide, reflecting the suppression of endogenous insulin secretion by low glucose levels. If insulin and C-peptide measurements are discordant, the presence of antibodies to insulin should be excluded. Insulin antibodies may cause spuriously high or low insulin measurements, depending on the method used in the insulin assay. The presence of circulating antibodies should also be excluded by direct measurement using specific assays and by measuring insulin levels on serial dilutions of plasma samples. Nonlinear correlation between measured insulin and plasma dilution indicates the presence of a substance that interferes with the insulin assay. In the past, the presence of insulin antibodies was thought to be prima facie evidence of exogenous insulin administration. However, modern, highly purified, recombinant human insulin rarely causes clinically significant antibody production, and it is now clear that antibodies may also occur in rare patients with autoimmune hypoglycemia and prior to the clinical onset of type 1 diabetes. Therefore, detection of insulin antibodies should not be regarded as a specific and sensitive assay for the diagnosis of factitious hypoglycemia. In the past, all commercially available insulin was obtained from beef or porcine pancreas. Thus, species-specific assays could be developed to prove the exogenous origin of circulating insulin. Today, most commercial insulin is of human origin, making these assays obsolete; however, the increasing use of insulin analogues may cause a revival of this approach.

In contrast to surreptitious administration of insulin, secretagogue-induced hypoglycemia is associated with elevation of both insulin and C-peptide levels. Plasma levels of C-peptide fail to be suppressed in response to the insulin hypoglycemia test, and the response to different stimuli, such as glucagon and glucose, may be excessive, similar to the findings in patients with insulinoma. Therefore, the diagnosis of factitious hypoglycemia due to insulin secretagogues is usually a difficult challenge. For confirmation or exclusion of the diagnosis, blood levels of some of the relevant drugs should be measured during hypoglycemia in an experienced toxicology laboratory. The increasing number of drugs available that stimulate insulin secretion is making this task progressively more difficult.

On certain occasions, when there is strong clinical suspicion of factitious hypoglycemia, it may be necessary to search the hospital room of a patient to find insulin vials, syringes, needles, or drug tablets to confirm the diagnosis of factitious hypoglycemia. A room search is considered by some to be unethical and should be performed only after careful consideration and approval of the appropriate hospital authorities.

The treatment of factitious hypoglycemia is the same whether it is mediated by insulin or sulfonylurea and includes immediate relief of hypoglycemia by intravenous glucose followed by psychiatric intervention to prevent recurrent episodes of hypoglycemia. Management involves a supportive confrontation followed by long-term psychiatric care. Factitious hypoglycemia is a serious psychiatric disturbance. Although some patients admit that the motive is to gain attention, sympathy, or some other secondary gain, in the majority insight is limited and the longterm prognosis is poor. Hypoglycemia may recur or may be followed by other psychosomatic symptoms or drug abuse. Some patients may later commit suicide (58).

ENDOGENOUS CAUSES OF HYPOGLYCEMIA

Hypoglycemia Due to Critical-Organ Failure

Sepsis and diseases that cause severe hepatic, cardiac, or renal failure are common causes of hypoglycemia among hospitalized patients. Patients with malnutrition or with failure of more than one critical organ are more susceptible to severe hypoglycemia.

HEPATIC DISEASES

Hepatic glycogenolysis and gluconeogenesis play critical roles in the maintenance of postabsorptive blood glucose. Since the normal liver has a very large capacity for glucose production, hypoglycemia will occur only in the face of massive destruction of the liver parenchyma or in the presence of accelerated utilization of glucose. Accelerated utilization of glucose may be present in several clinical conditions, including treatment with insulin or oral medications and during sepsis. Hypoglycemia has been reported in patients with severe liver failure due to toxic hepatitis, fulminant viral hepatitis, fatty liver, or hepatitis associated with alcohol administration and cholangitis. In the latter, sepsis complicating biliary obstruction may contribute to the development of hypoglycemia. Hypoglycemia is uncommon in patients with cirrhosis. Plasma levels of insulin may be relatively high because of the presence of portal-systemic shunts and reduced hepatic insulin extraction (59).

CARDIAC FAILURE

Occasionally, hypoglycemia may occur in patients with severe congestive heart failure. The primary mechanism causing hypoglycemia in these patients is not known but may be the combination of cachexia, lack of gluconeogenic substrate, and liver dysfunction due to hepatic hypoxia and congestion. Patients admitted to intensive care units may develop ischemic hepatitis resulting from episodes of acute heart failure and hypotension. A retrospective study of patients with ischemic hepatitis showed that hypoglycemia is common, occurring in one third of the patients (60).

RENAL FAILURE

Renal insufficiency may be associated with hypoglycemia, particularly in patients with end-stage renal disease (61). In one retrospective study, 3.6% of patients with end-stage renal failure admitted to the hospital had hypoglycemia (62). The most common associated pathologies were drug-induced hypoglycemia and sepsis. Severe malnutrition was associated with 7% of hypoglycemic episodes in these patients. Hypoglycemia associated with either sepsis or malnutrition was associated with a particularly high mortality.

Diabetic and nondiabetic patients undergoing either hemodialysis or peritoneal dialysis can develop spontaneous hypoglycemia during or immediately after dialysis (63). This is thought to be caused by increased insulin secretion induced by a high glucose concentration in the dialysis fluid combined with reduced renal insulin clearance. In addition, hypoglycemia may occur when the patients are dialyzed with a glucose-free dialysis fluid. Patients with an initially low plasma glucose level and those who do not eat during dialysis are particularly at risk for hypoglycemia. The hormonal response to hypoglycemia is blunted, and hypoglycemia unawareness is common (64).

The pathogenesis of hypoglycemia in renal failure involves multiple mechanisms, including reduced supply of substrate for gluconeogenesis, especially in patients with severe cachexia, malnutrition with decreased carbohydrate intake, resistance to the hyperglycemic effect of glucagon, and inhibition of gluconeogenesis (65). In healthy volunteers, renal glucose production accounts for 25% of systemic glucose appearance in the postabsorptive state. Furthermore, epinephrine infusion, which increased plasma epinephrine to levels observed during hypoglycemia, increased the renal release of glucose nearly twofold so that, at the end of the infusion, renal glucose release accounted for 40% of systemic glucose production and essentially all of the increase due to adrenergic stimulation (66). Thus, renal glucose production may have an important role in glucose homeostasis in the postabsorptive state and during hypoglycemia. Patients with renal failure are therefore more susceptible to hypoglycemia (67). A considerable number of patients with end-stage renal failure have diabetes. These patients may develop hypoglycemia as a result of decreased clearance of hypoglycemic drugs or insulin.

Sepsis

Sepsis frequently is associated with hypoglycemia in hospitalized patients. In experimental animals, there are several metabolically distinct phases. In the early phase of sepsis, glucose production and utilization are increased and the animals may be hyperglycemic. Hyperglycemia is followed by a hypoglycemic phase in which hepatic glucose production is decreased. This phase is characterized by a rapid depletion of hepatic glycogen content, impaired glycogenesis, and depressed gluconeogenesis, combined with increased peripheral utilization of glucose (68). Regulation of glucose metabolism by the liver is a complicated process that includes several hormonal regulatory factors, such as insulin, glucagon, and catecholamines. Transcriptional and posttranscriptional regulation of β_2 -adrenergic receptor gene expression may be responsible for the altered hepatic glucose metabolism during the progression of sepsis (69). Increased utilization of glucose during sepsis is explained by increased use of glucose by macrophage-rich tissues such as liver, spleen, and lung (70). The muscle and fat cells make only a only modest contribution to the increase in glucose utilization. Cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor- α released during sepsis can increase insulin secretion and stimulate glucose transport, leading to imbalance between glucose production and utilization (71,72). Some of these factors have also been implicated in induction of insulin resistance in states of sepsis.

Endocrine Deficiency Disorders and Hypoglycemia

Decreased secretion of multiple glucoregulatory hormones secondary to recurrent hypoglycemia in patients with insulinoma or type 1 diabetes may exacerbate hypoglycemia and prevent prompt recovery of glucose levels. However, in the adult, hormone deficiencies alone are rarely directly responsible for spontaneous hypoglycemia, since insulin secretion is suppressed in response to hypoglycemia and the counterregulatory mechanisms are partially redundant.

Glucagon and Catecholamine Deficiency

Glucagon and epinephrine are important in the counterregulatory response to short-term hypoglycemia. Glucagon increases endogenous glucose production by stimulating hepatic glycogenolysis and gluconeogenesis. In contrast to glucagon, which exclusively affects glucose production, catecholamines have multiple effects on glucose homeostasis, including suppression of endogenous insulin secretion, stimulation of gluconeogenesis and glycogenolysis, and inhibition of glucose utilization. The relative importance of glucagon compared with catecholamines in the physiologic response to hypoglycemia is controversial; however, deficiency of both glucagon and epinephrine in the presence of insulin may result in severe hypoglycemia (73). In clinical practice, isolated deficiency of glucagon and/or epinephrine in patients without diabetes is extremely rare. There are very few case reports of children with hypoglycemia that was presumed to be due to selective deficiency of epinephrine or glucagon (74,75). In some patients with presumed glucagon or epinephrine deficiency, other causes of hypoglycemia, such as hyperinsulinism, were not excluded and the secretion of other glucoregulatory hormones was not studied. Hypoglycemia does not occur in patients receiving glucocorticoid and mineralocorticoid replacement therapy after bilateral adrenalectomy and in patients treated with adrenoreceptor blockers (73). Thus, isolated deficiencies of epinephrine or glucagon rarely, if ever, cause spontaneous hypoglycemia in the absence of hyperinsulinism or an additional factor that decreases glucose levels.

GROWTH-HORMONE AND CORTISOL DEFICIENCIES

In contrast to the rapid-acting hormones glucagon and epinephrine, growth hormone and cortisol are more important in the late response to hypoglycemia. The counterregulatory effects of these hormones are evident after more than 3 hours of hypoglycemia. Growth hormone and cortisol increase plasma levels of free fatty acids and glycerol, resulting in suppression of glucose utilization and an increase in gluconeogenesis. In addition, cortisol increases gluconeogenesis by induction of hepatic gluconeogenic enzymes (1). The major glucoregulatory effects of growth hormone and cortisol are on hepatic gluconeogenesis. Therefore, deficient growth hormone and/or cortisol may cause hypoglycemia, especially after a prolonged fast when hepatic glycogen stores are depleted. The problem may be compounded when both hormones are deficient, as seen in patients with hypopituitarism.

In clinical practice, however, most adults with growthhormone and/or cortisol deficiency do not develop spontaneous hypoglycemia. Fasting plasma glucose concentrations of patients with primary adrenal insufficiency and patients with corticotropin deficiency are similar to those in normal controls (76). Plasma glucose concentrations after prolonged insulin infusion were lower in patients with panhypopituitarism; however, the recovery from hypoglycemia was intact (77), and the risk of hypoglycemia is not higher compared with that in patients with isolated deficiency of growth hormone or corticotropin. When present, the tendency to develop hypoglycemia following prolonged fasting can be corrected by glucocorticoid replacement, whereas growth-hormone replacement has minimal effect on fasting glucose (77). Adults with hypopituitarism may develop hypoglycemia when glucose production is decreased, as during alcohol ingestion or sepsis, or when glucose utilization is increased, such as during vigorous exercise or pregnancy. Newborns and young children with hypopituitarism are more susceptible to hypoglycemia. Thus, cortisol and growth hormone are probably more important in glucose counterregulation in early life. This hypothesis is supported by experimental data showing that glucocorticoid-deficient newborn mice develop hypoglycemia more frequently during fasting than do adult mice (78).

Immune Hypoglycemia

Hypoglycemia may rarely result from autoantibodies directed against insulin or the insulin receptor. The antibodies disrupt the synchronous coupling between changes in blood glucose and insulin action, thus leading to hypoglycemia.

HYPOGLYCEMIA CAUSED BY ANTIBODIES TO INSULIN

The most common cause for the presence of circulating insulin antibodies is the administration of insulin to patients with diabetes. The antibodies may reduce the levels of free insulin postinjection, resulting in higher postprandial levels of glucose, but may also increase the half-life of insulin (79). Theoretically, a prolonged half-life of insulin causes late hypoglycemia after a bolus injection of insulin. In practice, however, the antibodies do not have a major effect on glycemic control and the incidence of severe hypoglycemia (80). Antibodies to insulin also may develop in patients with recent-onset type 1 diabetes before insulin treatment, relatives of patients with type 1 diabetes or other autoimmune disorders, and occasionally in otherwise healthy subjects (81).

In rare patients, insulin antibodies may be a primary cause of hypoglycemia. The majority of patients with hypoglycemia induced by antibodies to insulin are Japanese. The higher prevalence of autoimmune hypoglycemia in the Japanese population is probably explained by the higher prevalence of specific HLA class 2 alleles that are strongly associated with the disease in this population (82). Hypoglycemia is often postprandial, although fasting hypoglycemia may also occur. Patients often develop hyperglycemia immediately after a meal or glucose load followed by hypoglycemia 2 to 3 hours later. The severity of hypoglycemia varies, and the presentation may be of severe neuroglycopenia with symptoms of confusion, cognitive dysfunction, and even coma. Patients may have other

autoimmune diseases, such as Graves disease, systemic lupus erythematosus, or rheumatoid arthritis (80). Exposure to sulfhydryl-containing medications, especially methimazole, was reported for almost half of the patients (82). Interferon- α and medications that cause drug-induced lupus, such as hydralazine, procainamide, and isoniazid, also may cause the development of insulin antibodies and hypoglycemia. Several patients with plasma-cell dyscrasias were reported to have hypoglycemia due to monoclonal insulin-binding antibodies with a low affinity for insulin and a high binding capacity (80). Insulin levels in patients with insulin antibodies causing hypoglycemia usually are high (>100 μ U/mL). The endogenous insulin antibodies may interfere with the insulin assay, leading to spurious high or low results, depending on the insulin assay used. C-peptide levels are not fully suppressed because insulin is endogenously secreted. In contrast, surreptitious insulin injection leads to high plasma insulin levels together with complete suppression of C-peptide secretion. The presence of insulin antibodies can be confirmed by high binding of radioactively labeled insulin to polyethylene glycol-precipitated serum samples or by enzyme-linked immunosorbent assay (81). Insulin autoantibodies associated with hypoglycemia cannot be distinguished from those found in insulin-treated patients with diabetes.

The pathogenesis of hypoglycemia caused by insulin antibodies reflects the equilibrium between bound and free insulin, leading to inappropriate release of free insulin that dissociates from the antibodies while the blood glucose concentration is already decreased. Other possible mechanisms, including enhancement of insulin binding to its receptor resulting from cross-linking by the insulin antibodies or direct stimulation of insulin secretion by insulin antibodies, may be operative in some patients (80).

Most patients with autoimmune hypoglycemia due to insulin antibodies experience spontaneous remission (82). If autoimmune hypoglycemia is precipitated by a medication, it should be discontinued and the problem of hypoglycemia will resolve. Patients with recurrent nonremitting hypoglycemia may benefit from frequent low-carbohydrate meals to reduce postprandial hyperglycemia and insulin secretion. Medications that reduce glucose absorption or insulin secretion, such as acarbose, diazoxide, and octreotide, have also been used; however, the results are not consistent. Finally, glucocorticoid therapy and plasmapheresis have also been tried, with the goal of lowering the titer of insulin antibodies (80).

HYPOGLYCEMIA CAUSED BY ANTIBODIES TO INSULIN RECEPTOR

Most patients with hypoglycemia caused by antibodies to the insulin receptor are women. A history of concomitant autoimmune disease is common, and several patients with Hodgkin disease have been reported. The hypoglycemia may be fasting or postprandial and often presents with severe symptoms of neuroglycopenia. Hypoglycemia may be preceded by a phase of severe insulin resistance associated with acanthosis nigricans and hyperglycemia in some patients, whereas others present only with hypoglycemia. The reason for the versatility in the biologic function of the insulin receptor antibodies, even in the same patient at different time points, is not clear. It may be related to the possibility that the polyclonal antibodies to insulin receptor are composed of different subpopulations of immunoglobulins, some activating the insulin receptor and others inhibiting insulin action. Thus, variation in the titer of different antibody populations over time may determine whether the patient presents with insulin resistance or hypoglycemia. The titer of the insulin-receptor antibodies also may affect the

clinical presentation. Low antibody titer with partial occupation of the insulin receptor may induce maximal stimulation of the insulin receptor, leading to hypoglycemia. However, a high titer of insulin antibodies may increase the degradation of the insulin receptor and decrease the number and function of the receptors, leading to insulin resistance and hyperglycemia. It also was suggested that the appearance of low-affinity insulin receptor sthat are resistant to the inhibitory effects of insulinreceptor antibodies may contribute to the switch from insulin resistance and hyperglycemia to hypoglycemia in some patients with insulin-receptor antibodies (80).

Insulin levels are usually higher than expected for the glucose concentration and may suggest the presence of an insulinoma. However, C-peptide levels are usually partially or completely suppressed. The cause of the nonsuppressed insulin levels is not known and may be related to decreased clearance of circulating insulin by receptor-mediated endocytosis and/or activation of the insulin receptors on pancreatic β -cells, which may augment insulin production (83). The prognosis of hypoglycemia associated with antibodies to insulin receptor is poor, with a high mortality rate due to severe concomitant autoimmune disease or malignancy and potentially severe hypoglycemia. Hypoglycemia may respond to a high-dose glucocorticoid therapy. Plasmapheresis and cytotoxic drugs such as cyclophosphamide can also be used to reduce the titer of antibodies to insulin receptor; however, the clinical effect is inconsistent and the experience with these therapies for hypoglycemia induced by insulin-receptor antibody is limited (80).

Tumor-Associated Hypoglycemia

INSULINOMA

Insulin-producing islet-cell tumors occur with an incidence of 4 per 1 million person-years. The onset is usually insidious. About 94% of the tumors are sporadic, while the rest occur as part of the multiple endocrine neoplasia type 1 syndrome [MEN1; Mendelian Inheritance in Man (MIM) no. 131100; at http://www.ncbi.nlm.nih.gov/Omim/]. Between 5% and 10% of tumors are malignant (84). Diagnosis is made by submitting the patient to a prolonged fast, which is terminated either when neuroglycopenia is demonstrated or after 72 hours. The definitive diagnosis is based on the Whipple triad, combined with levels of nonsuppressed insulin, C-peptide, and proinsulin. A recent publication suggests that a 48-hour fast may be sufficient to confirm the diagnosis in almost all cases (85). It is of critical importance to differentiate tumor hyperinsulinism from factitious hyperinsulinism caused by surreptitious injection of insulin or by ingestion of β -cell–stimulating drugs (see above). Insulinomas are discussed in more detail in Chapter 70.

NON-ISLET CELL TUMOR HYPOGLYCEMIA

Hypoglycemia may rarely occur in association with non-islet cell tumors. The majority are large mesenchymal and epithelial tumors such as sarcoma, mesothelioma, fibroma, hemangiopericytoma, and hepatoma. Two thirds of the tumors are either retroperitoneal or abdominal; most of the rest are in the thorax. Other common cancers occasionally associated with hypoglycemia include cancer of the lung, breast, kidney, and the gastrointestinal tract and endocrine tumors such as carcinoid and adrenocortical carcinoma. Patients with hematologic malignancies such as leukemia and lymphoma may rarely develop hypoglycemia. In these patients, tumor-associated hypoglycemia must be distinguished from pseudohypoglycemia caused by *in vitro* glucose metabolism by the markedly elevated white blood cells (see above). Rarely, hypoglycemia may be the presenting symptom in patients with non-islet cell tumors, although it is more common for it to develop in a patient with a known malignant tumor.

The clinical symptoms resemble those of an insulinoma, with neuroglycopenia being the prominent feature. Glucose utilization is markedly increased, and patients may require large quantities of intravenous glucose to maintain normal plasma glucose concentrations. Hypoglycemia may be severe and refractory to medical treatment. When possible, complete surgical resection will ameliorate the hypoglycemia. Patients for whom complete resection is not feasible may benefit from partial removal of the tumor, which can be associated with prolonged remission of hypoglycemia.

The pathogenesis of non–islet cell tumor hypoglycemia (NICTH) is complex, and multiple factors may be involved. The tumor itself utilizes large amounts of glucose; however, glucose uptake by peripheral tissues is also increased and hepatic glucose production is inhibited, suggesting increased insulin-like activity (86,87). Levels of circulating insulin, C-peptide, and proinsulin are suppressed.

