Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the editors, authors and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, express or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The editors, authors and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in clinical practice.

Preface

We are pleased to present this 14th edition of *Joslin's Diabetes Mellitus.* This textbook continues to evolve and address the newest and most important insights into this very old but very challenging disease. Indeed, as this book goes to press, despite multiple medical and scientific advances, we are facing a worldwide epidemic of diabetes. This involves a steady increase in type 1 diabetes and almost an exponential increase in type 2 diabetes. The latter is accompanied by a parallel increase in obesity, the metabolic syndrome, and other closely related disorders. Thus we are at a fascinating point in the evolution of diabetes and a fascinating point in the evolution of a book devoted to this disease.

The first edition of the Joslin textbook was published in 1916, a single-handed contribution by a man of extraordinary dedication, vision, and energy, Dr. Elliott P. Joslin. Dr. Joslin began his practice in 1898 in the pre-insulin era, and in this setting, developed a unique understanding of the natural history of diabetes. This perspective was clearly evident in the first edition, which was published some five years before the discovery of insulin by Banting, Best, Macleod, and Collip.

The third edition, published in 1923 shortly after the discovery of insulin, showed how quickly Joslin grasped the principles of insulin therapy, adopting approaches that would be considered modern even by today's standards. As a student of metabolism, Dr. Joslin was unwavering in his conviction that blood glucose levels should be kept as close to normal as possible, even though the importance and even the existence of chronic complications of diabetes were not appreciated until many years later. He understood the critical role of education for people with diabetes and made it the cornerstone of all treatment programs. His insights into the interaction between diet, exercise, and glucose control were also remarkable, considering how difficult it was to assess control accurately at this time. His descriptions of the symptoms of hypoglycemia are as well defined as can be found anywhere today, and he rapidly determined the small quantity of carbohydrate required to treat insulin reactions. Any serious student of diabetes should spend time with these early editions.

The evolution of the Joslin textbook mirrors the development of the field of diabetes and in some ways the development of Joslin Diabetes Center. Although the book was originally written entirely by Dr. Joslin himself, in subsequent editions he included his colleagues in the task, taking advantage of their special expertise. Eventually, substantial contributions to the book were provided not only by the staff of Joslin Diabetes Center, but also by clinicians from the adjacent New England Deaconess Hospital, where most Joslin patients were hospitalized. Patients come to Joslin and its affiliated institutions from all over the world, knowing that whatever problems they have can be addressed by someone who understands the full complexity of diabetes. Thus, the Joslin staff consists of adult and pediatric diabetologists, nephrologists, ophthalmologists and optometrists, and mental health professionals, as well as nurse educators and nutrition specialists. Problems in vascular disease, cardiology, neurology, and in virtually all other areas of medicine, are now managed in collaboration with colleagues at the Beth Israel Deaconess Hospital (BIDMC). Women with diabetes also receive coordinated care between Joslin and BIDMC, and sick children often are hospitalized at Children's Hospital Boston.

To meet the challenges of the epidemic of diabetes, Joslin has established Affiliated Centers with 22 sites throughout the United States and our first international Affiliate in Bahrain. Because there are experts at these institutions who have extensive experience in virtually every aspect of diabetes care, some have joined with Joslin staff to write the clinical chapters, describing the characteristics and outcomes of their patients in the context of the broader literature.

Research has always been a fundamental focus at Joslin and as such has been reflected in all of the editions. Dr. Joslin himself was a fine clinical investigator who made astute observations about his patients and recorded the information in meticulous fashion, as can be appreciated in his numerous publications. He also recognized the need for a more organized approach to research and appointed Dr. Alexander Marble as the first head of research in 1934. The research programs were greatly expanded when Dr. Albert Renold took over the leadership in 1957, and further enhanced under the leadership of George Cahill, Stuart Soeldner, C. Ronald Kahn, and now George King.

Thus, the most recent editions of *Joslin's Diabetes Mellitus*, including the current edition, reflect not only the practice and experiences of the physicians of the Joslin Diabetes Center, but also the remarkable body of new scientific information that has had such an impact on the field. In addition, we have called upon former fellows and trainees of Joslin, now numbering over 1,200, and our academic colleagues elsewhere, to help present the latest advances in basic and clinical research.

The 14th edition is very different from the 13th edition published a decade ago. These differences demonstrate the dramatic advances in knowledge and research. Progress in the basic sciences has been explosive in recent years, particularly in the areas of immunology, insulin signaling, cell and molecular biology, and genetics. This has resulted in a remarkable

vi preface

increase in our understanding of the basic processes underlying type 1 and type 2 diabetes, as well as diabetes complications.

Because of this rapid rate of new knowledge, this text, like all modern biomedical texts, must be considered a living document, subject to change and updated regularly. Every reasonable effort has been made to have the 14th edition closely reflect our current understanding of diabetes.

In addition, while less emphasis has been given to the local Joslin experience in describing various aspects of diabetes care and more effort has been made to incorporate the experiences of others described in the literature, an effort has been made to retain the flavor of Joslin's clinical strategies and the emphasis on the importance of the team approach.

The Joslin Diabetes Center stands today as an institution on the front lines of the world epidemic of diabetes, leading the battle to conquer diabetes in all of its forms through cutting-edge research and innovative approaches to clinical care and education. Our task, of course, is to realize our vision of a world without diabetes and its complications. Disseminating the most current diabetes research and approaches to care is part of our vision and mission.

This 14th edition of *Joslin's Diabetes Mellitus* is dedicated to a number of special individuals—first, to Dr. Robert F. Bradley, who arrived at Joslin in 1950 as a young clinician fresh out of the Navy. By 1968, he had become the Medical Director of the Joslin Clinic, and in 1977, he became President of the fully integrated Joslin Diabetes Center. Under his leadership, Joslin grew steadily in both its clinical and research missions.

Perhaps Dr. Bradley's most significant contribution was his role in a major controversy of the mid-1970s over the use of oral drugs in the treatment of diabetes. A large NIH-funded study, the UGDP, suggested that the available oral agents for diabetes, the sulfonylureas, might not be safe. In fact, the study suggested that these agents might cause more deaths by producing certain cardiovascular side effects than they saved through treatment of diabetes. Dr. Bradley found this conclusion contrary to his own experience with thousands of patients with diabetes, and so he challenged this study, not just quietly and privately, but loudly and in the public eye. Consequently the UGDP study was found to be seriously flawed, and thus sulfonylureas, very important drugs for the treatment of type 2 diabetes, remained on the market. As a result, millions of patients with diabetes have benefited from improved diabetes control.

During his tenure, Dr. Bradley also edited the Joslin textbook, gave numerous lectures, and served on the first National Diabetes Advisory Board from 1977 to 1980. Bob retired in 1987 and died on October 12, 2003. He will always be remembered as a soft-spoken, highly dedicated leader and for the wonderful legacy he left for Joslin and people with diabetes throughout the world.

Second, we dedicate this 14th edition of *Joslin's Diabetes Mellitus* to all of the patients with diabetes and their families who have allowed us to care for them over the 106-year history of the Joslin Diabetes Center. They are the reason for our existence and the inspiration for working even harder. They inform our search for knowledge and our efforts to improve the lives of people with diabetes across the globe.

We also dedicate this 14th edition of *Joslin's Diabetes Mellitus* to all of those who have so generously supported Joslin with their efforts and funds to support research, clinical care, and education. Without that support, the institution could not survive and continue to work toward the cure, prevention, and improved treatment of diabetes and its complications.

Last, we wish to thank all of the individuals who worked together to bring this book to fruition. The authors of the various chapters spent untold hours thinking, researching, and writing to reach the level of excellence expected of a book of this stature. Two individuals, with whom it has been a pleasure to work, have made great contributions to the project. Susan Sjostrom, the Director of Publications at Joslin, was remarkably efficient at keeping track of all the manuscripts, disks, correspondence and e-mail. Nancy Voynow, the editorial assistant in Boston, was thoroughly professional, skilled, and efficient throughout, doing a wonderful job editing this enormous amount of complicated material. We also greatly appreciate the efforts and skill of our publisher, Lippincott Williams & Wilkins.

And, of course, most of all, we thank our families for their support and tolerance of the never-ending intrusion of this book into evenings, weekends, and at times even vacations.

CONCLUSION 15

When Elliott Proctor Joslin first published his textbook The Treatment of Diabetes Mellitus more than 85 years ago in 1916, it represented the first rendition of its kind in the English language (1). During Joslin's long professional life, he remained the senior editor for 10 editions, maintaining the same enthusiasm as he and his team continued to report the experience of the Joslin Clinic and increasingly that of other investigators. Elliott P. Joslin (1869–1962) (Fig. 1.1) was part of the last generation of physicians who received much of their postgraduate training in Europe (2). After his 1895 graduation from Harvard Medical School, he became inspired by the examples of the French and German medical schools that sought to combine laboratory and clinical medicine. From the start of his practice in 1898, he continued to attract assistants and students to observe and apprentice with him in the treatment of an increasing number of patients with this hitherto poorly defined condition, diabetes.

Fifteen years before the discovery of insulin, Joslin began collaborating with the physiologist Francis Benedict of the Carnegie Institute on studies of metabolic balance (3). Joslin's simultaneous association with the young polymath investigator Frederick Allen at the Harvard Medical School also proved fortunate. Allen, who was observant of all the known literature on the subject up to that time, was able to translate his ideas from his experimental animal models to humans on the wards of the new Rockefeller Institute (4). By 1914, Joslin, desperate to lower the death rate from ketoacidosis in his mostly young patients with diabetes, combined Benedict's balance study format with diets in a wide range of human subjects in near or actual acidosis (2). By 1917, he had become progressively convinced that he had developed a regimen that could extend the life expectancy of these fatally ill patients (5).

In his writings and lectures on diabetes, Joslin was an early proponent of several concepts, with two being especially important. First, as early as 1920 he emphasized the need to contain the "epidemic" of the disease by judicious diet and exercise (6); second, he pioneered patient education as a primary part of treatment. His goals were to prevent the onset of the disease or to retard its progression. To accomplish these aims, he created a freestanding clinic devoted to a single disease.

Joslin's interest in all matters of medicine could be inferred from pictures on the walls of his office, as well as from the bas relief panels on the modern exterior of his institute, where sculptured portraits were displayed of many of his "medical saints," as he phrased it, from Thomas Hunter, the father of comparative anatomy, to Charles Best, the "codiscoverer of insulin." Three investigators of the 19th century particularly influenced Joslin's world: Louis Pasteur, Claude Bernard, and Rudolf Virchow. Two were Frenchmen, Pasteur, who understood the cause-and-effect contributions of microbes in the pathogenesis of infection, and Bernard, who established modern physiologic investigation. The third investigator, Virchow, the leading German pathologist of his time, demonstrated that disease entities were characterized primarily by a disruption of the integrity of normal cellular health (7).

The story of diabetes and dates in the life of Joslin were closely intertwined. In 1869, the year of Joslin's birth, Paul Langerhans,

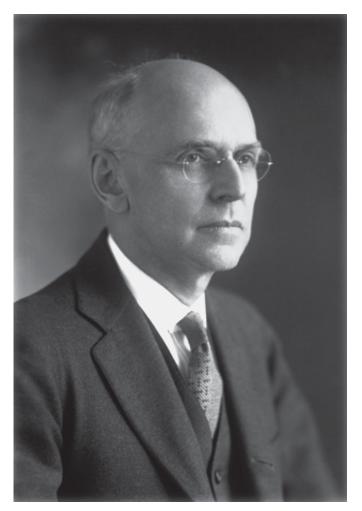

Figure 1.1. Eliott Proctor Joslin at 60.

a senior medical student in Virchow's department, published his medical dissertation on pancreatic histology in which he described "clumps of cells," which were named the *islets of Langerhans* shortly after his premature death in 1888 (8–10). By 1889, the year that Minkowski and Von Mering, in Strassburg, Germany, discovered the central role of the pancreas in diabetes (11,12), Joslin decided to spend a postgraduate year in physiologic chemistry at Yale's Sheffield School of Science, an experience that led to his initial interest in diabetes. It was not until midcareer, when Joslin was in his early 50s, that the discovery of insulin ended years of frustration encountered in caring for desperately ill patients with diabetes.

By 1952 organizational efforts in many countries developed to the point that the International Diabetes Federation was formed to increase awareness of the disease and to promote better investigation and treatment programs worldwide. Elliott Joslin became honorary president of the International Diabetes Federation, confirming his role as the international "dean" in the cause of diabetes. By this time he had initiated the first population survey and follow-up studies demonstrating a surprisingly high prevalence rate of diabetes in a typical U.S. population, the study being carried out in his hometown of Oxford, Massachusetts. In addition, the prevalence rate was nearly equally divided among those people with undetected disease and those with diagnosed diabetes (13). These studies set the stage for early-detection programs countrywide sponsored by the American Diabetes Association. Joslin and his early associates became identified with the conservative viewpoint that "good" control delayed or prevented microvascular complications, particularly in type 1 diabetes. This position inaugurated an intense nationwide 30-year debate that only ended in 1993 with the publication of the results of the Diabetes Control and Complications Trial (14), which clearly supported Joslin's claim.

THE ROAD TO INSULIN

The story of the earliest recognition of diabetes and the path to the discovery of insulin is filled with marvelous insights as well as egregious errors, serendipity and futile labors, triumphs, and defeats. The best early evidence of a description of the symptoms of diabetes in the world's literature is recorded in the Ebers papyrus that appears to date from 1550 B.C. This links the description of polyuria to Imhotep, a man of medicine, architecture, and magic, who was a high priest and minister to the Pharaoh Zosser in 3000 B.C. (15). Two Greek physicians in the Roman era, Galen (A.D. 130–201), who practiced in Rome, and Arateus of Cappadocia, delineated the disease further. Arateus is credited, despite the survival of only fragments of his documents, with some of the best descriptions of medicine in the ancient literature. In his work *Acute and Chronic Diseases*, he coined the term *diabetes*, meaning "siphon," to explain the "liquefaction of the flesh and bones into urine" (16).

The following masterly description of severe diabetes by Arateus from about A.D. 150 represents the sum of our knowledge up until the second half of the 17th century (17):

Diabetes is a wonderful affection, not very frequent among men, being a melting down of the flesh and limbs into urine. Its course is of a cold and humid nature, as in dropsy. The course is the common one, namely, the kidneys and the bladder; for the patients never stop making water, but the flow is incessant, as if from the opening of aqueducts. The nature of the disease then, is chronic, and it takes a long period to form: but the patient is short-lived, if the constitution of the disease be completely established; for the melting is rapid, the death speedy.

In 1674, Thomas Willis, a physician, an anatomist, and a professor of natural philosophy at Oxford, discovered (by tasting) that the urine of individuals with diabetes was sweet (18). This was actually a rediscovery, for unbeknownst to him, an ancient Hindu document by Susruta in India in about 400 B.C. had described the diabetic syndrome as characterized by a "honeyed urine" (19). Willis could not pinpoint the chemical nature of the "sweet" substance, because a variety of different chemical substances could be equally sweet to the sense of taste. It was Matthew Dobson of Manchester, England, who demonstrated, in 1776, that persons with diabetes actually excrete sugar in the urine. After boiling urine to dryness, he noted that the residue, a crystalline material, had the appearance and taste of "brown sugar" (20).

Dobson's definitive finding soon began influencing clinicians as to the possible causes of the disease and the bodily organs primarily involved. The prevalent view up to that time was that the kidneys were the major source of the problem, because its most striking signs and symptoms were the frequency and degree of urination. Some clinical observers also noted a tendency toward enlargement of the liver, which we now know to be usually due to intense infiltration of the organ with fat in persons with uncontrolled diabetes. In a case report, which also gave a detailed description of postmortem findings, Thomas Cawley reported in 1788 (without particular comment) on a shriveled pancreas with stones in a diabetic patient at autopsy (21). This may have been the first published reference to the pancreas in relation to human diabetes, but no deductions were drawn regarding etiology.

It was John Rollo, Surgeon General of the Royal Artillery, who in 1797 first applied the discovery of glycosuria by Dobson to the quantitative metabolic study of diabetes. Aided by William Cruickshank, "apothecary and chemist to the ordinance," Rollo devised the first rational approach to the dietary treatment of the disease, shifting the view then current that the primary seat of the disorder was the kidneys to a view of its being the gastrointestinal tract (22). Rollo studied Captain Meredith, a corpulent man with adult-onset diabetes and severe glycosuria. Rollo made daily recordings of the amounts and kinds of food Meredith ate and weighed the sugar cake obtained by boiling Meredith's daily urine output. Rollo noted that the amount of sugar excreted varied from day to day, depending primarily on the type of food ingested. "Vegetable" matter (i.e., breads, grains, fruits) increased glycosuria, whereas "animal" matter (i.e., meat) resulted in a comparatively lower excretion of sugar. Rollo and Cruickshank concluded, therefore, that the glycosuria was secondary to the "saccharification" of "vegetable" matter (i.e., carbohydrate-containing foods in the stomach and the influx of sugar into the body) and concluded that the "morbid" organ in diabetes was not the kidney but the "stomach," which overproduced sugar from "vegetable" matter. The indicated treatment was thus a diet low in carbohydrates and high in fat and protein (22). It was not until the advent of insulin that this dietary prescription was altered significantly.

Although Rollo suspected the presence of excessive sugar in the blood of persons with diabetes, at that time there was no convincing proof of the existence of hyperglycemia. William Wollaston (1766–1828), a renowned chemist and physician, tried to measure "sugar" in the blood but failed to detect it, possibly because he assumed it had the same chemical characteristics as table sugar (19). In 1815, Chevreuil showed that blood sugar behaved chemically as if it were "grape" sugar (i.e., dextrose or glucose) (23). Only in the period 1914 to 1919 were specific methods of analysis devised and used to measure glucose as the major "reducing substance" in the serum and urine (24–26). Rollo's predictions were confirmed—that in diabetes an increase in blood sugar level causes the excretion of sugar and that the "seat" of diabetes was outside the kidneys.

Lavoisier's Legacy

A set of experiments initiated in the late 18th century deepened understanding of the basic metabolic principles of human physiology and had far-reaching consequences for medicine and for diabetes in particular. Antoine Lavoisier (1743-1794) established the concept of the respiratory quotient and with the aid of calorimetric studies measured oxygen consumption at rest and under different conditions, such as during food ingestion and work; however, his studies were interrupted by his death by guillotine during the French Revolution. A generation later, Baron Justus von Liebig (1803-1873) advanced the field of physiologic chemistry by determining that there were three categories of food: protein, carbohydrate, and fat. As described by Rosen (27), Liebig showed how protein was used to build up or repair the organism while carbohydrate and fat were used for fuel. He determined how much oxygen was needed to burn the different classes of food and how much energy was released as heat. Carl Voit, writing in 1865, described his teacher's work in these terms: "Liebig was the first to establish the importance of chemical transformations in the body. He stated that the phenomena of motion and activity which we call life arise from the interaction of oxygen, food and the components of the body.

He clearly saw the relation between metabolism and activity and that not only heat but all motion was derived from metabolism...." Voit's work, as carried on by his student Max Rubner in Germany and by his American students Graham Lusk and W. O. Atwater, made it possible to study metabolic activities more precisely and to apply the results to clinical and theoretical problems. Rubner, in 1888 to 1890, finally produced incontrovertible experimental proof that the principle of the conservation of energy held for living systems, a finding confirmed for humans by Atwater and Benedict in 1903 (28). In 1874 the unique respirations seen in diabetic ketoacidosis were described by Adolph Kussmaul as being deep and having long pauses between expiration and inspiration (29).

Turning their attention to the pancreas, clinicians in England, France, and Germany in the mid-1800s described cases of diabetes with postmortem findings of diseased, atrophic, or stone-filled pancreases. Speculations on the role of this organ in diabetes abounded, but the evidence was not at all convincing, because in the vast majority of patients with diabetes, the pancreas was of normal size and appearance at autopsy. With the pancreas being thought of only as a purely exocrine gland, the finding of pathologic lesions in the pancreas in a small group of diabetic individuals was interpreted as only a chance phenomenon.

In France, Claude Bernard was aware of the findings and speculations regarding the possible role of the pancreas in diabetes. To test this hypothesis, he ligated pancreatic ducts of dogs and/or injected them with oil or paraffin to block all secretion, which led to profound atrophy of the gland. Because only a few strands of what appeared to be lifeless scar tissue remained, Bernard assumed that the atrophy was indeed complete. Despite this, the animals showed neither glycosuria nor any other indication of diabetes (30). Such experiments also were performed by Moritz Schiff, with equally negative results. "antipancreatic" viewpoint was thus immeasurably strengthened by the authoritative voices of the foremost physiologists of the age. Bernard's celebrated findings of glycosuria after "piqure" of the IVth ventricle drew attention to the possibility that alterations in the central nervous system could be etiologically related to diabetes. A lesion in the brain would cause hyperglycemia by way of the "visceral" nerves acting on the liver.

The Search for the Cause of Diabetes

Between 1840 and 1860, physiologic studies in metabolism as they relate to diabetes began their advance, especially in France under the leadership of Claude Bernard. His epoch-making discovery that blood glucose was derived in part from glycogen as a "secretion" of the liver thus identified the liver as a central organ in diabetes and explained how a diabetic patient whose liver was scarred by the end stages of cirrhosis might be "cured" of his hyperglycemia and glycosuria.

The two strongest forces arguing for a "pancreatic" factor in the etiology of diabetes were Apollinaire Bouchardat and E. Lancereaux. Bouchardat, who trained in organic chemistry and was an early pioneer in the study of fermentation and a professor of public health, did meticulous long-term studies on human diabetes. These began in 1835 and were gathered into his 1875 book, *De la Glycosurie ou Diabète Sucré* (31). He followed the essentials of Rollo's dietary regimen in treating diabetes but added a very important therapeutic arm by encouraging hard physical labor, having observed ameliorative effects of muscular work on glycosuria and hyperglycemia. Yet above all, his clinical experience taught him to distinguish at least two different types of diabetes: the severe type in younger persons who

4 JOSLIN'S DIABETES MELLITUS

responded poorly to his regimen and the type in older, obese persons for whom the prescribed therapy of diet and physical exertion worked admirably. The clinical behavior of the two types of diabetes and the postmortem findings led Bouchardat to suggest that the more severe form was pancreatic in origin.

Lancereaux and his students came to identical conclusions about etiology and introduced the terms *diabète maigre* (diabetes of the thin) and *diabète gras* (diabetes of the fat) for the two common clinical forms of the disease (32). Because *diabète gras* was the more frequently occurring type, it now became understandable why severe pancreatic damage was found less frequently than expected. A pancreatic etiology for *diabète maigre* thus became an acceptable postulate, even though one could not yet form a sound notion about the mechanisms involved.

The concept that the body possesses glands that deliver their products directly to the blood (ductless or "blood" glands) gained substantial ground through Berthold's study of castration in 1849 (33), the clinical description of Addison disease in 1849 (34), and the experimental ablation of the adrenal gland by Charles Brown-Séquard in 1856 (35).

Pancreatic Diabetes

A decisive turning point in the history of diabetes was marked by the experimental work of Joseph von Mering and Oscar Minkowski in 1889 (11,12). Von Mering was interested in the possible role of the pancreas in the digestion and absorption of fats. From the literature then available, primarily the writings of Claude Bernard, von Mering understood that it was virtually impossible for an animal to survive total removal of the pancreas. He consulted with Minkowski, the assistant to Albert Naunyn, the foremost European clinician in diabetes at that time. Undaunted by the previous experiments, von Mering and Minkowski operated on two dogs, and both animals survived the complete pancreatectomy. Within less than a day, these animals exhibited unexpected behavior-in particular, frequent and voluminous urination. Minkowski's experience with severe human diabetes led him to examine the urine for sugar. During the next 2 years, Minkowski extended this serendipitous finding into an in-depth, now classic, study of experimental diabetes and its metabolic deviations. The study remains a model of scientific physiologic inquiry. He demonstrated clearly that the pancreas was a gland of internal secretion and that a small portion of the gland, when implanted under the skin of a freshly depancreatized dog, prevented the appearance of hyperglycemia until the implanted tissue was removed or had degenerated spontaneously.

Confirmation of these findings came very quickly from Hedon and coworkers in France. In 1893 Laguesse drew proper attention to the almost forgotten original observations of Langerhans and suggested the collections of interacinar cells (which he designated the *islets of Langerhans*) as a gland of secretion within the pancreas (36).

Thus, modern experimental and clinical endocrinology developed during the last decade of the 19th century. The term *hormone* was introduced by William Bayliss and Ernest Starling in 1902 to designate a specific chemical material elaborated by a ductless gland into the blood that is conveyed to other parts of the body and exerts an effect upon its "target" tissues (37). In 1910, Jean de Meyer suggested that the pancreatic secretion that was lacking in the diabetic state should, when found, be called "insulin" to denote its origin from the "insulae" of Langerhans (38).

Between 1895 and 1921, experimental work developed in two directions. One was the careful histologic study of the islets, which led to the finding of several distinct cell types, thus foreshadowing our present knowledge that the islets of Langerhans are the site of production and secretion of several hormones in addition to insulin. Of note was the description of hyalinization in islets of people with diabetes by E. L. Opie in 1900 (39). This hyalinization has since been shown to be the amyloid commonly found in the islets of people with type 2 diabetes, but this observation again linked the islets of Langerhans with diabetes. The other was a search for insulin itself. The requirements for insulin as a potential therapeutic agent were stringent: (a) the preparation had to be of consistent potency; (b) it should reverse the metabolic abnormalities of the depancreatized animal; (c) it should reverse the signs, symptoms, and chemical abnormalities of human diabetes; and (d) it should produce no harmful side effects.

The difficulties in the early attempts to isolate insulin were legion. There was total ignorance of the chemical nature of the postulated antidiabetic substance, making the extraction procedure a hit-or-miss proposition. At that time, quantitative estimates of the blood sugar required inordinate amounts of blood and the procedure was not generally available. Because of ignorance about the profound effects of low blood sugar levels on the nervous system (hypoglycemic convulsions), they were also not recognized as such and were initially attributed to a "toxic" action of the extract. In addition, fever and infections were frequent sequelae of the injections of extracts. In view of the protein nature of the hormone (which, of course, was not yet known), it is obvious that those workers who used oral administration of the extract were bound to fail. Of the many forerunners of Banting and Best, those who came closest to the mark were E. L. Scott, Israel Kleiner, Ludwig Zuelzer, and Nicolas Paulesco, as has been well described by Bliss (40). Indeed, Paulesco, a distinguished Romanian physiologist, produced a pancreatic extract that fulfilled all the criteria for "insulin" in animal experimentation but did not succeed in showing its application in human diabetes (41). Thus, the significance of his contribution was appreciated only much later.

Frederick Banting, a young surgeon; John Macleod, a professor of physiology; Charles Best, a graduate student; and J. B. Collip, a skilled chemist, succeeded during the years 1921 and 1922 in fulfilling all of the criteria for a therapeutically active insulin and produced the first useful and consistently successful insulin preparation for the treatment of human diabetes. Thus, the pancreatic etiology of diabetes was finally established (42).

The Nobel Prize for the Discovery of Insulin

The awarding of the Nobel Prize in Medicine in October 1923, 18 months after the first news of the discovery of insulin, was part of a gripping tale of success, disappointment, and conflict. The story of Banting, Best, Collip, and Macleod brought to light the tensions of a 6-month period that began in the summer of 1921 and intensified when the new extract corrected the metabolic acidosis in the first person to receive the substance in January 1922 (Leonard Thompson, age 14 years, at the Toronto General Hospital in Canada).