The presence of a humoral factor that mediates the tumorinduced hypoglycemia has been studied extensively. Insulinlike growth factor II (IGF-II), a protein with high homology to proinsulin, is expressed and secreted from mesenchymal tumors that cause hypoglycemia (87,88). IGF-II can bind to the insulin receptor, causing insulin-like activity in the absence of insulin. Circulating levels of IGF-II are modestly increased in some but not all patients with tumor-induced hypoglycemia and return to normal after surgical resection of the tumor and resolution of hypoglycemia (89). Overproduction of an incompletely processed form of IGF-II with a higher molecular weight ("big" IGF-II) is found in most patients with non– β -cell tumors and hypoglycemia (90,91).

Under physiologic conditions, IGF-II forms a 150-kDa complex together with insulin-like growth factor-binding protein 3 (IGFBP-3) and an acid-labile subunit (ALS). Normally, the majority of the circulating IGF-II is transported as part of the 150-kDa complex, only 25% being in a free form. The large complex crosses the capillary bed very poorly; thus, only a small fraction of IGF-II can bind to insulin receptors in the target tissues and exert its hypoglycemic effect. In some patients with tumor-induced hypoglycemia, big IGF-II forms smaller complexes and the 150-kDa complex is absent or decreased. The cause of this failure to form the "normal" 150-kDa complex is not clear and may vary in different patients. Abnormal glycosylation of big-IGF-II has been proposed, but it is not certain that this is responsible for the abnormal complex formation (92,93). Other possible mechanisms include defects in the secretion of the ALS and preferential binding of the big IGF-II to proteins other than IGFBP-3 and ALS. Baxter et al. (94) suggested that big IGF-II itself may inhibit acid-labile subunit binding to the IGFBP-3 directly, thus preventing the formation of the 150-kDa complex. Regardless of the mechanism involved, failure to form the 150-kDa complex causes a larger fraction of IGF-II to be transported in small complexes or as a free protein that is more readily available for binding to insulin receptors. Therefore, although total IGF-II may be normal or only mildly elevated, the levels of the bioactive IGF-II are typically increased (90-92).

Patients with NICTH frequently have low serum levels of growth hormone, which may further decrease hepatic glucose production and exacerbate the hypoglycemia (89). Although insulin and total IGF-I levels are typically low in patients with NICTH, free IGF-I levels in plasma recently were shown to be markedly elevated, suggesting a possible mechanism to explain the low levels of growth hormone seen in these patients (91). The diagnosis of NICTH is suggested when hypoglycemia is found in combination with suppressed insulin, C-peptide, and total IGF-I concentrations. IGF-II levels may be elevated, but the measurement of big IGF-II may be superior for the definitive diagnosis of NICTH.

Ectopic insulin secretion in non–islet cell tumors is exceedingly rare. It was convincingly shown in one recent case report of a patient with carcinoma of the uterine cervix (95). Relative hyperinsulinemia was demonstrated in a few other patients; however, ectopic insulin secretion by the tumor was not proven (96,97).

NONINSULINOMA, PANCREATOGENOUS HYPOGLYCEMIA SYNDROME

Hyperinsulinemic hypoglycemia not caused by an insulinoma was described in five patients evaluated at the Mayo Clinic (98). All patients had neuroglycopenic symptoms 2 to 4 hours after a meal but not during a prolonged (72 hour) fast. No insulinoma was found during operation by palpation and intraoperative ultrasound. All patients had a positive response to arterial calcium stimulation and underwent gradient-guided partial pancreatectomy. There was no recurrence of symptoms during prolonged follow-up after surgery. Pancreatic tissue from all patients showed islet hyperplasia and nesidioblastosis. No insulinoma was found in the resected pancreatic tissue. Mutations in the SUR1 and Kir6.2 genes that are common in patients with familial persistent hyperinsulinemic hypoglycemia of infancy were not identified in these patients. This syndrome is rare, as there were only nine adult patients with histologic findings of nesidioblastosis among 300 patients who underwent surgery for suspected insulinoma at the Mayo Clinic. The precise etiology of this entity, which may represent a novel mechanism of hypoglycemia, is not known. Previous studies have described rare cases of hypoglycemia due to "nesidioblastosis" in adults, but the genetic studies were not done at the time (99,100).

Rarely, patients with hyperinsulinism due to mutations of glutamate dehydrogenase, glucokinase, or of either of the β -cell K_{ATP}-channel genes (see below) may have mild disease that only comes to medical attention during adulthood. A complete medical history may reveal episodes of idiopathic epilepsy or other signs of neuroglycopenia after prolonged fast or during intercurrent illness in the neonatal period or during childhood.

Reactive Hypoglycemia

Reactive hypoglycemia refers to disorders in which hypoglycemia occurs exclusively after meals and not in the postabsorptive state. All the disorders that cause postabsorptive hypoglycemia also can produce hypoglycemia in the postprandial state. Thus, the term "reactive hypoglycemia" does not have any implication regarding the etiology, and the presence of a syndrome causing postabsorptive hypoglycemia should always be considered in patients with postprandial hypoglycemia.

Congenital defects in carbohydrate metabolism, such as galactosemia and hereditary fructose intolerance, cause postprandial hypoglycemia in children (see below). In adults reactive hypoglycemia can be subdivided into three categories: (a) hypoglycemia after surgery of the upper gastrointestinal tract (alimentary hypoglycemia), (b) hypoglycemia in patients with elevated glucose in an oral glucose tolerance test (early diabetes hypoglycemia), and (c) idiopathic functional hypoglycemia.

ALIMENTARY HYPOGLYCEMIA

Alimentary hypoglycemia occurs in some patients after gastrectomy with or without gastric drainage procedure and rarely in the absence of gastrointestinal surgery (101). The hypoglycemia results from accelerated movement of ingested food into the small intestine, followed by rapid absorption of glucose that stimulates insulin secretion. Stimulation of enteric hormone secretion may further augment insulin secretion. The hypoglycemic effect of the secreted insulin persists after the glucose load is cleared from the circulation, thus leading to hypoglycemia. Typically, hyperglycemia develops within half an hour, followed by hypoglycemia approximately 1.5 to 3 hours after food ingestion. Symptoms may be severe, including seizures, coma, and even death. Alimentary hypoglycemia should be distinguished from the dumping syndrome that may cause similar symptoms within 1 hour after eating in the absence of hypoglycemia. The dumping syndrome is caused by contraction of the plasma volume due to fluid shift into the gastrointestinal tract (23). Both dumping syndrome and alimentary hypoglycemia have become very rare, since most patients with peptic ulcer disease are now treated medically.

REACTIVE HYPOGLYCEMIA ASSOCIATED WITH EARLY DIABETES MELLITUS

Reactive hypoglycemia was reported to be an early manifestation of type 2 diabetes more than four decades ago (102). Diabetic patients with reactive hypoglycemia usually have mild hyperglycemia and develop symptoms of hypoglycemia 3 to 5 hours after a meal. It was suggested that the hyperglycemia provokes a gradual increase in insulin secretion, which may persist after the disposal of the ingested glucose, leading to the late hypoglycemia. The prevalence and significance of reactive hypoglycemia in patients with diabetes is controversial. Type 2 diabetes is a common disease; however, spontaneous postprandial hypoglycemia has been documented in very few patients. Moreover, in some patients the diagnosis was based on an oral glucose tolerance test (OGTT) that showed elevated blood glucose levels within the first 2 hours after glucose load, followed by glucose levels below 50 mg/dL. The correlation between low blood glucose concentrations several hours after an oral glucose load and postprandial hypoglycemia is poor. For example, only 5% of patients with early diabetes and hypoglycemia after an oral glucose load had symptoms of hypoglycemia after meals (103). It is possible that patients frequently develop asymptomatic hypoglycemia during the early stages of diabetes; however, there are no data to support this hypothesis.

IDIOPATHIC FUNCTIONAL HYPOGLYCEMIA

Symptoms suggestive of hypoglycemia several hours after a meal are common. The appearance of postprandial autonomic symptoms is commonly diagnosed as "reactive hypoglycemia"; however, blood glucose concentrations are not usually measured during such "hypoglycemic" episodes and when measured are usually normal. Most patients with autonomic symptoms after meals evaluated for hypoglycemia have been found to have psychoneurotic disturbances with frequent somatic complaints (104,105). An effort to document the correlation between glycemia and symptoms was made by measuring blood glucose in 28 patients during a total of 132 reported episodes of symptomatic hypoglycemia. Only six (5%) of these episodes were associated with blood glucose levels below 50 mg/dL (2.8 mmol/L), and these occurred in five (18%) different patients. Relief of symptoms by ingesting food was more often associated with low than with normal blood glucose levels (24). In another study of 118 patients with suspected postprandial hypoglycemia, only five (4%) were found to have hypoglycemia after a glucose load and after meals (106).

In many patients, low glucose levels during an OGTT are used to diagnose reactive hypoglycemia because it may be dif-

ficult to document glucose levels during symptomatic episodes. However, when critically evaluated, no correlation was found between plasma glucose levels measured after oral glucose administration and glucose levels measured during symptoms. Furthermore, most patients with low blood glucose levels after an oral glucose load have normal glucose levels after a mixed meal (23). In a large study of 650 healthy subjects who remained asymptomatic during a 100-g OGTT, 25% had a circulating glucose nadir below 54 mg/dL, 10% below 47 mg/dL, 5% below 43 mg/dL, and 2.5% below 40 mg/dL (106). The fact that approximately 10% of the general healthy population has nadir glucose levels lower than 50 mg/dL indicates that a low glucose level on OGTT is not a reliable criterion for the diagnosis of reactive hypoglycemia, and thus this test should not be used for this purpose. Establishment of the diagnosis of reactive hypoglycemia requires documentation of low blood glucose levels during spontaneous symptomatic episodes. Although true idiopathic reactive hypoglycemia probably exists, it is rare even in a referral population.

The pathogenesis of true idiopathic reactive hypoglycemia is unknown. Insulin sensitivity is increased in patients with idiopathic reactive hypoglycemia (107). The changes in insulin sensitivity are probably not explained by increased binding of insulin to its receptor, and there is no evidence that insulin secretion is increased. A reduced glucagon response may play a role in the development of late hypoglycemia after glucose ingestion; however, there are few data that support this hypothesis (108).

TREATMENT

Low-carbohydrate or high-fiber diets, avoidance of simple sugars that are rapidly absorbed, and the use of multiple small meals are recommended for patients with reactive hypoglycemia. A high-protein diet is often administered to patients with reactive hypoglycemia; however, this diet is also high in fat and its clinical efficacy is unknown. Therefore, it should no longer be recommended. Cornstarch, doxepin, α -glucosidase inhibitors, biguanides, and anticholinergic agents have been successful in some patients with reactive hypoglycemia. The efficacy and the precise role of such treatments in the management of reactive hypoglycemia need to be determined in larger studies (23).

DIAGNOSTIC AND THERAPEUTIC APPROACH TO THE HYPOGLYCEMIC PATIENT

The symptoms and signs of hypoglycemia are nonspecific; therefore, the first step in the evaluation of a patient with suspected hypoglycemia is always to document low blood glucose when the patient experiences spontaneous symptoms. The demonstration that symptoms are relieved by an increase in blood glucose level following ingestion of food or glucose further supports the diagnosis of hypoglycemia (Whipple triad). Repeated normal blood glucose measurements during the occurrence of symptoms exclude the possibility of hypoglycemia, and no further evaluation is required for this diagnosis. In some patients, documentation of blood glucose during spontaneous symptoms may be difficult because the symptomatic episodes are infrequent, the duration of symptoms is short, and the patient is far from a medical facility. Glucosemeter measurements of capillary blood glucose can be used to correlate patient symptoms with blood glucose levels and to exclude hypoglycemia as the cause of the symptoms. However, the results should be interpreted with caution because the measurement of blood glucose may be technically poor because it is

performed by an inexperienced patient suffering from autonomic and potentially neuroglycopenic symptoms.

A careful history of the occupation of the patient; the existence of family members with diabetes being treated with sulfonylureas or insulin; and alcohol abuse, predisposing illnesses, and medications taken by the patient is crucial to making the correct diagnosis. The patient should be asked about the frequency and duration of symptomatic episodes, the presence of neuroglycopenia and/or autonomic symptoms, whether they are relieved by ingestion of glucose, and when the symptoms occur (fasting vs. postprandial). Patients who develop hypoglycemia only during the postprandial period may have idiopathic reactive hypoglycemia. However, other hypoglycemic disorders, including insulinoma, may present as postprandial hypoglycemia, and therefore prompt evaluation of other causes of hypoglycemia should be performed.

If hypoglycemia is confirmed or the clinical suspicion for hypoglycemia is high but measuring blood glucose during spontaneous symptoms is not feasible, the patient should be admitted for further testing (Fig. 69.4). The next diagnostic step is to measure insulin, C-peptide, and, if possible, proinsulin levels. Alcohol and medications known to cause hypoglycemia should always be considered and discontinued before the patient is evaluated. This may prevent unnecessary, time-consuming, and expensive tests. If the episodes of hypoglycemia are infrequent, it may be necessary to provoke hypoglycemia by a prolonged 48- to 72-hour fast or by insulin infusion to test Cpeptide suppression. Relatively high levels of insulin, C-peptide, and proinsulin during spontaneous or induced hypoglycemia and the failure to suppress C-peptide secretion in response to insulin-induced hypoglycemia suggest the diagnosis of insulinoma (see Chapter 70 on islet-cell tumors). Blood levels of oral insulin secretagogues should always be measured during hypoglycemia to exclude surreptitious administration of drugs. Rare patients with insulin antibody-mediated hypoglycemia may also have hyperinsulinemic hypoglycemia with nonsuppressed C-peptide. Hypoglycemia associated with high levels of insulin and suppressed C-peptide suggests surreptitious administration of insulin; however, patients with autoimmune antibodies to insulin receptor may also present with inappropriately high levels of insulin and suppressed C-peptide during hypoglycemia. Suppression of both insulin and Cpeptide levels during hypoglycemia suggests the diagnosis of tumor-induced hypoglycemia, and determination of plasma IGF-II and appropriate imaging studies should be performed. Deficiencies in glucoregulatory hormones, including cortisol and growth hormone, should always be excluded, although deficiencies in glucoregulatory hormones alone in otherwise healthy subjects will rarely cause hypoglycemia under normal conditions.

The acutely ill patient suffers from multisystem disease, and multiple factors may cause hypoglycemia. Organ failure, including renal, hepatic, and cardiac failure, is common. These patients are at risk for iatrogenic hypoglycemia (e.g., insulin added to total parenteral nutrition or pentamidine-induced hypoglycemia in patients with pneumocystis pneumonia). Sepsis and inanition are common contributing factors. Some of the acutely ill patients admitted to the hospital suffer from underlying malignancy that may cause tumor hypoglycemia (NICTH). Treatment of the underlying acute illness, improvement in critical-organ function, and careful monitoring of the drugs administered to the patient result in resolution of hypoglycemia, and extensive hormonal evaluation is usually not required.

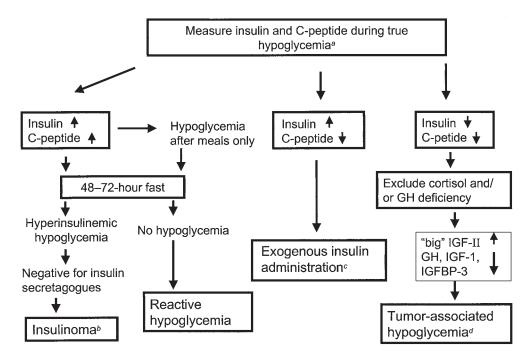

Figure 69.4. Workup of hypoglycemia in the non–acutely ill patient. ^aSee text for definition of true hypoglycemia. ^bRare patients with insulin antibody–mediated hypoglycemia may also have hyperinsulinemic hypoglycemia with nonsuppressed C-peptide. The endogenous insulin antibodies may interfere with the insulin assay, leading to spuriously high or low results, depending on the insulin assay used. Measurement of antibodies to insulin is not part of the routine workup of hypoglycemia; however, it should be considered in some patients. ^cPatients with autoimmune antibodies to insulin receptor may also present with inappropriately high levels of insulin and suppressed C-peptide during hypoglycemia; however, it should be considered in some patients. ^dEthanol and other medications that inhibit gluconeogenesis may lead to suppression of endogenous insulin production secondary to hypoglycemia.

HYPOGLYCEMIA IN NEONATES AND INFANTS

A separate discussion of hypoglycemia in the young child is appropriate since the problem in this age group differs from that in adults in several important ways. Neonatal hypoglycemia frequently is caused by a specific genetic defect. In some cases, the precise genetic etiology is known, whereas in others, the information presently available is limited. Our understanding of the genetic etiology of disease is expanding at an exponential rate, and the latest information is constantly being updated in the online version of MIM (http://www.ncbi .nlm.nih.gov/Omim/). For this reason, whenever possible, we have included the MIM numbers of specific genetic entities in parentheses. The reader is encouraged to consult the MIM Web site for the latest genetic information and updated clinical references on these diseases.

Glucose Homeostasis in Infants and Children

The basic mechanisms of glucose homeostasis in the neonate are similar to those of the adult, although some critical differences make the neonate more prone to hypoglycemia. Glucose requirements of the neonate are considerably higher than those of the adult, primarily because of the increased ratio of brain to body mass. Premature infants require 5 to 6 mg/(kg · min) and full-term neonates require 3 to 5 mg/(kg · min), whereas adults require only 2 to 3 mg/(kg · min) (3,109). The fetus receives the glucose it needs as a constant supply from the placenta. As soon

as the umbilical cord is cut, the neonate must suddenly rely on oral intake, glycogenolysis, and gluconeogenesis. However, the healthy breastfeeding infant gets little oral nutrition immediately after birth. Glycogen stores are relatively low and are rapidly depleted. The gluconeogenic pathway may be immature, since in the fetus of a well-nourished mother, glycogenolysis and gluconeogenesis are virtually absent. All of the gluconeogenic enzymes except phosphoenolpyruvate carboxykinase (PEPCK) are expressed early in fetal development. PEPCK, the rate-limiting enzyme in the gluconeogenesis pathway, is not expressed in the mammalian fetus but appears immediately after birth. The rapid decline in insulin and the surge in plasma glucagon appear to be responsible for induction of its transcription and activation. Stable-isotope studies in healthy humans have shown that both gluconeogenesis and ketogenesis are active 12 to 24 hours after birth (110,111). Both of these, however, require a steady supply of substrates. In infants who are small for gestational age, or in infants of mothers with inadequate nutrition, adequate supplies of these substrates may not be available.

Therefore, normal neonates are at risk of hypoglycemia from the moment of birth. Blood glucose levels fall naturally, and significant hypoglycemia is avoided only if all of the necessary mechanisms function properly and rapidly. The precise level at which this normal decline in glucose endangers neurologic development is not known; therefore, the need for therapeutic intervention is still controversial. Congenital defects in any of the mechanisms required to maintain euglycemia will result in more severe and persistent hypoglycemia. Rapid diagnosis and effective treatment of these disorders will have a profound impact on long-term prognosis.

Defining Hypoglycemia in the Newborn Period

The definition of hypoglycemia in the newborn has been the subject of controversy for the last several decades. Even today, there is no clear consensus on how hypoglycemia should be defined in each specific category of patient. The subject has recently been extensively reviewed (112,113).

METHODOLOGIC ISSUES

Accurate laboratory determination of circulating glucose levels is not a trivial problem, even as we enter the 21st century. Bedside capillary glucose determinations are designed primarily for use by persons with diabetes and are therefore calibrated to differentiate between euglycemia and hyperglycemia. Although some of these determinations may be adequate as screening aids, none are sufficiently accurate or sensitive to reliably confirm the diagnosis of hypoglycemia. Reliable and sensitive laboratory analyses are required before the diagnosis of hypoglycemia can be confirmed, and any method used must be validated at glucose concentrations below 40 to 50 mg/dL (2.2 to 2.8 mmol/L) (112,113).