The drama started when Frederick Banting, a World War I veteran surgeon who was barely employed, was asked to be an instructor in physiology at the University of Western Ontario in Canada and became inspired by reading an article in the fall of 1920 by the pathologist Moses Barron. The article was entitled "The Relation of Islets of Langerhans to Diabetes with Special Reference to Cases of Pancreatic Lithiasis" (43). Armed with this information, the 29-year-old Banting persuaded Professor Macleod of the University of Toronto to provide him the space and equipment to attempt to extract a pancreatic hormone from dog pancreases. Banting's original idea was to extract the

substance, or "ferment," from the dog pancreas after ligating the pancreatic ducts, but this failed. They were successful only with the total extraction of the pancreas from numerous laboratory dogs followed by injection of the resultant crude extract to demonstrate partial correction of the elevated blood sugar level in depancreatectomized dogs. Alone, except for one graduate student (Best), during the first 3 months of the project, because Macleod was in Europe, starting in August 1921, Banting and Best demonstrated a significant lowering of the elevated glucose level in depancreatectomized dogs with their dog pancreas extract.

By November, Macleod felt that biochemical expertise was critical for further refinement of the "hormone," then given the name *isletin* by the young investigators. The following month James Collip, a young professor of biochemistry on a sabbatical leave in Macleod's department, joined the three researchers. Despite Collip's ability in January to prepare an effective extract for the first human recipient, Leonard Thompson, the success did not last. By the spring of 1922, both Banting and Best, as well as Collip, found it impossible to reproduce useful material. The prospects for the production of insulin brightened with the help of a brilliant strategist, George Clowes, the research director at the then small company called Eli Lilly, who developed a favorable contract with the trustees of the University of Toronto to work out conditions for large-scale production (40). Clowes fortunately had employed a rare talent at that time in the person of a chemical engineer by the name of George Walden, who made the critical observation in the fall of 1922 that maintenance of the isoelectric point of insulin afforded a maximum extraction of insulin from beef and pork pancreases (44). This paved the way for production of enough insulin to meet the needs of desperate patients and physicians worldwide.

Apart from the objective merits of the work and the investigators who produced it, the complexity of the Nobel Committee's assignment of merit to only Banting and Macleod requires comment. In 1951 the Nobel Foundation published a historical commentary on its work, which contained information about the selection process in 1923 (45). Banting and Macleod, but not Best, were nominated, an essential requirement for Nobel laureate consideration. Furthermore, the Nobel report admitted that the committee reviewed only three presentations reporting on the insulin discovery. These articles did not include the first Banting and Best article of February 1922 (42), but they did review the seven-authored May 1922 article published in the Transactions of the Association of American Physicians (46). From their vantage point of the mid-20th century, the Nobel report concluded that Collip and Best had probably been assumed to be assistants and therefore not prime candidates for recognition (45).

The historian Michael Bliss, after all the principal parties in the case had died, was able to search anew, mainly in the archives at the University of Toronto, and concluded that all four of the investigators were essential to the discovery and could share in what a sage of the early 1920s had remarked was "glory enough for all" (40). Likewise, the scholar investigator Rachmiel Levine gave a good degree of closure on this matter when he commented in the 1993 version of this chapter:

As such things commonly proceed [the discovery of insulin in 1921], there was a tendency to overdo the interpretation. First, all diabetes was ascribed to insulin deficiency. The role of other hormones in metabolic control and an awareness of the bewildering heterogeneity of the diabetic syndrome belong to the half century and more that has elapsed since that momentous summer in Toronto in 1921. In 1922 Banting and Macleod received a Nobel Prize for this historic discovery. There was immediate controversy about the omission of Best and Collip from the

prize—a controversy that has continued to the present day. Recent historical research into the details of the Banting and Best collaboration confirm that J. J. R. Macleod, Professor of Physiology at the University of Toronto, facilitated as much as he could the research suggested by Banting and was probably an appropriate co-recipient of the Nobel Prize [(44)]. It has always been clear that, of the participants, Macleod was certainly the most knowledgeable in the fields of carbohydrate metabolism and diabetes mellitus. The success of the work by Banting and Best was due to Macleod's basic knowledge, Banting's stubborn persistence, and the important specific skills of Best and Collip [(47)].

THE INSULIN ERA

The Years 1922 to 1960

During the period from the discovery of insulin through the 1950s, the effects of the availability of insulin were felt in three notable ways: an improved life expectancy for patients with type 1 diabetes, a surge of interest in understanding the mechanism of action of insulin on intermediary metabolism, and an increasing recognition of the syndromes we have come to appreciate as the chronic complications of diabetes. A combination of factors promoted a longer life span for the beleaguered patient with the disease, beginning with the near elimination of death from diabetic coma that coincided with improved means of treating the complications of diabetes. Hormonal regulation of glucose metabolism was clarified, with progress made in understanding the role of hepatic, adipose, and muscle tissues in the uncontrolled diabetic state. Success in defining the entire endocrine network, especially in demonstrating the importance of the pituitary-adrenal axis, gave the field of endocrinology a specialty status.

The Insulin Timetable

The discovery of insulin changed forever the treatment of diabetes; these and related developments are outlined in Table 1.1 (48).

The arrival of an adequate supply of commercial insulin for patients from 1923 onward was followed by the development of procedures for purifying and standardizing insulin. By 1926 crystalline insulin in concentrations of 10, 20, and 40 units per milliliter became available worldwide. The task of purifying insulin continued for decades, starting with early efforts to avoid contaminants such as glucagon. Starting in 1936 protamine and zinc were used to prolong the action of insulin (49). In the 1970s, self-monitoring of blood glucose became a standard of care. Further changes were made possible with the tools of molecular biology, which allowed the production of human insulin and analogues that change absorption characteristics. These insulin variations, coupled with the arrival of finer, less painful, needles, facilitated multi-injection programs that provide better glucose control. Pump delivery systems also became available. It is difficult for those involved with diabetes today to comprehend fully the changes that have taken place since the introduction of insulin. The first Joslin patient to receive insulin was Elizabeth Mudge, R.N., who was first treated on August 7, 1922, at the New England Deaconess Hospital in Boston. She had not been able to leave her apartment for 9 months, but after 6 weeks of insulin therapy, she could walk 4 miles daily, and she lived for 25 more years. Regarding the preinsulin days, Dr. Joslin noted, "I used to count the days my diabetic children lived" (50). This is emphasized by an episode that took place in the crowded original offices of the Joslin Clinic

6 JOSLIN'S DIABETES MELLITUS

TABLE 1.1. Insulin Timetable: 1921 through the Present		
1921	Pancreatic extracts demonstrated to lower blood sugar levels in experimental diabetic dogs (Banting, Best, and Macleod, Toronto)	
1922	Insulin first used in human (Leonard Thompson, Toronto)	
1923	"Isoelectric point" produced larger quantities of higher-potency insulin from animal sources—enough to satisfy commercial supply (Lilly Company)	
1925	First international insulin unit defined (1 unit = 0.125 mg of standard material). U40/80 insulins become available	
1926	Crystallized amorphous insulin adds to insulin stability (Abel)	
1936	Addition of zinc to protamine insulin (PZI) to create a prolonged duration of action of the hormone (Scott, Fisher, and Hagedorn)	
1939	Globin insulin with a shorter duration of action than PZI developed	
1950	NPH (neutral protamine Hagedorn) insulin developed with controlled amounts of protamine (Nordisk Company)	
1951	Lente insulins developed by acetate buffering of zinc insulin (Novo Company, Hallas-Moller)	
1955	Structure of insulin delineated (Sanger and coworkers)	
1960	Radioimmunoassay of insulin becomes available (Berson and Yalow)	
1967	Proinsulin discovered (Steiner)	
1967	First pancreas transplant (Kelly, Lillehei, and coworkers)	
1971	Insulin receptor defined (Roth, Cuatrecasus, and coworkers)	
1972	U100 insulin introduced to promote better accuracy in administration	
1973	Small-dose intravenous insulin treatment for acidosis emerges as alternative to large-dose subcutaneous treatment (Alberti and coworkers)	
1976	C-peptide becomes clinical tool (Rubenstein et al.)	
1977	Insulin gene cloned (Ullrich, Rutter, Goodman, and others)	
1978	Purified "single-peak" pork insulin introduced (Lilly Company)	
1978	Open-loop insulin delivery system clinically introduced (Pickup and coworkers)	
1981	Insulin-receptor kinase activity described (Kahn and coworkers)	
1982	Recombinant human insulin becomes available (Lilly Company)	
1989	First islet transplants (Lacy and coworkers)	
1990s (early)	Insulin pen delivery devices become popular	
1996	Short-acting insulin analogue introduced—insulin lispro (Humalog)	
2000	"Edmonton Protocol" improved results of islet transplantation	
2001	Long-acting insulin analogue introduced—insulin glargine (Lantus, Aventis Company)

on Bay State Road in the 1940s, when a child patient became more than a bit noisy. Dr. Joslin came by and said, "Make all the noise you want. We love noisy children around here. For many years there were no normal children. They were very quiet and after a visit or two they did not return" (L. P. Krall, personal communication).

Prior to the use of insulin, most young patients with diabetes died shortly after diagnosis. The Joslin Clinic experience (51) showed the commonest cause of death to be ketoacidosis (63.8% until 1914 and 41.5% until August 1921). The improvement from 1914 to 1921 was probably due to the introduction of Frederick Allen's "semistarvation" therapy in about 1915. Even though patients with type 1 diabetes could sometimes survive for years using this form of starvation therapy, most died sooner. By comparison, in affluent countries, the rate of death due to coma is now a rare event, although in some developing countries, death rates still approach preinsulin levels.

When Joslin wrote the preface to his third edition of *The Treatment of Diabetes Mellitus* late in 1923, the experience he drew upon was based on 3,000 cases and his use of insulin had been extended to 1 year (52). He wrote: "Compared to the last decade, the doctor now has twice as many diabetics to treat.... Of the 48 children cared for in this period, 46 remain alive ... and as for Bouchardat, Cantani, Kulz, Lepine and all the other diabetic saints, how they would have enjoyed this year!"

The Study of Diabetes and the Development of Clinical Care

The original physicians on the first Insulin Committee of the University of Toronto in 1922 were Elliott P. Joslin of Boston;

Robert Williams of Rochester, New York; Frederick Allen of Morristown, New Jersey; Rollin Woodyatt of Chicago, Illinois; Russell Wilder of the Mayo Clinic, Rochester, Minnesota; and Richard Geyelin, of New York City (53). These men, each in his own way, were leaders in the new treatment of diabetes in the first decade after the discovery of insulin. They were the first physicians to report on the detailed management of children and adults presenting in metabolic acidosis. With time, new clinical problems emerged in the medical literature as the first decade of insulin use ensured longer-living patients. By the early 1930s, the occurrence of lower extremity neuritis was becoming more common, as was the number of persons with a combination of Bright's disease (nephrotic syndrome) and hypertension. In 1928 Joslin described neuritis on one page of his 500-page fourth edition (54), but by his eighth edition (1946) the subject had been expanded to an entire chapter (55). By World War II the goals were clear: first, prevent death from diabetic coma; and second, train patients to help decrease the appearance and impact of diabetic complications.

Diabetic Manuals and Early Diabetes Education

Most of the leading physicians of the 1920s and 1930s who were interested in diabetes produced instructional guidebooks that covered the use of insulin, care of equipment, and management approaches to hyperglycemia and hypoglycemia. However, the majority of these instructional renditions went through only one edition, with the notable exceptions of the guidebooks of R. D. Lawrence of London and Joslin, which were revised approximately every 4 years. Lawrence titled his book appropriately *The Diabetic Life*, which set a publication record, reaching 17 editions by 1965 (56).

Joslin began to publish his first manuals shortly after the first edition of his diabetes textbook in 1916 (1), and by his third edition in 1923 (52), he had quickly adapted the contents to the arrival of insulin while maintaining the length of the manual to fewer than 200 pages. This practical "reader" for patients reached more people with diabetes in America than any other guide in the immediate decades following the introduction of insulin. The early editions were subtitled For Mutual Use of Doctor and Patient, as the practitioner absorbed, along with the patient, the details of the new treatment (57). Each table of contents boldly proclaimed the value of self-care in matters as far reaching as prevention of gangrene and constipation and proper dental care. He maintained that steady care of oneself, with proper treatment defined as a combination of more than one adjustable daily insulin dose (as a rule) and dietary restrictions along with regular, planned exercise, favored a longer life. His life-expectancy predictions for people with diabetes underlined the value of his advice by showing a steady improvement in longevity.

Joslin was a highly organized person who not only was interested in his patients' health but also found time to inquire into the details of their lives. From the first use of "diet therapy," he recognized the value of hospitalization in a hospital "cottage" or "schoolroom" setting that was dedicated to patient treatment *through* education. These cottages later evolved into an ambulatory inpatient ward he termed the *Diabetes Treatment Unit*. Patients were expected, while under supervision in this ambulatory setting, to enter into a team approach with doctor and educator in choice of insulin doses according to exigencies of the particular day's program. However, in recent years, cost-containment restraints on medical insurance have moved diabetes education to outpatient venues.

Recognition of the Complications of Diabetes

Continuous reporting of protocols on treating diabetic coma with improvements in mortality rates was at the core of the most often published communication coming from Joslin's early clinic. Joslin's associate, Howard Root, published a collection of articles in monograph form on diabetes and tuberculosis, a much-feared infection decreasing significantly after 1940 (58).

Classification of neuropathy was to be continuously readdressed in the 30 years following the publication of one of the most definitive reports on the emerging subject by a Joslin associate, W. R. Jordan (59). In this anthology of the many presentations of diabetic neuropathy came one of the earliest notations of severe joint neuropathy, diabetic osteoarthropathy, which is now better known as the Charcot foot phenomenon. A monograph on the visual problems in diabetes published in 1935 by Waite and Beetham (60) was to be a basis for Beetham's later studies on the natural history of retinopathy (61). His extensive experience obtained from a 30-year observation of the Joslin patients allowed him to formulate the potential value of laser photocoagulation in treating diabetic retinopathy. His critical observation was based on the observation that neovascular changes were never seen in the retinas of patients who already had evidence of previous chorioretinitis (62).

In 1936, Kimmelstiel and Wilson's article on a kidney lesion that seemed pathognomonic for diabetes rounded out the early description of diabetic complications (63). Implicit in many of the discussions in these monographs, particularly those on pathology, diabetic coma, and retinopathy, was the concomitant presence of severe macrovascular disease. The suggestion of a high incidence of coronary artery disease emphasized in these publications was clearly substantiated in Bell's monumental study on arteriosclerosis (64).

The Team Approach to the Treatment of Diabetes

The study of clinical diabetes in the early years of insulin use convinced Dr. Joslin of the need for different strategies for delivery of care. A half-dozen initiatives were incorporated into his clinic programs, some of which have gained broad acceptance in the decades since their initiation. The common denominator in his plan was to create teams of subspecialists to maximize the benefit to the patient. He was fond of citing the value of the "fecundity of the aggregation" (65).

The team approach to care was originally an approach to treating diabetic coma. The use of special-duty nurses with expertise regarding fluid replacement, constant observation of signs and symptoms, and the monitoring of laboratory results was championed by Joslin before the replacement of intravenous fluids and electrolytes became routine. In the late 1930s, the addition of a special intravenous nurse team to administer fluids and to act as phlebotomists for the critically ill and often dehydrated patient was a pioneering step.

Along with the publication in 1928 of the first monograph, entitled *Diabetic Surgery*, by the surgeon L. S. McKittrick and the internist H. Root, Joslin created a "foot team" (66). This group acknowledged the need for a special foot-dressing nurse to apply frequent bandages to prevent progression of foot lesions from neuropathic, ischemic, or "mixed" lesions. In addition to the surgeon and internists, importance was placed on the team's schedule of daily and weekly conference rounds, with the inclusion of a chiropodist (podiatrist) to provide preventive foot care with proper booting of the patient.

Always a pioneer, Joslin appointed Priscilla White to his practice team "to study and care for children with diabetes" (65) (Fig. 1.2). She quickly saw the need for good control as a preventive for the growth retardation that plagued children with chronic hyperglycemia. Later, as the teenagers matured, their desire for pregnancy became White's major challenge. She favored the emphasis on "pregnancy complicated by diabetes," not vice versa (67). After working on these problems for more than a decade, by 1937 she had devised a team approach to prenatal care for pregnant women with diabetes. Cesarean sections

Figure 1.2. Priscilla White at the telephone.

at or near the 37th week of gestation were inaugurated as early as 1928 to avoid the dangers of edema of the fetus on the one hand and respiratory distress on the other. Her experience with variations in the response to pregnancy in these women who had a spectrum of diabetes (from gestational diabetes to pregnancy complicated by the diabetic nephrotic syndrome) allowed her to formulate by 1949 a classification of diabetic pregnancy that was accepted worldwide and still is known as the White classification (68).

A unique venture introduced by Joslin in the management of diabetic youth came at the time insulin was made available in the creation of the "wandering" or "visiting nurse" to join families and adjust the new insulin to the daily activity and the changing dietary needs of the growing child (69). These nurses supervised the initial Joslin diabetes camp effort. In the past three decades, professionals other than doctors and nurses have joined the education team; these have included nutritionists, psychologists, and exercise physiologists. Today, the status of diabetes educators has been strengthened by a rigorous credentialing process that leads to the designation "certified diabetes educators" (CDE) (70). Moreover, diabetes has become a field that lends itself logically to including nurse practitioners and physician assistants as members of the diabetes care team.

The educator mission was to be extended to all settings, from the recovery time after a critical illness all the way to camp programs, starting with the creation in 1932 of the Clara Barton Birthplace Camp for Girls in Oxford, Massachusetts. These summer camp experiences had their diabetes education dimension, as the daily schedule was divided evenly between typical camp activities and instructional opportunities that could be provided by the staff.

Modern Endocrinology Comes of Age

Endocrinology as a medical specialty developed quite late compared with most other fields. Endocrinology had its beginning in the 19th century with reports describing conditions of hormone excess, as in Graves disease, and deficiencies, as in Addison disease. By 1891, the first example of treatment with desiccated thyroid was realized and heralded as effective "replacement" therapy for thyroid "deficiency" (71). However, it was not until the decades embracing the arrival of insulin that impressive advances were seen in the chemistry of and therapy for a full range of the endocrine- and vitamin-related disorders and that they were defined as we presently understand them. As an example, the early 20th century witnessed the first descriptions of an impressive number of nutritional deficiencies, starting with the work in England of Hopkins and Funk with the B vitamins (named the "vital amines" and abbreviated as "vitamins"). Nobel prizes in 1937 went to Szent-Györgyi for elucidating ascorbic acid and in 1934 to three Americans, Minot, Whipple, and Murphy, who spearheaded the spectacular success with liver therapy for pernicious anemia (16). George Minot (1985-1950) was characterized by his doctor, Elliott Joslin, as "saved" by insulin when it fortuitously became available in 1922, preventing an almost certain lethal descent for the young hematologist and assuring him a brilliant research career (72).

By the third decade of the 20th century, there had been sufficient development in topics such as body salt and water balance, digestive functions, and intermediary metabolism to allow recognition of the role of humorally transported integrators, a term originally used to describe hormones (72). The arrival of insulin certainly became one of the main engines of growth for the development of endocrinology over the next 35-year period. A centerpiece of this new age in the study of metabolism was the work of the Nobel laureate Bernardo Houssay of Argentina. His 30-year perspective on the field of metabolism following the discovery of insulin was summarized in Houssay's address at the dedication of the new Banting and Best Institute in Toronto in 1952 (73).

Working with Biasotti; I found the hypophysectomies diminished the severity of diabetes by pancreatectomy in the dog. Implantation of the pars distalis (anterior lobe of mammals) again increases the severity of diabetes. The diabetogenic effect of the hypophysis was thus demonstrated. The severe symptoms of pancreatic diabetes were due to two factors: (a) presence of a hypophyseal hormone, and (b) a lack of secretion of insulin. The diabetogenic effect of hypophyseal extract in mammals was demonstrated in 1932 simultaneously in three laboratories: in Evan's, in Marine's, and in mine. In 1932, I was able to provoke permanent diabetes by hypophyseal treatment in dogs previously submitted to partial pancreatectomy. Young obtained this effect in dogs with intact pancreas in 1937.

Houssay's work became the needed fulcrum for the advancements in understanding of the whole endocrine network that we appreciate today. In the 10 years following the availability of insulin, Houssay was able to study the action of insulin by applying his earlier investigations on the effects of thyroid, adrenal, and pituitary ablation upon glucose regulation. Diabetes became a convenient and measurable parameter in the study of metabolism for him and his contemporaries.

During the 1930s there was an eruption of information about hormonal regulation of intermediary metabolism. Carl Cori (74) and Hans Krebs (75) were leaders in defining steps in glucose regulation. Developments in the field of pharmacology spearheaded advances in the clinical isolation of hormones. An American pioneer in the field, J. J. Abel (1857–1938), isolated epinephrine and later produced crystalline insulin, an advance that facilitated production of insulin for therapy (76).

The adrenal gland became a continued focus of investigation, aided by Cushing's work on human adrenal pathology earlier in the decade (77). Long's work on the effect of adrenal hormones on carbohydrate metabolism was a significant step in understanding the regulation of blood sugar in health and disease states like diabetes (78).

As Harvey pointed out in his "Classics in Clinical Science," Dana Atchley and Robert Loeb during this time made major contributions to the understanding of the treatment of diabetic acidosis (79).

In the early 1930's Atchley and Loeb in their metabolic "study unit" in New York conducted studies on the electrolyte changes in diabetic acidosis. Atchley suggested that they bring well-regulated diabetic patients into the hospital and follow the sequential metabolic changes after discontinuing their insulin. They selected three patients: in the first, when insulin was taken away, the diabetes was so mild that little change occurred. The second had more severe diabetes, and the third had very severe diabetes and became seriously ill within a few hours after his insulin was discontinued. Their quantitative observations demonstrated the progressive loss of body water, sodium and potassium. These elegant balance studies represent one of the classic contributions in the evolution of our understanding of the electrolyte changes that occur in diabetes mellitus.

It took another decade and a half before the practical implementation of correct replacement of electrolytes in diabetic acidosis was completed. The better availability of infection-free intravenous solutions was crucial to providing optimal care for the acutely ill diabetic patient. The arrival in 1948 of the flame photometer for more rapid determination of potassium levels focused attention on the need to replace this electrolyte in almost all cases of diabetic acidosis.

From today's perspective the last major advance in the treatment of diabetic coma came with the use of intravenous insulin

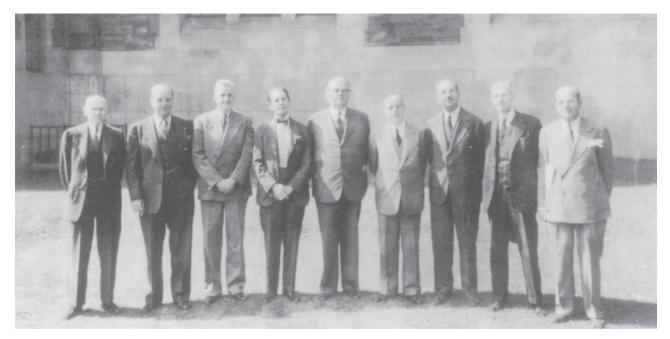

Figure 1.3. Officers and honored guests at the celebration of the 25th anniversary of the discovery of insulin, in Toronto, September 16–18, 1946. Left to right: Elliot P. Joslin, Boston, honorary president, American Diabetes Association; Charles H. Best, Toronto, codiscoverer of insulin; Russell M. Wilder, Rochester, Minnesota, president-elect, American Diabetes Association; Robert D. Lawrence, London, founder, the Diabetic Association; H. C. Hagedorn, Denmark, discoverer of protamine insulin; B. A. Houssay, Buenos Aires, researcher, "Houssay phenomenon"; Joseph H. Barach, Pittsburgh, president, American Diabetes Association; Eugene L. Opie, New York, discoverer, islets of Langerhans pathology; Cecil Striker, Cincinnati, first president, American Diabetes Association.

infusions in the 1970s. Since 1980, the formula for correcting the insulin deficit in patients with ketoacidosis has been contained in a mere half-page of the treatment guidelines of the American Diabetes Association (80). This abbreviation of the treatment of diabetic acidosis parallels the marked decrease in mortality that has been observed over the past several decades.

The principals who marked the celebration of the 25th anniversary of insulin in 1946 are shown in Figure 1.3. This sampling of investigators and their particular fields of interest illustrate the beginning of what has become a virtual army of different scientific disciplines now employed in the study of diabetes. Best, Houssay, and Hagedorn were basic scientists; Wilder was a pioneer clinical endocrinologist; Opie was a pathologist; and Joslin, Lawrence, Barach, and Striker were eminent diabetologists.

Early Work in the Epidemiology of Diabetes

Joslin's interest in epidemiology, pursued with diligence during his 60-year professional life, centered on three areas: first, maintaining vital statistics on his patients with diabetes; second, promoting epidemiologic studies; and third, garnering information from these to translate principles into practice for individual patients.

From the very start of his practice, he devised a registry of patients with diabetes and strove to follow them through their life span. Gradually his "black books" were enlarged into a system of vital statistics on his patients, increasing over decades to become the largest medical record system devoted to diabetes in the world. He collaborated with the medical director of the Metropolitan Life Insurance Company so that his compilations could receive the expertise of actuarial professionals (81).

The rising incidence of diabetes during the past five decades provides one of the best examples in medicine of the emergence of a chronic disease as a threat to world health. Elliott Joslin had an appreciation of epidemiology even in the earliest stages of his career, beginning with his pioneering report in 1898 on the 75-year review of medical records on diabetic patients at the Massachusetts General Hospital (one of the earliest hospital record systems in the United States) (82), which revealed a dismal outlook for patients with diabetes over this time period. As early as 1921, he appreciated the concept of epidemiology and even applied the term "epidemic" to diabetes (6) and made the following prescient comment:

In a country town in New England . . . on its peaceful, elm-lined Main Street, there once stood three houses, side by side, as commodious and attractive as any in the village. In these three houses lived in succession four women and three men—heads of families—and of this number, all but one has subsequently succumbed to diabetes. . . . Although six of the seven persons dwelling in these adjoining houses died from a single complaint, no one spoke of an epidemic. Contrast the activities of the local and state boards of health if these deaths had occurred from scarlet fever, typhoid fever or tuberculosis. Consider the measure which would have been adopted to discover the source of the outbreak and to prevent a recurrence. Because the disease was diabetes, and because the deaths occurred over a considerable interval of time, the fatalities passed unnoticed (6).

Joslin's registry recorded experience with 1,000 cases of diabetes by the time he was able to assess his own 5-year trial with Allen's "undernutrition" regimen. Therefore, in 1916, armed with evidence showing an increase in the short-term life span for his patients with type 1 diabetes following the Allen undernutrition regimen, he felt justified in publishing a definitive monograph on all the known facts related to the disease, which contained a wealth of epidemiologic information (1).

By 1928, when he had 5 years of experience in the use of insulin treatment, Joslin had started to employ a follow-up plan on the medical status of all his patients. He regularly wrote patients a personalized message on a detailed form letter and

10 JOSLIN'S DIABETES MELLITUS

recorded their answers about health and disease in his ledgers. By this device, Joslin enhanced an already close relationship that afforded him the most comprehensive set of medical data on diabetes then in existence. By 1980, this resource led to a valuable series of analyses of the complications of three cohorts of patients with type 1 diabetes from the years 1939, 1949, and 1959 (83). This type of investigation clarified the changing appearance of the chronic diabetic syndrome, particularly with the occurrence of renal failure.

In a sense, this textbook was an epidemiologic tract that was to be continually updated in each edition with information garnered from the "follow-up" system of his medical record ledgers. The Oxford Study in 1947, instigated by Joslin, was the first whole-town survey of the incidence of diabetes. It established a 4% prevalence rate for diabetes in the United States, underscoring that the disease was undetected in half the population with the disease (84).

Earlier, Joslin had been involved in some of the original fieldwork on the prevalence of diabetes. He reported on his experience in Arizona in 1940 and corrected the perception that the incidence of diabetes was less than that noted in the eastern United States (85). He did not observe the well-known high prevalence of diabetes in Native Americans, perhaps because a large proportion of the population was probably still active in farming in the 1930s. For example, prevalence data from surveillance of a Pima Indian population in a reservation in New Mexico showed that more than 50% of the population over 35 years of age had diabetes (86).

The Current Era (1960 to the Present)

The past four decades have witnessed major advances in the treatment and understanding of diabetes. The field has been aided greatly by organizational agreement on an upgraded terminology necessary to properly classify the heterogeneity of the diabetes syndrome.

By the 20th century's end, the long-term acrimonious debate over the value of good glycemic control of diabetes became resolved with the results of several large well-designed and well-executed clinical studies. However, despite major improvement in the options for care and the depth of research in affluent areas, this progress is dampened by the challenge seen in an increasing epidemic of diabetes throughout the world among disadvantaged populations both in this country and beyond.

The Classification of Diabetes

A major step in world recognition and confirmation of diabetes as a major health problem was the development of improved criteria for diagnosis and classification of the types of diabetes, particularly for types 1 and 2 diabetes. Table 1.2 charts these developments (55, 87, 88, 89).

Defining diabetes in the past was, at best, a sorting-out process. The father of modern medicine, Sir William Osler (1849-1919), composed a one-authored text of internal medicine in 1893 as he awaited the first class of students at the Johns Hopkins University Medical School in Baltimore, Maryland. He placed diabetes under the topic of "Constitutional Diseases" and implied that it was "familial" (90). The timing of the Osler textbook nearly coincided with the finding of Minkowski and von Mering that the pancreas was central to the disease. Lancereaux, a student of the French clinician Bouchardat, had divided diabetes into a "lean" and a "fat" category (31). Since that time, various adjectives have been employed to classify and describe diabetes (Table 1.2). In the 1960s it became apparent that separate criteria needed to be employed for gestational diabetes (91). By the mid-1970s, these descriptions and the half-dozen diagnostic criteria had become unworkable. The 1979 National Diabetes

TABLE 1.2. Understanding D	iabetes: A Century of Effort in Classifying the Disease (1880 to the Present)			
Type 1 (insulin-dependent diabetes mellitus; IDDM)				
Preinsulin era Insulin era	Diabète maigre (lean) True diabetes (Naunyn) Asthenic/Unterdruk type Juvenile-onset type			
	(JODY = juvenile-onset diabetes of youth) Ketosis prone Brittle diabetes			
Type 2 (non-insulin-dependent diabete	Type 2 (non-insulin-dependent diabetes mellitus; NIDDM)			
Preinsulin era	<i>Diabète gras (big)</i> Sthenic, Überdruk type			
Insulin era	Adult-onset diabetes Maturity-onset type diabetes Ketosis-resistant diabetes Stable diabetes (MODY = maturity-onset diabetes of youth)			
Gestational diabetes mellitus (GDM) Impaired glucose tolerance (IGT) Impaired fasting glucose (IFG)	Established firmly in 1964 (O'Sullivan and Mahan (91)			
Other types (associated with pancreatic diseases, removal endocrinopathies, genetic syndromes)	c Secondary diabetes			
From Joslin EP, Root H, White P, et al. <i>The treatment of diabetes mellitus</i> , 8th ed. Philadelphia: Lea & Febiger, 1946:310–313; National Diabetes Data Group. Classification and diagnosis of diabetes mellitus and other categories of glucose intolerance. <i>Diabetes</i> 1979;28:1039–1057; Fajans SS, Cloutier MC, Crowther R. Banting Memorial Lecture. Clinical and etiologic heterogeneity of idiopathic diabetes mellitus. <i>Diabetes</i> 1978;27:1112–1125; Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. <i>Diabetes Care</i> 2002;25[Suppl 1]: S5–S20.				

Data Group Committee, with a wide assembly of epidemiologists and students of the disease, agreed upon new definitions (87). Although it was a compromise, it was accepted by the National Institutes of Health, the American Diabetes Association, the European Association for the Study of Diabetes, the International Diabetes Federation, and the World Health Organization.

From a historical perspective, the 1979 classification "institutionalized" the concept that insulin resistance is important (91a). The British investigator H. P. Himsworth should be credited with the initial formulation on the subject 50 years previously (92). Prophetically, Himsworth stated: "Diabetes mellitus is a disease in which the essential lesion is a diminished ability of the tissues to utilize glucose . . . [this disease] is referable either to deficiency of insulin or to insensitivity to insulin, although it is possible that both factors may operate simultaneously." The concept of two forms of diabetes, type 1 [formerly juvenile-onset or insulin-dependent diabetes mellitus (IDDM)] and type 2 [formerly adult-onset or non-insulin-dependent diabetes mellitus (NIDDM)], became accepted and has helped greatly with communication on the subject. Although communication with laymen and professionals was enhanced, this simplistic terminology can overlook the complexity of the diabetic syndrome. The classic review by Fajans et al. in 1978 pointed out the variability of the syndrome that this disease can present to physician and researcher alike (88).

The criteria for the diagnosis and classification of diabetes have continued to evolve with the accumulation of new knowledge. The 1979 report was updated by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus in 1997 and then modified in 1999 to make some changes in the diagnosis of gestational diabetes (89). The major categories now include types 1 and 2 diabetes described by Arabic numbers rather than Roman numerals. The "other specific types" include various genetic, endocrinopathic, drug-induced, and infectious causes. Gestational diabetes has its separate criteria. A particularly important category is impaired glucose tolerance (IGT) for which the term impaired fasting glucose (IFG) is now often used. One of the major changes in 1997 was the increased emphasis upon fasting plasma glucose levels, with the cut-off for diabetes being lowered to 126 mg/dL (7.0 mM) from the earlier value of 140 mg/dL (7.7 mM).

Efforts have continued to update the classification and clarify diagnostic criteria in a drive to enhance promulgation of information on this topic. Each January, the clinical organ for the American Diabetes Association produces a supplement to the journal *Diabetes Care* entitled "Clinical Practice Recommendations." This issue contains position statements and a summary of revisions to the practice recommendations of the association.

Oral Hypoglycemic Agents

The introduction of sulfonylurea agents in 1955 provided a valuable treatment option for insulin-fearing patients and provided a new tool for research. The earliest sulfonylureas gave way to second-generation and third-generation agents (Chapter 41). In 1957, at a symposium on these agents held at the New York Academy of Sciences, Rachmiel Levine encapsulated the past and predicted the future in the following excerpt from his concluding remarks (93). "To me the most important aspect of the research in this field has been the stimulus it has provided to renewed work on the etiology of diabetes mellitus and on the synthesis of insulin, its storage, and the control of its release. We may say that, in addition to stimulating the B cells, the sulfonylureas have stimulated the investigators." Other oral agents soon followed, with the biguanide metformin succeeding over phenformin, which was discredited because of concerns about lactic acidosis. The α -glucosidase inhibitors (acarbose and miglitol) became more widely used in the 1980s. The thiazolidinediones were introduced in the 1990s, although troglitazone (Rezulin) was rapidly withdrawn because of hepatic toxicity; however, pioglitazone and rosiglitazone are now in widespread use. Other recent additions include the nonsulfonylureas repaglinide and nateglinide that work through pathways similar to those of the sulfonylureas but have shorter half-lives.

The Diabetic Control Controversy

Any history of diabetes since the discovery of insulin would be incomplete without an explanation of the control and complications controversy [see Chapter 48 and (94)]. The first generation of physicians after the discovery of insulin, many of whom had cared for dying patients during the decade before 1923, felt that tight control of diabetes by blood glucose and urine determinations was of paramount importance. In the 1920s, Joslin, having been interested in diabetes as long as any physician at that time, thought that the careful treatment of diabetes would lead to partial remission of the condition. He felt that restricted nutrition had been helpful in prolonging the life of some patients between 1915 and 1923 and that these dietary measures should be extended with modification to the insulin era. Other practitioners, however, felt that with the advent of insulin treatment, the diet could be greatly liberalized. Therefore, the diabetic "diet" became the target of debate in the earliest years of insulin use.

The founding members of the American Diabetes Association quickly became polarized on this issue. For instance, Joslin, along with H. Ricketts of Chicago, often faced off with H. Mosenthal and E. Tolstoi of New York City (95). Indeed, about the time of the 25th anniversary of insulin, Tolstoi wrote a monograph that was a rallying cry for "purely symptomatic" care of diabetes (96). Some of the best summaries can be found in debates published in 1966 (97) and 1974 (98) entitled *Controversies in Internal Medicine*. The earlier dialogue on diabetes entitled "Are the Complications of Diabetes Preventable?" had Alexander Marble of the Joslin Clinic and Harvard Medical School paired off with Philip Bondy of Yale Medical School. As usual, these discussions were energetic but inconclusive. All agreed this area would be aided by future prospective studies.

The considerations regarding the value of "loose" or "tight" control led to the development of a well-intended, but flawed, long-term prospective clinical trial with insulin, oral agents, and diet called the University Group Diabetes Program (UGDP). This study that was concluded in 1970 failed to show that "improved control" prevented or slowed the development of complications (99). These findings caught the attention of the entire medical community in 1970 and were subsequently debated and discussed almost ad infinitum in the literature (100,101). Although the UGDP study was a laudable attempt, if it were designed today, the protocol would no doubt be quite different. However, because no effort has been made to repeat the study, the conclusions are largely ignored today, although the package inserts for the sulfonylureas state that they are to be used with some caution.

A decade later, the National Institute of Diabetes, Digestive and Kidney Diseases developed a study called the Diabetes Control and Complications Trial (DCCT), which was focused on insulin therapy only and confined its analysis only to patients with type 1 diabetes (14). In 1993, the results of the DCCT were reported, with the remarkable finding that almost all of the 1,441 patients from 29 centers completed the study. The major conclusion was that intensive control of the blood sugar over a 7-year study interval reduced the progression of diabetic

12 JOSLIN'S DIABETES MELLITUS

retinopathy, nephropathy, and neuropathy but also resulted in a threefold increased risk of serious hypoglycemia.

The relationship between control and complications in type 2 diabetes was evaluated in the United Kingdom Prospective Diabetes Study (UKPDS) (102,103). This study of 14 years' duration enlisted more than 5,000 patients with newly diagnosed diabetes, who were followed up for an average of a decade. The study concluded that for every 1% decrease in glycosylated hemoglobin A_{1c} (Hb A_{1c}) there was a 35% reduction in the risk of microvascular complications. Although the effect of reduction in glucose levels on macrovascular complications was of marginal statistical significance, the importance of blood pressure improvement with regard to cardiovascular events was clearly shown.

These two studies, coming as they did at the end of the 20th century, gave patients with diabetes and their care team solid confirmation of the benefits of good control, thus ending nearly 50 years of divisiveness and confusion on this central matter in the treatment of the disease.

Advances in Diabetes Management

Advances in the medical management of diabetes over the past 50 years have had a major impact on the attainment of better glycemic control. Equally important is the recent effort to provide financial mandates to cover the cost of diabetic medical supplies, including the insulin pump delivery units, along with reimbursement of patient instruction (104). For the past two decades these technical and economic gains have facilitated regimens that more accurately mimic normal insulin action patterns, allowing for some patients to reach near-physiologic control (105).

SELF-MONITORING OF BLOOD GLUCOSE

Replacement of urine testing by self-monitoring of blood glucose (SMBG) beginning in the late 1970s represents the single most important advance in fostering better management of diabetes since the introduction of insulin. The "Benedict" urine test introduced in 1911 by the chemist S. R. Benedict (1884–1936) was time consuming and odorous in preparation. With the advance of glucose oxidase-impregnated paper strips or the "Clinitest" tablets introduced in the 1950s, the use of urine glucose measurements remained, at best, a crude indicator of control. SMBG, introduced first by the glucose oxidase strip method, was a significant advance in management, contributing greatly to the patient's sense of control over treatment. In recent years an array of models have been marketed by more than a half-dozen medical technology firms in the United States and Europe. Some of the improvements include requirements for less blood, faster readings, and computer storage of measurement results. Newer but still unproved approaches to glucose monitoring include a watchlike device that can measure glucose on fluid driven through the skin by the process of iontophoresis (106) and a subcutaneous needle device with a tip impregnated with glucose oxidase that allows continuous measurement of glucose levels (107). Both approaches need frequent calibration and require further refinement.

GLYCOSYLATED HEMOGLOBIN

In the late 1970s, the glycosylated hemoglobin assay gained rapid application. The use of this property of glucose to bind to hemoglobin was noted serendipitously in 1968 when an investigator discerned that a subgroup of subjects with diabetes had a marked difference in the minor hemoglobin fraction during an electrophoresis analysis (108,109). The hemoglobin moiety most often used is HbA_{1c}. This property provides a practical and objective means of assessing average blood glucose levels over a time frame of about 2 months and has proven to be a very useful adjunct to SMBG.

INSULIN DELIVERY

The development of fine needles (up to 29 gauge) has made it easier for many patients to switch to multi-injection insulin therapy, this being especially helpful for children. Continuous subcutaneous insulin infusions (CSII) via pumps had limited popularity after their introduction in the early 1980s (110), but in recent years, along with their becoming smaller and more sophisticated, their popularity has increased.

NEW INSULINS

In the past decade and a half, fierce competition for patient allegiance to a brand name of insulin has intensified. The European company Novo acquired its competitor Nordisk to become Novo Nordisk and entered the American market, vying with Eli Lilly. Both companies attempted to increase their market share by various means, including various "insulin pen" delivery systems with their convenient "dose-dialing" features. Further competition has come from Aventis, which introduced the longacting insulin glargine, a recombinant insulin analogue that is growing in popularity. Other insulin analogues include lispro and insulin aspart, which are short-acting insulins designed to cover meals. These insulins have made it easier for people to use more intensive approaches with multiple injections when a pump is not suitable or available.

DIET

Despite the growing epidemic of worldwide obesity, dietary options for persons with diabetes have became more diversified, with the steady appearance of a wide variety of foods with fewer calories. Carbohydrate-free soft drinks and low-fat foods have become options for menu planning of health-conscious Americans. The "Mediterranean"-style diet consisting of a preponderance of fish, pasta, and olive oil has gained favor, especially in advancing low-animal-fat substitutions in the so-called "Western" diet. However, recent reviews have highlighted a threefold increase over the past 30 years in childhood obesity, with a concomitant increase in type 2 diabetes. One factor noted is the neglect of the old guide of a "measured" diet, ironically not for its once dreaded "sugar" content of menus of the early insulin era but for an equal emphasis on total caloric intake of each meal (111). Emphasis on "portion control" of all categories of food is now seen as a strategy equal to the need to decrease animal fat in the diet (111). Restaurant and fast-food establishments have made sporadic attempts to offer "heart-healthy" and low-calorie selections, and the food industry has been mandated into providing better food labeling. The use of more intensive insulin regimens, such as "carbohydrate counting," to help plan premeal insulin doses has become more widespread (see Chapter 36).

In summary, in the past decades these advances have given an impetus to a changed role for the person with diabetes from a dependent "patient" to an active participant in control of his or her diabetes management. These improvements in technology have also led to a shift to a "consumer" attitude, as cost and quality comparisons of medical equipment and diet choices became evident. Recent estimates of healthcare expenditures have shown that the costs of caring for persons with diabetes are about three times those for persons without diabetes (112). Despite the rationing of health insurance coverage by managed-care organizations in the past 20 years that usually limited payment for diabetes education and supplies, patients' rights groups have prevailed in many state legislatures, forcing insurance companies to cover these services. Another encouraging trend is the inauguration of standards of care, often developed by the American Diabetes Association, that have been employed by various health plans.

Treatment Advances for Diabetes Complications

Complementing the arrival of practical management aids to help with glycemic control of diabetes has been the progressive improvement in the treatment of complications. Limb salvage arterial bypass operations have continued to become more efficacious, as have coronary bypass and angioplasty procedures. It is now common for octogenarian diabetic patients with cardiac risk factors to undergo femoral artery bypass surgery, with this being facilitated by modern anesthesiology and improved postoperative care. The pharmacologic revolution in the hypertension-cardiovascular area has become a boon to the vascularly compromised patient with diabetes.

Treatment of end-stage renal disease for all age groups is another example of the remarkable advances in the treatment of life-threatening diabetic complications. A very important step was taken in 1972, with the passage of legislation by Congress stipulating that chronic renal failure was to be covered as a disability by Medicare (113), which made it possible for many more people with diabetes to be treated with dialysis or transplantation.

One of the most impressive improvements in the quality of life for the person with diabetes has been the development of laser treatment for diabetic retinopathy. This advance followed earlier complex and less efficacious treatments such as pituitary ablation and the futile use of various medications. Laser therapy moved rapidly from the research phase to acceptance and use. The multicenter Diabetes Retinopathy Study started in 1971 and reached the conclusion by 1975 that laser therapy was very effective in preserving vision and preventing blindness (114). Furthermore, the Early Treatment of Diabetic Retinopathy Study, which was completed in 1990, clearly showed that laser treatment could preserve vision in patients with macular edema (115). Thus, laser treatment, coupled with the new devices and aids that help the visually handicapped, has had a major impact on people with diabetes.

Advances in Diabetes Research (1960 to the Present)

The development of the radioimmunoassay for insulin in 1960 led to important insights about insulin secretion and helped clarify some of the differences between type 1 and 2 diabetes (116). A few years later, it was determined that proinsulin was a biosynthetic precursor for insulin, which provided a fundamental insight into how cells process proteins and led the way to the useful radioimmunoassay for C-peptide. The insulin gene was cloned in 1977, which made human insulin available for clinical use and helped bring diabetes research to the new era of molecular biology. This recombinant technology also has permitted the development of the insulin analogues that are now in widespread use. During the past 40 years, research institutions around the world have been engaged in studies that impact on cause, prevention, and improvement in the treatment of diabetes, providing remarkable advances in many areas.

CELLULAR AND MOLECULAR BIOLOGY

The new technologies in the areas of molecular biology, biochemistry, and cell biology have greatly increased our understanding of how cells work at a basic level. This has led to a much deeper appreciation of such areas as insulin action; glucose transport; the function of muscle, adipose, liver, vascular, and islet cells; cellular growth and differentiation; and the biochemistry of the complications of diabetes.

METABOLISM

There have been important advances in the understanding of whole-body metabolism. Much of this has been made possible with the use of such technologies as stable isotopes, magnetic resonance imaging, positron emission tomography, and sophisticated analyses of biopsy specimens. There is a much improved understanding of fuel fluxes between organs, with delineation of the contributions of gluconeogenesis, glycogenolysis, lipogenesis, and lipolysis. Important new insights have emerged in the areas of exercise and weight maintenance. The complex contributions of the central nervous system, the autonomic nervous system, and the gastrointestinal tract to metabolism are now far better understood.

PATHOPHYSIOLOGY AND GENETICS OF DIFFERENT TYPES OF DIABETES AND OBESITY

Work in only the past 30 years has made it clear that type 1 diabetes is caused by an autoimmune process with strong genetic determinants, particularly from the human leukocyte antigen (HLA) system (117). Antibodies to β -cell antigens have proved to be very useful markers of autoimmunity, allowing the process to be identified years before the onset of hyperglycemia and thus allowing prediction, which opened the way to trials focused on prevention (118). For type 2 diabetes, there is now general appreciation that its development is usually dependent on both of two major processes: insulin resistance that results from a combination of our modern sedentary, foodabundant lifestyle and failure of β -cells to compensate adequately. Genetics is known to play a major role in the susceptibility to type 2 diabetes. In addition to types 1 and 2 diabetes, other discrete forms of diabetes are being defined. These include the MODY (maturity-onset diabetes of the young) forms of diabetes, most of which are now known to be caused by genetic defects in transcription factors that are important in islet development and function. Another form of MODY (MODY 2) is caused by mutations of the glucokinase gene. Another form of diabetes that is better understood at a molecular level is caused by mutations in mitochondrial DNA that lead to defective β -cell function. There has been an explosion of studies of obesity, with the identification of many peptide mediators that appear to be critically important for the control of food intake, including leptin, melanocortin, ghrelin, peptide YY (PYY), and neuropeptide Y (NPY).

VASCULAR CELL BIOLOGY AND COMPLICATIONS

There have been major advances in understanding the molecular basis of large- and small-vessel disease and in understanding the pathogenesis of diabetic nephropathy and neuropathy. The process of atherosclerosis is now better understood, and much is being learned about the abnormalities in vascular reactivity that occur in the early stages of disease. A great deal is now known about lipid metabolism, and the widespread use of statin drugs to lower low-density lipopolysaccharide (LDL) cholesterol appears to be having a significant impact. An important example of the progress made in understanding the pathophysiology and genetics of hypertension is the extensive use of angiotensin-converting enzyme (ACE) inhibitors for the treatment of hypertension, congestive heart failure, and diabetic nephropathy. The roles of vascular endothelial growth factor and protein kinase C in the development of microvascular disease are being defined.

14 JOSLIN'S DIABETES MELLITUS

β-CELL REPLACEMENT THERAPY

A great deal of attention is now being focused on the potential of β -cell replacement therapy, which could be important for both types 1 and 2 diabetes. The first successful pancreas transplants were performed in the 1960s, and by the 1980s the treatment had become available at many medical centers. It is hoped that transplantation of islets alone will supersede the transplantation of whole organs because the morbidity associated with islet transplantation is so much lower. After initial success with rodent islet transplants in the 1970s, the first serious islet transplants were carried out in the 1990s, with few of the recipients becoming insulin independent. The greatly improved results reported by workers in Edmonton, Canada, in 2000 have given new energy to the field. This success seems to be due to the use of a steroid-free immunosuppression regimen, the use of rapamycin, and the provision of enough high-quality islets, with two or more donor cadaver pancreases usually being necessary. The major problem facing islet transplantation is the shortage of insulin-producing cells due to the small number of cadaver donors. Many investigators are now joining the search for an abundant supply of insulin-producing cells, with considerable hope being placed in the potential of both adult and embryonic stem cells

THE DIABETES RESEARCH ENTERPRISE

Starting in the late 1990s, the interest of the diabetes community in increasing funding for diabetes research was greatly intensified, resulting in planning and lobbying on many fronts. In 1999 a congressionally established diabetes research group published a report entitled *Conquering Diabetes: A Strategic Plan for the 21st Century* (119). This group described the current state of knowledge about diabetes and developed a plan of priorities for areas of research needing more attention. Recognizing the personal toll of diabetes, the financial costs that exceeded \$100 billion annually, and impressive research opportunities, they recommended marked increases in spending for diabetes research from the fiscal year (FY) 1999 National Institutes of Health (NIH) budget figure of \$442.8. In FY2001, the NIH expenditures for diabetes reached \$720.5 million. The Juvenile Diabetes Research Foundation also reassessed its priorities and fund-raising strategies. While more sharply focusing its goals, it increased contributions to diabetes research from \$27.7 million in 1997 to \$115 million in 2001. The American Diabetes Association has also placed more emphasis on raising funds for diabetes research, as have an important number of private foundations. In addition to the work being done in academic laboratories in the United States, institutions in many other countries place a high priority on diabetes research. Moreover, industry has made major investments in developing new treatments for people with diabetes.

The Worldwide Epidemic of Diabetes

Today the United States 2000 census serves as an updated warning about race and its relationship to diabetes (120). The Hispanic population in the United States has grown by 61% in the past 10 years to the 25 million level, and there has been a 20% increase in the African-American population. These figures alone predict heavy pressure on healthcare budgets, as the diagnosis of diabetes is more prevalent in these population groups. In addition, people in many countries, especially the United States, are becoming heavier, more sedentary, and older, which further increases the prevalence of type 2 diabetes. The increase in type 2 diabetes in children is an even more startling trend (Fig. 1.4) (111). The reports of the World Health Organization (WHO) in the past decade have seen a march in prevalence of worldwide diabetes from 100 million a decade ago to 135 million in 1995, 151 million by 2000, and a projected number of 221 million by 2010 (121–123).

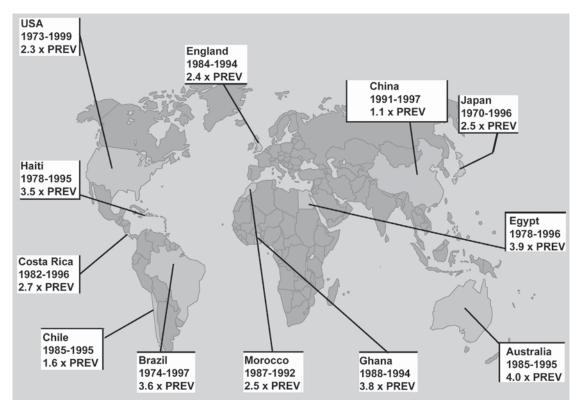

Figure 1.4. Global increase in prevalence (PREV) of childhood obesity—predictor of type 2 diabetes in youth. (Modified from Ebbeling CB, Pawlak DB, Ludwig DS. Childhood obesity: Public-health crisis, common sense cure. *Lancet* 2002; 360: 476.)

Prevention of Diabetes

After World War II, a combination of factors promoted the understanding of diabetes as a rising health problem in the world. Following the example of the British Diabetes Association in 1934, other organizations concerned with diabetes were founded in rapid succession, including WHO in 1948 and the International Diabetes Federation in 1952. These two latter organizations collaborated, and by the 1980s, three international standard reference documents on public health aspects of diabetes became available. Along with this development, a variety of study groups under the auspices of WHO began collecting data on many aspects of diabetic complications. These developments formed the initiative for preventive care programs at the regional level (121). Following the Oxford Study of 1947, the American Diabetes Association launched a nationwide detection drive that became a popular part of the Association's annual goal of lay education.

During the Nixon administration in the 1970s, the United States embarked on "crusades" against important diseases. A congressional mandate led to the National Commission on Diabetes in 1976, which led to a comprehensive report on diabetes and established centers to foster research and translate these findings to the diabetic population (124).

An appreciation of the relation of diabetes to both societal and genetic factors increased. A common denominator accounting for a growing diabetes population is the phenomenon of the migration of agrarian peoples to urban centers during time of war or industrialization. The resultant inactivity, coupled with obesity, has no doubt been responsible for most of the increase in the incidence of diabetes.

Interventions in lifestyle have been recently studied in the "prediabetic" person with IGT. A small reduction in weight and an increase in exercise led to a substantial reduction in the development of diabetes (125,126). The appearance of diabetes was also delayed by the pharmacologic agent metformin (126).

The U.S. Postal Service recently produced a Diabetes Awareness stamp (127) (Fig. 1.5) and publicized the fact that 8% of the current population (18 million) has diabetes (127). Figure 1.5 represents diabetes in the United States at a figure double the 4% estimate found in Joslin's 1947 Oxford, Massachusetts, study (84), underscoring the true extent of the diabetes epidemic in the United States.