DEFINITION

Pathologic hypoglycemia can be defined in several ways, including (a) glucose levels less than 2 standard deviations below the mean for age-matched controls, (b) glucose levels causing clinically evident symptoms of hypoglycemia, (c) the glucose threshold for acute symptoms of neuroglycopenia determined in healthy neonates, and (d) the glucose threshold below which irreversible brain damage may occur. Clearly, the latter definition is the most important in terms of long-term prognosis; however, it is also the most difficult to delineate. The degree of neurologic damage is related not only to the glucose level achieved but also to the frequency and duration of hypoglycemia. In addition, factors other than glucose play important roles in determining the neurotoxic potential of any particular glucose level. One of the most important among these factors is the availability of alternative fuels such as ketone bodies. The infant brain is capable of utilizing ketone bodies as a partial source of energy. Therefore, the same level of hypoglycemia may be less damaging in the presence of elevated ketone bodies. For this reason, hypoketotic hypoglycemia due to hyperinsulinism or defects in fatty acid metabolism may be particularly damaging.

Comparison with Healthy Control Populations

Population surveys in the 1960s and 1980s have established the range and standard deviations of glucose values for different categories of neonates (Table 69.3) (113). While these studies provide normative data, they do not necessarily define the threshold for irreversible brain damage and do not take into consideration the duration of hypoglycemia. Therefore, although they provide a useful reference range, they have limited impact on the clinical decision-making process.

Clinical Definition

The classical definition of hypoglycemia is based on the Whipple triad as defined above. In the adult or the older child, symptoms of adrenergic stimulation and neuroglycopenia can usually be readily identified (Table 69.1). In the newborn, however, signs may be nonspecific, including cyanosis, apnea, irritability, poor feeding, or hypothermia. Therefore, the rapid diagnosis of symptomatic neonatal hypoglycemia requires a high index of suspicion on the part of the treating physician.

Neuroglycopenia

More recently, there has been an attempt to correlate glucose levels with objective measures of neural function. In 1988, Koh et al. (114) observed abnormal auditory evoked potentials in neonates with glucose levels ranging from 25 to 47 mg/dL (1.4 to 2.6 mmol/L). Pryds et al. (115) measured cerebral blood flow and plasma catecholamine levels in hypoglycemic infants [glucose <30 mg/dL (1.7 mmol/L)] and normoglycemic controls and demonstrated an increase in cerebral blood flow and concentrations of epinephrine. The recent development of methods for the microanalysis of hormones and substrates, along with the availability of methods permitting *in vivo* measurements of cerebral blood flow, glucose uptake, and high-energy phosphate content, will open up the way to more accurate assessments of the effects of hypoglycemia on neural function.

	Blood glucose values by birthweight class (mg/dL in serum or plasma)		
Basis for definition	Term AGA	LBW	VLBW
Population survey (2 SD below population means)			
<48 h old	<35	<25	<25
>48 h old	<45	<45	<45
Functional correlations (brain electrophysiology, counterregulatory responses, and cerebral blood flow)	<30	—	—
Adverse long-term outcome	_	47	_
Proposed treatment guidelines			
<24 h old	45	45	45
24–72 h old	50	50	50
>72 h old	60	60	60

AGA, average for gestational age; LBW, low body weight; VLBW, very low body weight. Modified from Cornblath M, Ichord R. Hypoglycemia in the neonate. *Semin Perinatol* 2000;24:136–149.

The reader is referred to this publication for a more detailed description of the criteria.

Long-Term Outcome Data

None of the methods outlined above answer the cardinal question: At what glucose level does irreversible brain damage occur? Most studies have tried to answer this question retrospectively by correlating neurologic status of older children with hypoglycemic events in infancy. Lucas et al. (116) determined that, in infants with a birth weight less than 1,850 g, glucose levels lower than 47 mg/dL (2.6 mmol/L) on 5 or more days correlated positively with abnormal neurologic and developmental outcome at 18 months. However, this appeared to be at least partially reversible, because by 7 to 8 years of age, the neurologic deficit appeared to be much milder. More recently, Duvanel et al. (117) demonstrated that recurrent episodes of hypoglycemia were strongly correlated with persistent neurologic and developmental deficits at the age of 5 years. In fact, infants with recurrent, moderate hypoglycemia had a poorer neurologic outcome than did those with a single, severe episode of hypoglycemia. A prospective, randomized trial of alternative treatment regimens is still needed to establish the policy that assures the best possible long-term neurologic outcome in premature and small-for-gestational-age infants.

Operational Definition of Hypoglycemia

In view of the limited data available for long-term implications of hypoglycemia, Cornblath et al. (112) have proposed an "operational threshold" of hypoglycemia to be used as an indication for action but not necessarily diagnostic of pathology. They recommended that the operational threshold be defined as a plasma glucose level lower than 30 to 36 mg/dL (1.7 to 2 mmol/L) during the first 24 hours of life in a healthy full-term or preterm (24 to 27 weeks of gestation) formula-fed infant. If the level persists after feeding or recurs, treatment should be initiated to maintain a glucose level above 45 mg/dL (2.5 mmol/L). In sick, low-birth-weight, or premature infants, this threshold may be increased to 45 to 50 mg/dL (2.5 to 2.8 mmol/L), because these infants may have increased glucose requirements due to sepsis, hypoxia, or other systemic disease. After the first 24 hours, an operational threshold of 40 to 50 mg/dL (2.2 to 2.8 mmol/L) is recommended. Below these values, therapy should be initiated to increase levels above the threshold, although this alone should not be taken as diagnostic of neuroglycopenia or neurologic damage. Infants of any age with confirmed glucose levels below 20 to 25 mg/dL (1.1 to 1.4 mmol/L) should be treated rapidly and aggressively with parenteral glucose. If hypoglycemia persists or recurs beyond the first week of life, then a full diagnostic evaluation is indicated.

Transient Neonatal Hypoglycemia

As soon as the fetus is disconnected from the constant glucose supply through the umbilical cord, it becomes dependent on an immediate endogenous supply of glucose to maintain its energy needs. This is initially supplied by the liver through glycogenolysis and soon thereafter by gluconeogenesis using substrates supplied by fat and muscle. Any prenatal problem that limits the availability of either of these substrates puts the newborn at risk for hypoglycemia. The liver begins to store glycogen in the ninth week of gestation, but most of the glycogen stores are accumulated during the last weeks of gestation. Adequate stores are dependent on adequate delivery of substrate from the mother, which may be deficient in fetuses with retardation of intrauterine growth and in infants who are postterm. Therefore, all premature (gestation less than 38 weeks), small-for-gestational age, and postterm infants are at risk of having inadequate glycogen stores and hence of having hypoglycemia immediately after birth. In all of these cases, oral or

parenteral replacement of glucose at rates similar to normal neonatal glucose requirements will prevent hypoglycemia. Once adequate intake is established and adequate glycogen and fat stores are available, hypoglycemia resolves and does not recur.

ASPHYXIA

Perinatal asphyxia may cause hypoglycemia and in some cases transient hyperinsulinism. Initially, it may be difficult to differentiate between apnea due to hyperinsulinemic hypoglycemia and hyperinsulinism secondary to asphyxia, because insulin levels and parameters of glucose metabolism may be similar. However, the latter is transient, and spontaneous resolution of the hyperinsulinism within a few days is expected. The pathophysiology of asphyxia-induced hyperinsulinism is not known (118–122).

INFANT OF DIABETIC MOTHER

Infants born to diabetic mothers are at high risk for developmental anomalies, macrosomia, respiratory distress syndrome, and neonatal hypoglycemia. Although the precise mechanisms have not yet been defined for all of these defects, it is clear that maternal glycemic control has an important impact on all of them. The macrosomia is thought to be caused by intrauterine hyperinsulinism due to chronic fetal exposure to high glucose levels from the mother. This hyperglycemic stimulus may also result in β-cell hyperplasia and hyperresponsiveness, resulting in hyperinsulinemic hypoglycemia when the supply of maternal glucose is abruptly interrupted. This clinical picture is essentially identical to the initial presentation of infants with hyperinsulinism of infancy (see below), confirming the importance of prenatal hyperinsulinism. Not uncommonly, neonates with hyperinsulinism of infancy are misdiagnosed as being infants of diabetic mothers if a careful prenatal history is not obtained.

Good glycemic control during the first 9 to 12 weeks of pregnancy greatly decreases the incidence of birth defects, while good glycemic control during the last 3 months of pregnancy decreases the incidence and severity of macrosomia and postnatal hypoglycemia (see Chapter 61).

BECKWITH-WIEDEMANN SYNDROME

Beckwith–Wiedemann syndrome (BWS; MIM no. 130650) is associated with macrosomia, macroglossia, and abdominal wall defects. Hypoglycemia is present in 30% to 50% of the patients and is usually mild and transient, resolving within the first few days of life. Rarely, hypoglycemia may be more severe and persistent, requiring continued medical treatment or even partial pancreatectomy. Insulin levels may be high or inappropriately elevated for the prevailing glucose level. Prompt glycemic response to glucagon during hypoglycemia confirms that the primary etiology of the hypoglycemia is hyperinsulinism.

Although the genetic etiology of BWS has not been confirmed in all cases, the syndrome may be caused by any of several different genetic mutations on chromosome 11p15.5. This chromosomal region contains at least three imprinted genes, including *IGFII*, which is expressed only from the paternal allele, and *H19* and $p57^{kip2}$, which are expressed only from the maternal allele. IGF-II is an important growth factor, particularly during fetal development. In transgenic animals, overexpression of *IGFII* by β -cells results in islet hyperplasia (123). H19 is an untranslated RNA molecule thought to be an important regulator of levels of IGF-II mRNA (124), and p57^{kip2} (CDKN1C, MIM no. 600856) is an important inhibitor of several G₁ cyclin/Cdk complexes and thus is involved in cell-cycle arrest in terminally differentiated cells (125).

Mutations associated with BWS mutations include duplication of the paternally derived allele or loss of imprinting, resulting in expression of the maternally derived IGFII allele (126). Both of these defects would be expected to result in increased IGFII expression, and in fact, overexpression of this growth factor has been documented in approximately 20% of cases. Although IGFII overexpression may explain the generalized overgrowth seen in this syndrome, and perhaps the β -cell hyperplasia, it is not clear that it explains the hyperinsulinism and hypoglycemia, since the hyperplastic β -cells should still be normally regulated. Recently, patients have been identified who have maternally inherited mutations in the cyclin-dependent kinase inhibitor $p57^{kip2}$ (127). As with the abnormalities of IGFII expression, underexpression of this growth-regulating gene could explain the overgrowth phenomena and β -cell hypertrophy, but it is not clear how this alone causes unregulated insulin secretion.

In the focal form of hyperinsulinism of infancy (see below), somatic loss of the maternal allele at this locus is associated with β -cell adenomatous hyperplasia. However, these patients have severe, diazoxide-unresponsive hypoglycemia, which appears to be caused by a concomitant mutation on the paternal allele of one of the two subunits of the β -cell K_{ATP} channel. Therefore, the transient, diazoxide-responsive, hyperinsulinemic hypoglycemia seen in 30% to 50% of patients with BWS has not yet been entirely explained. The 5% of patients with BWS who have severe, drug-unresponsive hypoglycemia may have concomitant mutations on the K_{ATP}-channel genes (128).

HYPOGLYCEMIA IN ERYTHROBLASTOSIS FETALIS

Transient hyperinsulinemic hypoglycemia has been reported in association with erythroblastosis fetalis (EF), although the precise etiology and pathophysiology is still unclear. The incidence of hypoglycemia appears to correlate with severity of EF, ranging from 17% to 31% in patients with severe disease to as low as 2% in patients with milder disease. Insulin levels are usually inappropriately elevated, and elevated pancreatic insulin content with hypertrophy and hyperplasia of the pancreatic islets has been reported. Although hypoglycemia may be present before exchange transfusions are initiated, it may appear or be further exacerbated 1 to 2 hours after the transfusions. Because early feeding does not prevent the hypoglycemia in all cases, glucose levels should be monitored in all EF patients, and if hypoglycemia is diagnosed, intravenous glucose supplementation should be given until oral feedings are well established and provide adequate caloric intake (129–132).

Endocrine Deficiency Disorders

Both growth hormone and cortisol deficiency result in decreased hepatic gluconeogenesis and decreased availability of gluconeogenic substrates. Although symptomatic hypoglycemia is rarely associated with deficiency of either or both of these hormones in the adult (see above), in the neonate and small child, hypoglycemia is common, particularly if both hormones are deficient. Pituitary hormone deficiencies can be single or multiple (MIM nos. 173110 and 601538) (133,134) and can occur either as isolated entities or as part of a syndrome of midline defects such as microphallus or septooptic dysplasia (MIM no. 182230). Primary adrenal insufficiency may be due to congenital adrenal hyperplasia (MIM no. 201910, no. 202010, no. 202110) or primary adrenal hypoplasia (MIM no. 240200, no. 300200) (135).

Patients typically present with ketotic hypoglycemia, suppressed insulin levels, and blunted glycemic response to glucagon. At initial presentation, patients with isolated growthhormone deficiency may have low plasma levels of ketone bodies and may not have ketonuria. The diagnosis is made by measuring growth hormone and cortisol during spontaneous or induced hypoglycemia. Treatment is based on immediate correction of the hypoglycemia with intravenous glucose, followed by appropriate hormone replacement. Another stimulatory test may be indicated to confirm the diagnosis. Recurrent hypoglycemia per se may secondarily blunt the cortisol response to acute hypoglycemia (136). Therefore, an isolated, blunted cortisol response in the face of recurrent hypoglycemia must be interpreted with caution.

Although a decreased epinephrine response to hypoglycemia has been reported in patients with recurrent hypoglycemia, this is unlikely to be a primary defect and is more likely secondary to recurrent hypoglycemia, very much like the hypoglycemia unawareness syndrome seen in some patients with diabetes.

Ketotic Hypoglycemia

Ketotic hypoglycemia, also called substrate-limited hypoglycemia, is claimed to be the most common form of childhood hypoglycemia. Ketotic hypoglycemia usually presents between the ages of 18 months and 2 years and typically resolves in mid childhood. It is more common in boys than in girls and is associated with decreased muscle mass and body fat. Affected children develop hypoglycemia with ketonemia and ketonuria upon fasting or during periods of caloric restriction or high caloric requirements, such as intercurrent illnesses. The precise etiology is still unknown, but alanine levels tend to be low, implying a defect in protein catabolism or amino acid efflux from skeletal muscle. The response of counterregulatory hormones to hypoglycemia is normal, except for that of epinephrine, which tends to be low. This is unlikely to be a primary defect, however, and is more likely due to recurrent mild hypoglycemia. Treatment is based on the avoidance of fasting and the careful monitoring of urinary ketone levels during intercurrent illness. Fluids high in carbohydrates should be given in situations of increased caloric requirement, and intravenous glucose is necessary if oral feeding must be interrupted for any reason (137).

Inborn Errors of Intermediate Metabolism

Many enzymatic defects may lead to hypoglycemia by interfering with glycogenesis, glycogenolysis, or gluconeogenesis. The defect may block one or more critical metabolic steps directly or may exert its effect indirectly by limiting the availability of necessary substrates. Alternatively, specific defects may prevent the production of alternative energy sources so that the glucose requirement surpasses the normal production capacity. We have classified the major metabolic defects that are typically associated with clinically relevant hypoglycemia according to the major metabolic pathway disrupted (Fig. 69.5).

GLYCOGEN STORAGE DISEASES

The glycogen storage diseases are a class of diseases caused by mutations in any of several enzymes responsible for the generation or breakdown of glycogen (137,138). Because glycogen is the major source of glucose during a short fast, these diseases are characterized by fasting hypoglycemia, the severity of which depends on the specific gene mutated and the nature of the specific mutation (Fig. 69.5).

Glycogen synthase catalyzes the conversion of glucose-6phosphate to glycogen. Deficiency of this enzyme (glycogen storage disease type 0, MIM no. 240600) is extremely rare, but it results in a severe decrease in glycogen stores. Because hepatic

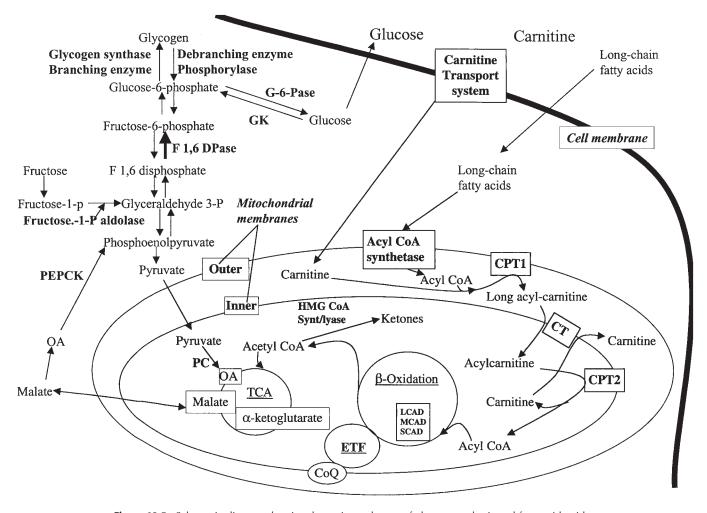

Figure 69.5. Schematic diagram showing the major pathways of glucose synthesis and fatty acid oxidation. Defects in any of many steps in the process (in bold type) can cause hypoglycemia. G-6-Pase, glucose-6-phosphatase; F 1,6 DPase, fructose-1,6-diphosphatase; PEPCK, phosphoenolpyruvate carboxykinase; PC, pyruvate carboxylase; HMG-CoA synt/lyase, 3-hydroxy-3-methylglutaryl CoA synthase and lyase; CPT-1, CPT-2, carnitine palmitoyl transferase 1 and 2; CT, carnitine translocase; LCAD, MCAD, and SCAD, long-, medium- and short-chain acyl-CoA dehydrogenases; ETF, electron-transport-flavoproteins; OA, oxaloacetate.

glycogen is the major source of glucose during the first 12 to 24 hours of a fast, patients typically present with hypoglycemia after an overnight fast. Blood levels of ketones are markedly elevated, whereas levels of alanine and lactate are low. Glycogen is also the major repository for the excess glucose during the postprandial period. Therefore, it is not surprising that patients with glycogen synthase deficiency have postprandial hyperglycemia. Recently, mutations have been documented in the glycogen synthase gene (*GYS2*) in several patients with this clinical syndrome (139,140).

Glucose-6-phosphatase catalyzes the conversion of glucose-6phospate to glucose, the final step in both glycogenolysis and gluconeogenesis. The enzyme system consists of the enzyme itself and three translocase systems that allow the entry of glucose-6-phosphate into the endoplasmic reticulum (ER), and the exit of phosphate and glucose from the ER. Defective enzyme activity (glycogen storage disease type I, MIM no. 232200, no. 232220, and no. 232240) can be caused by mutations in the enzyme itself (type IA) or in any of the translocase systems (types IB–D) and is usually associated with severe hypoglycemia presenting shortly after birth. Hypoglycemia occurs after short periods of fasting and is associated with mild ketosis, lactic acidosis, and severe hyperlipidemia. The latter leads to eruptive xanthomas and pancreatitis. Accumulation of glycogen in the liver results in severe hepatomegaly, and hepatic adenomas usually develop later in life. In addition to the features of glycogen storage disease type IA, patients with types IB and IC may also have neutropenia, recurrent infection (mainly skin abscess), and inflammatory bowel disease. The diagnosis is suspected when hypoglycemia is associated with increased lactate and lipid levels. Glucagon administration results in little or no increase in plasma glucose, differentiating this class of diseases from hyperinsulinemic hypoglycemia. The definitive diagnosis is made by enzyme analysis of liver biopsy tissue. Treatment is based on the continued supply of glucose throughout the day. Initially, this is accomplished by frequent feedings during the day and continuous nasogastric feeding at night. Raw cornstarch has been effectively used throughout the day to provide a steady supply of glucose. Liver transplantation has been attempted successfully in recent years (137).

Other enzymatic defects of glycogenesis or glycogenolysis can produce a similar clinical picture, although the hypoglycemia is typically less severe because the gluconeogenesis pathway is intact. These include debrancher enzyme deficiency (glycogen storage disease type III, MIM no. 232400), brancher enzyme deficiency (glycogen storage disease type IV, MIM no. 232500), and phosphorylase deficiency (glycogen storage disease type VI).