Organizational Growth

The organization and mobilization of worldwide resources in the fight against diabetes by researchers, clinicians, and persons with diabetes themselves have been some of the most remarkable

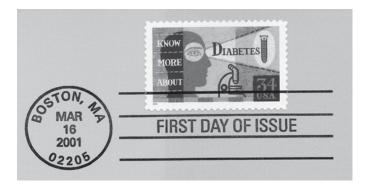

Figure 1.5. Diabetes Awareness Stamp, first issued on March 16, 2001, by U.S. Postal Service. United States, 8% prevalence rate (122); 4% rate in 1947 (84).

advances of the past several decades. In 1935, the British Diabetes Association was established under the sponsorship of two celebrities who had diabetes: H. G. Wells, the writer, and R. D. Lawrence, a physician, who was one of the first persons in the country to receive insulin. The organization was largely a lay endeavor. In 1937, a group of U.S. physicians interested in diabetes met during a meeting of the American College of Physicians in New Orleans (128) and after many discussions started the American Diabetes Association (ADA) in 1941. The first meeting, held in Cleveland, Ohio, on June 1, 1941, was attended by about 300 physicians who discussed the scientific aspects of diabetes. Cecil Striker of Cincinnati was the founder and first president. The ADA grew rapidly, and by 1960, there were more than 25,000 members. The organization, which had started as a physicians-only group, recognized that its many goals could be fulfilled only by including laypersons, particularly those with diabetes, and other interested parties.

Vigorous growth of the ADA has continued, and it is now at the forefront of all issues relating to diabetes, with more than 9,000 professional members and 250,000 general members. The ADA raises money for research, hosts meetings, publishes four journals, and is concerned with every aspect of the well-being of those with diabetes. One of its major publications for the lay public is the journal *Diabetes Forecast*, which started with a circulation of 50,000 in 1948 and now has a worldwide circulation of 275,000.

The need for more emphasis on funding for research also spawned the Juvenile Diabetes Research Foundation in 1970, whose primary goal is the prevention and cure of juvenile diabetes through increased research. This same movement toward research and education was taking place in Europe, where the European Association for the Study of Diabetes was formed for similar purposes in 1965. Paralleling these developments was the organization by diabetes educators of the American Association of Diabetes Educators, which has played a key role in training and certification.

Because diabetes is a problem in virtually all nations, there was recognition of the need for attention to the problem. In June 1949, the president of the Belgian Diabetic Association, J. P. Hoet; his counterpart from England, R. D. Lawrence; and 75 other physicians and patients from 11 countries discussed their mutual problems. Meeting again in Amsterdam in 1950, they started the International Diabetes Federation (IDF) (129), with one lay delegate and one medical delegate from each country. The First Congress of the new organization was held in Leiden, The Netherlands, in 1952, attracting 241 representatives from 20 countries. Recent meetings held in Helsinki (1997) and Mexico City (2000) have hosted more than 8,000 attendees. The IDF is a confederation of some 85 world diabetes associations, the largest of which is the ADA, which has developed many education and service programs worldwide. Increasingly, its direction is moving toward regions that need the most help, with valuable assistance and coordination coming from WHO, the health arm of the United Nations.

CONCLUSION

As we start a new millennium, writers of medical publications, especially texts like this, can reflect on past events that have made "a difference" in the lives of the sick. The *New England Journal of Medicine* has assessed this progress in clinical medicine over the past thousand years and pointed out that most of the advances have occurred in the past century. Specifically, the dozen examples cited that gave the "greatest benefit to mankind" in the form of a longer life included the treatment of diabetes (130).

16 **IOSLIN'S DIABETES MELLITUS**

These advances have coincided with the 87-year interval since the publication of the first edition of Joslin's first monograph in 1916 and help explain the need for a book of this size to describe the condition. When one views the spectrum of progress named in this historical overview, ranging from a greatly increased understanding of the pathophysiology of diabetes all the way to the continued advances in the prevention and treatment of diabetes and its complications, the adage "to know diabetes is to know medicine" becomes axiomatic (47).

The 21st century will continue to focus on the premise that the diabetic state may really be *prevented* or *cured* through the power of modern science, targeting interventions at the genetically prone person that are aimed at correcting core abnormalities before they emerge. Such advances should bring preventive medicine into a realm never envisioned by Elliott Joslin, a true pioneer in the field.

CONCLUSION 36

The vertebrate pancreas is an essential organ, responsible for both digestion and glucose homeostasis. The pancreas is also the sole source of insulin production in vertebrates, and impairment leads to a major health problem, diabetes mellitus. Current research on early development of the pancreas is aimed at elucidating the generation of pancreatic cells and the genetic mechanisms underlying

the anatomy and physiology of the pancreas. More specifically, the central goals of pancreas developmental studies include mapping of the spatiotemporal origins of endocrine cells and the identification of key genes that determine endocrine character. These studies also examine regulatory factors that direct the proliferation and differentiation of the pancreas from its initial commit-

ment in the endoderm through morphogenesis and growth during postnatal life. The possibility of islet neogenesis *in vitro* and transplantation as a potential treatment for diabetes makes the study of the basis for β -cell development and insulin production particularly significant (1). In addition, the prospect of using pluripotent stem cells to generate an unlimited supply of β -cells underscores our need to understand the regulation of normal endocrine cell generation in the embryo (2).

In this chapter, we will present studies on the development of the pancreas in humans and in model organisms, including mice, rats, chickens, and frogs (3-6). Fundamental genetic mechanisms controlling germ layer and organ development are highly conserved throughout evolution, and conclusions drawn from model organisms can often be extrapolated generally. We will first review the principal landmarks of pancreatic function and anatomy. We define fundamental cell types that comprise the pancreas and examine in detail the commitment, patterning, and morphogenesis of the pancreas. We also discuss cell-lineage relationships among pancreatic cells, providing insights into the origins of endocrine cells. In addition, we introduce current research on putative pancreatic stem cells and the potential for therapeutic applications. Last, we will briefly review some of the important transcriptional regulators and growth factors demonstrated to play critical roles during islet development.

THE PANCREAS

General Anatomy

The human pancreas is a racemose, lobulated gland that weighs 60 to 170 g, is 13 to 25 cm long, and is located just caudal to the

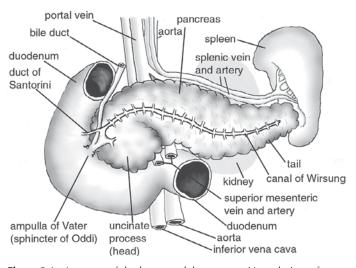

Figure 2.1. Anatomy of the human adult pancreas. Ventral view of pancreas; anterior is toward the top of the page. The body of the pancreas lies posterior to the stomach and extends laterally from the duodenum to the spleen (stomach has been omitted at top of figure). The head of the pancreas is tucked into the curvature of the duodenum, and the tail of the pancreas contacts the spleen and left kidney. The principal excretory duct, or the canal of Wirsung, spans the length of the pancreas and connects to the duodenum via the ampulla of Vater, where it joins the bile duct. The sphincter of Oddi, within the ampulla of Vater, regulates secretions from the pancreas into the gastrointestinal tract. An accessory pancreatic duct, or the duct of Santorini, joins the duodenum more anteriorly. The posterior portion of the pancreas, or the uncinate process, extends behind the superior mesenteric artery and vein. The body of the pancreas lies in proximity to multiple large blood vessels, including the portal vein (connected to the splenic vein and superior mesenteric veins), the aorta (connected to the splenic and superior mesenteric arteries), and the inferior vena cava.

stomach and opposite the liver along the gastrointestinal tract (7,8) (Fig. 2.1). Its head (proximal portion) lies in the crook of the duodenum, and its tail (distal portion) contacts the spleen. It is also in juxtaposition to a number of large blood vessels, including the aorta, the inferior vena cava, and the superior mesenteric vein and artery and is in direct contact with the portal and splenic veins (8). The pancreas consists primarily of exocrine, endocrine, and ductal cell types that together with a blood supply coordinate to regulate nutritional equilibrium. The exocrine function of the pancreas is carried out by acinar cells, which secrete digestive enzymes and other nonenzymatic components into the duodenum. Acinar cells are located at the tips of the smaller ducts, which connect to an extensive system of larger ducts and in turn join the primary excretory duct of the pancreas. This duct, also called the canal of Wirsung, extends transversely through the body of the pancreas and connects to the duodenum at the ampulla of Vater, where it joins the common bile duct (9). The endocrine function of the pancreas is carried out by the islets of Langerhans. These are compact, spheroid clusters of cells scattered throughout the more abundant exocrine tissue. Islets consist of four different cell types that secrete hormones into the bloodstream to regulate glucose homeostasis. Islets are therefore penetrated by a network of fenestrated microvasculature and nerve fibers that help administer this regulation (10-13). It has long been observed that both endocrine and exocrine cells originate in the pancreatic endodermal epithelium and then migrate into the surrounding mesenchyme before undergoing differentiation (14-17).

The Exocrine Pancreas

The exocrine pancreas constitutes the bulk of pancreatic tissue and comprises primarily acinar cells. Acinar cells are organized into acini, which are epithelial pouches located at the tips of a branched network of ducts (Fig. 2.2A,D). These secretory cells are linked to each other by large gap junctions and are flanked by centroacinar cells at the neck of the acini. Acinar cells are pyramidal in shape and contain an extensive secretory apparatus at the apical end, including numerous zymogen granules (18). These granules contain digestive enzymes, including amylases, proteases, nucleases, and lipases, which are secreted into the duodenum. Initially, these are produced and secreted as inactive proenzymes, which are then activated by limited proteolysis once they enter the digestive tract. The ducts connect the acini and constitute a tubular epithelial network that is continuous with the gut tube. It is through the ducts that the exocrine secretions are transported into the duodenum. The duct cells produce mucins and a bicarbonate-rich fluid, which is used to neutralize the acidic product of the stomach (19). The ducts contain scattered endocrine cells, and it has been hypothesized that the ducts include a population of precursor cells that can give rise to endocrine and exocrine cells (6,17,20).

The Endocrine Pancreas

The endocrine function of the pancreas is performed by a number of cell types in the islets of Langerhans. These structures were identified by the German physician Paul Langerhans in 1869. Islets are tight aggregations or clusters of cells embedded in the surrounding exocrine tissue. There are four cell types found in pancreatic islets: α -cells, β -cells, δ -cells, and PP-cells (pancreatic peptide; also called γ -cells) (Fig. 2.2A–C). The β -cells are the majority of the endocrine cell population of the pancreas and secrete insulin, the insulin antagonist amylin, and other peptides (21). Insulin release is stimulated by high glucose levels, as well as by glucagon, gastric inhibitory peptide, epineph-

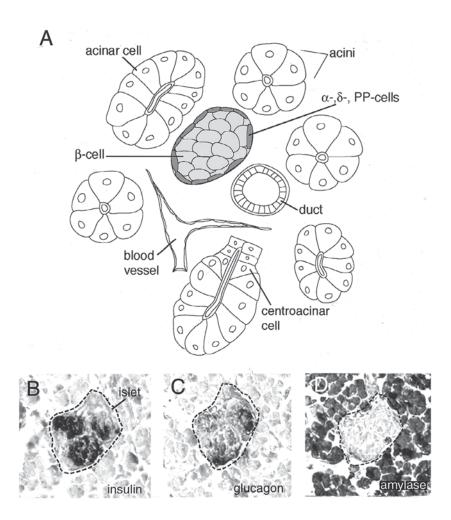

Figure 2.2. Principal pancreatic cell types. A: Schematic representation of cell types in the pancreas. An islet is surrounded by more abundant exocrine tissue. β-Cells (light gray) and peripheral non-β-cells (dark gray) are indicated. Acini are composed of acinar and centroacinar cells. A duct and blood vessel are also represented. Both form extensive networks throughout pancreatic tissue, and usually lie in proximity to islets. **B–D:** Adjacent sections through an islet in pancreatic tissue of an E18.5 mouse embryo stained using antibodies to pancreatic gene products. B: β-Cells clustered within the islet. Immunostain for insulin. C: β-Cells located at the periphery of the islet. Immunostain for glucagon on adjacent section to B. D: Exocrine tissue composed of acinar cells surrounding the islet. Immunostain for amylase on adjacent section to C.

rine, and increased levels of amino acids (see Chapter 6). β -Cells are polyhedral and packed with secretory granules (22). The α -, δ -, and PP-cells secrete glucagon, somatostatin, and pancreatic polypeptide, respectively. In most mammals, the β -cells lie in the middle of the islet and are surrounded by a thin layer of α -, δ -, and PP-cells (one to three cells thick) (23). These peripheral cells are smaller than β -cells and are also well granulated. In humans and other primates, the concentric segregation of cells within the islet is less defined, with islets sometimes taking on oval and cloverleaf patterns (24,25). The endocrine cells that produce some islet hormones are found in other regions of the gut; however, within the endoderm, insulin-expressing cells are found only in the pancreas (26).

In the islets of the mature human pancreas, β -cells constitute approximately 70% to 80% of the islet mass; α -cells, approximately 15% to 20%; δ -cells, approximately 5%; and PP-cells, up to 1%. The pancreas of an adult human of average weight (70 kg) contains between 300,000 and 1.5 million islets (27), adult mice have approximately 100 to 200 islets (JM Wells and DA Melton, unpublished observations), and some fish have a single islet (28). Hormones produced by the islets appear sequentially during development, and the order of appearance varies slightly among different organisms. In the mouse embryonic pancreas, differentiated glucagon cells first appear at E9.5 (9.5 days postconception) followed by insulin-expressing β -cells at E10.5, and finally by somatostatin- and PP-expressing cells at E15.5 (29,30). Endocrine gene transcription, however, can be detected earlier. Somatostatin transcripts are first detectable throughout the foregut epithelium at E8; insulin and glucagon transcripts are found a day later at E9; and last, pancreatic polypeptide is detectable at E10 to 10.5 (31). Transcription of exocrine genes begins slightly later than that of all endocrine genes. Despite the synthesis of endocrine hormones during embryogenesis, it is unclear whether islets are actually functional at this time. In mouse embryos, endocrine cells respond to glucose only after fetal day 18 (32).

Overview of Pancreatic Development

In the early rodent embryo, the pancreas derives from distinct dorsal and ventral endodermal evaginations caudal to the developing stomach (33) (Fig. 2.3A,B). The dorsal bud becomes evident slightly before the ventral bud. The buds then grow and proliferate rapidly into highly branched structures. As the epithelium grows, it depends on its intimate association with a growing cap of mesodermal mesenchyme surrounding it (34,35). The dorsal and ventral anlagen then fuse during gut rotation, when the ventral bud rotates around the duodenum and joins the dorsal bud on the dorsal portion of the gut tube (Fig. 2.3C,D). The dorsal bud will form the largest portion of the pancreas, including part of the head and all of the body and tail of the pancreas, while the ventral bud will form the posterior portion of the head. Exocrine, endocrine, and ductal cell types arise from the endodermal epithelium, whereas the mesenchyme forms smooth muscle and supportive tissue (36).

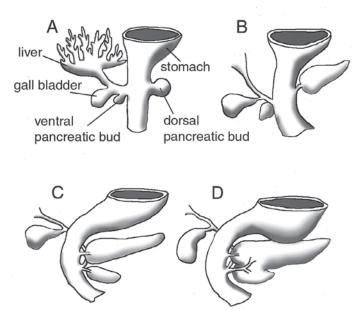

Figure 2.3. Development of the pancreatic primordia. All diagrams are ventrolateral views. A: Schematic drawing of the dorsal and ventral pancreatic evaginations located posterior to the stomach along the gut tube. The gallbladder and liver connect to the duodenum via the common bile duct. This stage of pancreatic development is comparable to an E10.5 mouse and to a human in the early 5th week of gestation. B: The dorsal pancreas grows and extends dorsally. The ventral pancreas rotates dorsally around the gut tube in the direction of the dorsal pancreas. This stage is comparable to an E11 mouse embryo and to a human in the late 5th week of gestation. C: After rotation of the duodenum and migration of the ventral pancreas, the dorsal and ventral pancreata come to rest in proximity. This stage is comparable to an E12.5 mouse embryo and to a human in the early 6th week of gestation. D: The dorsal and ventral buds fuse. The dorsal pancreas appropriates the ventral duct and the duct systems anastomose. This is comparable to an E14.5 mouse embryo and to a human in the late 7th week of gestation.

Although the key landmarks of pancreatic development have been investigated quite thoroughly, many questions remain. For instance: What are the early events that result in regionalization of the endoderm along the developing gut? What determines the position of committed pancreatic endoderm between the stomach and duodenum? Are there common signals that direct the formation of pancreatic buds on both the dorsal and ventral portions of the gut tube? What is the nature of the signals from the pancreatic mesenchyme to the endoderm that are necessary for later morphogenesis and cell differentiation? Most important for diabetes research, What are the specific combinations of factors that give rise to β -cells?

ENDODERMAL ORIGINS OF ENDOCRINE CELLS

Germ Layers

During gastrulation, three fundamental germ layers are established in the embryo: the ectoderm, the mesoderm, and the endoderm (Fig. 2.4). The ectoderm gives rise to the epidermis and nervous system. The mesoderm develops into the notochord, the muscle, the heart, the kidney, the vasculature, the gut mesenchyme, and the blood. The endoderm gives rise to a variety of organs along the anterior-posterior axis, more specifically that of the gastrointestinal and respiratory tracts (Fig. 2.5). Pharyngeal endoderm gives rise to the pharynx, as well as to portions of the thymus and thyroid gland. Foregut endoderm

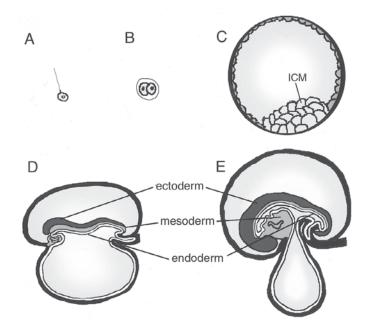

Figure 2.4. Schematic drawing of germ layer development in the early amniote. **A:** Fertilization of egg. Sperm binds to the oocyte zona pellucida. This occurs 12 to 24 hours after ovulation in humans. **B:** Two-cell stage, at approximately 30 hours after fertilization in humans. **C:** Early blastocyst stage embryo, prior to implantation at 5 days post-fertilization. Inner cell mass (ICM) cells give rise to the embryo and are surrounded by trophoblast cells, which give rise to the placenta. **D:** Germ layers of a seven-somite human embryo. Ectoderm (*dark gray*), mesoderm (*light gray*), and endoderm (*white*) are indicated. The endoderm lines the developing gut tube. The anterior and caudal intestinal portals are beginning to form. **E:** Embryonic germ layers of a 35-somite embryo. This represents the embryo at the end of the first month of gestation in humans. At this stage the anterior and caudal intestinal portals have met and the yolk stalk is constricting.

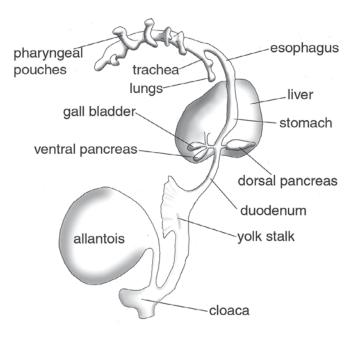

Figure 2.5. Stylized drawing of endoderm illustrating major landmarks of embryonic endoderm. Lateral view; dorsal is to the right and anterior is up. The pancreas develops from two evaginations of the endodermal epithelium that emerge posterior to the stomach and just anterior to the duodenum. The ventral pancreas originates adjacent to the gallbladder and liver along the common bile duct. The dorsal pancreas evaginates opposite the ventral bud on the dorsal side of the gut tube. (Adapted from endodermal derivatives of the 10 mm pig embryo, as drawn in Shumway W. *Vertebrate embryology*, 2nd ed. London: John Wiley and Sons, 1930.)

forms the esophagus, lungs, stomach, liver, gallbladder, and both the endocrine and exocrine cells of the pancreas. The midgut endoderm gives rise to the jejunum, the ileum of the small intestine, and the anterior colon; and the hindgut endoderm forms the caudal large intestine and rectum. In all cases, the endoderm generates primarily the epithelial lining of the organs. Splanchnic mesodermal mesenchyme surrounds the endoderm and is active in inducing and supporting its proliferation and morphogenesis.

Endoderm Formation in Amphibians

The genetic basis for endoderm cell specification is presently not well understood. The signals that determine endodermal cell fate remain largely unknown, although a growing number of candidate molecules are being identified, including members of the transforming growth factor– β (TGF- β), fibroblast growth factor (FGF), and Wnt (small secreted glycoproteins) growth factor families (37,38). It is also unclear at what point embryonic cells become determined to form endoderm. This process appears to be complete by the end of gastrulation because all three germ layers are identifiable at this time.

Studies in amphibians have identified a number of genes that can direct endodermal cell fate. In the frog Xenopus laevis, the endoderm arises from the vegetal blastomeres, which invaginate through the blastopore and become internalized. The fate of these blastomeres becomes increasingly restricted to endoderm after the mid-blastula transition, as shown by transplantation experiments (39,40). These experiments have suggested that both cell-autonomous and non-cell-autonomous mechanisms are involved in the initiation of early endodermal gene expression. Several nodal-related molecules (41-43) and two vegetally localized maternal determinants, Vg1 and VegT, have been implicated in the regulation of both mesoderm and endoderm (44,45). In addition, several endoderm-specific factors have been identified that can direct the fate of endodermal cells in a cell-autonomous fashion. For example, the transcription factors Mixer, Mix.1, and Sox $17(\alpha \text{ and } \beta)$ and the ribonucleic acid-binding molecule XBic-C are expressed exclusively in the early endoderm and can direct ectopic endoderm formation when expressed in ectoderm cells, such as animal caps (46-49). Furthermore, when dominant-negative forms of some these molecules are expressed in the endoderm, its formation is disrupted (50). Mammalian and avian orthologues of these endoderm genes have not yet been identified.

Endoderm Formation in Amniotes

In amniotes, the primitive streak is directly involved in endoderm cell fate specification. As cells delaminate from the epiblast and migrate through the primitive streak, they become committed to either a mesodermal or an endodermal cell fate (51). Lineage tracing shows that the definitive endoderm in mice and humans originates from a group of cells at the most distal end of the primitive streak (52). In chick embryos, the endoderm originates from the posterior third of the epiblast (53).

In mice, chimeric embryo experiments demonstrate that TGF- β signaling is required for the specification of the definitive endoderm. In these experiments, *Smad2* mutant embryonic stem (ES) cells extensively colonize ectodermal and mesodermal derivatives of the early embryo but are not recruited into the endoderm lineage during gastrulation (54). This reveals that *Smad2* signals promote recruitment of epiblast cells into the definitive gut endoderm. FGF signaling has also been implicated during endoderm formation. FGF-4 is expressed in the

primitive streak, and gene-targeting experiments demonstrate that FGF-4 is required for initial outgrowth of the epiblast (55). FGF-4 is also capable of inducing endoderm differentiation in a concentration-dependent manner and may therefore act as a posterior morphogen for endoderm in the embryo (56). In addition, FGF receptor 1 (FGFR-1) mutant ES cells fail to populate endodermal derivatives in chimeric embryo experiments (57). A direct role for other growth factors in mammalian endoderm formation remains under investigation.

Neural Origin of Endocrine Cells Refuted

For many years, it was postulated that endocrine cells might originate from the neural crest rather than from the endoderm (58–60), a theory based on the shared characteristics of islet and neuronal cells of "amine precursor uptake and decarboxylation" (APUD) (61). The APUD hypothesis received considerable attention because it seemed to be supported by numerous lines of evidence. Endocrine and neural cells express many of the same genes and share cytochemical and ultrastructural characteristics. For instance, pancreatic endocrine cells express the neuronal marker tyrosine hydroxylase, whereas neurons located in the neural tube express the insulin gene (62). In fact, a surprising number of genes are expressed in both tissues, including an L-amino acid decarboxylase (63), a specific acetylcholinesterase (64), a neuron-specific enolase (65), the glycoprotein synaptophysin (66), and the antigens PGP9.5 (67) and A2B5 (68). More recently identified genes that also are found in both tissues include Pax6, Isl1, Nkx2.2, and HNF-3B (see discussion below). Endocrine cells will extend neurites when grown in culture under certain conditions (69,70).

In addition to similar gene expression patterns of neural and endocrine cell types, analogies have been drawn between the mechanisms underlying the specification of these cell types. The neurectoderm and pancreatic endoderm are controlled, at least in part, by inductive interactions with the notochord (see below) (71). In addition, comparative studies in vertebrates and invertebrates have reinforced this intriguing link between endocrine and neural cells (33,72). For instance, somatostatinexpressing cells are found in the paired cerebral ganglia of the flatworm *Dugesia lugubris* (73). In hornworm moths and blowflies, all four pancreatic endocrine cell types are detected in the brain and the corpus cardiacum (74,75). In the invertebrate chordates, tunicates and amphioxus, both the brain and the gastrointestinal tract contain somatostatin-, PP-, and glucagonexpressing cells (72).

Despite all the evidence for a similarity and coincidence in gene expression, it is a mistake to conclude that cells expressing similar genes derive from a common precursor. Indeed, the neural origin of pancreatic endocrine cells has no direct support from experimental studies and, in fact, the hypothesis has been rendered untenable on the basis of chick-quail chimera lineage studies. In chick-quail chimera experiments, quail neural tube or neurectoderm is grafted to the endomesoderm of the chick and allowed to develop. Invariably, both pancreas and gut endocrine cells are shown to be of chick origin, thus demonstrating that the endocrine cells of the pancreas do not arise as a result of cellular migration from neural tissues (76,77).

PATTERNING OF THE GUT TUBE

Formation of the Gut Tube

In fish, birds, and mammals, the result of gastrulation is the formation of an endodermal sheet, which must be trans-

formed into a proper gut tube. This sheet overlies the yolk sac and first develops tubelike folds at the anterior and posterior extremities. Once formed, these blind cavities are called the anterior and caudal intestinal portals. As development proceeds, the portals move toward each other and meet at the increasingly constricted yolk stalk, leaving an endodermally lined tube in their wake. Cells originally at the midline of the endodermal sheet now constitute the dorsal midline of the embryonic gut tube. Cells originally at the lateral edges of the sheet are now located on the ventral side of the gut. Genetargeting experiments reveal that a number of genes are important for this gut folding and closure, including *GATA4*, its Drosophila homologue *Serpent*, the proprotein convertase gene *Furin*, and the bone morphogenic protein genes (*BMP1*, 2, 4, 5, and 7) (78–82).

Regionalization of the Gut Tube

How is this developing gut endoderm patterned along the anterior-posterior axis? The answer to this question is likely to be complex, and it is only beginning to be addressed. As previously mentioned, it is likely that a certain level of patterning occurs during gastrulation. Immediately after gastrulation, and before formation of the gut tube, the early mouse endoderm already expresses some genes in a regionalized manner. For instance, cerberus-like, Otx1, and Hesx1 are expressed in the anterior endoderm at this time, while the posterior endoderm expresses IFABP and Cdx2 (38,83-86). The factors that regulate this early regional expression of genes remain largely unknown, although members of the FGF family have been implicated (38). Numerous studies demonstrate that the endoderm continues to receive signals from adjacent mesoderm and ectoderm long after gastrulation and that these tissues are dependent on reciprocal signaling for proper differentiation (see discussion below). Once the gut tube is formed, it must undergo further anterior-posterior and dorsal-ventral patterning to ensure that prospective organ territories are appropriately assigned and that derivative organs develop at their correct location. Early endoderm regionalization is thus translated into patterning along the gut tube as a requisite prelude to organogenesis. Recent fate-mapping experiments and geneexpression analyses in a number of different organisms indicate that organs have overlapping presumptive domains that become restricted during development (87). The subsequent onset of organogenesis is evident as localized thickening and budding of the endodermal epithelium.

HOX GENES

Hox genes are excellent candidates for patterning molecules in the endoderm. Hox genes are expressed in sequential, overlapping patterns in the vertebrate mesoderm and ectoderm, and particular combinations of these genes lead to positional commitment along the anterior-posterior axis in the limb, vertebrae, and neurectoderm. Recent gene-expression studies in the chick embryo reveal that only a small number of Hox genes can be detected in the endoderm by in situ hybridization (87). However, the anterior expression boundaries of *Hox* gene expression in the surrounding intestinal smooth muscle match anatomic boundaries in the intestinal epithelium (88,89). When a posterior mesodermal Hox gene, Hoxd-13, is misexpressed in the midgut mesoderm, the underlying endoderm acquires a morphology reminiscent of the hindgut. Therefore, Hox genedirected positional information exists in the visceral mesoderm and this information is transmitted vertically to the underlying endoderm.

MORPHOGENESIS AND DIFFERENTIATION OF THE PANCREAS

Epithelial Budding

During vertebrate embryogenesis, the first morphologic sign of pancreatic development is an evagination of the dorsal endodermal epithelium and a condensation of the dorsal mesenchyme that lies above it. This pancreatic bud formation is evident at the 22- to 25-somite stage or E9.5 in mice (4,34), at the 30-somite stage or stage 15 in chickens (90,91), and during the fourth week of gestation in humans (92). Subsequently, approximately 12 hours later, the ventral bud becomes evident (Fig. 2.6A,B). The dorsal bud arises from the endodermal epithelium caudal to the stomach anlage and slightly caudal to the biliary duct. At this point, the liver has developed into a trilobular structure and is joined to the duodenum via the biliary duct. The ventral bud arises from epithelium at approximately the same anterior-posterior location as the dorsal bud but on the ventral side of the gut tube at the base of the biliary duct. Some organisms (such as the rat and human) have only one ventral bud and others have two (chick and frog) (93). In the mouse, two ventral buds are detectable transiently during bud evagination (93; E Lammert and DA Melton, unpublished observations).

Branching and Bud Fusion

As development proceeds, the dorsal pancreatic bud begins to proliferate and branch, progressively forming a tree-like structure (Figs. 2.7 and 2.8) (5,6). This process begins around the 25to 35-somite stage in mice (E10.5) and the 26-somite stage in chicks and continues throughout pancreatic development (6,90). Initially, the branching epithelium appears as a solid tissue; however, it actually consists of a compact bulb of highly folded epithelium. It has been hypothesized that branching occurs because the number of cells in the wall of the diverticulum increases while the bud remains the same size (6), causing lateral pressure until the epithelium buckles and produces a digitation. Unlike the branching that occurs in kidney epithelium, including both lateral and terminal bifid branching, or the asymmetric branching of lungs, pancreatic branching is not stereotyped (94,95).

After the 25-somite stage in mice (E10), mesodermal mesenchyme continues to condense around the pancreatic bud and accumulates on the left side of the gut tube, breaking the symmetrical morphology of the pancreatic rudiment (4). At this stage, islet structures begin to protrude from the pancreatic epithelium (14). Bud growth and elaboration is followed by a constriction at the base of the pancreatic diverticulum, near the duodenum, and formation of a narrow stalk (4). As development proceeds, between E11 and E12, the gut tube bends and rotates, swinging the ventral bud dorsally and bringing it into immediate proximity to the dorsal bud (Fig. 2.6C,D). The dorsal and ventral buds then fuse sometime around E13 (96). In humans, mice, and rats, this fusion occurs between a dorsal bud and a single ventral bud, whereas in chicks and amphibians, the dorsal bud fuses with paired ventral buds. At E14.5, acini and ducts become clearly visible as distinct structures embedded within the more abundant exocrine tissue. Subsequently, the pancreas continues to grow and extend into adulthood (Fig. 2.6E,F).

Dorsal and Ventral Bud Derivatives

The dorsal and ventral buds later develop into different portions of the mature pancreas. The dorsal bud connects to the duodenum via the duct of Santorini and forms the upper part

2: DEVELOPMENT OF THE ENDOCRINE PANCREAS 27

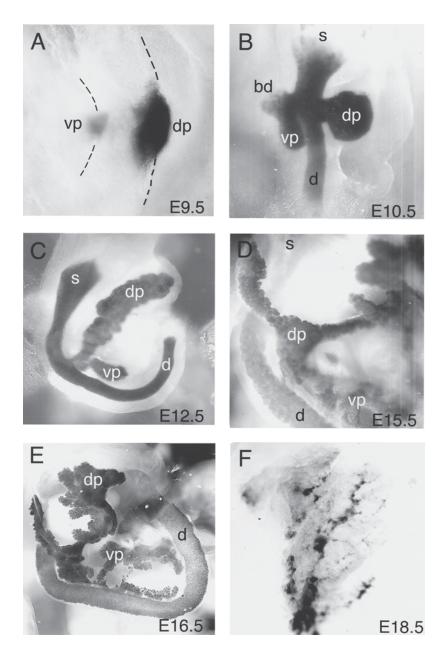

Figure 2.6. Stages of pancreatic bud development in the mouse. Whole-mount β -galactosidase staining of Pdx1-LacZ transgenic embryos showing Pdx1 expression in the pancreas. Series of photographs show pancreatic bud development during embryogenesis. All pancreases shown are cleared with glycerol and dissected away from the embryo. Ventrolateral view; dorsal is toward right and stomach is at top of each panel. A: E9.5. Dorsal pancreatic bud is evident along the gut tube (*right*) and ventral bud is appearing at this stage (*left*). Gut tube is outlined with dashed lines. **B:** E10.5. Dorsal pancreatic bud has grown and connection to the duodenum has narrowed. Ventral bud is evident on the opposite side of the gut tube. C: E12.5. Both dorsal and ventral pancreatic bud are in close proximity on the dorsal side of the gut tube. Both buds have branched and elongated, although each remains encased in surrounding mes-enchyme. **D:** E15.5. Pancreas continues to grow, and acini are visible at this stage. The mesenchymal layer surrounding each bud is relatively thinner. Dorsal and ventral buds have fused proximally at this stage. Extensions of the pancreas can be seen around the stomach and posteriorly along the duodenum. E: E16.5. Branches of the pancreas extend in multiple directions around the stomach and duodenum. Expression of Pdx1 in pancreatic epithelium can still be seen throughout the pancreatic epithelium. **F:** E18.5. Dorsal pancreatic tissue. Expression of Pdx1 is declining in most pancreatic tissues, except in δ - and β -cells. Dorsal pancreas (dp), ventral pancreas (vp), stomach (s), duodenum (d), and bile duct (bd) are indicated.

All sections are counterstained with eosin. **A:** E9.5. 20× **B:** E10.5. 20× **C:** E12.5. 20× **D:** E13.5. 10× **E:** E14.5. 10× **F:** E15.5. 10× Dorsal pancreatic bud (dp), ventral pancreatic bud (vp), gut tube lumen (g), blood vessels (v), and mesenchyme (m) are indicated.

of the head of the pancreas; the body; and the tail, or splenic portion, of the pancreas. The ventral bud connects to the duodenum via the duct of Wirsung and forms the lower part of the head of the pancreas, or the uncinate process. Generally, after the fusion of the primordia, the dorsal pancreas appropriates the duct of the ventral pancreas proximally and it becomes the primary pancreatic duct, or the duct of Wirsung. More distally, the dorsal pancreas sometimes retains its own connection to the duodenum, or the duct of Santorini. Many of the smaller epithelial ductules anastomose during the fusion process, leading to functional connections between tissue of dorsal and ventral origin (97).

The dorsal and ventral anlagen, as well as their adult derivative portions of the mature pancreas, differ in their component cell types. The dorsal pancreas develops larger insulin-secreting islets that contain more insulin-producing and glucagon-producing cells and fewer PP-producing cells than do those of the ventral pancreas. The ventral pancreas develops mainly into exocrine acinar tissue interspersed with smaller islets that contain many more PP-cells (98). One study determined that the dorsal pancreas is composed of 82% β -cells, 13% α -cells, 4% δ -cells, and 1% PP-cells and that the ventral pancreas is composed of 79% PP-cells, 18% β -cells, 2% δ -cells, and 1% α -cells (99). However, the relative concentration of islets is more or less equivalent in the two tissues (100,101).

Normal Development of Embryonic Islets

Morphologically distinguishable islets of Langerhans arise late during embryogenesis (Fig. 2.9). However, the endocrine cells that will aggregate to form islets appear much earlier. The process by which these endocrine precursors delaminate from the endoderm, migrate, and coordinate to form a functional islet is one that has been noted repeatedly during the past century in fish, amphibians, birds, and mammals. Initially, endocrine precursors are observed as scattered individual cells, often still embedded in the epithelium of the ducts (16,97). These precursors have recently been referred to as islet precur-

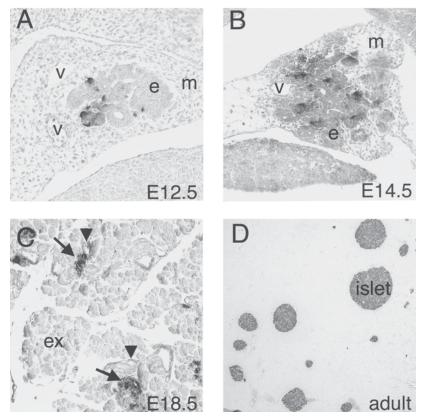

Figure 2.9. Islet development in the mouse. Immunohistochemical staining of sections through the pancreas using an antibody to insulin. A: E12.5. A few insulin-positive cells are found scattered in the pancreatic epithelium of the early branching pancreas. B: E14.5. The number of insulin cells increases as the pancreas branches and grows. Insulin cells are distributed throughout the epithelium. C: E18.5. Insulin cells aggregate into clusters (*arrows*), closely associated with smaller ducts (*arrowheads*). D: Adult. Insulin cells are located in mature compact islets. Blood vessels (v), mesenchyme (m), pancreatic epithelium (e), and exocrine tissue (ex) are indicated.

sor cells and are thought to be multipotent (102). The first endocrine cells that can be identified in the developing pancreas are the α -cells or glucagon-expressing cells (30). Insulinexpressing cells are detectable soon after. These endocrine precursors remain associated with the ducts as individual cells until well into embryogenesis—as late as E15.5 in the mouse. These cells then begin to dissociate from the duct epithelium, migrate a short distance away from the ducts, and aggregate into small clusters. Shortly before birth, compact islets have formed and are recognizable by their characteristic concentric arrangement of β -cells surrounded by α , δ , and PP endocrine cell types. Studies with aggregation mouse chimeras clearly indicate that islets are not clonally derived but are rather the result of the clustering of individual endocrine cells or clusters of cells that arise independently of each other (103).

INDUCTION OF PANCREATIC CELL FATE

Commitment to Pancreatic Cell Fate

The initiation of pancreatic commitment to a pancreatic cell fate occurs before overt morphogenesis of the pancreas. Mouse pancreatic buds cultured *in vitro* will grow and branch, revealing that foregut epithelial cells of the early pancreatic bud are already programmed to take on a pancreatic fate (4). However, the pancreas is said to be committed even earlier, at the 8- to 12-somite stage in mice, or E8.5 (4), and the 13-somite stage in chickens, or stage 11 (98). This commitment has been shown in experiments involving the culture of isolated mouse foregut tissues. For example, when the pancreatic endoderm and associated mesenchyme are excised from an eight-somite mouse embryo and cultured in isolation, morphologically distinct

exocrine tissue develops, with acinar cells filled with distinguishable zymogen granules. This commitment is likely to be influenced by both intrinsic and extrinsic factors. The endoderm alone is said to be committed by the 15-somite stage, at which time it has the capacity to form exocrine tissue in response to signals from heterologous mesenchyme. *In vitro* culture of committed pancreatic endoderm in combination with either pancreatic or heterologous mesenchyme leads to the differentiation of pancreatic cell types; however, culture of isolated endoderm does not (4,34,96,104). This shows that the competence to form pancreas is intrinsic to the pancreatic epithelium but that inductive signals from adjacent mesenchyme or other tissues are required.

Sources of Inductive Signals

Regionalized gene expression in the gut tube is generated by early interactions with adjacent mesoderm, ectoderm, or anterior visceral endoderm. As the dorsal pancreatic anlage develops, it comes in contact with a number of different neighboring tissues that may be sources of inductive or maintenance signals, including the notochord, the dorsal aorta, and the visceral mesenchyme (Fig. 2.10). The notochord, for instance, is embedded in the endodermal epithelium following gastrulation. The notochord remains in contact with the endoderm from the time it becomes morphologically recognizable as a rod of cells until well into embryogenesis (105). The entire endoderm, including the region that will give rise to the pancreas, remains in immediate contact with the notochord throughout the period during which pancreatic fate becomes committed. This contact persists until about the 13-somite stage in mice (E8) and the 22-somite stage in chicks (embryonic day 2.5). Studies of chicks have shown that the notochord sends permissive signals to the pan-

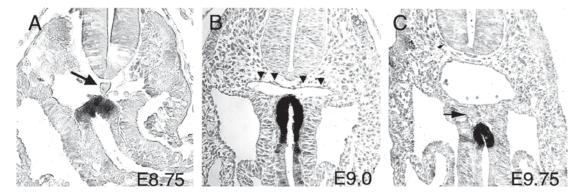

Figure 2.10. Tissues juxtaposed to the developing pancreatic endoderm. **A:** Transverse section through an E8.75 mouse embryo. Prepancreatic *Pdx1* expressing endoderm (*dark gray*) is immediately in contact with the notochord at this stage (*arrow*). **B:** Transverse section through an E9.0 mouse embryo. Prepancreatic *Pdx1*-expressing endoderm is in direct contact with the dorsal aorta. The paired dorsal aortae have fused at the midline over the dorsal pancreatic bud evagination (*arrowheads*). **C:** Transverse section through an E9.75 mouse embryo. Dorsal pancreatic bud expresses *Pdx1* and is surrounded by mesenchyme (*thin arrow*).

creatic endoderm (71). Removal of the notochord in chick embryos leads to the elimination of the expression of insulin, glucagon, and carboxypeptidase A. However, the recombination of notochord with endoderm not fated to become pancreas cannot induce the expression of pancreatic gene expression, suggesting that some patterning of the endoderm has already occurred by the stage at which these experiments are carried out (106). Additional experiments demonstrate that the notochord signal is possibly composed of activin- β B and FGF-2 signaling and participates in repressing *Shh* in the underlying pancreatic endoderm (108). This repression of *Shh* is required for the initiation of the expression of pancreatic gene expression and development. It is interesting that cyclopamine, which acts as an inhibitor of *hedgehog* signaling, can mimic the notochord signal and promote pancreatic development (107).

Epithelial-Mesenchymal Interactions

Reciprocal epithelial-mesenchymal interactions have also been shown to be critical for the regionalization of the gut tube and the development of most endodermally derived organs (108). Generally, gut endoderm signals to the splanchnic mesoderm, recruiting it to surround the gut tube as visceral mesoderm (109,110) and inducing region-specific gene expression in the mesoderm (111). The mesoderm, in turn, signals back to the endoderm and directs its morphologic differentiation (109,112). Heterologous recombination experiments in which mesoderm from different anterior-posterior locations along the gut tube is cultured with endoderm have been carried out in chicks (113), rats (114), and mice (4,115). For instance, when chick foregut mesoderm is recombined with midgut endoderm, the endoderm becomes respecified to take on foregut endoderm morphology (109). Similarly, intestinal mesenchyme can cause the respecification of stomach epithelium into intestinal epithelium (116–119). It has been suggested that the basis for the epithelialmesenchymal interactions may depend on the formation of distinct basement membrane components at the interface of the two tissues (97).

Development of the pancreas also requires the origination of signals in the surrounding pancreatic mesenchyme. In fact, pancreatic endoderm alone fails to grow and shows only limited differentiation in the absence of pancreatic mesenchyme (34). This mesenchyme accumulates around the growing epithelial bud and is required for proliferation of the epithelium. It is interesting that heterologous mesenchyme derived from other branching organs also can promote the development of pancreatic cells (120,121). When presumptive pancreatic epithelium is recombined with salivary gland mesenchyme, endoderm cells differentiate into morphologically distinct acini that express amylase (33). In addition, this inductive effect occurs across a filter, suggesting that the mesenchyme secretes soluble factors. Despite the many attempts made to identify and purify this mesenchymal factor, its nature remains unresolved (122,123). A number of experiments have shown no effect of basic FGF (bFGF), recombinant human hepatocyte growth factor (rhHGF), insulin-like growth factor-2, platelet-derived growth factor, and nerve growth factor on pancreatic tissue (124), but others suggest that HGF/scatter factor (SF), FGF-2, FGF-7, and follistatin may be involved (125-128).

Mesenchymal signals have also been shown to be important in determining the ratio of exocrine to endocrine cell types. Studies have shown that removal of large portions of the mesenchyme at a certain time will promote differentiation of endocrine cell types (129). It has been concluded that mesenchyme suppresses endocrine cell differentiation and that therefore the default pathway for the pancreatic epithelium is to form islets. In addition, recent studies have begun to shed light on the identity of the factors involved in this ratio determination. Follistatin, for instance, is expressed in the pancreatic mesenchyme and is thought to suppress factors important for endocrine differentiation such as TGF-β1. Follistatin alone can mimic some of the functions of the mesenchyme in culture and promote exocrine cell differentiation (128). However, the development of the pancreas appears to be normal in follistatin-deficient mice (130). TGF- β 1, in contrast, is expressed in the pancreatic epithelium, and overexpression of TGF-β1 can inhibit the development of acinar tissue and promote the development of endocrine cells, especially β - and PP-cells (124).

LINEAGE OF ENDOCRINE AND EXOCRINE CELLS

Precursors in the Epithelium

Critical to an understanding of the factors responsible for β -cell development and function is an understanding of the lineage of

pancreatic endocrine cells. Where do they come from and what signals do they receive? Does a common progenitor give rise to both endocrine and exocrine cell types? Are there precursors that give rise to multiple endocrine cell lineages? As mentioned previously, there is ample histologic evidence demonstrating that endocrine precursors originate in the pancreatic endodermal epithelium (14). In early experiments, in vitro culture of pancreatic rudiments demonstrated that in fact both exocrine and endocrine cells can arise from isolated epithelium and that neither form in isolated mesoderm (6). Recent recombination experiments using genetically marked epithelium and unlabeled mesenchyme support these observations and convincingly demonstrate that all exocrine and endocrine cells originate in pancreatic epithelium (36). However, it is still unclear whether both tissues arise from a single cell type within the epithelium or distinct progenitors exist that give rise exclusively to either endocrine or exocrine cells. In addition, the lineage relationships of the four islet endocrine cell types are just as far from being resolved. Intense interest in questions of endocrine cell lineage continues to demand investigation. Elucidation of these relationships may help shed some light on the parameters that will prove important for the production of islets as a potential therapy for diabetes.

Experimental Approaches to Lineage Analysis

Lineage relationships among pancreatic cell types have been investigated with a variety of experimental approaches. These include analysis of coexpression of genes in pancreatic cells and the phenotypes resulting from gene-ablation experiments and analysis of transgenic animals in which reporter genes, oncogenes, or toxins are driven from endocrine hormone promoters. All these approaches, however, are filled with uncertainties, and thus the conclusions that can be confidently drawn are limited. It is clear that co-localization of gene expression cannot be used for drawing definitive conclusions about lineage relationships. Expression of endocrine genes may be transient, and descendant cells may not give rise to distinct endocrine progeny. Furthermore, all the transgenic approaches used to address questions of lineage depend on the accurate expression of the endocrine promoters that are used and on the cell autonomy of the ablation or oncogenic effects. In more general terms, cell identity is known to depend both on intrinsic factors, such as gene expression, and on extrinsic factors, such as microenvironments consisting of secreted factors, cell-cell interactions, or extracellular matrix (131). Therefore, cells experiencing equivalent extrinsic factors, but having different origins, could initiate similar gene expression patterns that would make lineage impossible to ascertain. However, despite the limitations and uncertainties inherent in any lineage study, pancreatic lineage studies provide tantalizing hints as to the possible common progenitors of endocrine cell types.

Analysis of Endocrine Gene Coexpression and Lineage Tracing

Numerous lineage relationships have been inferred on the basis of coexpression of genes in cells of the developing pancreas. The coexpression of various genes in the pancreatic epithelium, such as insulin and glucagon or glucagon and PP, led to the proposal that these coexpressing cells represent precursors that give rise to multiple endocrine cell types in the islets (62,132–134). Yet another study inferred the existence of common endocrine precursors on the basis of the coexpression of the peptide hormone YY in all islet cell types (135). More recently, the observed coexpression of the homeobox gene *Pdx1*

(pancreatic duodenal homeodomain-containing protein 1) in both endocrine and exocrine precursors has led to the suggestion that these tissues may arise from common Pdx1-expressing precursors (136). These correlations, however, do not provide indisputable evidence for a common endocrine precursor cell, since cells of different origins may transiently express the same genes.

The assumptions drawn from coexpression studies are nonetheless supported by gene-ablation experiments in mice. In a number of mouse mutants lacking the function of endocrine genes, the absence of multiple lineages suggests the possibility that common precursors may be deleted as a direct result of the gene ablation. For instance, mutant mice lacking the function of the homeobox gene *Pdx1* fail to develop all pancreatic tissues, including both endocrine and exocrine lineages. It could be presumed from these observations that all pancreatic cell lineages originate from *Pdx1* precursors. In addition, the bHLH (basic helix-loop-helix) gene ngn3 is found to be expressed in endocrine precursors and its expression is required for the development of all four islet endocrine cell types (137,138). Other examples of genes whose absence leads to the failure of multiple endocrine lineage development include Pax4, Pax6, and Nkx2.2 (see discussion below). However, once again it is impossible to determine conclusively that common precursors are being lost in these mouse mutants. The effect of these mutations may not be entirely cell autonomous. For instance, endocrine cells may develop from a lineage that is completely separate from exocrine cells. It is also possible that exocrine cells are absolutely required for the proper development of endocrine cells. A mutation in a gene required only for exocrine development would therefore be misinterpreted as also being required for endocrine cell formation because of the failure of endocrine cell formation.

Another approach that has been used to determine cell-lineage relationships is the use of endocrine gene promoters to drive various reporter genes in transgenic mice. When the rat insulin promoter is used to drive expression of the SV40 T antigen (Tag), coexpression of Tag is detectable in all endocrine cell types in the islet (62). Because insulin is not detectable in all endocrine cells, these experimental results imply that all endocrine cells arise from a common insulin-expressing progenitor. A different conclusion is reached in a more recent study. In this experiment, islets are irreversibly "tagged" using the activity of Cre recombinase (139). More specifically, glucagon or insulin promoters are used to drive expression of Cre recombinase, which then activates a reporter gene and marks all descendants of founder cells that express the promoters. In these experiments, adult glucagon- and insulin-expressing cells are shown to derive from cells that have never expressed the reciprocal gene, demonstrating that islet α - and β -cell lineages arise independently during embryogenesis. In addition, further experiments demonstrate that β -cells, but not α -cells, share a common progenitor with PP-expressing cells. Finally, when *Pdx1*-expressing cells are tagged, both adult α - and β -cells are observed to express Cre recombinase. Therefore, it is likely that both insulin- and glucagon-expressing cells arise independently during embryogenesis but that they share a very early common precursor.

Islet Cell Tumors

Another approach to the study of endocrine cell lineage comes from studies of islet cell tumors. This approach is based on the analysis of the heterogeneous cell populations within tumors, which can then be correlated back to an originally transformed founder cell. Islet cell tumors frequently consist of mixed cell populations that produce multiple hormones (140,141). Of

course, in most cases it is unclear whether these tumors result from the simultaneous transformation of a number of cell types or from the transformation of a single pluripotent progenitor cell. This uncertainty has been resolved by showing that clonal cell lines derived from a pancreatic islet tumor simultaneously express all four endocrine hormones (142). Subsequently, multiple islet cell types are generated from a single cell clone, suggesting the existence of common precursors. In other experiments, when an oncogenic transgene is targeted to the pancreas using the glucokinase promoter, tumors develop in close association with the duct epithelium that give rise to cells expressing multiple islet hormones when cultured (143). Assuming that these tumors derive from individual transformed cells, this again lends support to the idea that multiple islet cell types can be derived from common progenitors.

Toxigenes

Finally, additional evidence for lineage relationships comes from studies of transgenic mice with the expression of toxic genes in different islet cell populations. One such transgenic study made use of the diphtheria toxin driven behind the insulin, glucagon, or PP promoters (144). At extremely low levels, this toxin blocks protein synthesis, and its effects are cell autonomous, since it is not passed on to neighboring cells. In the resulting transgenic mice, it was found that only one specific cell type was affected in both the insulin- and glucagonpromoter driven lines (either β - or α -cells, respectively). In agreement with lineage-tracing experiments described previously, this strongly argues for independent lineages for β - and α -cells. However, when the diphtheria toxin was driven behind the PP promoter, both insulin- and somatostatin-producing cells were markedly decreased, implying that the lineages of these two cell types share a common progenitor. Additional islet hormone promoter-driven endocrine cell lineage-tracing and ablation experiments should contribute to our understanding of lineage relationships. However, like coexpression and lineage-tracing studies, cell-ablation experiments depend on the accurate expression of promoters used and on the absence of transient expression by unrelated cell types.

POSTNATAL DEVELOPMENT OF THE PANCREAS

Normal Pancreatic Growth

A number of reports indicate that islets in higher vertebrates arise throughout embryogenesis but that the generation of islets decreases precipitously shortly after birth (145). This led to the belief that one acquired all the β -cells one would have during embryonic development. Studies of growth in the postnatal pancreas, however, have identified changes in endocrine cell populations and have described a slow but measurable increase in cell division in all pancreatic cell types after birth and into adulthood. These data are based on studies of mitotic index or of labeling with tritiated thymidine, bromodeoxyuridine, Ki-67, or PCNA (145–150). In the rat, the estimated β -cell mass of the adult (100-day-old animal) is up to 9.8×10^6 cells, and the reported rate of β-cell replication has been calculated to be almost 3% new cells per day (147,151). If an equivalent rate of associated apoptosis is assumed, measurements have estimated that the life span of a β -cell is between 30 and 90 days (147,152-154). The endocrine pancreas is therefore slowly and continuously replacing itself during all of postnatal life.

The process by which new endocrine cells are generated in the growing postnatal and adult pancreas remains unclear.

Generally speaking, new endocrine cells might arise in a number of different ways (103,143,151,155). They could arise either from the replication of pre-existing differentiated cells, such as resident islet cells, or from the transdifferentiation of cells from surrounding tissues, such as endothelium or mesenchyme or exocrine tissue. Alternatively, new endocrine cells could arise from the differentiation of duct cells by a process termed neogenesis, which represents a recapitulation of embryonic islet development. Or, finally, the new cells could develop from an entirely separate population of pancreatic stem cells dedicated to replenishing islet endocrine cells and themselves. This question is presently under active investigation, and observations have been made that could support any one of these three possible mechanisms. In particular, the theory of duct origin of endocrine cells has recently gained much attention. However, despite our increasing understanding of pancreatic development and growth, many questions remain regarding the landmarks of the endocrine cell life span. What is the normal source for endocrine precursors in the adult? What regulates the balance of cell proliferation, cell differentiation, and cell loss in pancreatic tissue and how do these processes coordinate to shape the population of endocrine cell types in the islets? Understanding the mechanisms that regulate β -cell generation in the adult will further our understanding of islet cell regeneration and will help in the development of therapies for diabetes mellitus.