DISORDERS OF GLUCONEOGENESIS

Mutations in any of several of the enzymes in the gluconeogenesis pathway can result in hypoglycemia. Fructose 1,6-diphosphatase deficiency (MIM no. 229700) is similar to glycogen storage disease type I, presenting with lactic acidosis and hypoglycemia (141). Hypoglycemia is less severe, occurring primarily during fasting or intercurrent illness. Glucose response to glucagon can be normal in the postprandial period, emphasizing the importance of performing the glucagon test during fasting hypoglycemia, when glycogen stores are depleted in the absence of circulating hyperinsulinism. Treatment consists of a high carbohydrate diet, avoidance of fasting, and intravenous glucose during catabolic situations.

Pyruvate carboxylase deficiency (MIM no. 266150) causes severe mental retardation and subacute encephalomyelopathy, whereas hypoglycemia is not common.

HEREDITARY FRUCTOSE INTOLERANCE (MIM NO. 229600)

The enzyme fructose-1-phosphate aldolase catalyzes the cleavage of fructose-1-phosphate to form dihydroxyacetone phosphate and D-glyceraldehyde. Deficiency of the enzyme, caused by any of a number of genetic mutations, results in the inability to metabolize fructose and the inhibition of gluconeogenesis and glycogenolysis by the accumulation of fructose-1-phosphate. Infants present with failure to thrive, recurrent vomiting, and hepatomegaly and renal Fanconi syndrome. Hypoglycemia worsens after fructose-containing feedings, and administration of intravenous fructose can be fatal. These patients are entirely asymptomatic until fructose is introduced into the diet in the form of fruits or sucrose. Avoidance of fructose in the diet prevents the hypoglycemia and other symptoms.

GALACTOSEMIA

Deficiency of the enzyme galactose-1-phosphate uridyl transferase results in accumulation of galactose-1-phosphate, which inhibits glycogenolytic enzymes. Although hypoglycemia may occur, it is uncommon, and patients more typically present with vomiting, diarrhea, jaundice, and sepsis precipitated by inclusion of galactose in the diet. Long-term effects, thought to be caused by elevated circulating levels of galactose-1-phosphate, include intellectual impairment, cataracts, hepatic dysfunction, renal tubular disease, cerebellar syndrome, and ovarian dysfunction. A galactose-restricted diet prevents the acute symptoms, but long-term side effects may persist.

MAPLE SYRUP URINE DISEASE

Autosomal recessive mutations in any of the subunits of branch-chain α -ketoacid dehydrogenase results in accumulation of the branched-chain amino acids (BCAA), leucine, isoleucine, and valine. A common mutation in the E1 α subunit has been found in the Mennonite population in the United States. Classical maple syrup urine disease (MSUD; MIM no. 248600, no. 248610, and no. 248611) manifests between 5 and 15 days of life with decreased feeding, vomiting, and progressive encephalopathy. During acute decompensation, hypoglycemia and ketosis are common. The mechanism causing hypoglycemia is not clear but may be due to decreased availability of amino acids, particularly alanine, as substrates for gluconeogenesis. Magnetic resonance imaging of the brain shows a unique

pattern of edema that eventually evolves to cerebellar atrophy and ataxia. Inadequate adjustment of the diet may result in a typical dermatitis, scalded-skin syndrome, caused by isoleucine deficiency. The urine has a characteristic odor, which should raise suspicion of the disease. The diagnosis can be made by plasma amino acid analysis by either high-performance liquid chromatography or tandem mass spectrometry. The enzyme activity can be measured in leukocytes or fibroblasts. Treatment of acute decompensation consists of removing the metabolic toxins by hemodialysis or hemofiltration, followed by total parenteral nutrition with glucose, insulin, and amino acid mixtures free of BCAA. Chronic treatment consists of BCAA-free formula. The prognosis is variable, but normal or near-normal growth and development can be achieved with early diagnosis and aggressive treatment.

PROPIONIC ACIDEMIA AND METHYLMALONIC ACIDEMIA

Both propionic acidemia and methylmalonic acidemia disrupt the metabolic pathway that converts propionyl-CoA to succinyl-CoA. The former is a rare disorder occurring in nonconsanguineous populations at an incidence of one in 500,000 or less. It is a severe disorder with a poor prognosis. Presentation is within the first week of life, with chronic vomiting and anorexia. Patients are immunocompromised and may present first with the presumptive diagnosis of immune deficiency. Laboratory findings include hyperanmonemia and ketoacidosis with mildly elevated lactic acid levels. Neutropenia may be present during crisis. Treatment includes dietary manipulations and metronidazole to reduce propionate production by the gut bacteria.

Methylmalonic acidemia is more common than propionic acidemia, with an incidence of one in 48,000 to 61,000 births, and can be caused be a variety of defects of the conversion of methylmalonyl-CoA to succinyl-CoA, a process that requires cobalamin (vitamin B₁₂). The disease can be caused by mutations in methylmalonyl-CoA mutase itself; defects in the cytoplasmic, lysosomal, or mitochondrial processing of cobalamin; or severe vitamin B12 deficiency. Cobalamin-related defects usually produce relatively mild disease, and in the majority of cases, there is a significant clinical response to treatment with pharmacologic doses of vitamin B₁₂. Infants of strict vegetarians may present with methylmalonic acidemia, megaloblastic anemia, and homocystinuria with normal or low plasma methionine levels as a result of a severe deficiency in dietary vitamin B₁₂ (142). The mechanism causing hypoglycemia, which is usually mild to moderate, is not clear.

DISORDERS OF FATTY ACID OXIDATION

Fatty acid β -oxidation is an important energy source, particularly during fasting and times of metabolic stress such as acute illness. Disorders of fatty acid oxidation are rare but are important causes of hypoglycemia in the infant. Recent molecular genetic studies have identified the precise etiology of several distinct clinical entities. We will review the salient features of this class of disorders, providing additional details on the most common forms. For more detailed information, the reader is referred to two recent comprehensive reviews (137,143).

The process of fatty acid β -oxidation is complex and involves a cascade of enzymes, transporters, and cofactors (Fig. 69.5). Fatty acids enter the cell and form fatty acyl-CoA, with the reaction catalyzed by acyl-CoA synthase. Long-chain acyl-CoAs are transferred into the mitochondria by the carnitine shuttle. In the mitochondria, fatty acyl-CoA undergoes β -oxidation repetitively by transferring electrons to flavoprotein-linked dehydrogenases and then to the mitochondrial respiratory chain. The process is catalyzed by a series of enzymes, including acyl-CoA dehydrogenases, which act on short-, medium-, or long-chain acyl-CoAs; 3-hydroxy-acyl-CoA; and a mitochondrial trifunctional protein. The final product of fatty acid oxidation is acetylCoA, which is then used to produce acetoacetate and β -hydroxybutyrate (ketone bodies), which are released into the circulation.

Disruption of this process at any level will result in failure to metabolize fatty acids, leading to loss of a critical energy source and failure to produce ketone bodies. During prolonged aerobic exercise, fasting, or any intercurrent illness, fatty acid oxidation accounts for a major part of oxygen consumption by muscle. In contrast, energy requirements of the brain are supplied primarily by glucose and secondarily by oxidation of ketone bodies. Patients with disorders in fatty acid oxidation have both hypoglycemia and hypoketonemia and are thus particularly prone to neurologic damage. In a recent review of 50 patients with longchain 3-hydroxy-acyl-CoA dehydrogenase deficiency, hypoketotic hypoglycemia was the presenting symptom in 78%. Lactic acidosis was a common feature of metabolic crisis. Mortality was high (38%), and surviving patients continued to suffer from recurrent metabolic crises despite medical treatment. Interestingly, 86% of the patients had chronic, nonspecific symptoms prior to metabolic decompensation that could have led to earlier diagnosis had the index of clinical suspicion been higher. Early diagnosis appears to be associated with improved survival and long-term prognosis (144).

The mechanism by which these disorders cause hypoglycemia is unclear and is thought to be due the combined effect of at least two factors: Increased peripheral utilization of glucose due to the absence of fatty acids and ketone bodies as alternative energy sources may rapidly deplete glycogen stores and overtax the gluconeogenesis machinery. Hepatic gluconeogenesis may be further inhibited nonspecifically because of a decrease in energy sources needed to drive the process or specifically by inhibition of pyruvate carboxylase, the first gluconeogenic enzyme, since this enzyme requires acetyl-CoA for optimal activity (145).

The clinical presentations of most disorders of fatty acid oxidation are similar. The diagnosis is suspected clinically when fasting hypoketotic hypoglycemia is found in the absence of hyperinsulinism. Metabolic derangement typically associated with Reye syndrome, such as encephalopathy with hyperammonemia, metabolic acidosis, and elevated transaminases, may be present. It has been suggested that since the incidence of true Reye syndrome is decreasing, the majority of children presenting with this constellation of symptoms in fact have an inherited metabolic disorder (146). Myopathy and/or cardiomyopathy may also be prominent features. Acute symptoms are typically precipitated by fasting or by acute intercurrent illness.

The diagnosis can be made by analysis of urine for organic acids and measurement of plasma carnitine and acylcarnitines. Electrospray tandem mass spectrometry can be used to obtain an acylcarnitine profile, which is usually diagnostic for specific defects. This analysis can be performed on a dried blood spot, and it is currently being investigated for use in routine neonatal screening (147–149). The definitive enzymatic defect can be identified by direct enzyme assays on cultured fibroblasts or the identification of specific genetic defects.

Carnitine Deficiency

Carnitine is required for the transfer of long-chain fatty acids into the mitochondria for oxidation. Primary carnitine deficiency is caused by a defect in the plasma membrane carnitine transporter in the kidney and muscle (MIM no. 212140). Recessive mutations in this transporter result in urinary carnitine wasting and decreased intracellular levels of carnitine. Patients

presenting before the age of 1 year typically present with hypoketotic hypoglycemia, liver failure, and acute encephalopathy, whereas older patients present with skeletal or cardiac myopathy. Free carnitine and acylcarnitine levels in plasma are very low, and patients respond to dietary supplements. Defects in carnitine palmitoyl transferase 1 (CPT-1; MIM no. 255120) and carnitine-acylcarnitine translocase (MIM no. 212138) result in a similar clinical picture with variable severity, depending on the specific defect. Each has a typical carnitine/acylcarnitine plasma profile. In contrast, carnitine palmitoyl transferase 2 (CPT-2; MIM no. 255220) frequently presents in adolescents or young adults with predominantly muscle involvement, although a more severe neonatal form and an intrauterine malformative form also exist. The age at onset and severity seem to correlate with the specific mutation inherited and with the level of residual enzyme activity. Patients suffering from other organic acid disorders frequently have secondary carnitine deficiency, presumably due to excretion of large quantities of acylcarnitines in the urine, and dietary carnitine supplementation may be beneficial (150).

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD; MIM no. 201450) deficiency is one of the most common organic acidemias and is also one of the first to be described. Although more than 25 mutations have been described, a single founder mutation (A985G) is responsible for about 90% of cases (151). MCAD is responsible for the first step in the oxidation of fatty acyl-CoA esters of chain length C4 to C12, and the diagnosis can be made by finding increased urinary excretion of C6 to C8 dicarboxylic acids and their glycine conjugates. The disease presents in early childhood with Reye syndrome-like symptoms, including hypoglycemia, coma, and fatty liver, usually associated with febrile disease or other metabolic stress. This disease may be one cause of sudden infant death syndrome. Symptoms may develop rapidly and result in death before intervention can be initiated. Recent studies have suggested that the severity and relative frequency of this disease may justify routine neonatal screening (148,152,153).

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD; glutaric aciduria type 2) is a rare organic acidemia that can be caused by mutations in any one of three molecules: either subunit of the electron transfer flavoprotein or electron transfer flavoprotein dehydrogenase. This enzyme system is involved in the transfer of electrons from acyl-CoA dehydrogenases to coenzyme Q of the mitochondrial electron transport chain. The clinical severity of the disease correlates with the severity of the metabolic defect. The severe form (MADD:S) is associated with severe neonatal acidosis and hypoglycemia, as well as multiple congenital malformations similar to those observed in the intrauterine, lethal form of CPT-2 deficiency. Most patients do not survive the neonatal period. Milder disease may be diagnosed later in life, usually during childhood or adolescence, and frequently after a metabolic stress such as febrile illness. The mechanism by which MADD causes its associated metabolic abnormalities emphasizes the complex interaction between different metabolic pathways. The enzyme complex is responsible for the oxidation of short-, medium-, and longchain fatty acids, as well as for the oxidation of glutaryl-CoA, a degradation product of lysine. Blockage of the latter reaction results in the hallmark finding of glutaric aciduria. Hyperammonemia probably is caused by decreased availability of acetyl-CoA, resulting in decreased synthesis of N-acetylglutamate, which is required for the first step of the urea cycle. Hypo-

glycemia is caused by increased utilization of glucose and decreased gluconeogenesis, as with other disorders of fatty acid oxidation. Glutaryl-CoA may interfere with the malate shuttle, further compromising mitochondrial function. Heart, liver, and muscle damage are caused by accumulation of acylcarnitine. Binding of CoA esters to carnitine causes a secondary carnitine deficiency that further exacerbates the metabolic defect. Treatment consists primarily of prevention of catabolic states. Supplementation with riboflavin and carnitine may be of benefit to patients with mild disease. The diagnosis is made by typical acylcarnitine profile on tandem mass spectrometry and can be confirmed by enzyme analysis in fibroblasts (144,154–156).

DEFECTS OF KETOGENESIS

Ketones are an important source of energy for extrahepatic tissues. They are generated almost exclusively in the liver by conversion of acetyl- and acetylacetyl-CoA to acetoacetate, a process that requires the mitochondrial enzymes 3-hydroxy-3methylglutaryl-CoA (HMG-CoA) synthase and lyase. A mitochondrial HMG-CoA synthase mutation was recently reported in a 6-year-old patient with severe hypoketotic hypoglycemic coma and normal levels of carnitine and urinary organic acids. This case demonstrates the importance of the mitochondrial form of this enzyme in ketone production and the importance of ketone bodies in the prevention of hypoglycemia during prolonged fasting (157).

HMG-CoA lyase also catalyzes the final step in leucine degradation; however, its main role in the liver is to cleave HMG-CoA to acetoacetic acid and acetyl-CoA. Deficiency of this enzyme (MIM no. 246450) causes severe hypoketotic hypoglycemia with metabolic acidosis and increased excretion of organic acids (158). The clinical picture is more severe than in HMG-CoA synthase deficiency, but decompensation can be avoided by glucose supplementation during catabolic stress. Restriction of leucine intake does not appear to be particularly helpful, because the primary metabolic defect is ketone deficiency and not the accumulation of toxic metabolites. Secondary carnitine deficiency may develop, and dietary supplementation may be beneficial.

Hyperinsulinism of Infancy

Hyperinsulinism of infancy (HI) has been referred to by a number of names, including "nesidioblastosis," β -cell dysmaturation syndrome, persistent hyperinsulinemic hypoglycemia of infancy, and others (MIM no. 256450). The pathogenesis of this disease has just recently begun to be elucidated. However, our current knowledge is still limited and is only beginning to affect the clinical diagnosis and treatment of patients with this devastating disease. For a more complete discussion on the etiology, diagnosis, and treatment of this syndrome, the reader is referred to a number of recent comprehensive reviews (159–162). Given the rapidity of progress over the last few years, it is likely that our understanding of the disease will continue to grow rapidly and that the diagnostic and treatment approaches to these patients will evolve quickly over the next few years.

DIAGNOSIS

The biochemical diagnosis of hypoglycemia secondary to insulin hypersecretion is based on documentation of inappropriately elevated insulin levels in the presence of symptomatic hypoglycemia (163,164). Grossly elevated insulin levels can usually be readily demonstrated in patients with severe disease that appears shortly after birth. In milder cases, however, fasting insulin levels may fluctuate greatly, and it may be difficult to convincingly demonstrate the presence of pathologically ele-

vated concentrations of insulin. Surrogate measurements of insulin action, including inappropriate hypoketonemia, exaggerated glycemic response to glucagon, and a markedly elevated glucose requirement to prevent hypoglycemia, are particularly useful in such patients. Mildly to moderately elevated serum levels of ammonia suggest the presence of the recently discovered hyperinsulinism/hyperammonemia syndrome (165–167). A systematic approach to the diagnosis of HI has recently been reviewed in detail (167).

Although the clinical diagnosis may be difficult, for most patients the definitive diagnosis can be made rapidly if the appropriate blood and urine samples are obtained during an episode of spontaneous hypoglycemia (Table 69.4) and adequate attention is paid to the glucose dose required to prevent recurrent hypoglycemia (159,168). However, if the index of suspicion is not sufficiently high, the diagnosis may be missed in patients with relatively mild disease.

ETIOLOGY

Mutations in any of at least five different genes can cause HI. Two of these, the sulfonylurea-receptor gene, *SUR1* (ABCC8), and the potassium-channel gene *Kir6.2* (KCNJ11), code for subunits of the β -cell K_{ATP} channel. Two other genes code for glucokinase and glutamate dehydrogenase, which are enzymes important for the regulation of β -cell metabolism. The fifth gene codes for mannose phosphate isomerase. The mechanism by which mutations in this gene cause hypoglycemia is not yet understood. Each genetic etiology has its own specific clinical characteristics that affect the treatment approach and make genetic counseling complex.

Hyperinsulinism Due to Mutations in K_{ATP}-Channel Genes (HI-K_{ATP}) (MIM no. 256450)

The β -cell K_{ATP} channels are open in the resting state, allowing free passage of potassium ions out of the cell and maintaining the cell membrane in a hyperpolarized state. Metabolism of glucose and other fuels results in an increase in the adenosine triphosphate/adenosine diphosphate (ATP/ADP) ratio, which causes the K_{ATP} channel to close. This results in membrane

depolarization, opening of the voltage-gated calcium channels, an influx of calcium into the cell, and ultimately insulin secretion. Thus, the K_{ATP} channel "senses" the intracellular metabolic state and uses this information to regulate insulin secretion (Fig. 69.6).

The K_{ATP} channel is made up of two subunits. The first, the sulfonylurea receptor (SUR-1), is the regulatory subunit of the channel, having two nucleotide binding domains and domains that bind channel openers such as diazoxide, and channel closers such as drugs of the sulfonylurea class. An endogenous regulator of this subunit, endosulfine, was recently cloned, but its physiologic significance is not yet known (169). The second subunit (Kir6.2) creates the ion-specific pore. The functional channel is a hetero-octamer, made up of four molecules of SUR1 and four of Kir6.2. The genes for these two subunits are located adjacent to each other on the short arm of chromosome 11, about 30 centimorgan (cM) centromeric to the insulin gene.

Genetic mutations that decrease the function of either of these two subunits will cause defective K_{ATP} channels, resulting in membrane depolarization and unregulated insulin secretion. To date, more than 50 different mutations have been reported, three in the *Kir6.2* gene and the remainder in the *SUR1* gene. The vast majority of these mutations are recessive, meaning that

channel function will be compromised only if there are mutations in both alleles. However, the structure of the channel suggests that dominant mutations are also possible, and indeed, the first dominant *SUR1* mutation in humans was recently reported in an isolated Finnish population. Patients with this mutation have relatively mild, diazoxide-sensitive hyperinsulinism. All patients inherited their mutation on the maternal allele, a finding that cannot be readily explained (170).

Most patients with HI have diffuse pancreatic involvement (diffuse-HI), with all β -cells showing large nuclei and abundant cytoplasm, histologic evidence of metabolic hyperactivity. In these cases, the HI is caused by genomic mutations that affect all β -cells equally. Patients may be homozygous for a single mutation or compound heterozygous for two different recessive *SUR1* or *Kir6.2* mutations.

In about 30% to 40% of patients with HI, however, a limited region of their pancreases shows a distinct histologic finding of β -cell hyperplasia. B-Cells within the lesion show the typical features of metabolic hyperactivity, whereas β -cells throughout the remainder of the pancreas are small, with small nuclei and sparse cytoplasm, suggesting a metabolic resting state (162). It was recently discovered that these are clonal lesions in which the precursor cell has undergone somatic loss of the maternal

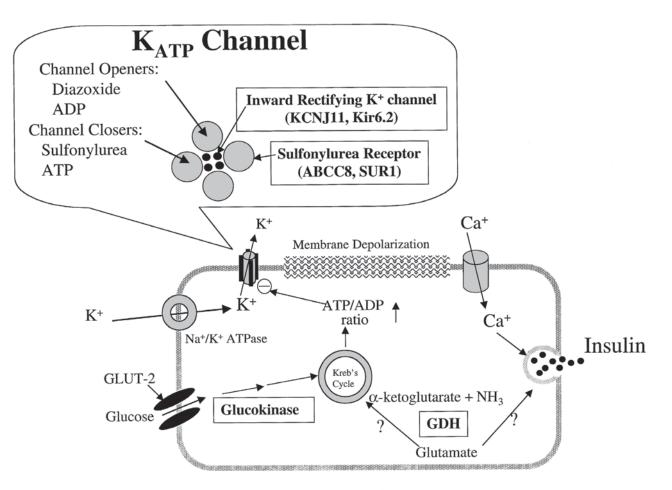

Figure 69.6. Schematic diagram showing the major pathway of glucose-regulated insulin secretion. The K_{ATP} channel is composed of four molecules of SUR1 and four molecules of Kir.6.2, as shown in the box in the upper left corner. Glucokinase is the rate-limiting step in glucose metabolism, and glutamate dehydrogenase (GDH) catalyzes the conversion of the amino acid glutamine to α -ketoglutarate. Hyperinsulinism of infancy can be caused by mutations in any of the four proteins highlighted by boxes. The mechanism by which activating GDH mutations cause hyperinsulinism is controversial. (Modified from Glaser B. Hyperinsulinism in the newborn. *Semin Perinatol* 2000;24:150–163.)

allele of chromosome 11p15, the region containing the KATPchannel genes as well as imprinted genes such as IGFII, p57kip2 and H19 (171). IGF-II is a growth-stimulating factor expressed only from the paternal allele. H19 and p57kip2 inhibit proliferation through different mechanisms and are expressed exclusively from the maternal allele. These patients are also heterozygous for a genomic, recessive SUR1 or Kir6.2 mutation that is always located on the paternal allele (172,173). Therefore, β -cells within the lesion carry only mutant K_{ATP}-channel genes, express the growth factor, and lack expression of the two inhibitors of proliferation. The result is clonal proliferation of βcells that release insulin in an unregulated manner, resulting in a syndrome of diazoxide-unresponsive severe hyperinsulinemic hypoglycemia. Resection of the hyperplastic region results in cure of hyperinsulinism and the return of normal insulin secretory dynamics (174). As discussed below, it is important to differentiate between the diffuse and focal forms of HI, since the treatment considerations are different. Since the genetic differentiation of these two forms of disease is not yet feasible, a number of clinical tests are being developed to differentiate between focal and diffuse HI (175–177).

Hyperinsulinism Due to Mutations in the Glutamate Dehydrogenase Gene (MIM no. 138130)

In 1996 a clinical syndrome of hyperinsulinemic hypoglycemia with mild to moderate hyperammonemia (HI/HA) was described (165). It was subsequently demonstrated that most cases are due to dominant gain-of-function mutations in the regulatory domain of the mitochondrial enzyme glutamate dehydrogenase (GDH) (Fig. 69.6). This enzyme catalyzes the reversible conversion of glutamate to α -ketoglutarate. The exact mechanism by which this results in unregulated insulin secretion is still controversial (166,178,179). The associated hyperammonemia is thought to be caused by increased activity of the same enzyme in the liver, where the conversion of glutamate to α -ketoglutarate is accompanied by the production of ammonia. GDH overactivity causes depletion of glutamate, resulting in a decrease of N-acetylglutamate, a regulator of carbamoylphosphate synthase, the first enzyme in the pathway of NH₃ detoxification. Thus, hyperammonemia is caused by a combination of increased production and decreased metabolism of NH₃.

Patients with HI/HA tend to suffer from both fasting and postprandial hypoglycemia, which becomes evident after a few months of age (180). They may be very sensitive to high-protein meals, and indeed this may be the etiology of the entity "leucine-sensitive hyperinsulinism" described in the 1970s. In most patients, the hypoglycemia responds well to treatment with diazoxide, and therefore surgical intervention is rarely needed (see below). The hyperammonemia appears to be benign, with no apparent neurologic manifestations. HI/HA appears to be responsible for disease in 3% to 5% of hyperinsulinemic infants. In some of these, no GDH mutations have been identified, suggesting that mutations in other genes may cause this phenotype.

Hyperinsulinism Due to Mutations in the Glucokinase Gene (MIM no. 602485)

We recently described a family with fasting and postprandial hypoglycemia caused by a dominant mutation in the glucokinase gene (181). *In vitro* studies documented that the mutation increased the affinity of the enzyme for glucose and decreased the glucose threshold for insulin secretion, consistent with the clinical findings in the affected patients. Mutations that have the opposite effect on glucokinase affinity for glucose have been previously reported to cause one form of maturity-onset diabetes of the young (MODY) (182). These findings provided further evidence that glucokinase is the β -cell "glucose sensor." Despite extensive genetic testing, very few patients with hyperinsulinism due to mutations in the glucokinase gene (HI-GCK) have been reported.

Hyperinsulinism Due to Mutations in the Mannose Phosphate Isomerase Gene (MIM no. 602579)

Mutations in the mannose phosphate isomerase (MPI) gene cause a novel variant of the carbohydrate-deficient glycoprotein syndrome, designated CDGS type 1b. The syndrome manifestations include protein-losing enteropathy with chronic diarrhea, hepatic disease, and coagulopathy. Neurologic manifestations that characterize CDGS type 1a, which is caused by mutations in the mannose phosphate mutase gene, are notably absent. Recently, four cases of CDGS type 1b with hypoglycemia were reported, and in two, absolute or relative hyperinsulinism was documented. The mechanism by which MPI mutations cause hyperinsulinism is not known, but diazoxide treatment appears to be effective. Diagnosis requires a high level of clinical suspicion, because the routine biochemical evaluation may be identical to that found in HI due to other genetic etiologies, and gastrointestinal symptoms are common in HI-KATP. The biochemical diagnosis is made by documenting protein hypoglycosylation, usually by isoelectric focusing of serum transferrin. Definitive diagnosis can be made by determining enzyme activity in lymphocytes or fibroblasts, or by genetic evaluation. Precise diagnosis is critical, since patients respond well to mannose therapy (183,184).

Other Causes of Hyperinsulinemic Hypoglycemia

Despite extensive genetic evaluation, in about 40% of patients with clinical evidence of HI, no mutation can be identified in any of the five genes described above. Some mutations could have been missed, because the mutation-detection methods used were only 85% to 90% sensitive and intronic mutations and deletions were not systematically sought. However, it seems likely that the clinical syndrome may be more heterogeneous than previously suspected. Evidence for multiple other genetic etiologies for hyperinsulinemic hypoglycemia comes from numerous recent publications reporting hyperinsulinism as part of several, apparently unrelated clinical syndromes, including Kabuki syndrome (185), short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (186), and exercise-induced hyperinsulinism (187). It seems likely, therefore, that the coming years will witness a flurry of publications documenting novel genetic forms of hyperinsulinism.

TREATMENT

Treatment can be divided into several phases. After the initial diagnostic blood samples are obtained (Table 69.4), the hypoglycemia must be corrected immediately using intravenous glucose at a dose sufficient to prevent further hypoglycemia and thus prevent irreversible brain damage. This dose may be very high [>15 mg/(kg · min)] and frequently requires central venous access.

Until recently, the next phase of treatment was entirely empiric. Attempts are made to decrease and stop parenteral glucose requirement by adding a combination of medical therapies, which include diazoxide, somatostatin analogue (188), nifedipine (189), and glucagon (190). Additional pharmacologic interventions have been proposed, including recombinant IGF-I, which has been shown to suppress insulin secretion in patients with HI (191); glucocorticoids, which induce resistance to endogenous insulin and correct the inadequate cortisol response sometimes seen in these patients; and growth hormone given in combination with somatostatin analogue to counteract the suppression of growth hormone by somatostatin. However, the clinical utility of these interventions has yet to be critically assessed. The definition of what is adequate glucose control has been the subject of considerable discussion. Most investigators recommend maintaining all glucose levels above 60 mg/dL (3.3 mmol/L), a level that leaves a sufficient margin of error to prevent frequent episodes of neuroglycopenia (192). In only a minority of cases can this goal be attained with medical therapy alone without concomitant intensive dietary intervention.

Once stabilized, and the diagnosis of HI confirmed, a decision must be made regarding the need for surgical intervention and the extent of such intervention. It is generally accepted that those patients who respond well to medical treatment can be treated chronically without undue risk of long-term complications. Surgery must be considered for patients who do not respond adequately to medical treatment. Patients with focal disease can be readily and successfully treated by localized resection of the hyperplastic region, whereas patients with diffuse disease require extensive pancreatic resection (80% to 95%) and are at risk for persistent hypoglycemia postoperatively and/or insulin-requiring diabetes later in childhood. The decision to proceed to surgery is complicated by the finding that medically treated patients tend to improve with time and that even those requiring very intensive medical management during the newborn period may enter clinical remission after several months or years of medical management. Although no consensus has been reached, the current trend is to consider early surgery for patients with focal disease, because the surgical results are excellent, whereas to attempt intensive long-term medical treatment for patients with diffuse disease and to opt for surgery only if this is not successful.

GENETIC COUNSELING

The genetic heterogeneity of HI makes genetic counseling extremely complex. The fact that in many cases the precise genetic etiology of disease is not known makes it even harder. In patients with HI/HA or HI-GK, the disease is transmitted as an autosomal dominant trait. If one parent is affected, subsequent siblings have a 50% chance of having the disease. If the disease is caused by a spontaneous mutation in the patient, the risk to subsequent children appears to be negligible. In patients with HI-K_{ATP} and diffuse disease, the disease is most probably transmitted as an autosomal recessive trait, and thus subsequent children would have a 25% risk of developing the disease. However, as described above, dominant mutations in this gene are possible and must be considered in individual cases. In patients with focal disease due to paternally inherited SUR1 or Kir6.2 mutations, the risk to subsequent siblings is determined by the incidence of somatic mutations causing loss of the maternal allele of Ch11p in β -cell precursors. This risk is not known; however, analysis of siblings of patients with known SUR1 mutations suggests that the risk for disease in a sibling inheriting one mutation on the paternal allele is very small-probably less than 2% to 3%. More data are needed to provide a more accurate risk estimate.

Diagnostic Approach to the Hypoglycemic Infant

Cost-effectiveness analyses may not support routine glucose testing in all neonates. However, the index of suspicion must be high, and glucose measurements should be made if the infant presents with any of the nonspecific symptoms possibly associated with neonatal hypoglycemia. In addition, infants at particular risk for hypoglycemia, such as those who are small or large for gestational age or who are premature, should be monitored for the first 24 to 48 hours or longer if necessary. While bedside glucometer testing has improved considerably, confirmation with laboratory measurements is required to convincingly diagnose or exclude hypoglycemia (see above).

Persistent hypoglycemia, defined as glucose levels less than 40 to 50 mg/dL (2.2 to 2.8 mmol/L) beyond the first 48 hours of life, requires more complete evaluation. Because it may take time to obtain results from many of the laboratory tests, early and complete laboratory evaluation will greatly facilitate rapid accurate diagnosis and hence more effective treatment. If the clinical situation allows, performance of a glucagon stimulation test during hypoglycemia will have both diagnostic and therapeutic significance. The dosage of glucagon is controversial and dosages ranging from 0.03 mg/kg to a 1-mg total dose have been recommended (159,168). A glycemic response over 30 mg/dL (1.7 mmol/L) is considered highly suggestive of hyperinsulinism and excludes primary defects in glycogen synthesis or glycogenolysis. It also provides an indication of whether glucagon can be useful in the specific patient as an emergency treatment of hypoglycemia should the need arise in the future.

If the performance of a glucagon test is technically not possible, if the results are negative, or if hypoglycemia recurs, immediate resuscitation with glucose is necessary. In the asymptomatic and otherwise healthy infant, 30 to 60 mL of 5% glucose in water given orally may be sufficient. It is necessary to perform serial glucose measurements every 15 to 30 minutes. If the infant is symptomatic, or in preterm neonates, intravenous treatment should be initiated with a 2-mL/kg bolus of 10% dextrose solution (D₁₀W), followed by a continuous infusion of glucose that approximates the normal glycemic requirement of the newborn [5 to $6 \text{ mg}/(\text{kg} \cdot \text{min})$]. Recurrent episodes of hypoglycemia should be treated with repeated doses of 2 mL/kg D₁₀W followed by increases in the glucose infusion rate by increments of 2 mg/(kg · min). Glucose requirements above the normal hepatic glucose uptake are highly suggestive of increased peripheral glucose utilization secondary to hyperinsulinism. In these patients, glucose requirement may be extremely high—greater than 20 mg/(kg · min). Requirements greater than 12 mg/(kg · min) require central venous access to avoid vascular damage and to guarantee uninterrupted infusion.

Once stabilization has been accomplished, the specific diagnosis must be established (Fig. 69.7). Low levels of ketone bodies, low levels of free fatty acids, absence of reducing substances, and normal lactic acid levels suggest either hyperinsulinism or a fatty acid disorder. Determination of serum carnitine/acylcarnitine profile will provide the specific diagnosis.

The presence of appropriate ketotic response without hepatomegaly suggests ketotic hypoglycemia or counterregulatory hormone (growth hormone or cortisol) deficiency. Hepatomegaly in the presence of ketosis suggests a defect in glycogenolysis. The presence or absence of lactic acidosis will further narrow the diagnostic possibilities since deficiencies in pyruvate carboxylase, PEPCK, glucose-6-phosphatase, or fructose-1,6-diphosphatase will result in high lactate levels, whereas in glycogen storage disease types III and VI, lactate levels will be normal.

In many cases, the definitive diagnosis cannot be made during episodes of spontaneous hypoglycemia, and a diagnostic fast is needed. Because fasting can be particularly dangerous in patients with defects in fatty acid oxidation, and because the fast is of little diagnostic value in these patients, it is recommended that a carnitine/acylcarnitine profile be obtained before a diagnostic fast is attempted. If a disorder of fatty acid oxidation is suspected, definitive testing should be accom-

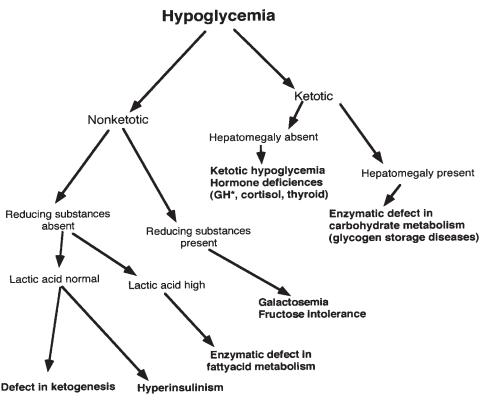

Figure 69.7. Schematic approach to the differential diagnosis of hypoglycemia. *Ketones may be temporarily absent in infants deficient in growth hormone (GH). (Data from Glaser B, Landau H, Permutt MA. Neonatal hyperinsulinism. *Trends Endocrinol Metab* 1999;10:55–61.)

plished and any form of fasting should be scrupulously avoided.

Once the initial clinical/biochemical diagnosis is made, specific treatment should be initiated as outlined above for each of the specific diagnoses. Further testing may be needed to define the specific enzyme defect. At this point, it is highly recommended that referral to a tertiary care center specializing in the specific class of defects identified be considered. This is particularly true for patients with hyperinsulinism (159). Medical management of these patients is particularly challenging because of the technical difficulties involved in maintaining the very high rates of glucose administration, the volatility of glucose control, and the vulnerability to unexpected and unpredictable severe hypoglycemia. If pancreatic surgery is required, localization studies such as pancreatic venous sampling or intraarterial calcium infusions may be indicated, and these are rarely available except in highly specialized tertiary care centers.

In terms of long-term prognosis, neonatal hypoglycemia can be divided into two major groups. The first consists of the transient hypoglycemia frequently seen in small-for-gestational age or premature infants. The precise definition of hypoglycemia in these infants has not been determined, and the long-term consequences of treatment have not been prospectively studied. However, correlations with poor neurologic outcome have been made (116). Therefore, given the severe, life-long consequences of inadequate treatment and the relative ease of correction of hypoglycemia in these infants, it seems prudent to treat them with the goal of restoring glucose values to the normal physiologic range (113).

In the second group of patients, those with clear metabolic defects resulting in moderate to severe persistent hypo-

glycemia, there is no doubt that success of treatment correlates directly with ultimate neurologic outcome. This is particularly true of hyperinsulinism, in which inadequate treatment routinely results in severe neurologic damage or even death, whereas successful prevention of severe recurrent hypoglycemia is almost always associated with normal on near-normal neurologic outcome (193).

Acknowledgments

The authors thank Drs. Orly Elpeleg and Erol Cerasi for their critical review of the manuscript and for their many helpful suggestions.

PROGNOSIS 1186

Pancreatic endocrine tumors make up only 1% to 2% of all tumors of the pancreas but form an important group in that they tend to be more benign and treatable than the common exocrine tumors. Although the identification of the menin gene has provided some insights into the tumorigenesis of the rare familial form of pancreatic endocrine tumors, the heterogeneity of phenotypes and the absence of menin mutations in some cases remain unexplained. With the advent of technological advances facilitating the retrieval and analysis of large data sets, such as gene expression microarray profiling and multivariate analysis of complex traits (1), we are now poised to identify subsequent molecular events and use the information to prognosticate and risk stratify patients with the menin gene mutation. In addition, these techniques will permit comparison of the findings in patients with multiple endocrine neoplasia type 1 (MEN1) with those in patients with the more common sporadic form of disease in whom no menin mutation is apparent and to relate the pathogenesis of these potentially distinct but related tumor entities. To maximize the power of these basic science techniques, this analysis of the complex pathways in relation to tumor behavior will necessitate ever more rigorous clinical assessment of phenotype definitions. Indeed, geneexpression data have already been shown to provide invaluable prognostic information with regard to breast carcinoma (2,3), prostate carcinoma (4), and diffuse large B-cell lymphoma (5) and can predict imminent metastatic behavior in malignant melanoma (6).

Pancreatic endocrine tumors are derived from the diffuse neuroendocrine system of the gastrointestinal tract (7) and were

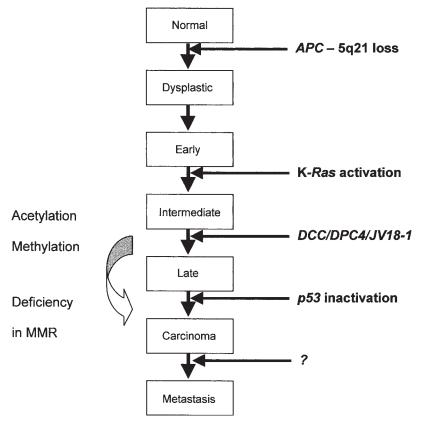

formerly classified as apudomas (tumors of the *a*mine *p*recursor *u*ptake and *d*ecarboxylation system). These neuroendocrine cells can produce a myriad of hormones, many of which are also present in the brain. The hormones provide a complex network of communication, each having endocrine, paracrine, autocrine, or neurotransmitter functions crucial to the finely tuned functioning and regulation of the gastroenteropancreatic system.

INCIDENCE

Although the annual incidence of neuroendocrine pancreatic tumors is about 3.5 to 4 per million population, there is a vast discrepancy between the clinical incidence and that found post mortem, suggesting an abundance of asymptomatic disease. Pancreatic endocrine tumors have been detected in 0.3% to 1.6% of unselected autopsies in which only a few sections of the pancreas were examined, whereas they were found in up to 10% when the whole pancreas was examined systematically (8). Unlike neuroendocrine tumors of the gut, carcinoid tumors rarely occur in the pancreas and will not be covered in this chapter.

ETIOLOGY

The etiology of pancreatic endocrine tumors has many similarities to tumorigenesis in the better-studied colorectal carcinoma model. The similarities will be discussed in this section, and this

analogy will help in understanding the development of pancreatic endocrine tumors.