Embryonic and Postnatal Pancreatic Cell Populations

There are numerous examples of dynamic changes in endocrine cell populations during islet growth, both before and after birth. In the rat, at gestational day 16, α -cells constitute over 96% of the endocrine cell mass (148). Shortly before birth, however, there is a rapid increase in the mass of all endocrine cells, particularly β -cells. The predominant cell type in islets at birth are β -cells, which constitute more than 65% of the islets, while the percentage of α -cells has decreased to 32% (156). A number of studies also have noted interesting periods of accelerated proliferation of endocrine cells 4 days after birth and just before weaning, possibly indicating remodeling of the pancreas (145,147). Changes in specific endocrine populations in different portions of the human pancreas have also been analyzed. In the posterior part of the head of the pancreas, the percentage of PP- and insulin-expressing cells is constant during fetal life, at approximately 50% and 25%, respectively. However, these percentages increase after birth and surpass 70% and 30% in adults (157–159). In the upper part of the head of the pancreas, the percentage of glucagon-expressing cells increases during gestation to over 30% but then decreases to 20% just before birth, remaining at this level into adulthood (16). The proportion of somatostatin-expressing cells remains stable at 20% during fetal development but decreases to about 10% in adults (157). The relative proportions of different endocrine cell types change dramatically during normal postnatal growth and development.

Postnatal and Adult Neogenesis of β-Cells

New islets are indeed generated postnatally and throughout adulthood. In one study, the number of islets itself was observed to change dramatically during postnatal growth, increasing from over 600 in the rat neonate to over 4,500 in the adult rat (160). The relative proportion of islets to the rest of the pancreas, however, falls from approximately 4% to 1.5% during the first 200 postnatal days (161). That new endocrine cells are

produced continuously as pancreatic mass increases during postnatal growth and during maintenance of adult pancreatic tissue is supported by the finding of measurable mitotic activity in adult islet cells and the presence of islet precursors in the adult duct epithelium (162,163). In addition, changes both in β cell number (hyperplasia) and in β -cell volume (hypertrophy) have been detected in the adult pancreas. Other studies have focused on endocrine cell populations during pancreatic adaptation to changing physiologic demands. Indeed, the number of postnatal β -cells has been shown to be remarkably dynamic. This flexibility and adaptability of β -cells can be observed during pregnancy, obesity, or insulin resistance (164). Pregnant rats show a 50% increase in β -cell mass directly caused by β -cell proliferation induced by placental lactogen (165). Mice that lack the function of the insulin receptor and the insulin receptor substrate 1 (IRS-1) are severely insulin resistant and have a 10- to 30-fold increase in β -cell mass (166). Islet growth and the maintenance of islet mass during normal postnatal growth, however, are under strict regulatory controls and have generally been correlated with body weight (148,151).

Regeneration of the Pancreas under Experimental Conditions

Dramatic changes in β -cell mass in the postnatal pancreas have also been demonstrated under experimental conditions. One of the most striking examples is the regeneration that occurs after partial pancreatectomy of young rats (167-169). Surgically removing all but 10% of the pancreas results in the rapid regeneration of both endocrine and exocrine tissues due both to replication of differentiated tissue and to neogenesis from duct epithelium. Other methods have yielded more limited regeneration. For instance, wrapping the head of the pancreas in cellophane also can induce the formation of new islets (170). Specifically, this manipulation causes a continuous inflammation of the pancreas, which in turn leads to duct proliferation, the reduction of smaller duct secretion, and islet budding from ductules. Similar experimental islet neogenesis is observed with a number of other methods. These include destruction of β -cells by streptozotocin in newborn and neonatal mice (171), administration of alloxan (172), dietary treatment with soybean trypsin inhibitors (173) or ethionine in combination with a protein-free diet (174), ligation of pancreatic arteries (175), or expression of high levels of interferon-γ or specific growth factors (126). Overall, these methods demonstrate that exocrine tissue is capable of rapid and robust regeneration, whereas β -cells are generally resistant to regeneration. Taken together, however, these data point to the existence of endocrine precursor cells, perhaps pancreatic stem cells, with the capacity to differentiate into functional islets.

PANCREATIC STEM CELLS

Islet Cell Expansion and Transplantation

The occurrence of β -cell neogenesis in the adult pancreatic ducts offers the possibility of generation of β -cells for transplantation into patients with diabetes. During the latter part of the 20th century, transplantation of whole pancreases and of purified islets has achieved a certain level of success at stabilizing glucose levels in rodents and humans with diabetes mellitus; however, these procedures are costly, invasive, and require tissue that is of limited availability (149). *In vitro* proliferation of preparations of adult islet has offered some promise but usually has involved a concurrent loss of insulin production, rendering

the islets biologically impotent (176,177). The prospect of identifying and expanding putative pancreatic stem cells has stimulated a number of studies aimed at identifying regions of active cell proliferation in the adult pancreas, culturing and expanding pancreatic duct preparations, and possibly isolating stem cells.

Stem Cell Developmental Potential

Stem cells have the capacity to reproduce themselves throughout the life of the organism and to generate multilineage differentiated cells (178,179). Stem cells also are thought to maintain an undifferentiated or embryonic phenotype, to divide very slowly, and to divide asymmetrically, producing daughter cells that can differentiate. If pancreatic stem cells in fact exist in the mature pancreas, they have not yet been identified histologically. Morphologic studies of pancreatic islets find no indication of "undifferentiated" or otherwise distinguishable cell type (180). Nonetheless, there is increasing evidence that stem cells or precursor cells are located in duct epithelium. A number of studies show that culturing duct epithelium can result in the expansion of β -cells (see below). In addition, members of the Notch family of genes are expressed in pancreatic duct cells (181). Notch genes have been implicated in regulating the balance between cell proliferation and differentiation, and disruption of Notch signaling leads to accelerated endocrine differentiation, disrupted pancreatic branching, and exocrine differentiation (182).

It is also possible that pancreatic stem cells may be found within the islets themselves. Recently, the gene *Nestin* was found to be expressed in a small number of cells within islets of postnatal juvenile mice (183). Nestin, an intermediate filament protein, has been called a marker for neural stem cells because it is expressed in central nervous system (CNS) cells that are capable of differentiating into various neural cell lineages. Finally, it is also possible that pancreatic stem cells emerge following the dedifferentiation of committed pancreatic endocrine cells. Human islets are known to lose insulin and *Pdx1* expression when cultured *in vitro* and can become duct-like in appearance when embedded in three-dimensional collagen gels (176,184). However, these may actually result from an expansion of contaminating duct cells.

Pancreatic Duct Expansion

In the past few years, an increasing number of studies have shown the broad potential of stem cells (185–188). These studies show that stem cells not only are found in a wide range of tissues but also have broad differentiation repertoires. For instance, neural stem cells and muscle progenitors have been shown to give rise to blood cells, hematopoietic stem cells can differentiate into myocytes, and bone marrow stem cells can generate astrocytes. Although pancreatic stem cells have not yet been identified, a number of studies have focused on the properties of pancreatic ducts. In one study, immature but functional islets were generated by the culture of islet precursor cells isolated from duct epithelium (189). These cells, kept in long-term cultures, reversed insulin dependence when implanted into diabetic mice (102). Recent studies have demonstrated that preparations of adult tissue composed primarily of duct cells can be expanded and differentiated *in vitro* into functional islets that secrete insulin in response to glucose stimulation (164). Although these recent experiments offer new hope for largescale generation of islets, an actual pancreatic stem cell has yet to be isolated and the mechanisms by which duct tissue expands remain unclear. The cellular and molecular characteri-

zation of stem cells or multipotential precursors in the pancreatic epithelium presents important challenges for the future.

MOLECULAR MARKERS OF THE DEVELOPING PANCREAS

There is increasing evidence that the molecular mechanisms controlling tissue patterning and cellular differentiation are surprisingly conserved throughout evolution—from worms and flies to mice and humans. The genes that regulate these early processes during development of the pancreas and differentiation of endocrine cells are steadily being identified. On the whole, pancreatic genes have proven surprisingly similar in their expression patterns in different species and in their functions in most metazoans, including humans. The study of pancreatic genes and the factors they encode will advance our understanding of differentiation of endocrine cells and of the factors that give the β -cell its functional identity. We summarize below some of the regulatory factors that have been implicated in cell-fate decisions in the development of the pancreas and the morphogenesis of islets.

Pdx1

Pancreatic duodenal homeodomain-containing protein 1, or Pdx1, is expressed in the pancreatic anlagen and plays a critical role in the development of the pancreas. The gene Pdx1 was originally isolated in the frog X. laevis as XIHbox8 (190,191). Since then, the gene product has undergone intense investigation and is known by a number of different names, including insulin-promoter factor-1, islet/duodenum homeobox-1, somatostatin transactivating factor-1, glucose-sensitive factor, and glucose-sensitive transcriptional factor. Expression of Pdx1 in mice is initiated at E8.0 in regions of the endoderm that will form the ventral pancreas. Slightly later, at E9.0, expression of *Pdx1* is found in the epithelium that spans the midgut, including both the dorsal and ventral pancreatic anlagen during most of fetal development, and in the caudal stomach and rostral duodenum (136,192). Shortly before birth, expression of Pdx1becomes restricted to β - and δ -cells and to the duodenum. In vitro experiments demonstrate that Pdx1 can bind specific DNA promoter sequences and activate insulin, somatostatin, glucokinase, glucose transporter 2 (GLUT2), and islet expression of the amyloid polypeptide gene (193-198). Mice or humans with homozygous null mutations of Pdx1 are born apancreatic because of the arrest in development of pancreatic epithelium during early bud formation (199-201). In these mutant buds, a few insulin cells and glucagon cells appear; however, without Pdx1 function, the epithelium is unable to respond to mesenchymal signals that promote pancreatic branching and growth. However, the pancreatic mesenchyme itself grows and develops both morphologically and functionally, independent of the epithelium (202). Therefore, Pdx1 acts autonomously in the endoderm, and the failure of pancreatic development is due to defects specifically in pancreatic epithelium.

In adults, Pdx1 is expressed in pancreatic islets. When Pdx1 is specifically ablated in mouse β -cells, the mice initially appear healthy but later diabetes mellitus develops (203). Analysis of these mutants reveals that the number of insulin- and amylin-expressing cells decreases by approximately 60%, while the number of glucagon-expressing cells increases almost 250%. Pdx1 appears to be required for insulin secretion from β -cells, and this requirement is dosage dependent. Heterozygous mutation of Pdx1 in humans results in maturity-onset diabetes of the young (MODY4), which is characterized by defects in insulin

secretion (201). Heterozygous Pdx1 mice have a reduced number of β -cells, decreased expression of insulin and GLUT2 in those β -cells that remain, a thicker mantle of non– β -cells, and impaired glucose tolerance (204). It has therefore been suggested that normal levels of Pdx1 protein are required for β -cell homeostasis and that reduction of these levels may contribute to type 2 diabetes mellitus (124). Chronic exposure of β -cells to a high concentration of either glucose or fatty acids causes a concomitant decrease in Pdx1 expression over time (205). Thus, there seems to be a dual function of Pdx1 during development and later endocrine function. Initially, it is required for early pancreas formation and elaboration, while later its expression in β -cells is required to maintain proper hormone production by β -cells.

ngn3

ngn3 is a basic helix-loop-helix factor (bHLH) that is expressed in both the CNS and the pancreas. Expression of ngn3 in the pancreas can be seen in scattered cells in the pancreatic duct epithelium (206). Expression of ngn3 can first be detected at E9.5, reaching its highest levels at E15.5 and decreasing until birth (182); it cannot be detected in the adult pancreas. It is interesting that ngn3 is never observed in differentiated endocrine cells that express pancreatic hormones and has therefore has been described as a "pro-endocrine" gene that drives islet cell differentiation. ngn3 protein is detected along with early islet differentiation factors Nkx6.1 and Nkx2.2, but not with differentiated islet hormones or the islet transcription factors Isl1, Brn4, Pax6, or Pdx1. The role of *ngn3* has recently been demonstrated in pancreatic endocrine cells. Mice that lack ngn3 function fail to develop any pancreatic endocrine cells and die of diabetes a few days after birth (138). Specifically, expression of Isl1, Pax4, Pax6, and NeuroD is lost, and endocrine precursors are not observed in the mutant pancreatic epithelium. When ngn3 is overexpressed in pancreatic cells under the control of the Pdx1 promoter, the pancreas lacks all exocrine cells and develops hyperplastic endocrine cells. Precocious expression can also cause early differentiation of endocrine cells. In the chick, when ngn3 is ectopically expressed in combination with *Pdx1*, ectopic glucagon cells are induced in most regions of the gut tube (207). ngn3 is thus required for the formation of all four types of islet cells.

Shh

Sonic hedgehog (Shh) and Indian hedgehog (Ihh) are members of the hedgehog family of potent intercellular signaling molecules. Both these genes are uniformly expressed throughout the mouse gut endoderm, with the striking exception of the dorsal and ventral pancreatic anlagen (208,209). Correspondingly, Patched (Ptc), the candidate receptor for Shh, is expressed in the mesoderm surrounding the stomach and duodenum; however, it is also absent from the mesenchyme surrounding the pancreas (72). In transgenic mice that ectopically express Shh in the pancreatic endoderm, proper pancreas and spleen morphogenesis is completely disrupted, although some endocrine and exocrine cytodifferentiation occurs normally (209). Specifically, pancreatic mesoderm is completely converted into smooth muscle and interstitial cells of Cajal, which are characteristic of the intestine, and the pancreatic epithelium initiates some intestinal gene expression. In vitro experiments with explants of pancreatic endoderm cultured in the presence of Shh protein show the same initiation of intestine differentiation. This repression of Shh in the pancreatic endoderm is likely mediated by signals from the notochord, possibly activin-BB and FGF-2

(70,104). Removal of the notochord in early chick embryos leads to ectopic expression of *Shh* in the pancreatic epithelium and to the failure of pancreatic development. *In vitro* culture of pancreatic epithelium with activin- β B or FGF-2 restores the repression of *Shh* and the expression of pancreatic genes. In addition, prevention of Shh signaling using antibodies that block *hedgehog* activity has the same results. Therefore, repression of *Shh* in the pancreatic endoderm seems to be required for proper pancreatic development. Recent observations have been made in mice with disrupted hedgehog signaling (210). *Ihh*-null mice exhibit ectopic branching of the ventral pancreas, resulting in a pancreatic annulus encircling the duodenum. *Shh* null mice and *Shh/Ihh* double mutants have a relative increase in pancreas mass and a fourfold increase in endocrine cell numbers.

Hb9

Hlxb9 (Hb9) is a homeobox gene expressed in the CNS and transiently in regions of the endoderm that will give rise to the respiratory and gastrointestinal tracts, including the pancreatic anlagen (211). Initially, expression is found in the notochord, the entire dorsal gut endoderm, and the ventral endoderm in the pancreatic region. In the dorsal pancreas, Hlxb9 expression begins slightly before *Pdx1* expression, while in the ventral pancreas their expression begins concurrently. Later in development, *Hlxb9* expression in the pancreas is restricted to β -cells. In mice lacking Hlxb9 function, dorsal pancreatic bud development is dramatically inhibited and Pdx1 expression is completely absent (212,213). The dorsal pancreatic mesenchyme, however, develops normally but lacks expression of *Isl1*. The ventral pancreas develops almost normally, showing some limited disruption in the proportion and spatial organization of endocrine cells. There is a reduction of approximately 20% to 65% in the number of insulin-expressing cells and a threefold increase in the number of somatostatin-expressing cells in the ventral bud. In addition, there is a lack of GLUT2 expression in those insulin cells that remain. *Hlxb9* is therefore required for the initial evagination of the pancreatic epithelium and for subsequent development of the dorsal pancreatic bud. The requirement for Hlxb9 demonstrates a clear molecular distinction between the dorsal and ventral pancreas.

BETA2/NeuroD

BETA2/NeuroD is a bHLH protein that is expressed in the CNS, pituitary gland, intestine, and pancreatic islets. In the developing pancreas, BETA2 is found in scattered cells in the pancreatic epithelium that coexpress glucagon as early as E9.5 in mice. Later, BETA2 can be found in α -, β -, and δ - cells in the islets. BETA2 has been shown to transactivate insulin, glucagon, Pdx1, and secretin genes (30). Examination of BETA2 expression shows that it partially overlaps that of ngn3, and ectopic ngn3 can induce ectopic BETA2NeuroD in Xenopus embryos (214). In addition, in vitro binding assays have demonstrated that ngn3 can bind E boxes in the BETA2 promoter directly and is therefore likely to lie upstream in a regulatory pathway during endocrine cell development. When BETA2 is disrupted by targeted ablation, mutant mice die of diabetes a few days after birth (215). Closer examination of the pancreas in null embryos reveals that endocrine cells fail to organize into mature islets and that their numbers decrease by almost 60% around E17.5 during embryonic development. Specifically, the number of βcells was strikingly reduced. Decreased Pdx1 expression is not observed in BETA2 null mice, however. The decrease in the number of endocrine cells is thought to result from increased programmed cell death, because TUNEL (TdT-mediated dUTP-x

*n*ick *e*nd *l*abeling) assay of the mutant pancreas shows an increase in the number of apoptotic cells. BETA2 has therefore been suggested to be important in the proliferation, rather than the differentiation, of endocrine cells in the pancreas (216). It is interesting that, in humans, two mutations in *NEUROD1* have been associated with the development of type 2 diabetes mellitus in the heterozygous state (217).

Is1

Isl1 is a member of the LIM family of homeodomain proteins and was originally isolated because of its ability to bind insulin gene regulatory sequences (218). Isl1 is expressed in a wide variety of tissues, including the CNS, lung, kidney, and pancreas. In the pancreas, Isl1 is expressed in differentiated islet cells that have left the cell cycle during embryonic development, and in the adult, its expression is found in all classes of islet cells in the pancreas (219). Isl1 also is expressed in the mesenchyme that surrounds the pancreatic dorsal bud (120). Mice lacking Isl1 function fail to develop any differentiated islet cells or dorsal pancreatic mesenchyme. In addition, there is a failure of exocrine cell differentiation in the dorsal, but not ventral, bud. In vitro culture of mutant pancreatic endoderm with wildtype mesenchyme, however, can restore exocrine but not endocrine cell differentiation in these mutants. Isl1 is therefore required for islet cell development, but it is unclear if this requirement is direct or due to secondary effects mediated by mesenchyme.

Pax Genes

Pax genes encode paired-box transcription factors that regulate multiple aspects of embryonic development and organogenesis. Pax4 is expressed in the spinal cord and in scattered cells of the pancreatic epithelium starting at E10.5 in the mouse (220,221). Subsequently, around E15.5, Pax4 becomes expressed in a much larger population of cells, including insulin-positive cells. Pax4 is then restricted to the β -cells in the adult. Mice lacking *Pax4* function die of diabetes mellitus within 3 days following birth and exhibit a complete loss of mature β - and δ -cells and have an associated increase in the number of α -cells. However, at E10.5, insulin- and glucagon-producing cells can be identified in the pancreatic epithelium in mutant embryos and Pdx1 expression is normal. It is only later that the expression of both insulin and Pdx1 decreases precipitously. Pax4 may therefore be required for the maintenance of β - and δ -cells rather than for their initial formation. Like *Pax4*, *Pax6* also is expressed in the CNS, as well as other tissues, including the pancreas (222). Pax6 binds to the pancreatic islet cell enhancer sequence that is found in the promoters of insulin, glucagon, and somatostatin genes (223,224). Expression in the pancreatic bud begins at E9.0 and continues in all four endocrine cell types during fetal and postnatal life. In mice lacking *Pax6* function, all α -cells fail to differentiate (223). The decrease first becomes evident at E10.5. In addition, β -, δ -, and PP-cells are present in mutant embryos but fail to aggregate properly to form mature islets; *Pdx1* expression appears normal, however. Mice null for both Pax4 and Pax6 fail to develop any mature endocrine cells. Given that endocrine cells are initially present in mice lacking Pax6 gene function, it seems likely that Pax genes are required for the maintenance or maturation endocrine cell fate (221).

Nkx Genes

Another family of genes important during endocrine cell development is the NK homeobox family. *Nkx2.2* is expressed in both

the CNS and the pancreatic islets (225). Expression can first be detected broadly in the dorsal pancreatic bud at E9.5, and expression later becomes restricted to α -, β -, and PP-cells. Ablation of the *Nkx2.2* function results in mice that do not synthesize insulin, show severe hyperglycemia, and die a few days after birth (226). Large numbers of disorganized endocrine cells can be found that express some β -cell markers, but no insulin, suggesting that these may represent incompletely differentiated $\hat{\beta}$ cells. In addition, these mutants exhibit a significant general reduction in the number of α -, β -, and PP-cells. *Nkx2.2* is therefore important during the differentiation of a number of endocrine cells. Nkx6.1, on the other hand, is widely expressed in the pancreatic epithelium during early pancreas development but becomes restricted exclusively to β -cells by the end of fetal development (227). Targeted ablation of Nkx6.1 demonstrates that it is specifically required for β -cell differentiation (227). Initially, β -cell commitment appears to proceed normally; however, further differentiation is arrested at around E13.0. In contrast, α -, δ , and PP-cells are not affected. *Nkx6.1* is therefore likely to be important during the β -cell expansion that occurs late in embryogenesis and during the final differentiation of β cells. Nkx6.1 is thought to function downstream of Nkx2.2, because Nkx6.1 expression is lost in Nkx2.2 mutant embryos but the reverse is not true. In addition, recently generated Nkx2.2Nkx6.1 double mutants exhibit a phenotype identical to that of Nkx2.2.

CONCLUSION

Although the morphologic landmarks of pancreatic development have been characterized and studied extensively, we are only beginning to understand the multitude of regulatory factors and intercellular signaling molecules responsible for generating the fates of pancreatic cells. It is likely that a specific combination of gene products exists that determines the character of endocrine cells. Gene expression studies and analysis of lineage relationships have expanded the picture of how endocrine cells are generated in the developing pancreas. Identifying additional cell surface markers of islet cells may eventually prove useful for the characterization and possible purification of pancreatic precursors-possibly pancreatic stem cells. In combination with optimized culture conditions, this would be invaluable for the generation of replacement β -cells for patients with diabetes mellitus.

Acknowledgments

We thank Eckhart Lammert, Guoqiang Gu, and Maya Kumar for critical reading of the manuscript and for useful discussions. Dr. Cleaver is supported by the Cancer Research Fund of the Damon Runyon-Walter Winchell Foundation Fellowship, DRG 1534. Dr. Melton is an investigator of the HHMI. Work in this laboratory is also supported by the Juvenile Diabetes Foundation and the National Institutes of Health.

SUMMARY 50

The islets of Langerhans are clusters of endocrine tissue scattered throughout the exocrine pancreas in all vertebrates higher in evolutionary development than the bony fish (teleosts). In the adult mammal, the islets are 1% to 2% of the pancreatic mass and thus comprise approximately 1 g of tissue in the adult human. Islets are complex structures of cells and function both separately as micro-organs and in concert as the endocrine pancreas. Although the direct secretion of insulin and glucagon from islets into the portal vein has obvious advantages with respect to influence on hepatic function, it is not clear why the endocrine pancreas is dispersed throughout the exocrine pancreas. One suggestion is that the local insularacinar portal system helps regulate the exocrine function of the pancreas, with this function providing some evolutionary advantage (1).

The pancreas of the adult human contains approximately 200 U, or 8 mg, of insulin (2) and that of the adult rat contains about 100 μ g of insulin. The size of an islet can range from only a few cells and less than 40 μ m in diameter to approximately 10,000 cells and 400 μ m in diameter. The average rat islet is 150 μ m in diameter and contains approximately 45 ng of insulin. In the rat, and probably in other mammals, islets smaller than 160 μ m in diameter represent 75% of the islets in number but only 15% of the islet volume, whereas islets larger than 250 μ m in diameter represent only 15% of the islets in number but 60% of the islet volume (3).

Islet mass is dynamic, adjusting to meet the changing needs of the individual, whose size and level of activity vary at different stages of life. When islet mass cannot adjust to meet the demand, diabetes mellitus results.

Although studies of the islets of nonmammalian vertebrates have been useful in extending our knowledge, we have a far more detailed understanding of the structure, function, and changes in mass of mammalian islets. In a text on diabetes, the emphasis should be on the human islet, but our present understanding of islets is based mainly on rodent studies. Thus, the rodent islet will be used as the paradigm.

This chapter will first address the cellular components of the islet and their organization. We now know that islets are not all the same, and this heterogeneity will be discussed. The manner in which the structural organization of an islet defines its function will be addressed. Finally, issues of islet growth after birth, both normal and compensatory, will be discussed. Embryonic development of the endocrine pancreas has been discussed in the previous chapter (Chapter 2).

OVERALL PANCREATIC ANATOMY

The origin of the pancreas as separate primordia is thought to be the basis of the regional distribution of glucagon-producing and pancreatic polypeptide–producing cells (4). The dorsal pancreas, supplied with blood by the celiac trunk via the gastroduodenal and splenic arteries and drained by one main pancreatic duct, contains the glucagon-rich islets with few pancreatic polypeptide–containing cells. The opposite distribution is

found in the ventral pancreas, which is supplied with blood from the superior mesenteric artery via the inferior pancreaticoduodenal artery and is drained by a separate exocrine duct. Here the islets contain pancreatic polypeptide–producing cells and few, if any, glucagon-producing cells. The degree of fusion of these ducts differs among species.

The normal organization of the islet, with its central core of β -cells and its peripheral non- β -cells, is observed only after fetal day 18.5 (5). In adult mammals, 70% to 80% of the islet consists of insulin-producing β -cells, 5% is somatostatin-producing δ -cells, and 15% to 20% is either glucagon-producing α -cells or pancreatic polypeptide–producing PP cells. The proportions of the different cell types differ with age because the different islet cells do not have the same pattern of growth. For example, in both rats and humans, the percentage of islet cells that are δ -cells is considerably greater in perinatal than in adult individuals (6). At birth the β -cells are usually only 50% of the islet, and with postnatal replication of the β -cells and increase in cell volume (7), their proportion increases.

Islets differentiate from the pancreatic ductal epithelium as do exocrine cells, but the question of whether they are derived from the same or different precursor/stem cell populations remains unanswered. Embryonic development of the pancreas as ductules that proliferate, branch, and then differentiate was described by Pictet and Rutter (8). Islet hormone-containing cells are first seen as single cells among the exocrine cells of the terminal pancreatic tubules and then as clusters of cells within the exocrine basement membrane. These clusters then become separated from the exocrine tissue to form distinct islets (8). In the adult pancreas, sometimes the only separation between exocrine and islet cells are their respective basement membranes (Fig. 3.1). However, islets are usually surrounded by at least a partial capsule of fibroblasts and collagen fibers.