Genetic Model from Colorectal Tumorigenesis

It is becoming increasingly clear that tumorigenesis involves a series of multiple genetic alterations leading to activation of oncogenes and/or inactivation of tumor suppressor genes and ultimately to loss of apoptosis. The genetic basis of colorectal neoplasia has provided a salient model for this sequential process (9). The transition from healthy colonic epithelia through increasingly dysplastic adenoma to colorectal cancer involves the acquisition of mutations in specific genes, including *APC*, K-*ras*, *DCC*, and *p53* [Fig. 70.1; data also from (10)]. Furthermore, although the total accumulation of genetic alterations is important, the exact sequence of events is critical for determining the phenotype, as illustrated by the early loss of *Lkb1*, rendering the cells resistant to oncogene-induced transformation, in Peutz-Jeghers syndrome (11).

Mutations in the adenomatous polyposis gene (*APC*) occur both in autosomal dominant familial adenomatous polyposis (FAP) and sporadically. The initiation of tumorigenesis requires a two-hit process, as outlined in Knudson's model (12). In the case of germline mutations, the first hit to the *APC* gene is inherited with the germline, thus being identical in all cells. Alternatively, in somatic mutations the first hit can occur as a rare event in a particular somatic cell. A second hit in both germline and somatic cases inactivates the unaffected allele, resulting in loss of heterozygosity (LOH) and initiates tumorigenesis.

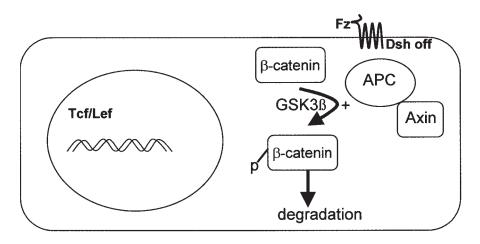

The *APC* gene, located on chromosome 5q21, encodes a 312kDa tumor suppressor protein with many possible protein/ protein interactions, including binding sites for β -catenin, endbinding protein-1 (EB1), and axin (13). It is termed a "gatekeeper" gene, because in normal human colonic cells, the **Figure 70.1.** Genetic changes associated with colorectal tumorigenesis. Mutations in the adenomatous polyposis gene (*APC*) initiate tumorigenesis, and tumor progression results from mutations in the other genes indicated. MMR, mismatch pair. (Adapted from Fearon ER, Vogelstein B. A genetic model for colorectal tumorigenesis. *Cell* 1990;61:759–767; and Kinzler KW, Vogelstein B. Lessons from hereditary colorectal cancer. *Cell* 1996;87:159–170; with additional data from Shannon BA, lacopetta BJ. Methylation of the hMLH1, p16, and MDR1 genes in colorectal carcinoma: associations with clinicopathological features. *Cancer Lett* 2001;167:91–97.)

APC/axin protein complex facilitates the phosphorylation and subsequent degradation of β -catenin, thus preventing β catenin–stimulated transcriptional activation and cell proliferation (Fig. 70.2) (14). It is therefore highly relevant that the majority of *APC* mutations in FAP result in the deletion of the carboxyterminal end, including the β -catenin and axin binding sites (15). This then initiates cell proliferation and tumorigenesis. Indeed, in addition to colorectal neoplasia, *APC* mutations have been associated with small-bowel tumors, desmoid tumors, and medulloblastomas.

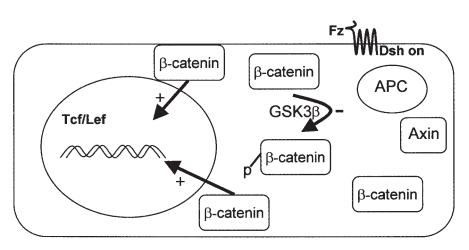

To a certain extent, there seems to be some correlation between genotype and phenotype in mutations affecting *APC*. Depending on the region of the gene affected, the resulting phenotype may be attenuated polyposis, classic polyposis, congenital hypertrophy of the retinal pigment epithelium (CHRPE), or Gardner syndrome (mandibular osteomas and desmoid tumors) (15). The resultant phenotype is determined by the functional consequences of the different mutations in *APC* and downstream modifying events.

Application of the Model to Pancreatic Endocrine Tumors

Although there is currently no direct evidence, it is likely that the process of tumorigenesis of pancreatic endocrine neoplasia follows the model of sequential accumulation of mutations, analogous to colonic neoplasia. In fact, there are many similarities between the two types of tumors. The familial form of pancreatic endocrine tumors is the autosomal dominant type MEN1, in which the other features include anterior pituitary tumors (27%); parathyroid hyperplasia (90%); and, more rarely, foregut carcinoid (14%), adrenocortical tumors (5%), and pheochromocytoma (<1%) (16). Nonendocrine tumors include angiofibroma (85%), collagenoma (70%), lipoma (30%), and

ependymoma (<1%). Pancreatic endocrine tumors can, however, also occur sporadically.

In 1988, Larsson and colleagues localized the MEN1 gene to chromosome 11q13 (17). Germline-inactivating mutations in this gene have been found in 95% of patients with familial MEN1, whereas in sporadic cases somatic mutations were found in a smaller proportion of patients: 21% of those with parathyroid adenoma, 33% with gastrinomas, 17% with insulinoma, 36% with bronchial carcinoids, and 50% to 70% with sporadic thymic and duodenal carcinoid (16,18-21). MEN1 is known to be a tumor suppressor, and it is likely that the transition from normal cells to neuroendocrine neoplasia in familial MEN1 requires a series of sequential genetic alterations starting with MEN1 [Fig. 70.3; data from (22-26)]. It is possible that, where there is no detectable MEN1 mutation (for instance, in the 5% of familial and in the majority of sporadic cases), the mutation cannot be detected given current techniques or that MEN1 is inactivated by mechanisms other than mutation, e.g., alterations in promoter methylation. It is interesting that the 5'region of MEN1 contains a CpG-rich area, and hypermethylation of similar regions in the promoter of the VHL and the *hMLH1* genes has been shown to be a frequent cause of somatic second hit in tumorigenesis in von Hippel-Lindau disease and colorectal carcinoma, respectively (27-29).

Similar to colorectal neoplasia, the initiation of tumorigenesis from the *MEN1* tumor suppressor gene requires a two-hit process [Knudson's model (12,23)]. In germline mutations, the Figure 70.2. The APC/axin β -catenin "destruction pathway" and regulation of transcription. The APC/ axin complex modulates the activity of GSK3β (glycogen synthase kinase 3B) and facilitates the phosphorylation of β-catenin, leading to the degradation of β-catenin. When the cells are exposed to Wnt (wingless and integration activated gene product), which acts on cell surface receptors of the frizzled family (Fz), the APC/axin complex is inactivated by an unknown mechanism requiring disheveled protein (Dsh), and β -catenin accumulates in the cell. This enters the nucleus and interacts with Tcf/Lef (T-cell factor/lymphoid enhancer binding factor) DNA-binding protein to activate new gene expression. An analogous situation occurs with inactivating mutations in *APC*. APC, adenomatous poly-posis. (Adapted from Peifer M, Polakis P. Wnt signaling in oncogenesis and embryogenesis-a look outside the nucleus. Science 2000;287:1606-1609; and Kinzler KW, Vogelstein B. Lessons from hereditary colorectal cancer. Cell 1996;87:159-170.)

first hit to the *MEN1* gene is inherited and only one more hit is required for loss of heterozygosity, whereas in somatic mutations of sporadic cases, two hits are required to result in tumorigenesis (17,30,31). In the mouse model with the homologue *Men1* germline mutation, the remaining wild-type *Men1* allele was retained until tumor formation, when somatic loss of this wild-type allele occurred in all tumors developed by the mice (22). The clinical features of familial MEN1 differ from somatic *MEN1* mutations, in that age of onset of tumor expression is usually earlier (in keeping with the Knudson's hypothesis) and that there is tumor multiplicity in terms of both multiple organs affected and also multiple tumors in one organ (16).

Menin, a 610-amino-acid protein, is the product of the *MEN1* gene, and the native form has been shown to bind to and inhibit JunD, an activator protein-1 (AP-1) transcription factor (32). In addition, menin suppresses p65-mediated transcriptional activation on NF- κ B sites (33), interacts with Smad3, facilitating transforming growth factor β (TGF- β)-mediated inhibition of cell growth (34), and may be important in the activity of a tumor metastasis suppressor nm23 (26), further suggestive of a tumor-suppressor role for menin (Fig. 70.4). Native menin has also been shown to inhibit insulin promoter activity and secretion and, when cotransfected into INS-1 insulinoma cells, results in inhibition of cell proliferation (35).

Despite the similarities of the etiologies of pancreatic neuroendocrine tumors and the colorectal tumorigenesis model, several differences need to be highlighted. First, the slower rate

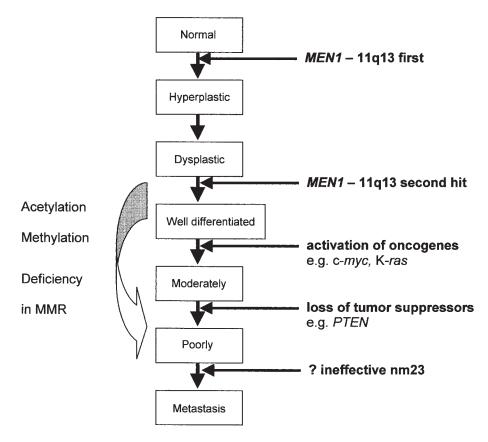

Figure 70.3. A model of genetic changes associated with pancreatic endocrine tumorigenesis. nm23 is a putative tumor metastasis suppressor. MEN1, multiple endocrine neoplasia type 1; MMR, mismatch pair; PTEN, phosphatase and tensin homologue. (Data from Crabtree JS, Scacheri PC, Ward JM, et al. of growth of neuroendocrine tumors and in many cases a more benign progression exists, and this may be due intrinsically to more signaling blocks and to less exposure to carcinogens. Second, there seems to be very little in the way of genotypephenotype correlation in *MEN1* mutations (36). The development of, for instance, an insulinoma rather than a gastrinoma may be determined by local factors such as the number of pancreatic β cells and their baseline proliferation rate. Most patients with familial MEN1 will develop nonfunctioning pancreatic tumors, whereas 40% will develop gastrinoma; 10%, insulinoma; and 2%, other functioning pancreatic tumors, such as glucagonoma, VIPoma (VIP, vasoactive intestinal polypeptide), and somatostatinoma (16).

Similarly, there is a wide spectrum in the aggressiveness of different pancreatic neuroendocrine tumors. The tumor phenotype will be determined by many factors (the particular *MEN1* mutation itself and many other downstream effects). As previously mentioned, familial MEN1 tends to result in a more aggressive tumor phenotype (earlier onset and multiplicity) compared with somatic mutations. The loss of expression of the phosphatidylinositol 3'-phosphatase and tumor suppressor gene *PTEN* (phosphatase and tensin homologue) on chromosome 10 has been shown in 54% (7 of 13) of poorly differentiated neuroendocrine tumors, whereas the two moderately differentiated neuroendocrine tumors in the series retained PTEN immunostaining (25). *PTEN* may be only one of many downstream factors that determine phenotype.

PHYSIOLOGY

There is a complex relationship between cells and enteric neurons in the gastroenteropancreatic system. This is orchestrated by a vast number of regulatory peptides secreted from neuroendocrine cells, which act in an autocrine, paracrine, and endocrine

manner as well as an neurocrine manner, in which the peptides behave as neurotransmitters and neuromodulators (7,37–40).

CLINICAL FEATURES

Despite the plethora of known gut hormones, it is possible that some still cannot be detected by current techniques. When a neuroendocrine tumor is diagnosed histologically, if no circulating gut hormone is found, it is termed "nonfunctioning." However, it may just be that the secreted hormone is as yet undetectable. The patients tend to be asymptomatic initially and to develop symptoms from tumor bulk at later stages of disease progression (41). On the other hand, for those "functioning" tumors that secrete detectable hormones (e.g., insulin or gastrin), the clinical picture is very much dependent on the nature of the secreted hormone, each giving a defined syndrome [Table 70.1; data from (40,42–45)], rather than on tumor bulk. Indeed, it is common for more than one hormone to be cosecreted at presentation or even for a tumor to dedifferentiate and start producing multiple hormones. This is particularly the case with MEN1. Genetic testing for MEN1 is now readily available, and screening of family members is recommended once a germline *menin* mutation is found.

IMMUNOCYTOCHEMICAL AND BASELINE BIOCHEMICAL MARKERS

The neuroendocrine tumors share certain general immunocytochemical markers, including the secretory granules chromogranins, neuron-specific enolase (NSE), pancreatic polypeptide, human chorionic gonadotropin (hCG) subunits, and peptide histidine-methionine (46–48). Chromogranins A, B, and C (CgA, CgB, CgC) are located alongside specific hormones in large

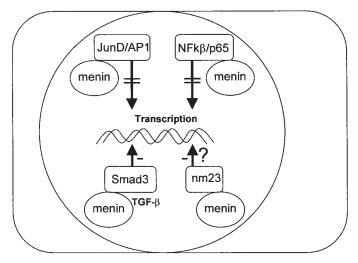

Figure 70.4. Interactions of native menin in its tumor-suppressor role. JunD is a member of the Jun family of proteins that dimerize with themselves or with Fos members to form the AP-1 (activator protein-1) transcriptional factor; menin binds JunD and inhibits JunD-mediated transcriptional activation. Menin also represses p65 (NF- $\kappa\beta$ protein)-mediated transcriptional activation. Smad3, a downstream component of the transforming growth factor β (TGF- β) signaling pathway, interacts with menin to alter transcription, leading to inhibition of cell growth. Finally, in the presence of the putative tumor metastasis suppressor nm23, menin attains atypical GTPase activity, and this may affect transcription. (Data from Yaguchi H, Ohkura N, Tsukada T, et al. Menin, the multiple endocrine neoplasia type 1 gene product, exhibits GTP-hydrolyzing activity in the presence of the tumor metastasis suppressor nm23. *J Biol Chem* 2002;277: 38197-38204; Agarwal SK, Guru SC, Heppner C, et al. Menin interacts with the AP1 transcription factor JunD and represses JunD-activated transcription. Cell 1999;96:143-152; Heppner C, Bilimoria KY, Agarwal SK, et al. The tumor suppressor protein menin interacts with NF-kappaB proteins and inhibits NF-kappaB-mediated transactivation. Oncogene 2001;20: 4917-4925; and Kaji H, Canaff L, Lebrun JJ, et al. Inactivation of menin, a Smad3-interacting protein, blocks transforming growth factor type beta signaling. Proc Natl Acad Sci U S A 2001;98:3837-3842.)

dense-core vesicles of neuronal and neuroendocrine cells, with CgA being the most widely distributed (49). With the exceptions of the lactotrophs of the pituitary and some pancreatic β -cell tumors, which show positive staining for CgB, CgA-positive tumors include anterior pituitary, parathyroid, medullary thyroid, gastroenteropancreatic, ectopic ACTH (adrenocorticotropic hormone), ganglioneuromas, neuroblastomas, pheochromocytoma, and small-cell lung and prostate tumors.

Some of the above-mentioned tissue markers can be detectable in plasma. Plasma CgA is elevated in 94% of pancreatic endocrine tumors, whereas pancreatic polypeptide is elevated in 74% (50). CgA, however, seems to be the best marker for metastatic carcinoid, whereas plasma CgB appears better for detecting benign insulinomas. A fragment of CgB termed GAWK (CgB-420-493) is a 74-amino-acid peptide originally isolated from human pituitaries, and high plasma concentrations are found in various neuroendocrine tumors, including pancreatic, pheochromocytoma, medullary carcinoma of the thyroid, and ACTH-producing lung tumors. GAWK is particularly elevated in pancreatic endocrine tumors, making it a useful marker (51). In another study of pancreatic endocrine tumors, pancreastatin was elevated in 33% of patients, whereas GAWK was elevated in 50% (52).

In addition to the general hormones associated with neuroendocrine tumors, the "functioning" tumors will also secrete specific hormones, e.g., gastrin, glucagon, pancreatic polypeptide, somatostatin, neurotensin, or VIP, which should be measured in the fasting state. Other baseline hormones, such as parathyroid hormone–related peptide (PTHrP), can be measured in the nonfasting state; the next section will discuss hormones requiring provocative testing for interpretation (e.g., insulin). Not uncommonly, tumors secrete multiple hormones (53). For instance, as many as 62% of patients have elevated gastrin despite only 30% presenting with peptic ulcer disease.

The diagnosis of gastrinoma requires an elevated fasting gastrin level in the presence of increased basal gastric acid output. The latter is required to make the diagnosis, because there are other causes of elevated gastrin, including proton pump inhibitors, H₂-antagonists, atrophic gastritis, hypercalcemia, and renal impairment. The fasting gastrin should be measured with the patient off proton pump inhibitors for at least 2 weeks and off H₂-blockers for at least 3 days. However, in view of the high risk of peptic ulcer perforation in gastrinoma, caution should be exercised before cessation of therapy, particularly when the clinical suspicion is high (e.g., family history of MEN1, hypercalcemia, or negative Helicobacter pylori status). Indeed, even with the patient on proton pump inhibitors, the fasting gastrin level may be interpretable in that very high levels (>500 pg/mL or >250 pmol/L) are highly suggestive of gastrinoma and should be followed by localization imaging rather than by repeat measurement of gastrin levels with the patient off therapy (54). Studies of basal gastric acid output often are required to distinguish primary from secondary hypergastrinemia, in which spontaneous basal acid (proton) outputs of 20 to 25 mmol per hour are almost diagnostic and >10 mmol per hour suspicious. The measurement of basal acid output is not readily available in many centers, and an alternative is the dynamic secretin test. This is particularly useful when the gastrin level during treatment is not high enough to be diagnostic and discontinuation of pharmacologic treatment for repeat gastrin testing is not feasible.

The diagnosis of insulinoma requires the measurements of insulin and C-peptide in the presence of hypoglycemia. This therefore requires the provocative test of a 3-day fast and is covered in the next section.

BIOCHEMICAL ASSAYS: DYNAMIC TESTS

Whereas a normal response to intravenous secretin is a decline in serum gastrin levels, an increase of more than 200 pg/mL (100 pmol/L) offers a sensitivity of 80% to 85% for the presence of gastrinoma (55,56). The diagnosis of insulinoma requires the measurement of insulin and C-peptide in the presence of hypoglycemia [glucose ≤2.2 mmol/L (40 mg/dL)]. The hypoglycemia is achieved with a 3-day fast, allowing free access to noncaloric fluids. By 24 hours, 66% of patients with insulinomas develop hypoglycemia, and by 48 hours, more than 95% of insulinomas can be diagnosed (57). If no hypoglycemia is achieved at the end of the 3-day fast, the patient's exercising for 15 minutes can further increase the sensitivity of the test. If hypoglycemia occurs, simultaneous plasma and urine samples need to be taken for sulfonylurea analysis to exclude drug-induced hypoglycemia. In the presence of hypoglycemia and a negative sulfonylurea screen, inappropriately elevated insulin and C-peptide are highly suggestive of an insulinoma. The finding of ketones on urinalysis during the fast is against the diagnosis.

An alternative diagnosis to insulinoma, giving the same results at the end of a 3-day fast, is nesidioblastosis. This is a condition in which nesidioblasts differentiate from pancreatic duct epithelium and form endocrine cells that are separate from the true islets, resulting in hyperinsulinism and hypoglycemia (58).

Histologically, hyperplasia of islet-like cells is seen, with no adenoma. In the neonate, this gives rise to persistent hyperinsulinemic hypoglycemia of infancy (PHHI), but adult-onset nesidioblastosis is being increasingly recognized (59). The mutations known to result in nesidioblastosis are inactivation of the sulfonylurea receptor gene 1 (*SUR1*), inactivation of the inward rectifying K⁺ channel subunit of the ATP-sensitive K⁺ channel (*Kir6.2*), activation of the glucokinase gene, and activation of the glutamate dehydrogenase gene (16,60). There seems to be no recognized susceptibility to malignancy with germline mutations in these tissue-selective genes.

LOCALIZATION BY IMAGING

Pancreatic surgery is fraught with difficulty, and accurate localization of pancreatic lesions is essential to guide the surgeon. There are four useful imaging modalities: dedicated pancreatic computed tomographic (CT) scanning, endoscopic

Gastroenteropancreatic Tumors (85)

 TABLE 70.2.
 The Proposed Classification into Benign, Uncertain, and Malignant Gastroenteropancreatic Tumors (85)

Data from Rindi G, Capella C, Solcia E. Cell biology, clincopathological profile; and classification of gastro-enteropancreatic endocrine tumors. *J Mol Med* 1998;76:413–420.

ultrasonography (EUS), pancreatic magnetic resonance imaging (MRI), and somatostatin-receptor scintigraphy (SRS). EUS has received much attention recently and has been shown to have a sensitivity of 80% to 90% for detecting pancreatic neuroendocrine tumors (61–65) and lower sensitivities for detecting extrapancreatic tumors (66–68). In one study, in fact, EUS showed the highest sensitivity in localizing insulinomas (94%) compared with SRS (12%), transabdominal ultrasound (12%), CT (29%), and MRI (13%) (65). The smallest lesion detectable by EUS was a 5-mm tumor in the pancreatic head. Intraoperative ultrasound is also useful in identifying small tumors that may not have been well defined preoperatively.

Another useful imaging modality is SRS, which has a sensitivity of up to 90% and a specificity of 80% for detecting functioning and nonfunctioning tumors of the pancreas, excluding insulinoma (69–71). Unlike other neuroendocrine tumors, insulinomas rarely express somatostatin receptors, thereby limiting the sensitivity of SRS to 10% to 50% (72,73). The exception is malignant insulinomas, which tend to express somatostatin receptors, and SRS is recommended for staging.

With very small tumors (<5 mm), or when multiple tumors can be seen, selective angiography with calcium gluconate (or secretin) injection into the main pancreatic arteries provides biochemical localization for functioning neuroendocrine tumors. The procedure involves cannulation of the gastroduodenal, inferior pancreaticoduodenal, superior mesenteric, splenic, and hepatic arteries in turn. The territory of each of these arteries is studied for the presence of a vascular blush, and then the secretagogue calcium gluconate (or secretin) is injected into each artery in turn. Venous samples are taken at 30-second intervals from the hepatic vein. The normal response to intraarterial calcium gluconate is a reduction in secretion of pancreatic neuroendocrine hormones; in the presence of neuroendocrine tumor, however, there is a doubling in neuroendocrine hormone release. This can be detected in the hepatic vein at 30 seconds (74-78). We find this technique invaluable at our institution because, first, it informs the surgeon of which artery supplies the territory of the tumor; second, it offers a biochemical diagnosis even before the tumor is large enough to be seen on imaging; third, where two types of tumors coexist (e.g., both insulinoma and gastrinoma in MEN1), they can be differentiated; and finally, since the hepatic artery is also injected with secretagogue, the technique provides biochemical evidence of the presence or lack of liver metastases.

Positron-emission tomography has also been applied to neuroendocrine tumors, and the use of such tracers as the monoamine oxidase inhibitor harmine for localization of non-functioning neuroendocrine tumors seems particularly promising (79). MIBG ([1123]-metaiodobenzyl guanidine) scanning, on

the other hand, is not useful diagnostically for gastroenteropancreatic neuroendocrine tumors, because they derive from endoderm, not neuroectoderm, and catecholamine synthesis is rarely found (80).

Finally, intraoperative and gamma probes provide the last form of imaging for the surgeon. These probes are able to detect accumulation of the tracer (indium-111-DTPA-D-Phe1)pentetreotide more efficiently (>90%) than SRS (68% to 77%), including lesions less than 5 mm in size, and radioguided surgery has been found to identify 57% more lesions than detected by the "palpating finger" (81).

CLINICOPATHOLOGIC CLASSIFICATION

In 1963 Williams and Sandler (82) were the first to classify gut neuroendocrine tumors, and subsequently numerous nomenclature systems have appeared. Most recently, a new classification of neuroendocrine gastroenteropancreatic tumors based on clinicopathologic patterns has been devised (83–85). The proposed classification into benign, uncertain, and malignant gastroenteropancreatic tumors is summarized in Table 70.2 (85). In the case of functioning pancreatic endocrine tumors, the biological behavior of the tumor is dependent as much on its pathologic features as on the endocrine hyperfunction syndrome present (Table 70.1) (86,87).

TREATMENT

Curative Surgery

RESECTION OF THE PRIMARY LESION

A primary pancreatic lesion should be resected if surgically possible, particularly if no metastases have developed. These tumors are often very slow growing, but the main problems with functioning tumors result from the secreted hormone rather than from tumor bulk. This is particularly the case with insulinomas, which can result in sudden death from inappropriate insulin secretion rather than from tumor bulk or metastases. In fact, approximately 90% of insulinomas can be enucleated from the pancreas without the need to perform local pancreatic resection.

RESECTION OF LIVER METASTASES

With improved liver surgery techniques, curative hepatic surgery is considered with increasing frequency if the primary tumor has been resected or is potentially resectable, if the liver can withstand the resection, and if there are no extrahepatic metastases. The outcome in recent studies show a 4- to 5-year

1184 JOSLIN'S DIABETES MELLITUS

survival of 70% to 85% with curative surgery (88–92). Best outcomes are achieved when there are fewer than four metastases (46 months median disease–free survival) (92).

LIVER TRANSPLANTATION

In exceptional cases in which the liver metastases are unresectable, a liver transplant may be considered. A meta-analysis of liver transplantation for neuroendocrine tumors with 30 cases (13 foregut and 15 pancreatic primaries) showed a survival of 52% after 1 year (93). The complication rate of the surgery was high, and 6 of the 12 patients who died within the first year died as a consequence of the transplant procedure itself. At our institution, a patient with a pancreatic PTHrPoma who underwent resection of the primary pancreatic tumor 17 years ago and a liver transplant for metastases 10 years ago remains alive. She has recently developed pleural and peritoneal metastases and is being treated with radiolabeled octreotide.

Medical

The medical treatments for the various endocrine hyperfunction syndromes are summarized in Table 70.3. These treatments should be put into operation pending curative surgery or if surgery is not possible. As can be seen, somatostatin analogues are frequently required.

SOMATOSTATIN ANALOGUES

Somatostatin analogues are effective for symptomatic control in many functioning neuroendocrine pancreatic tumors (94,95). Somatostatin is widely expressed throughout the body, and neuroendocrine tumors are frequently somatostatin positive (96). The longer-acting analogues of somatostatin (lanreotide and octreotide; Figure 70.5) preferentially bind the somatostatin 2 receptors (sstr2), and to a lesser extent, somatostatin 5 receptors (sstr5) (97,98).

Octreotide and lanreotide have been shown to have effects on hormone secretion and antiproliferative effects mainly via

.....

sstr2 (73,97–99). Although most gastroenteropancreatic neuroendocrine tumors express all five somatostatin receptors, those lacking somatostatin 2 [such as 50% to 90% of insulinomas (72,73)] are unresponsive to lanreotide and octreotide.

Both *in vitro* and *in vivo* experiments have indicated that somatostatin and its analogues have an antiproliferative effect, and there have been case reports of tumor regression (100–104). However, phase II trials of the effects of octreotide and lanreotide in patients with metastatic neuroendocrine tumors showed partial tumor regression in only 3% to 5% of patients treated with high-dose analogues, whereas stabilization of tumor was the best outcome, occurring in 36% to 70% of patients (105–108).

In nonfunctioning neuroendocrine tumors, somatostatin analogues should be used if the SRS scan is positive and the tumor is aggressive, with greater than 25% tumor growth in 1 year or evidence of high mitotic rate from histology (using the Ki67 value, CD44 expression, or somatostatin-receptor content) (80).

INTERFERON-α

Interferon- α (IFN- α) was first introduced for the treatment of carcinoid tumors for its ability to stimulate natural killer cells and control hormone secretion, symptoms, and tumor growth (109). Numerous series have used INF- α in malignant neuroendocrine tumors, and the largest studies have shown a 42% biochemical and 14% tumor response in carcinoid tumors and a 51% biochemical and 12% tumor response in neuroendocrine pancreatic tumors (110,111). However, side effects are common and include flu-like symptoms, weight loss, fatigue, and depression. The use of INF- α is limited now to metastatic carcinoid tumors, particularly when the tumor is not somatostatin analogue (112). Finally, the combination of octreotide and INF- α has been compared with monotherapies, and no difference in the antiproliferative response was found (80,112).

CHEMOTHERAPY

The slow growth rate of many neuroendocrine tumors (<25% in 1 year) would imply that chemotherapy should not be the treatment of choice except in the most aggressive tumors. However, well-differentiated pancreatic endocrine tumors (particularly VIPomas) seem to respond to streptozotocin combined with either 5-fluorouracil (5-FU) or adriamycin (with response rates of 40% to 69% and median survival 2.2 years) compared with metastatic carcinoid tumors (response rates around 20%) (113).

The chemosensitivity of undifferentiated and highly aggressive neuroendocrine tumors, on the other hand, is similar to that of small-cell carcinoma of the lung, and a response rate of 50% to 67% (median survival 9 months to 1.75 years) has been shown with a combination of etoposide (VP16) and cisplatin (CDDP) (114,115). The greatest benefit was seen in patients with undifferentiated pancreatic endocrine tumors and foregut carcinoid tumors. Not surprisingly, this combination was not effective in differentiated neuroendocrine tumors.

Interventional Radiology

HEPATIC ARTERY EMBOLIZATION

The liver is the most common site of metastases from gastroenteropancreatic neuroendocrine tumors. In the case of functioning tumors, these metastases will produce symptoms according to the hormone hyperfunction syndrome (Table 70.1). Should these metastases be unresectable, hepatic arterial embolization offers a therapeutic option. This is possible because the liver has a dual blood supply, receiving 20% to 25% of blood from the hepatic artery and 75% to 80% from the hepatic portal vein. It is crucial to ensure prior to the procedure that the portal vein is patent.

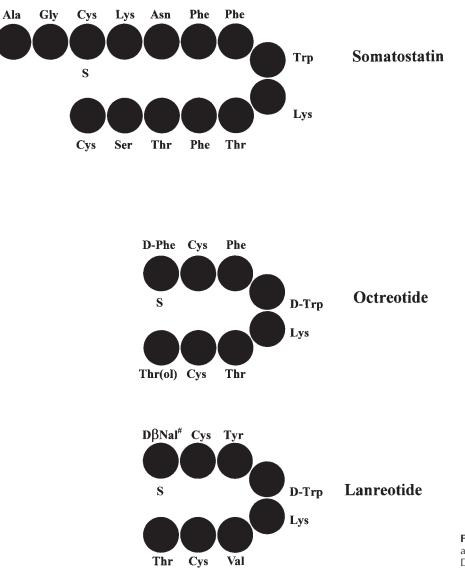

Figure 70.5. Secondary structure of somatostatin and its analogues octreotide and lanreotide. $D\beta Nal^{\sharp}$, β -(2-naphthyl)alanine.

Selective hepatic arterial embolization has been shown to reduce both hormonal symptoms and tumor burden in patients with pancreatic neuroendocrine tumors and carcinoid tumors (116-118). The symptomatic and biochemical response rates are impressive (40% to 90%), with a median duration of response between 10 and 15 months. The radiologic response rate, however, is lower, at 15% to 40%; this may reflect the fact that, although the metastasis may not have changed in size, it may have undergone central necrosis. Patients undergoing hepatic embolization need to be monitored closely for at least 1 week in the hospital, because the procedure has a high rate of postembolic syndrome, including pain, fever, nausea, leukocytosis, and derangements in liver enzymes (in 50% to 90%). More severe complications, including renal failure, hepatic abscess, liver necrosis, and gallbladder necrosis, occur in 10% of patients, with a mortality of 3% to 7%.

Formal hospital protocols for managing embolization procedures are essential, and include preembolization intravenous methylprednisolone; central venous pressure monitoring; intravenous octreotide, aprotinin, and broad-spectrum antibiotics; and oral allopurinol. With carcinoid, additional oral cyproheptadine and nicotinamide are required, whereas with insulinoma, careful monitoring of the blood glucose is necessary.

CHEMOTHERAPY COMBINED WITH HEPATIC ARTERIAL OCCLUSION

Systemic chemotherapy with 5-FU–streptozotocin alternated with adriamycin-dacarbazine has been combined with hepatic arterial embolization in the treatment of neuroendocrine tumors. In a large retrospective analysis, the response rate to this regimen was 20% higher and the time of tumor growth control increased from 4 to 22 months for pancreatic neuroendocrine tumors and from 10 to 24 months for the carcinoid tumors as compared with hepatic arterial occlusion alone (119). However, the patients were not randomized and patient groups were different.

CHEMOEMBOLIZATION AND RADIOEMBOLIZATION

Hepatic arterial occlusion can be combined with local cytotoxic chemotherapy—termed chemoembolization (120,121). Chemoembolization has recently been compared with curative hepatic resections and provided a median survival time after treatment of 32 months (range, 7 to 63 months) and an actuarial 5-year survival of 40% (92). As with hepatic arterial occlusion, chemoembolization is only palliative but has great functional benefits for patients with hypersecreting tumors. A comparison of chemoembolization, hepatic arterial occlusion alone, and hepatic artery

1186 JOSLIN'S DIABETES MELLITUS

occlusion followed by systemic chemotherapy has not yet been reported.

More experimentally, the procedure of radioembolization, involving the injection of microspheres labeled with a radioisotope (such as yttrium-90) into the arterial branches supplying hepatic metastases, has been devised (122). This results in simultaneous hepatic embolization and local irradiation (brachyradiotherapy). The procedure is still experimental but may offer some advantages in the future.

Hepatic Cryosurgery

Hepatic cryosurgery involves placing a cryoprobe into hepatic metastases, which induces cellular damage and subsequent tumor destruction. It is, however, contraindicated when the tumor occupies greater than 40% of the liver. It has been used in a small series of eight patients with neuroendocrine tumors, giving a symptom-free survival time of 12 months (median) and overall survival with disease of 25 months (median) (123). Further studies and comparisons with other treatment options, such as radiofrequency ablation (RFA), are needed.

Palliative (Cytoreduction) Surgery

In earlier series, palliative cytoreductive surgery did not prolong survival in patients with gastroenteropancreatic neuroendocrine tumors (124,125). With improved surgical techniques, more recent studies have shown better outcomes. Among 34 patients who underwent hepatic resections, 15 were potentially curative and 19 were palliative (90). The median survival had not been reached, but the estimated 5-year survival was 85% in the patients with complete resections, compared with 63% for patients with palliative resections.

Radiolabeled Somatostatin Analogues

Trials with radiolabeled somatostatin analogue therapy for SRSscan-positive neuroendocrine tumors are ongoing. Currently, indium-111-and yttrium-90-labeled octreotide and lanreotide compounds are being used. In fact, yttrium-90-DOTA-DPhe1-Tyr3-octreotide has been developed with high specificity for sstr2. In ten patients, this resulted in tumor volume reduction in two and partial remission or stable disease in two (126). More recently, 27 patients (24 carcinoid and 3 pancreatic endocrine tumors) were treated with two doses of indium-111pentetreotide, and this resulted in symptom improvement in 62%, biochemical improvement in 81%, and a decrease in Hounsfield units on CT scanning in 27%, with a partial radiographic response in 8% of patients (127).

This form of therapy is the most exciting development in the field of neuroendocrine tumors, and we eagerly await the results of the major trials.

PROGNOSIS

There is a wide spectrum of tumor behavior within neuroendocrine tumors; some are well differentiated and slow growing, and others are very aggressive and metastasize. Prognosis is related not only to tumor behavior but also to the endocrine hyperfunction syndrome present. For instance, a slow-growing, well-differentiated 1-cm insulinoma can cause sudden death from hypoglycemia, and similarly, a small gastrinoma can cause a life-threatening gastrointestinal bleed.

Clearly, the best prognosis is achieved if the primary tumor is resected before it metastasizes, with 5- and 10-year survival rates exceeding 50%. In unresectable tumors, the presence or development of liver metastases, the degree of differentiation, and the particular endocrine hyperfunction syndrome determine survival.

Index

figures; page numbers followed by "t" indicate a table concerning the subject. Abciximab, in coronary artery disease in diabetes, 983 Abdominal pain, in diabetes, 1073 Abel, J.J., 8 Abortion, spontaneous, 1036-1038 Abscess(es), perinephric, 1026 renal, 1026 Acanthosis nigricans, 1057 in insulin resistance, 494, 494 Acarbose, 703, 705, 1058 for older adults, 742 Accustimulation, in gastroparesis, 1086 Acesulfame K, 623 Acetic acid, 1139 Acetylcholine, 98 Achilles tendon, lengthening of, 1140 Acidemia, propionic and methylmalonic, hypoglycemia in, 1166 Acromegaly, diabetes in, 483-484 glucose intolerance in, 483-484 treatment of, 484 Acyl-CoA dehydrogenase deficiency, medium-chain, hypoglycemia in, 1167 multiple, hypoglycemia in, 1167-1168 Addison's disease, 400-401, 401, 401t Adenosine momophosplate-protein kinase A pathway, cyclic, 97, 97 Adenosine monophosphate, cyclic, 91 Adenosine monophosphate-activated protein kinase, exercise and, 138 Adenosine triphosphate (ATP), skeletal muscle and, 234, 235 K⁺Adenosine triphosphate-channel blockers, insulin secretion and, 96 K⁺Adenosine triphosphate-channel openers, insulin secretion and, 96 Adhesion molecules, circulating, and cardiovascular disease, 875 Adhesive capsulitis, of shoulder, 1061–1062 Adipo-hypothalamic axis, and energy balance, 538, 539 Adipocyte(s), and insulin resistance, 158, 158-159 function of, nuclear factors in, 135 glucose uptake and lipogenesis in, insulin in control of, 215 in metabolic regulation, 134 in regulation of food intake, 536-537 in regulation of systemic glucose homeostasis, 219 insulin action in, 134, 134-135, 135 metabolic activities of, and regulation of, 213-222 size of, and insulin resistance, 433-434 unilocular, 208 white versus brown, molecular features of,

Note: Page numbers in *italics* indicate

212-214, 213 Adipocyte complement-related protein-30 kDa, 220–221, 221 Adipogenesis, transcriptional control of, 211, 211-212 Adiponectin, 159 and obesity, 537 insulin sensitivity and, 431-432 Adipose tissue, 134–136 as endocrine organ, 431–433 biology of, 207–226 brown, 209–210, 210–211 coagulation and, 220 development of, 210-211 glucose disposal into, reduction of, 216-217 hormones and cytokines secreted by, cardiovascular dysfunction and, 219-222 insulin resistance and, 219-222 insulin resistance and, 427 physiology of, evolving concepts about, 207 regional release of free fatty acids by, 266-267, 267 structural features and anatomic distribution of, 208-211 visceral, and glucocorticoids, 270-271 white, 208, 208-209 Adipose tissue-derived factors, immunity and, 220 Adipsin, 220 Adolescents, decline in metabolic control in, 634 demands of diabetes self-care and, 634-635 diabetes control in, team approach to, 714, 714 diabetes identification for, 726 diabetes in, behavioral issues in, 730-732 glycemic control in, 716t, 716-719, 717, 717t goals of therapy in, 715–716, 716t in school setting, 732–733 incidence and prevalence of, 711-714 insulin therapy in, 719t, 719-722, 720t patient and parent education in, 714, 714-715 self-management training for, 730 treatment of, 711-736 uncontrolled, as behavioral risk factor, 730-732 eating disorders in, 725–726 exercise/physical activity for, 726-727 family/social environment of, and diabetes outcome, 639 nutrition therapy for, 628-629, 723-726 prevention of ketoacidosis in, 728-730 self-monitoring of blood glucose levels by, 727-728 type 1 diabetes in, 712 type 2 diabetes in, 712-713, 713t Adrenal function, in obesity, 536