In the pancreas of adults of many species, islet cells of all types can be immunolocalized in the pancreatic ducts as occasional single cells or small budding islets. An increased occurrence of these cells has been observed under numerous experi-

mental conditions, including dietary treatment with soybean trypsin inhibitor (9), overexpression of interferon- γ in the β -cells of transgenic mice (10), after partial pancreatectomy (11), and after cellophane wrapping of the head of the pancreas (12), as well as with some human diseases, including recent-onset type 1 diabetes mellitus (insulin-dependent) (13) and severe liver disease. Adult ductal epithelium can be stimulated to undergo morphogenic changes that result in a substantial formation of new islets. In the young adult rat, 3 days after a 90% pancreatectomy, 10% to 15% of the pancreatic remnant volume is composed of proliferating ductules, which differentiate into new islets and exocrine tissue within another 3 to 4 days and largely account for the doubling of remnant mass found within 1 week of surgery (11). When adult ductal epithelium was wrapped in fetal mesenchyme and implanted in nude mice, approximately 20% of the grafts were found to contain "islet-like cell clusters" with hormone immunostaining budding from the ducts (13,14). Adult human ductal tissue can be driven to differentiate into islets in vitro (15). The differentiation process can be reprogrammed, as seen in adult rats depleted of copper with a resultant destruction of acinar tissue but "normal islets and ducts." After copper repletion, hepatocytes, rather than acinar cells, regenerate in the pancreas, this being an example of transdifferentiation (16).

PHYLOGENETIC CONSIDERATIONS

The comparative aspects of the endocrine pancreas was the focus of much study in the 1970s (17–20). The first step in the development of a separate islet organ is found in the vertebrate class Agnatha, the primitive jawless fish (represented today by hagfish and lampreys). In hagfish all of the β -cells and most of the δ -cells are no longer in the gut mucosa and are restricted to the bile duct and adjacent islet organ, whereas the glucagon/gastrin-producing cells remain in the gut mucosa (17). The first appearance of a pancreas in which β -, α -, δ -, and

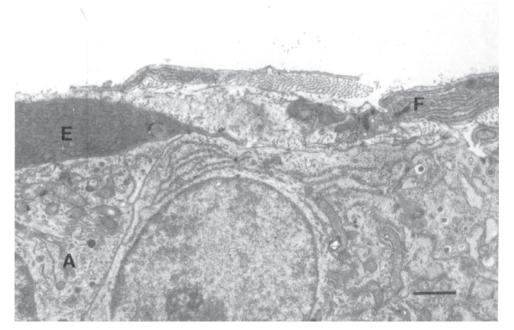

FIGURE 3.1. The periphery of a rat islet showing the capsule of a single layer of fibroblasts (*F*) and collagen fibers laid down by these cells. No capsule is seen between the exocrine cell (*E*) and the endocrine α -cell (*A*); the capsule often incompletely surrounds the islet. Scale bar = 1 μ m.

PP-cells are all represented is in the cartilaginous fish (class Chondrichthyes), in which the islet cells are found in the parenchyma, in the pancreatic ducts, or disseminated in the exocrine pancreas (17,21). The bony fish (class Osteichthyes) have large accumulations of endocrine tissue, sometimes called the Brockmann bodies, near the spleen and pylorus and, in addition, have small islets scattered throughout the exocrine tissue, often in association with small ducts. The descriptions of islets in amphibians and reptiles are widely variant, but there seems to be a pattern of three types of islets: large splenic islets with the α -cell population greater than the β -cell population; islets of intermediate size with more β -cells but still a majority of α -cells; and small islets with mostly β -cells. This heterogeneity of islets has been better defined for the birds (class Aves): Dark, or α , islets are composed of α - and δ -cells; and light, or β , islets are composed of β - and δ -cells (PP-cells are often extrainsular). In this class, as in mammals, the regional distribution of islet types has an embryologic origin.

COMPONENTS OF THE ISLETS OF LANGERHANS

Endocrine Cells

There are four major endocrine cell types in mammalian islets: the insulin-producing β -cell, the glucagon-producing α -cell, the somatostatin-producing δ -cell, and the pancreatic polypeptide-producing PP-cell (the latter three will be referred to collectively as the non- β -cells) (Fig. 3.2). Ultrastructural and immunocytochemical techniques are used to distinguish these cell types and have identified other minor cell types (Table 3.1). Numerous other peptides and hormones have been localized to the islet cells with the use of sensitive immunostaining techniques (Table 3.1). Localization of several of these peptides is confusing because the type of cells that are immunostained varies with species. For example, calcitonin gene-related peptide (CGRP) co-localizes with somatostatin in the rat δ -cells but with insulin in mouse β -cells (22). Similarly, an antibody to pancreastatin stains α - and δ -cells in humans but β - and δ -cells in pigs (23,24). An additional level of complexity is introduced by evidence that the hormones thyrotropin-releasing hormone and gastrin are expressed in the islets only during the perinatal

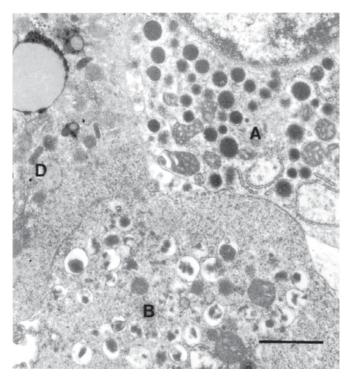

FIGURE 3.2. The secretory granules of the islet endocrine cells have a characteristic morphology. Represented here are those of the β -cell (*B*), the α -cell (*A*), and the δ -cell (*D*) of a human islet. Scale bar = 1 μ m.

period (25,26). It is presently unclear how any of these other hormones/peptides function in the islet. The sensitivity of the techniques and the overlap of antibody recognition may be responsible for some of these confusing data. Another explanation for the overlap may be the sequential differentiation of the islet cell types.

The β -cells are polyhedral, being truncated pyramids, and are usually well granulated, with secretory granules 250 to 300 nm in diameter (Fig. 3.3). It has been estimated that each mouse β -cell contains approximately 10,000 granules (27). There are

TABLE 3.1. Characteristics of the Endocrine Cells of the Islets of Langerhans ^a			
Cell type	Size of secretory granule (nm)	Percentage of islet cells	Hormonal content
β	250–350	60–80	Insulin, IAPP/amylin (thyrotropin-releasing hormone, calcitonin gene–related peptide, gastrin, pancreastatin)
α	200–250	15–20	Glucagon (glicentin, TRH, CCK, endorphin, glucagon-like polypeptide-1, peptide YY, DKP histidyl-proline diketopiperazine, pancreastatin)
δ	300–350 200–300	5–10	Somatostatin (met-enkephalin, CGRP, pancreastatin)
PP	120-160	15-20	Pancreatic polypeptide (met-enkephalin, peptide YY)
δ_1	100-130	<1	Vasoactive intestinal polypeptide
EC	300-350	<1	Substance P, serotonin
G1	300	<1	Gastrin (adrenocorticotropic hormone-related peptides)

^aThe secretory granules of each cell type have a characteristic size and morphology. The size of δ -cell secretory granules varies with species; hormonal content identified by immunostaining techniques; peptides in parentheses found in at least one species. Some of these peptides, for example, TRH, glucagon-like peptide 1, and gastrin, usually are found only in perinatal islets. The physiologic significance of the islet location is unclear.

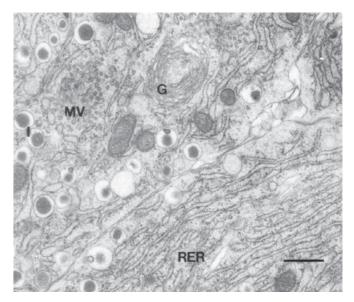

FIGURE 3.3. The synthetic and secretory machinery of the insulin-producing β -cell of a rat islet shown in three adjacent cells. RER, rough endoplasmic reticulum; MV, microvesicles; G, Golgi apparatus; I, insulin secretory granules. Scale bar = 0.5 μ m.

two forms of insulin granules: mature granules that have an electron-dense core and a loosely fitting granule-limiting membrane with the appearance of a spacious halo; and immature granules with little or no halo, moderately electron-dense contents, and a clathrin coat. Immature granules have been shown to be the major, if not the only, site of conversion from proinsulin to insulin (28). Other changes, such as the shedding of the clathrin coat, acidification of the granule contents, and crystallization of insulin, occur as the granule matures from a proinsulin-rich granule to an insulin-rich granule (28). In some species the electron-dense core of the mature granule is visibly crystalline. Insulin is not the only peptide in the granules; there are at least 100 other peptides (29).

The α -cells are usually smaller and more columnar than the β -cells and well granulated, with granules 200 to 250 nm in diameter (Fig. 3.2). The granules are electron-dense with a narrow halo of less-dense material and a tightly fitting granule-limiting membrane; there is little species variation.

The δ -cells are usually smaller than either α - or β -cells, are well granulated, and are often dendritic in shape. The electron density of granules within a δ -cell varies greatly (Fig. 3.2). Each granule, 200 to 250 nm in diameter, contains material of homogeneous moderate density that fills the granule-limiting membrane.

PP-cells are the most variable among species. In humans the granules are elongated, very electron dense, and 120 to 160 nm in diameter. In dogs and cats, the granules are spherical, variable in electron density, and approximately 300 nm in diameter (30).

Capsule

The existence of an islet capsule has been a controversial issue, perhaps because the capsule is only a single layer of fibroblasts and the collagen fibers laid down by these fibroblasts (Fig. 3.1). Furthermore, frequently the capsule between islet and exocrine cells is absent. The extant capsule does overlay the efferent blood vessels of the islet and seems to define a subcapsular interstitial space.

Microvasculature

The islet is highly vascularized and has a direct arteriolar blood supply (31). Islet capillaries are fenestrated, whereas fenestration is decreased or absent in capillaries of the surrounding exocrine tissue (32). The fenestrae render these capillaries highly permeable. The passage of horseradish peroxidase into the pericapillary interstitial space of the islet takes only 45 seconds, whereas it takes 5 minutes in cardiac muscle (33). The blood flow to the islets has been found to be disproportionately large (10% to 20% of the pancreatic blood flow) for the 1% to 2% of pancreatic volume (34-37). Factors regulating islet blood flow may affect islet hormone secretion. High concentrations of glucose have been shown to enhance pancreatic blood flow and to preferentially increase islet blood flow (38). In addition, several of the peptides immunochemically localized in islet nerves and/or endocrine cells, for example, CGRP, are vasoactive (39). The relation of the microvasculature to islet endocrine cells is discussed below. Lymphatic vessels, while common in the pancreas, have not been found within the islets (40).

Nerves

The pancreas is innervated by sympathetic fibers from the celiac and superior mesenteric ganglia and by parasympathetic fibers from the vagus nerve (41,42). These parasympathetic fibers synapse in small ganglia dispersed in the pancreas. They may act as pacemakers for the oscillations in hormone secretion (43) that occur without extrinsic nervous connections, as in the isolated perfused canine pancreas (44).

Within the pancreas, nerve fibers terminate in perivascular, periacinar, and peri-insular areas. Within the islets, the nerves follow the blood vessels and terminate within the pericapillary space, within the capillary basement membrane, or closely apposed to the endocrine cells. Because no specialized synapses are found, it has been suggested that neurotransmitters released into the interstitial space may affect a number of neighboring islet cells. In some species, nerve cell bodies are close to or even within the islets (45).

The distribution and number of the different types of nerve fibers differ among species (41,42,45). Cholinergic nerves, identified histochemically by cholinesterase activity or ultrastructurally by the presence of electron-lucent vesicles, are common in rat, cat, and rabbit islets. Adrenergic nerves, as identified immunochemically by antibodies to catecholamine-forming enzymes (including tyrosine hydroxylase) (45) and ultrastructurally by the presence of dense cored vesicles, are common in the hamster, dog, and cat. Peptidergic nerves are less well defined, being identified either immunochemically as containing substance P, enkephalin, vasoactive intestinal polypeptide (VIP), galanin, gastrin-releasing peptide, CGRP, or cholecystokinin, or ultrastructurally by the presence of large granules. A further complication is introduced by the finding of neuropeptide Y and galanin in adrenergic nerves and the identification of VIP in cholinergic nerves (46). Both substance P and CGRP seem to be localized in the sensory fibers. The presence of peptidergic nerve cell bodies in pancreatic ganglia suggests that some of these intrinsic nerves may be involved in the synchronization of islet secretion (45).

The autonomic nervous system modulates islet hormone secretion (41,45,47). Cholinergic stimulation elicits increased secretion of insulin, glucagon, and pancreatic polypeptide. Its effects on somatostatin are less clear but appear to be inhibitory. β -Adrenergic stimulation similarly elicits increased secretion of insulin, glucagon, pancreatic polypeptide, and somatostatin (48). β -Adrenergic stimulation decreases secretion of insulin and somatostatin, but its effect on glucagon secretion varies with species. The effects of stimulation of peptidergic nerves have not been studied as closely, but VIP, cholecystokinin, and galanin can affect islet-cell secretion. VIP causes an increase in insulin secretion that is direct (49). VIP neurons form a peri-insular network in rats (50), but the peptide does not change the islet blood flow as it increases the total pancreatic blood flow (49).

ORGANIZATION OF THE COMPONENTS OF THE ISLETS OF LANGERHANS

The distribution of the endocrine cells is nonrandom, with a core of β-cells surrounded by a discontinuous mantle of non-βcells one to three cells thick (51,52). The islets of most mammalian species have this pattern, but those of humans and other primates have a somewhat more complex arrangement (Fig. 3.4). Sections of human pancreas show many different islet profiles, including oval and cloverleaf patterns, differences that have resulted in controversy about whether they actually have a mantle-core arrangement (52-54). Nonetheless, in three dimensions, human islets can be considered as composites of several mantle-core subunits or as lobulated with mantle-core lobules (52,55). In sectioned tissue, incomplete fusion of such subunits and penetrations of islet vasculature can appear as invaginations of the islet periphery. Most of the non- β -cells are found along these invaginations and the periphery (52,53), thus maintaining a mantle-core arrangement. Confocal microscopy allows a better appreciation of the three-dimensional organization of islet cells (56). With confocal microscopy, α -cells are seen as a sheet or a peel at the islet periphery and δ -cells are seen as more peripheral to the α -cells in the human but less peripheral in the rat. This pattern of organization is based on intrinsic qualities of the cell surfaces of the different cell types, as shown by reaggregation studies. When single dispersed rat islet cells were allowed to reaggregate, the aggregates showed the same nonrandom organization as native islets, even when the proportions of β -cells and non- β -cells were reversed (57). Both β -cells and non- β -cells have high levels of calcium-dependent cell-adhesion molecules (cadherins), but non- β -cells also contain calcium-independent cell-adhesion molecules (58). It is thought that this differential

expression of cell-adhesion molecules may be responsible for the segregation of β -cells and non- β -cells.

The microvasculature forms the infrastructure of an islet. The rat islet has been studied most extensively and will serve as the prototype in this discussion, but this generalization needs to be verified. Afferent vessels to an islet number one to three arterioles, depending on islet size. Each arteriole penetrates the islet through discontinuities of the non- β -cell mantle and enters directly into the β -cell core, where it branches into a number of fenestrated capillaries (3). These capillaries follow a tortuous path, passing first through the β -cell core and then through the non- β -cell mantle. Often the vessels pass along the inside of the mantle before penetrating it. The efferent vessels are collecting or postcapillary venules. It is unclear where the transition from capillary to collecting venule occurs, but collecting venules can often be seen in indentations of the islet. There appears to be a single continuous circulation through the islet. Although each capillary should have functionally different arterial and venous portions, no morphologic differences have yet been found.

The pattern of microvasculature varies, depending on islet size (Fig. 3.5). In large islets, the efferent vessels coalesce into collecting venules within the subcapsular space. In small islets, the efferent capillaries extend into the exocrine tissue for 50 to 100 µm before coalescing into collecting venules. Within the islet, endocrine cells are organized around the microvasculature (Fig. 3.6). In the rat, the β -cells have been found to have two faces on capillaries (59). In cross-section, eight to ten β -cells are seen to form a rosette around one of the capillaries. In three dimensions this pattern would be tubelike. The outer face of each β-cell would be against a capillary, which is probably arterial and orthogonal to the central capillary. In β-cells experimentally degranulated with glyburide, the remaining granules are polarized toward the central "venous" capillary, suggesting an *in situ* polarity of the β -cells. Along the interface of three or more β -cells and extending from capillary face to capillary face are elaborate canaliculi (59). Desmosomes that act as mechanical attachments are preferentially found near these canaliculi. These canaliculi contain large numbers of microvilli (59,60) that have been found to be enriched in glucose transporter 2 (GLUT-2) (61). The presence of these elaborate structures suggests a bulk flow of interstitial fluid through these canaliculi in an arterial-to-venous direction and an uptake of glucose by the β -cells that is carried out mainly by the transporters on these

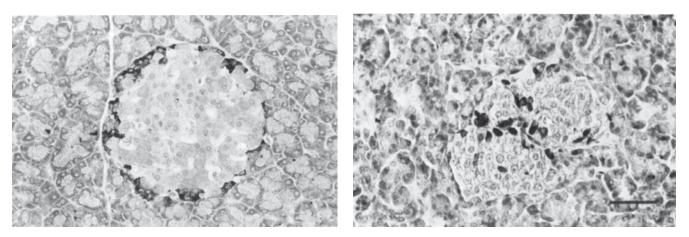

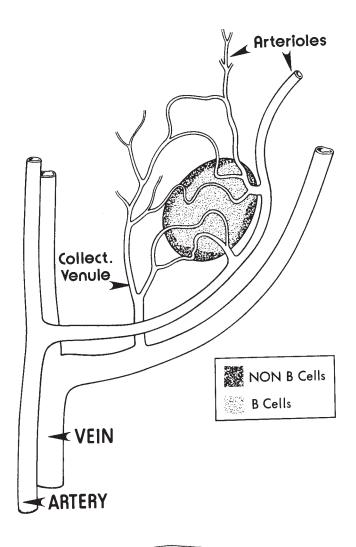

Figure 3.4. The pattern of a mantle of non– β -cells (the glucagon-, somatostatin-, and pancreatic polypeptide–producing cells) around a core of insulin-producing β -cells is seen in the rat (*left panel*) and in the human (*right panel*) with immunostaining of the non– β -cells. Human islets can be considered composites of several subunits and those of the rat, only one subunit. Scale bar = 50 µm.

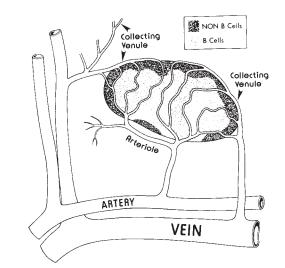

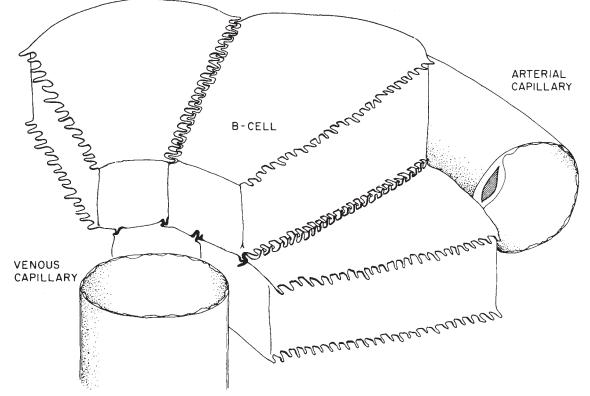

Figure 3.5. Diagrams of the microvasculature of the rat islet based on corrosion casts and serial reconstructions of immunostained paraffin sections. In both small *(left)* and large *(right)* islets, the efferent arteriole enters the islet in a gap or discontinuity of the non– β -cell mantle, such that it enters the β -cell core directly, where it breaks into a number of capillaries. These capillaries (fewer are drawn for diagrammatic purposes) traverse the β -cell core before passing along and through the non– β -cell mantle. In the small islets, the efferent capillaries pass 50 to 100 µm before coalescing into collecting venules, thus providing an insuloacinar portal system. However, in the large islets the efferent capillaries coalesce into collecting venules at the edge of the islet, even within the capsule. Thus, the drainage of large islets is directly into the venous system without passage through the exocrine tissue. (Copyright © 1982 American Diabetes Association. From Bonner-Weir S, Orci L. New perspectives on the microvasculature of the Islets of Langerhans in the rat. *Diabetes* 1982;31:883–889. Reprinted with permission from *the American Diabetes* Association.)

microvilli. Thus, these canaliculi may serve as the initial interface for glucose sensing by the β -cell. Insulin secretory granules appear to be released from the lateral and apical surfaces to enter the venous (central) capillaries.

HETEROGENEITY WITHIN THE ISLETS

We now realize that the islets within one pancreas are not all alike. Islets differ in cellular composition. There is a regional distribution of the glucagon-producing α -cell and the pancreatic polypeptide–producing PP-cell that is based on the embryologic derivation of the pancreas from distinct dorsal and ventral anlage (4). Thus, the splenic or dorsal portion (the tail, body, and superior part of the head) is glucagon-poor and pancreatic polypeptide–rich, while the duodenal or ventral portion (most of the head—sometimes designated as the uncinate process) of the pancreas is glucagon-poor and pancreatic polypeptide–rich. Physiologic data from either islets or perfusion of regions of the pancreas suggest that islets from different regions function differently, with the splenic islets releasing more insulin than the duodenal islets in response to glucose (62,63).

The different vascular relation to the exocrine tissue of islets of difference size was mentioned previously (3). Large islets (those > 250 μ m in diameter) are selectively located near the larger ducts and blood vessels. Their efferent vessels coalesce within the islet capsule; thus, they probably have little effect on surrounding exocrine tissue. However, the vascular pattern of the small islets and their abundance would lead to an effective insulo-acinar portal system.

The increasing evidence that not all β -cells within an islet are identical indicates another level of heterogeneity. Older physiologic data from studies of isolated islets suggested different sensitivities for insulin response (64,65). Studies on single islet cells have shown that individual β -cells may have different thresholds for glucose-induced insulin release; thus, with increasing concentrations of glucose, more β-cells are recruited in the response (66,67). This cellular heterogeneity has been extended to include the redox state and the threshold for glucose-induced biosynthesis of proinsulin (68) and glucoseinduced cytoplasmic concentration of free calcium (69). However, the question of whether such heterogeneity was artifactual and only the result of isolation as single cells has been raised (70). The recent study comparing the cytoplasmic concentration of free calcium in single and clustered islet cells in the same preparations showed recruitment of both single cells and small cell clusters (2 to 20 cells) with increasing glucose; however, although there was heterogeneity among the clusters, cells within clusters were usually homogeneous (70). With the use of luciferase dye injections, small territories of coupled β -cells, ranging from four β -cells in control conditions to 36 β -cells after treatment with diazoxide, have been shown in vitro (71). The increases in coupling (electrical and physical) were correlated with increases in gap junctions. It is likely that there are numerous coupled territories within an islet, each entrained with the β -cell within the cluster with the lowest threshold of response.

It is unclear if the heterogeneous nature of the β -cells as individual cells is intrinsic and constant for a particular cell through its lifetime, is related to the age of the cell, or is imprinted by a factor from the environment. Even the β -cells from the same islet are heterogeneous; in addition, the average insulin secretion per β -cell shows inter-islet variation (72). On the basis of the anatomy of an islet, one can speculate that the environment of a central β -cell is quite different from that of a peripheral one (see below for further discussion). Important questions are raised by this heterogeneity. Are certain populations of β -cells more susceptible than others to autoimmune destruction? Is one population preferentially or selectively lost during the development of non–insulin-dependent diabetes?

STRUCTURAL DEFINITIONS OF ISLET FUNCTION

It is important to understand how the three-dimensional organization of the islet may determine islet function. Experiments in which islet hormones were administered exogenously to isolated islets or to perfused pancreases have provided data indicating that islet hormones are capable of influencing the other islet cells in feedback loops (71,73). Thus, insulin can inhibit both α - and δ -cells, somatostatin can inhibit both α - and β -cells, and glucagon can stimulate both β - and δ -cells. (The role of pancreatic polypeptide or the PP-cell in these potential interactions has not been delineated.) These data have led to the concept that secretion of islet hormones is regulated by specific intraislet interactions (60). Three levels of interactions are possible: (a) cell-to-cell via junctional communication; (b) bloodborne via the vasculature; and (c) paracrine via the interstitium. What constraints on each of these levels does the anatomy of the islet provide?

Junctional Interactions

The intercellular contacts between the endocrine cells influence their function. Stimulated secretion is enhanced when β -cells have contact with at least one other β -cell (74,75). Gap junctions are the entities that allow cell-to-cell communication and coupling (71,76). Islet hormones would not be expected to pass through these junctions because of molecular-size limitations and, more importantly, because the hormones within a cell would be enclosed within granule membranes. Such junctions have been seen between all types of islet endocrine cells in both heterologous and homologous links. Several connexins, including connexin 43 and connexin 45, are part of gap junctions within the islet (77); recently, connexin 36, a connexin newly identified in mammalian brain and retina, was found to be abundant and selective in the β -cells within the islet (78). The overexpression of connexin 32 in β -cells by transgenesis led to improved electrical synchronization, increased cytosolic calcium, but reduced insulin secretion in response to glucose (79). Contact via gap junctions is thought to be involved, because heptanal, an alcohol that functionally uncouples gap-junction communication, causes paired $\beta\mbox{-cells}$ to function as if they were

Figure 3.6. Diagram of the intra-islet arrangement of pancreatic β -cells. β -Cells have two capillary faces, one essentially arterial and one venous. The lateral interfaces of β -cells are smooth surfaces; however, where three or more β -cells meet, a canalicular system is found that extends from one capillary to the other. The canaliculi contain microvilli that are enriched in glucose transporters. This specialized arrangement suggests that there is a preferential bulk flow of interstitial fluid through these canaliculi in an arterial to venous direction. (From Weir GC, Bonner-Weir S. Islets of Langerhans: the puzzle of intraislet interactions and their relevance to diabetes. *J Clin Invest* 1990;85:983–798 with permission from the American Society of Clinical Investigation.)

single cells. However, cell adhesion molecules such as integrins may also play a role. Integrins are usually thought to attach the cell to its extracellular matrix, but $\alpha 6\beta 1$ integrin, found on β cells and increased with secretagogues, has been associated with increased insulin secretion (80,81).

Bloodborne Interactions

The microvascular pattern of the islet confers a directionality to the blood flow-from the point of arteriolar entry outward through the β -cell core to the peripheral non- β -cell mantle. This directionality has been demonstrated visually by passing a bolus of dye through the islet of a living rabbit (31) and by a video study of blood flow in the living mouse pancreas (82). This pattern of flow would favor insulin having an effect on the α - and δ -cells by its being transported in high concentrations from the core to the mantle. The reverse, that of the β -cells being influenced by local bloodborne somatostatin or glucagon, is not supported by the vascular pattern. Physiologic data from the approach of passive neutralization, using alternating anterograde and retrograde perfusions of dog, rat, monkey, and human pancreas, provide support for a β to α to δ (B-A-D) directional pattern of blood flow (83). The local secretion of insulin is surely important for glucose control over α -cell function (60). This pattern does not preclude the effects of the islet hormones via the systemic circulation. Somatostatin 28, which comes mainly from the gut and reaches the islets via systemic arterial circulation, may have more potent effects than somatostatin 14 on the islet cells of rats but not on those of dogs (84).

Paracrine Interactions

The paracrine effects are defined here as those local events that occur by simple diffusion through the interstitium. Such effects are difficult to evaluate because of the lack of good methods for studying the diffusion of peptides throughout this islet compartment. The pericapillary and subcapsular interstitial space is $6\% \pm 2\%$ of the islet volume. In contrast, the vascular component (the endothelium and the luminal space) comprises approximately 14% ± 3% of the islet volume (S. Bonner-Weir, unpublished observations). Without having actual measurements, one can guess that the interstitial flow probably would be in the same direction as the blood flow. In such a case, diffusion inward to the core would be severely limited. Thus, in large islets, there would be a central core of β -cells that would be isolated by their distance from the non- β -cells and thus from all but systemically circulating levels of the other islet hormones. On the other hand, the peripheral β -cells could be under the local or paracrine influence of hormones secreted by adjacent or nearby non– β -cells. In small islets, essentially all β -cells might be close enough to the non- β -cells to be influenced by their hormones diffusing into the interstitial fluid and, thus, be regarded as peripheral. In fact, differences have been reported. Central β-cells of large islets have been reported to have smaller nuclei than either the peripheral β -cells of large islets or any β cells of small islets (85). Furthermore, in rats stimulated in vivo with either glucose or glibenclamide, central β-cells degranulate before peripheral β -cells (86). These patterns may reflect the protection of the central β -cells from paracrine secretions or, conversely, the paracrine influence on peripheral β -cells. Presently, we do not know if these differences seen in the whole islets in vivo account for the heterogeneity found in single cells in vitro.

Somatostatin and glucagon, perfused in the isolated canine pancreas at concentrations that are only a small fraction of their estimated inter-islet concentration, have been shown to have profound effects on the other islet cells (87). The implication of these findings was that at least some cells were protected from the secretory products of their neighbors, and a hypothesis of functional compartmentalization was suggested (87). This hypothesis stated that the interstitial space within the islet was separated functionally into an "exocytotic-venous pathway" and an "arterial-receptor pathway" (87). Tight junctions were suggested as limiting domains of the plasma membrane of islet cells to segregate their sensing and secretory functions. However, although tight junctions have been clearly demonstrated in collagenase-isolated islets (55), they are not common in rodent islets fixed *in situ* (88,89) and therefore do not provide important compartmentalization. A better anatomic basis for compartmentalization probably lies in the polarity of islet cells and the directionality of blood flow (59).

Attention has been given more recently to whether receptors for the different hormones are on the various islet cells since their presence would suggest potential function and specificity of response. Several somatostatin receptor (SSTR) isoforms are expressed in human islets, with SSTR1 being richly expressed in β -cells, SSTR2 in α -cells, and SSTR5 abundant in β - and δ -cells and moderate in α -cells (90). β -Cells can respond to glucagon via either the glucagon or glucagon-like peptide-1 (GLP-1) receptors, allowing detection both at dilute levels in the systemic circulation and at high concentrations in the interstitium (91). However, α -cells expressed neither glucagon nor GLP-1 receptors but did express glucose-dependent insulinotropic polypeptide (GIP) receptors; rat β-cells also expressed GIP receptors (92). The presence of insulin receptors on the β cells is more controversial. Both purified rat α - and β -cells express receptors for high-affinity insulin-like growth factor (IGF-1) that conveyed a low affinity for insulin binding (93), but an analysis of single rat islet cells by the reverse transcriptase-polymerase chain reaction found that β -cells express insulin receptor mRNA (94). β-Cell-specific insulin receptor knockout mice were generated, but these studies showed that insulin does not have a profound direct effect on the β -cell (95). At 4 months of age, these mice had no profound phenotype, being normoglycemic but hyperinsulinemic, with mildly impaired glucose tolerance and a small reduction in insulin content.

POSTNATAL ISLET GROWTH

Islet mass increases considerably from fetus to adulthood, while the volume of islet tissue relative to that of the pancreas decreases after birth. In newborn humans, islets comprise 20% of the pancreatic tissue; in children (1.5–11 years), 7.5%; and in adults, 1% (96). Similar data have been reported for cattle (97) and rats (98). The relative values are misleading, for by adulthood the islet mass has grown and increased about fivefold from that at birth. In fact, β -cell mass is linearly correlated with body weight in adult mice (99) and rats (100). The relative amount decreases, as the exocrine tissue increases about 15-fold during the same period. Thus, the growth of islet tissue is diluted by the more exuberant postnatal growth of the exocrine tissue after birth.

Islet mass is determined by the number of cells and their cell volume (size). New cells arise by (a) neogenesis or differentiation of islet endocrine cells from ductal epithelium, or (b) replication of existing islet cells. Whereas replication becomes a major mechanism for adding new β -cells (101), both neogenesis and replication continue postnatally (7,100,101). Many new islets are formed in the first few days after birth, and a second wave of neogenesis occurs at about weaning (102). β -Cell replication is

significantly higher during late gestation and the neonatal period than following weaning, with little change in replication rates occurring beyond 30 to 40 days of age (7). In rats, β -cells increase in number until the age of 15 months, and afterward they increase in size (hypertrophy) (100). The finding in 6-month-old rats of some pancreatic lobes with high amounts of 5-bromodeoxyuridine (BrdU) incorporation and others with almost no incorporation suggests that whole lobes of pancreas are formed even in adult animals (7).

During the neonatal period, the endocrine pancreas in the neonatal rat is remodeled (103). During the second week after birth, the β -cell mass does not increase even with a high replication of β -cells because a high level of apoptosis occurs simultaneously. This remodeling coincides with marked changes in the levels of messenger RNA for both IGF-I and IGF-II as well as with transient appearances of messenger RNA for IGF binding protein 1 (IGFBP-1) and IGFBP-2 (104), leading to the suggestion that an inadequate availability of survival factors such as the IGFs causes the increased cell loss (103,105). This hypothesis was supported by the suppression of the normal neonatal apoptosis by persistent IGF-II in overexpressing transgenic mice (106).

Cell Replication

What is known about the cell cycle of islets has been determined using isolated rat islets synchronized in culture by temporary exposure to hydroxyurea. A cell cycle of 14.9 hours was calculated and has been assumed to reflect that of the β -cell, the predominant cell of the islet (107). The length of the cell cycle does not change with glucose stimulation or with the age of the animals (107,108). Instead the growth rate is regulated by the number of β -cells that can enter the division phase (G₁) from the resting (G₀) phase. The accuracy of determinations of β -cell replication made by measuring the incorporation of thymidine in whole islets has been questioned because non-endocrine cells found in islets incorporate thymidine at a far greater rate than do islet endocrine cells (109). The measurement of choice is double labeling of insulin-immunostained cells with nuclear labeling (thymidine or BrdU incorporation or immunostaining of various cell cycle proteins such as Ki67, PCNA).

It is now clear that β -cells can replicate: Incorporated BrdU and tritiated thymidine have been localized to cells immunolabeled for insulin, and numerous micrographs of mitotic figures in cells with insulin granules have been published. Yet there may be functional differences between β -cells that can replicate and those that cannot. Nondividing β -cells can be recruited into the cell cycle, and most daughter cells will re-enter the cycle immediately (110). Replicative ability or "age" may be one of the possible bases of the functional heterogeneity of β -cells (111) discussed previously.

Stimuli for Growth

Although there may be numerous stimuli for β -cell growth, three major stimuli are known: prolactin, growth hormone, and glucose. Glucose is a stimulus both *in vivo* and *in vitro*. As early as 1938, Woerner reported an increase in islet tissue in guinea pigs after continuous glucose infusions (112). Such an increase has since been confirmed by several other studies (113–117). Glucose has been shown to stimulate modest growth of both neonatal and adult pancreatic β -cells in culture (118–120). Pregnancy has been shown to cause both increased replication and increased mass of β -cells (121–125). As a parallel finding, *in vitro* studies have shown that prolactin, placental lactogen, and growth hormone can stimulate replication of β -cells

(120,126,127). A neural stimulus has been suggested by the increase in islet mass after a ventromedial hypothalamic lesion (128). Possible effects of incretins on islet mass have been suggested by in vivo studies using a long-acting GLP-1 agonist, exendin 4, in normal rats. Exendin 4 stimulated β-cell replication as well as neogenesis (129). In addition to these known stimuli, a complex orchestration of, as yet, unidentified factors must be involved. As a means of identifying some of these, peptide growth factors have been studied in islet cultures. The most commonly tested factor has been IGF-I, but results have varied (120,127,130) IGF-I may function more as a survival factor for the islet cells (105). None of the factors studied so far have produced marked stimulation of replication in vitro, but the importance of their contribution to growth and development cannot yet be discounted. The coordination of many factors in islet growth promises to be exceedingly complex.

Compensatory Changes

Through a lifetime, there can be compensatory changes in function and mass of β -cells to meet demand and to maintain euglycemia. Functional compensation can be due to changes in βcell responsiveness by changes in threshold for glucose-induced insulin secretion (131), possibly caused by activation of glucokinase (132), or by recruitment of cells with heterogeneous response thresholds (111). Additionally, the mass of β -cells can be dynamic, with both increases and decreases, to compensate for changing demands, such as pregnancy, obesity, or insulin resistance. Regulation of replication, neogenesis, apoptosis, and the cell size (hypertrophy vs. atrophy) can contribute to these variations in mass (102,133). The physiologic occurrence of β cell apoptosis is found during the involution of the β -cell mass in the postpartum pancreas (102) and in a remodeling of the endocrine pancreas in the neonatal rat before weaning (103). In addition, substantial β -cell growth has been shown *in vivo* in several animal models (114,134,135). For example, after only 96 hours of glucose infusion, the β -cell mass in adult rats was increased by 50%; both hypertrophy of individual β -cells and hyperplasia contributed to this rapid increase of mass (114).

Because few mitotic figures are seen normally in adult islets and the postnatal proliferation rate of β -cells is low, it has been thought that the capacity for β -cell growth or regeneration is limited. However, the proliferation of differentiated β -cells must not be underestimated; it is adequate to maintain a slowly increasing β -cell mass. Even at the low replicative level of 3% per day, the number of β -cells could double in 30 days if cell death was not appreciable (101). In fact, the β -cell mass in the adult rat does double between the ages of 6 and 10 weeks and continues at a somewhat reduced rate throughout life. Therefore, the β -cell, like most other cell types, must have a finite life span. The frequency of apoptotic β -cells in the adult rat was found to be about 0.5% (100,103); this frequency cannot be equated with a rate because we do not know how long the apoptotic process takes or how long apoptotic bodies are visible. Since the steady-state replication rate is just over 2% a day, the life span of a rat β -cell can be estimated as approximately 58 days (7). The slowly increasing β -cell mass is balanced between cell formation and cell loss, such that the endocrine pancreas must be considered a slowly renewed tissue.

We must assume that the apparently low level of normal β cell growth in the adult is all that is needed to counterbalance cell loss and to accommodate functional challenges of increased body weight and insulin resistance. Diabetes mellitus results only if increased cell loss or functional demands cannot be met. While the regulation of β -cell mass may be complex, the drive to maintain glucose homeostasis could use glucose as the driv-

ing force. As insulin resistance increases, glucose uptake by peripheral tissues would be diminished, with resulting transient postprandial hyperglycemic excursions. Such mild hyperglycemia could signal the β -cells that more insulin is needed, so compensation would occur as enhancement in function, β -cell replication, and cell size. The resulting increased β-cell mass could secrete more insulin that would overcome the insulin resistance and maintain euglycemia. Such a scenario could be repeated numerous times, maintaining compensation as long as the β -cell mass can increase. However, if the hyperglycemia becomes chronic, there can be detrimental secondary effects such as loss of glucose-induced insulin response and even cell death; the term "glucose toxicity" has been used to describe these latter effects. In some strains or species (136,137), β -cells undergo apoptosis when exposed to hyperglycemia, but in other strains, β -cells can have more adaptive responses and maintain a stable mass even in chronic hyperglycemia (138,139). We do not yet know what genes affect renewal or turnover of β cells or their ability to increase their biosynthetic or secretory capacity.

SUMMARY

The islets of Langerhans are composed of various components that are organized to form micro-organs. The architecture or three-dimensional structure imposes certain constraints on interactions between islet cells. As our knowledge increases about the complex organization of the islet of Langerhans and the changes that islets undergo throughout life, we will be able to develop more meaningful interpretations of the physiologic and pathophysiologic characteristics of islet function.

Islets function both singly and in concert. Yet the diversity in islets appears to be greater than that previously recognized. There is functional heterogeneity among islets and among β cells within the same islet. Numerous peptides other than the four main islet hormones (insulin, glucagon, somatostatin, and pancreatic polypeptide) have been immunolocalized in islets, but the roles of most are still unknown.

The mass of islets within a pancreas is dynamic and changes both with growth and development and with functional challenges. As we learn more about the regulation of differentiation of islet cell types and the mechanisms of replication, we also may learn how to enhance the growth of islet cells, particularly the β -cells.

ISLET GENE TRANSCRIPTION AND TYPE 2 DIABETES MELLITUS 59

Despite their small size and apparent simplicity, pancreatic islets of Langerhans are remarkably sophisticated micro-organs. The four cell types that comprise each islet have in common basic endocrine-cell characteristics and are thought to derive from a common precursor during development. In the mature pancreas, however, each cell type functions quite differently, responding to different signals and producing different secreted products. These marked differences result from the differential expression of a unique set of genes. The mechanisms that control differential gene expression determine the functional characteristics of the islet cells (1–3).

The genes differentially expressed in the islet cells include the peptide hormone genes such as those encoding preproinsulin and proglucagon but also include a variety of genes involved at all levels of cell function, such as glucokinase, glutamic acid decarboxylase, the prohormone convertases, cell surface receptors, and cell adhesion molecules. Clearly, a complex regulatory network is needed to ensure that the complete set of genes is expressed at appropriate levels. This regulatory network in turn must quickly mature as each islet cell type develops from a common cluster of pluripotent progenitor cells. Understanding the genetic control of islet function requires an understanding of both how this network emerges during the differentiation of the islet cells and how it functions in the mature islet cell.

DIFFERENTIATION OF DISTINCT ISLET CELL TYPES DURING DEVELOPMENT

As described in the preceding chapter, the islet cells of the pancreas, along with the exocrine and duct cells, differentiate from a common pool of undifferentiated progenitor cells that form the initial pancreatic buds. This process of differentiation results from serial changes in gene expression as uncommitted precursor cells progress to mature, postmitotic, terminally differentiated cells (1–6).

Several models for the lineage relationships of pancreatic endocrine cells have been proposed, generally based on the order of appearance of cell types during fetal development. For example, because the earliest endocrine cells in the fetal pancreas express glucagon, it has been proposed that α -cells function as precursors for the other islet cell types that appear later (7,8). In the absence of labeling studies, however, order of appearance cannot establish a lineage relationship. In fact, a preponderance of recent evidence strongly suggests that α -cells are not precursors for β-cells. First, the early glucagon-expressing cells are postmitotic and thus cannot provide an explanation for the later appearance of much larger numbers of β -cells without cell replication (9-11). Furthermore, during the peak of formation of new β -cells (around embryonic day [E] 15 in the fetal mouse), no cells representing a transition between α - and β -cells with coexpression of glucagon and insulin can be detected (7,8). Finally, experiments with transgenic mice with toxic genes or cre recombinase labeling demonstrate that $\beta\mbox{-cells}$ do not develop from a precursor in which the glucagon promoter is active (12-14). Together, this evidence supports a model in which islet cell type is determined before the expression of the hormone genes.

Insulin-producing cells may develop via more than one pathway. The earliest insulin-producing cells in the mouse fetus, those appearing before E13, do not express the normal set of β -cell genes, because they lack GLUT2, express low levels of insulin, and may coexpress glucagon. These cells do not replicate, and their numbers are small; thus, it is unlikely that they contribute significantly to the population of β -cells in the mature islet. It still remains to be determined whether all of the β -cells present in the mature pancreas differentiated via a common pathway; but because they express the same restricted set of genes, the mechanisms that control gene expression are likely to be the same.

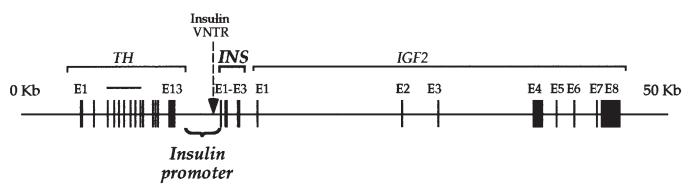

Figure 4.1. The human insulin gene (*INS*) and surrounding loci on chromosome 11. IGF2, insulin-like growth factor-2; TH, tyrosine hydroxylase.

Despite their obvious differences, the four different islet cell types share similar developmental pathways and related functions, and these connections are reflected in similarities in gene-expression mechanisms and in an overlapping set of expressed genes, some of which are also expressed in pancreatic ductal or exocrine cells. Because of its central role in energy metabolism, along with its robust expression and tight restriction to β -cells, the insulin gene has emerged as a paradigm of cell type-restricted expression in the endocrine pancreas.

THE INSULIN-GENE PARADIGM

Humans have a single insulin gene, located on chromosome 2, at 2p21 between the tyrosine hydroxylase (*THI*) gene and the insulin-like growth factor-2 (*IGF-2*) gene (Fig. 4.1) (15). The gene contains two introns, one interrupting the 5' untranslated sequence and the second interrupting the sequence encoding the C-peptide. This general structure is conserved, with few exceptions, among the other mammalian insulin genes, as well as among the related IGF genes (16).

The sequences upstream of the transcription start site comprise the insulin-gene promoter (17). The promoter directs RNA polymerase II to the correct transcription start site, restricts insulin-gene transcription to the β -cell, and responds to metabolic, hormonal, and neural signals by modulating the rate at which insulin-gene transcription is initiated. These functions of the insulin-gene promoter are relatively independent of chromosomal context: When removed from the remainder of the insulin gene, the promoter can similarly regulate any gene inserted downstream. The use of such chimeric genes, with the isolated insulin promoter driving the expression of an easily detectable marker gene such as chloramphenicol acetyl transferase, SV40 large T antigen, or firefly luciferase (18–24), provides a simple method of testing the importance of specific sequences within the promoter. When introduced into insulin-producing cells in culture or into transgenic mice, these chimeric genes demonstrate that a relatively small fragment of the insulin promoter, the proximal 250 to 400 base pairs (bp), provides the same regulation of transcription observed with the intact gene, although larger promoters increase the fidelity and the relative level of transcription in transgenic animals (25).

Careful mutational analyses within the proximal promoter have further delineated the specific sequences that contribute to the full activity of the promoter (22–24,26,27). Figure 4.2 outlines the general architecture, including functionally important sequences in the human and rat insulin-gene promoters. In some regards, the insulin-gene promoter is structurally similar to many cellular gene promoters and contains promoter elements that can function in all cell types. These include a consensus TATAA box, the binding site for the TFIID complex, located 30 bp upstream from the transcription start site, a CCAAT box, and one or more cyclic adenosine monophosphate regulatory elements (27–30).

Other portions of the promoter, however, are more unique and give the promoter the specificity that limits its activity to the β -cells. As shown in Figure 4.2, a number of sequence elements along the proximal promoter contribute to this specific activity, but comparison of the available mammalian insulingene promoter sequences reveals certain common themes. Most prominently, all of the mammalian insulin-gene promoters con-

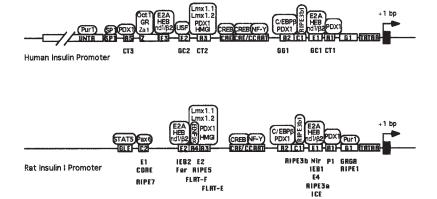

Figure 4.2. The human insulin gene and rat insulin I gene promoters with known sequence elements and binding factors. The boxes represent characterized sequence elements. The binding proteins are circled above the promoter. Older names for the sequence elements are listed below the promoter. GR, glucocorticoid receptor; nd1/ β 2, neuroD1/BETA2.

tain juxtaposed E and A sequence elements. The E elements contain the core sequence motif CCANCTG, and the A elements contain A/T-rich sequences with one or more copies of the sequence TAAT.

Function of the human and rat insulin promoters depends on the presence of at least one A element and one E element. Mutation of either of the two E elements in the rat insulin I gene results in a 90% loss of promoter activity in insulinoma cells, while mutation of both elements ablates all activity (26). The more proximal E element, E1, is absolutely conserved in all known mammalian insulin genes, and its importance has also been demonstrated in the rat insulin II promoter and the human insulin promoter (23,26,31,32). The A3 and A1 elements are both highly conserved in mammalian insulin genes, and the A3 element has been found to play an important role in both rat insulin-gene promoters and the human insulin promoter (23,26,31,32).

The Basic Helix-Loop-Helix Transcription Factors: NeuroD1

The sequences of the insulin E elements are a subset of the common CANNTG E box elements that play important roles in many cell type–specific promoters, including the promoters for the immunoglobulin genes and muscle-specific genes (33). E boxes are binding sites for proteins of the basic helix-loop-helix (bHLH) family. The bHLH proteins form dimers through their helix-loop-helix domains, and these dimers contact and bind to DNA with the basic domains. Because heterodimerization is permitted, and in most cases favored, a large variety of complexes are possible. Cell type–specific complexes generally result from heterodimerization of one of a limited number of ubiquitously expressed bHLH proteins (class A) with one of a large set of cell type–restricted bHLH proteins (class B).

β-Cells contain several bHLH complexes capable of binding to the insulin E boxes. Nuclear extracts from insulinoma cells demonstrate that the predominant complexes are formed from dimerization of a ubiquitous bHLH protein (the E12 or E47 products of the *E2A* gene or HEB) with the neuroendocrine bHLH protein neuroD1/BETA2 (24,34–39). NeuroD1 is expressed in all of the islet cells, in the endocrine cells of the gut, and in the central nervous system. The carboxyl-terminus of neuroD1 contains a potent transcriptional activation domain (40,41) (Fig. 4.3), and ectopic expression of neuroD1 can activate the insulin promoter in non–β-cells (38).

Mice homozygous for a targeted disruption of the gene encoding neuroD1 have a marked decrease in islet cells due to premature apoptosis and die of diabetes shortly after birth (42,43). In addition, absence of neuroD1 results in losses of enteroendocrine cells and in defects in several aspects of neural development (42–49). Interestingly, insulin is still produced by the remaining β -cells in the pancreas, suggesting either that neuroD1 function is not required for insulin-gene transcription or that other bHLH proteins may be able to substitute for neuroD1 on the insulin promoter (42).

Homeodomain Transcription Factors: PDX1

The A elements function as binding sites for homeodomain proteins, a broad family of transcription factors. Homeodomain proteins have been found in all eukaryotic organisms and are characterized by a conserved stretch of 61 amino acids called the homeodomain, which forms a helix-turn-helix structure that binds to DNA. Homeodomain proteins play critical roles in celltype determination and differentiation during development, as well as in the regulation of gene expression in the mature cells. 4: GENETIC REGULATION OF ISLET FUNCTION 55

PDX1

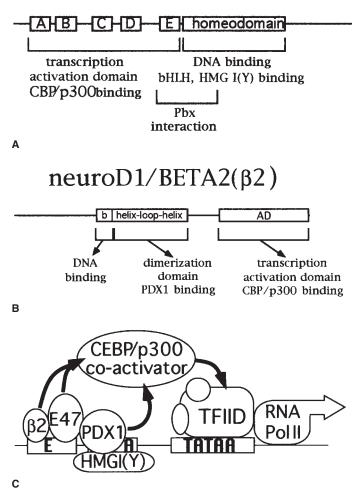

Figure 4.3. The insulin promoter transcription complex. **A:** The functional domains of the PDX1 protein are outlined. The regions labeled A–E represent conserved domains within the activation domain (90) **B:** The functional domains of the neuroD1/Beta2 protein are outlined. **C:** Interactions are shown among PDX1, the bHLH proteins, HMGI(Y), and p300 that result in transcriptional activation of the E–A mini-enhancer. β 2, neuroD1/BETA2.

In extracts from β -cell nuclei, the most abundant protein binding to the A elements is the homeodomain protein PDX1 (also called IPF1, IDX1, STF1, IUF1, and GSF1) (50–56). PDX1 belongs to the parahox family of homeobox genes and is expressed in the antral stomach, duodenum, and pancreas (50,57). Early in development PDX1 is expressed broadly in the pancreatic bud, but after E13 in the mouse, it becomes restricted, with high levels of expression in β -cells and some δ cells and lower levels of expression in acinar cells and duct cells. PDX1 can bind to all of the A elements in the rat and human insulin promoters and can activate portions of the insulin promoter in cell lines (50–52). Furthermore, forced expression of PDX1 has been reported to activate the endogenous insulin gene in some non– β -cells (58,59).

Mice homozygous for a targeted disruption of the gene encoding PDX1 have a profound defect in pancreatic growth, with essentially no development of the pancreas beyond initial bud formation, and die shortly after birth (60–62). A few hormone-producing cells, including insulin-producing cells, however, can be detected in the remaining dorsal bud (61). If instead

the *pdx1* gene is inactivated specifically in β -cells after the pancreas has formed, by using a cre-lox recombination system with the insulin promoter driving the cre recombinase, the differentiated phenotype of the β -cells is partially lost (63). In these animals with a β -cell–specific disruption of the *pdx1* gene, the β -cell mass decreases; and the remaining β -cells coexpress glucagon and have reduced GLUT2 and reduced glucose-stimulated insulin secretion. As in the β -cells lacking neuroD1, however, the β -cells lacking PDX1 continue to produce insulin.

The persistence of insulin-gene transcription in the absence of PDX1 suggests the presence of additional homeodomain proteins in β -cells that can drive insulin-gene expression *in vivo*. Although it is clearly the most abundant nuclear protein capable of binding the A elements in β -cells, PDX1 is not the only homeodomain transcription factor expressed in β-cells nor the only homeodomain protein in β -cells capable of binding and activating transcription through the A elements (54,64–66). Two β -cell homeodomain proteins, Cdx2/3 and lmx1A, have been shown to bind to and activate through the A3 and A4 sites in the rat insulin I promoter (65). In addition, the POU-homeodomain protein HNF1a is also expressed in βcells, and it binds to and activates the A4 site in the rat insulin I promoter, although the A4 site is not conserved in insulin genes from other species (66). Finally, β -cells express a diverse set of additional homeodomain transcription factors; some of these regulate insulin-gene transcription, but all play some part in β -cell gene expression (54).

Paired-Homeodomain Factors: Pax6

The E and A elements and the protein complexes that bind to them are essential to the function of the insulin promoter but cannot explain all of the activity of the promoter. A G/C rich sequence, C2, in the distal promoter contributes significantly to the activity of the rat insulin promoters both in insulinoma cells and primary-cultured β -cells (26,27,31). Because the C2 element and related elements in the glucagon and somatostatin gene promoters all function in an islet cell–specific manner and bind to an islet-specific complex, this common islet enhancer element has been termed PISCES (pancreatic islet cell-specific enhancer sequence) (67–72).

C2 and the other PISCES elements closely match the consensus binding sequence for the paired-homeodomain transcription factor Pax6, and Pax6 antiserum recognizes the islet-specific complex that binds to all three PISCES elements (73). Pax6 contains a potent transcriptional activation domain and three DNA-binding domains, a paired region composed of the pai and red domains and a homeodomain (74–76). Pax6 protein first appears during development in the nuclei of a few scattered cells in the gut endoderm where the dorsal bud and the first glucagon-producing cells will appear a few hours later (73). From that point on, it is expressed in the nuclei of all the endocrine cells in other tissues.

Mice carrying mutations in the *pax6* gene were previously identified and named small eye because of a defect in eye development in the heterozygous mice. Mice homozygous for the small-eye mutations or a targeted interruption of the *pax6* gene die at birth with multiple craniofacial and neurologic defects. In addition, the homozygous mutant animals have profound defects in islet development, with decreased numbers of all islet cell types (73,77). The remaining β -cells also have a significant decrease in the amount of insulin mRNA and protein per cell. These mice demonstrate that