486-487 β-Adrenergic receptor blocking agents, 1153 β-Adrenergic receptors, functions of, 218, 218 β-Adrenoreceptor agonists, 1153 Adriamycin, 1184 Adults (Adulthood), adaptation to diabetes in, social/family environment and, 639-640 early to middle years, adaptation to diabetes in, 635 late, developmental tasks and diabetes in, 636 latent autoimmune diabetes of, 414 older, diabetes in, atherosclerotic risks in, management of, 740 epidemiology and diagnosis of, 737–738, 738t hyperglycemia in, treatment of, 740-744 microvascular risks in, management of, 740 symptomatic hyperglycemia in, 739–740 treatment of, 739-745 goals of, 739, 739t hospitalized, management of, 745 in nursing homes, management of, 744–745 older frail, diabetes in, management of, 744 Advanced glycation end-products. See Glycation end-products, advanced. African Americans, demographics of, 511 diabetes in, 511-514 epidemiology of, 511-512 mortality associated with, 512 lifestyle and culture of, as influence on health, 514 Age, type 2 diabetes occurrence according to, 346-347, 347, 349, 349t Aging, carbohydrate metabolism changes with, 738 impaired insulin secretion with, 101 insulin resistance in, 440 physiology of, diabetes and, 738-739 Agouti locus, "yellow" mutations at, 308–309 Akee fruit, hypoglycemia and, 1154 Alanine, 131–132 insulin secretion and, 94 Alaska Natives. See Native Americans and Alaska Natives Alcohol, and antidiabetic drugs, interaction between, 1154 and hypoglycemia, 680, 1153–1154 guidelines for use of, 624 intake in diabetes, 488, 623-624 Aldose reductase inhibitors, 1136 in diabetic peripheral neuropathy, 959, 1119 in overactivity of polyol pathway, 845-846 Alizapride, 1089 Allen, Frederick, 1, 6 Alloxan-susceptible mice, 309

β-Adrenergic antagonists, inducing diabetes,

Alprostadil, intraurethral, 1010 Amenorrhea, hypothalamic, 748, 748 American Diabetes Association (ADA), 2, 9, 14, 15 diagnostic criteria for diabetes, 587-589 Amino acids, insulin secretion and, 94-95 metabolism of, skeletal muscle and, 236-237 released from muscle, 131, 131-132 Aminoguanidine, 1136 Amphotericin B, 1027, 1074 Amputation(s), as source of morbidity in dialysis, 945 avoidance of, management of foot disease for, 1111 in African Americans, 513 in diabetes, 778–779 in Hispanics, 510–511 in Native Americans, 517 partial, treatment following, 1116-1117 risk factors for, identification of, 1111–1113 Amylin, 100 Amyloid deposits, in type 2 diabetes, 454-455 Anaerobic cellulitis, nonclostridial, 1029 Analgesics, opiates, in painful neuropathy, 963 Anesthesia, metabolic and hormonal responses to, 1105 Angiography, digital subtraction, for diagnosis of vascular disease of lower extremities, 1128, 1128 fluorescein, in diabetic retinopathy, 909-910 in coronary artery disease in diabetes, 980, 981t Angioplasty, in coronary artery disease, 984-985 versus coronary artery bypass surgery, in coronary artery disease, 985-986 Angiotensin-converting enzyme inhibitors, 934t, 934–939, 935, 936, 937, 938 and hypoglycemia, 681, 1153 complications associated with, 939 in coronary artery disease in diabetes, 982-983, 983 in hypertension, 972 Angiotensin II, activation in diabetes, 859-860 Angiotensin II receptor blockers, in hypertension, 972–973 Angiotensin-receptor blockers, in nephropathy, 939-940 Angiotensinogen, adipose tissue and, 221 Ankylosing hyperostosis of spine, 1064 Anorectal function, in diabetes, 1091-1094, 1092, 1093 Antiarrhythmics, in painful neuropathy, 963 Antibiotics, oral, in foot ulcerations, 1114, 1115 Antibodies, to insulin, insulin resistance in, 501 Anticholinergic agents, in diabetic gastroparesis, 1085 Anticonvulsants, in painful neuropathy, 963 Antidepressants, in diabetic gastroparesis, 1085 in painful neuropathy, 962 Antidiabetic drugs, and alcohol, interaction between, 1154 Antifungal agents, in dermatophyte infections, 1050-1051 Antihyperglycemic agents, oral, and cardiovascular risk factors, in type 2 diabetes, 705t and insulin, combination therapy using, 705t, 705–707, 706t, 707t as monotherapy, 690-705, 691 in combination therapy, effect on glycemic control, 706t

in type 2 diabetes, 687–710 pharmacology of, 690–705 side effects of, 706t Antihypertensive therapy, in nephropathy, 929, 932t in type 1 and type 2 diabetes, 931, 932, 932t, 933 Antiinflammatory drugs, nonsteroidal, 1065 Antimalarial drugs, 1154 Antimicrobials, topical, 1139 Antioxidant defense, in diabetes, 828 Antioxidants, 625 Antipsychotics, atypical, diabetogenic effects of, 488 Antithrombotic factors, 979 Apligraf, 1119 Apomorphine, 1008–1009 Apoproteins, associated with plasma lipoproteins, 564, 564t Appetite, regulation of, central nervous system in, 537-540 Arachidonic acid, 91 Arateus of Cappadocia, 2 Arginine, insulin secretion and, 94–95 Arterial reconstruction, in diabetic foot, 1129–1130 Arterial stiffness, effects of diabetes on, 873 Arterial wall, insulin action on, 878, 879 Arteriograms, in diagnosis of vascular disease of lower extremity, 1128, 1129 Arteriosclerosis, impotence and, 1005–1006 Asians and Pacific Islanders, demographics of, 517-518 diabetes in, 517-519 epidemiology of, 518 genetic predisposition to, 518 mortality associated with, 518 lifestyle and culture of, as influence on health, 519, 519 Aspart, 660-661, 721 Aspartame, 623 Aspergilloma, renal, 1027 Asphyxia, perinatal, hypopglycemia in, 1163 Aspirin, in coronary artery disease in diabetes, 982 Association approaches, to identification of susceptibility genes, 357 Ataxia-telangiectasia, 502–503 Atchley, Dana, 8 Atherosclerosis, coronary lesions in, characteristics of, 869 dyslipidemia as mechanism for, 978 histologic classification of, 867-869, 868t in diabetes, 1137 insulin use and, 667 pathogenesis of, effects of diabetes on, 869, 869–872 Atherothrombosis, 871 Athlete's foot, 1050-1051 Atropine, 1091, 1092-1093 Atwater, W.O., 3 Autoantibodies, in prediction of diabetes, 415, 416 to insulin receptor, 417-418 Autoantigens, in insulitic process, 298–299 Autoimmune diathesis, clinical ramifications of, 400–402 Autoimmune disease, type II polyglandular, 754-755 Autoimmunity, allografts in absence of, 770 diabetes-related, 417–418 humoral, type 1 diabetes and, 410 transplant rejection and, control of, 769-770, 770t. Automobile/vehicle operation, in diabetes, 780-781

В

 β -Blockers, in coronary artery disease in diabetes, 982 in hypertension, 973 β-Cell replacement therapy, 14 for type 1 and type 2 diabetes, 765–766 β-Cell transcription factors, 382–383, 383 β -Cells, biosynthesis of insulin in, regulation of, 66-67 compensatory changes of, 49–50 cytoplasmic Ca² in, glucose increasing, 86-87,87 degradation of insulin in, 74 desensitization of, 100 dysfunction of, in type 2 diabetes, 451-454, 452, 453 mechanisms of, 455-458 exhaustion of, in hyperstimulation of insulin secretion, 455–457, 457 function of, C-peptide as marker of, 110 methods of quantitating, 109-110 human, expansion of, for islet transplantation, 770 identification of glucose of, 84, 84-85 insulin production by, trafficking and processing in, 67, 68 mass and structure of, in type 2 diabetes, 454-455 metabolism of glucose by, amplifying pathway and, 90 muscle and cerebral isoforms of phosphofructokinase in, 85 normal function of, 450, 450–451, 451 postnatal and adult neogenesis of, 32-33 response to glucose, putative messengers in, 90–91 secretory granule in, clathrin-coated immature, 69 maturation and refinement of, 69 mature, and insulin crystal, 72, 73 fate of, 73-74 protein constituents of, 72 transport to plasma membrane, 73 stimuli for growth of, 49 unresponsiveness to glucose, 451-453, 452, 453 Bacterial infections, 1051 Bacterial overgrowth, small-bowel, 1087 diarrhea in, 1090 Bacteriuria, 1025 Balanitis, candidal, 1050 Barach, Joseph H., 9, 9 Bardet-Biedl syndrome, 488 Barron, Moses, 4 Basal metabolic rate, calculation of, 552t Basement membrane, and extracellular matrix, 824 Bayliss, William, 4 Beckwith-Wiedemann syndrome, hypoglycemia in, 1163-1164 Beetham, W.P., 7 Behavioral issues, in diabetes in children and adolescents, 730-732 Behavioral research, and psychological issues, 633–648 Behavioral therapy, in gastroparesis, 1086 in obesity, 551t, 551–552 Bell, E.T., 7 Benedict, Francis, 1, 3 Benedict, S.R., 12 Berardinelli-Seip syndrome, 499–500 Bernard, Claude, 1, 3, 4 Berthold, H., 4 Best, Charles, 1, 4, 5, 9, 9 BETA2/NeuroD, 35 Betadine, 1139 Bezoars, gastric, treatment of, 1085

Bicarbonate, in diabetic ketoacidosis and hyperosmolarhyperglycemic state, 895-896, 896t Biguanide(s), 1153 for older adults, 742 Bile, lithogenic, 1094 Bile acid sequestrants, 577 Bile-salt malabsorption, diarrhea in, 1090 Biliary system, in diabetes, 1094–1095 gallbladder emptying and, 1094 gallstones and, 1094-1095 lithogenic bile and, 1094 Biliopancreatic diversion, 543-544 BioBreeding rat, as model of environmentally triggered diabetes, 304-305 genetics of type 1 diabetes in, 303–304 insulitis in, 303, 305 cellular analysis of, 304 thyroiditis in, 305 Bioengineered living-skin equivalents, 1119 Biofeedback training, in fecal incontinence, 1093, 1093–1094 Black Americans. See African Americans. Blindness, in diabetes, 778-779 Bliss, Michael, 4, 5 Blood glucose, control of, 146 Blood glucose levels, control in kidney disease, 927–928, 928 monitoring of, 666 and glycemic control, 731, 731 history of, 12 in sick-day management, 729 intensive insulin therapy and, 731–732 realistic expectations of, in children and adolescents, 731, 732 normal, in neonates, 1162t perimenstrual changes in, 749, 749-750 perioperative control of, 1030 physical activity and, 727 self-monitoring of, 12, 592 by children and adolescents, 727 Blood glucose monitors, "alternative-site," 728 Blood pressure, control of, in nephropathy, 930, 931, 931 nocturnal decline in, loss of, in diabetes, 970 target levels for, in diabetes, 971-972 Blood vessels, changes in. See Vascular changes. Body Mass Index, 548–549t, 615t classification of obesity by, 616t Bondy, Philip, 11 Bone density, in diabetes, 757, 758 Bone loss, diabetes and, 759, 759 Bone turnover, markers of, 757-758 Bones, and joints, in diabetes, 1061–1068 deformities of, correction of, ulcerations and, 1140 Bouchardat, Apollinaire, 3, 4, 6, 10 Bowel, small. *See* Small bowel. Brain, altered function of, in type 1 and type 2 diabetes, 644 insulin resistance and, 427-428 need for fuel, 127 role of insulin receptors in, 163 use of ketone bodies by, 132, 132–133 British Diabetes Association, 15 Brown-Sequard, Charles, 4 Bullae, diabetic, 1056 Bupropion, in obesity, 557 Bureau of home economics rats, 313-314

Ca²⁺, cytoplasmic, activation of effector system by, 87–89 as triggering signal, 85–86 glucose-induced changes in, 87, 88 in β-cells, glucose increasing, 86–87, 87

Ca2+-channel openers and blockers, insulin secretion and, 96 Caffeine, 557 Calcineurin, 234 Calcitonin gene-related peptide, 100 Calcium, metabolism of, disorders of, 486 Calcium-channel blockers, in hypertension, 973 in nephropathy, 940-941, 941 Calcium pyrophosphate deposition disease, 1065 Calcium release, skeletal muscle contraction in, 230 Callus, in diabetes, 1140 Caloric intake, and desirable body weight, for adults, 614t Calorie requirements, for children and adolescents, calculation of, 724, 724t Calories, for diabetic patient, 614-616 Calpain 10, 385–387, 387 Cancer, endometrial, 759-760 insulin resistance in, 436 obesity as risk factor for, 535 pancreatic, diabetes caused by, 481 Candida esophagitis, 1074 Candidiasis, 1049–1050 oral, 1026 vulvovaginal, 1026-1027 Capsulitis, adhesive, of shoulder, 1061-1062 Captopril, 937, 937 Carbohydrate(s), and lipids, stores of, mobilization of, 130 calories from, 616 counting of, 625 food choices for, 626t dietary, 616-619 dietary fiber and, 619 foods containing, glycemic index of, 617t, 617–618, 618t for diabetic patient, 616 hypoglycemia and, 727 metabolism of, changes with aging, 738 in menstruating women, 749, 749-750 skeletal muscle and, 235-236 sucrose in diet and, 618-619 Carbohydrate meal, fuel metabolism during, 129, 129 Carbohydrate metabolism, insulin effects on, free fatty acids and, 268 Carbohydrate nutrients, insulin secretion and, 10–111, 110 Carbohydrate response element binding protein, 259 Carbon balance, 244 Cardiomyopathy, diabetic, 989–990 Cardiovascular disease, and diabetes, comorbidity of, 876 and hormone replacement therapy, in diabetes, 755 diabetes as risk factor for, 867 glycemia levels and complications in, 818-819 hypertension and, 969 in African Americans, 513 in Asians and Pacific Islanders, 519 in diabetes, clinical features of, 980-981 in Hispanics, 510 in Native Americans, 517 lipid disorders and, 571, 572 morbidity and mortality in diabetes and, 823 mortality from, in diabetes, 976, 976 obesity as risk factor for, 535 pathogenesis of, 867-884 revascularization in, restenosis following, 871-872 risk factor clustering and, 876

risk factors for, 874t, 874-876 type 2 diabetes and, 527, 528 Cardiovascular system, complications of, biomechanical mechanisms associated with, 876-879 diabetic, pathophysiology of, 977-980 dysfunction of, hormones and cytokines secreted by adipose tissue and, 219-222 in autonomic neuropathy, 960 insulin secretogogues and, 697 preconception evaluation of, 1040 Caregivers, of child with diabetes, 634 role of, 790-791 Carnitine deficiency, hypoglycemia in, 1167 Carpal tunnel syndrome, 1064 Cast brace, removable bivalved, 1118, 1119 Catecholamines, 98, 99 deficiency of, hypoglycemia in, 1156 in maintenance of glucose concentrations, 1148-1149 metabolic effects of, 485 Cawley, Thomas, 2 c-Cbl-associated protein/Cbl pathway, and lipid rafts, 153 C57BL/6J mouse, 310 C57BL mouse, 306-307 Celiac disease, 401-402, 407 diagnosis of, 725 in children and adolescents, 725 symptoms of, 725 Cell-cycle regulation, intracellular signal transduction and, 829 Cell growth, growth factors and cytokines as regulators of, 829–831 Cell-mediated immunity, 1020 Cellular biology, advances in, 13 Cellulitis, nonclostridial anaerobic, 1029 synergistic necrotizing, 1029 Central nervous system, in regulation of appetite, 537-540 Cereal, consumption of, 543 Cerebrovascular disease, in African Americans, 513-514 in Hispanics, 511 in Native Americans and Alaska Natives, 517 Cesarean section, 1038 Charcot foot, 757, 1135, 1136 acute, treatment of, 1118 chronic, management of, 1118 Charcot foot phenomenon, 7 Charcot joint disease, 1063-1064, 1113, 1117–1119, 1118, 1119, 1135 Cheiropathy, 1062-1063 Chemical agents, inducing diabetes, 486-488, 487t Chemoembolization, in endocrine tumors of pancreas, 1185-1186 Chemotherapy, in endocrine tumors of pancreas, 1184 Chevreuil, M.E., 3 Children. See also Infant(s); Neonate(s). demands of diabetes self-care and, 634 diabetes control in, team approach to, 714, 714 diabetes identification for, 726 diabetes in, behavioral issues in, 730-732 glycemic control in, 716t, 716-719, 717, 717t goals of therapy in, 715–716, 716t in school or day-care setting, 732–733 incidence and prevalence of, 711-714 insulin therapy in, 719t, 719–722, 720t patient and parent education in, 714, 714-715 self-management training for, 730

Children, diabetes in (Continued) treatment of, 711–736 uncontrolled, as behavioral risk factor, 730-732 exercise/physical activity for, 726-727 family/social environment of, and diabetes outcome, 639 glucose homeostasis in, 1161–1162 incidence of type 1 diabetes in, 343, 343–344, 344t nutrition therapy for, 628-629, 723-726 obesity in, increase in, 14, 14 prevention of ketoacidosis in, 728-730 school age, diabetes in, 634 self-monitoring of blood glucose levels by, 727–728 type 1 diabetes in, 712, 728 type 2 diabetes in, 14, 712–713, 713t type 1A diabetes in, onset of, 413-414 Chloroquine, 1154 Chlorpropamide, 694, 1058 Cholecystitis, emphysematous, 1022-1023 Cholecystokinin, 98, 539 Cholecystokinin receptor agonists, in diabetic gastropathy, 1085 Cholelithiasis. *See* Gallstones. Cholesterol, lipoprotein, high-density, 569 low-density, 568-569 reduction of, in heart disease, 987 soluble fiber and, 622 Cholestyramine, 577 Chromium, in diet, 624 Chromosome 20, 388-389, 389 Chromosome 12q, 387–388, 388 Chromosome 12q1-q23, 385–387, 387 Chromosome 1q21-q23, 389–390, 390 Chronic illness, adaptation to, 636-640 adherence and burnout and, 640 coping ability and, 638-639 in diabetes, 638-639 social/family environment and, 639-640 stress and, 636-638 diabetes and, 636-638 Chylomicrons, formation and metabolism of, 564-565, 565 Cialis, 1009 Ciclopirox, 1051 Ciglitazone, 700 Ciprofloxacin, 1088 Cisapride, 1089 in diabetic gastropathy, 1084 Cisplatin, 1184 Clathrin-coated immature secretory granule, in β-cells, 69 "Claw toe," 1063–1064 Clonidine, 1091 in diabetic gastroparesis, 1085 Clotrimazole, 1074 Clowes, George, 5 Coagulation, adipose tissue and, 220 effects of diabetes on, 873-874 Coenzyme A, long-chain acyl, and malonyl coenzyme A, 91 malonyl, and long-chain acyl coenzyme A, 91 Cognitive function, problems of, in recurrent severe hypoglycemia, 683-684 in type 1 and type 2 diabetes, 644 Colchicine, 1065 Colestipol, 577 Collagen, disorders of, 1052-1054, 1063 Collip, J.B., 4, 5 Colon, cancer of, diabetes and, 1089 dilation of, in diabetes, 1088-1089 in diabetes, 1088-1089 motility in, in diabetes, 1088, 1088

Color Plates

ADIPOSE TISSUE

A: White fat cells. The cytoplasm appears as a thin rim at the periphery of the cell. Stored fat is the predominant component of the cell. The nucleus is flattened in the cytoplasm, permitting maximum storage of fat globules. The fat cell lipid is in the form of a single droplet, and these cells are described as unilocular. **B:** Brown fat is an uncommon variety of fat found in specific locations in the body. Unlike the more common white fat, brown fat cells contain a number of small lipid droplets; hence the name multilocular fat. (From Bergman RA, Afifi AK, Heidger PM. *Atlas of Microscopic Anatomy*, 2nd ed. Philadelphia: WB Saunders, 1989, with permission.)

SKIN MANIFESTATIONS

A: Acanthosis of the neck in a young woman with severe insulin resistance and obesity. B: Acute neuropathic ulcer in a 34-year-old man with diabetes who has had previous amputations for osteomyelitis secondary to ulceration. C, D: Necrobiosis lipoidica in a 24-year-old patient with type 1 diabetes. E: Disseminated granuloma annulare. F: Eruptive xanthomata of the abdomen in a 45-year-old patient with uncontrolled type 1 diabetes. G, H: Perforating folliculitis in a 50-year-old patient with diabetes with retinopathy and nephropathy.

Plate II

ULCERS

A: Early neuropathic ulcer over fifth metatarsal prominence. B: Chronic heel ulcer. C: Neuropathic forefoot ulcer over first metatarsal head with callus formation. D, E: Deceptively small metatarsal head ulcer with necrotic toe. Note true extent of ulcer, penetrating the foot to the dorsum.

Plate III

ULCERS AND CHARCOT FOOT

A, B: Advanced diabetic ulcers with extensive soft tissue and bone loss. Note clawing of toes. C, D: Charcot foot. Note ulcer forming over area of abnormally high pressure in this misshapen foot.
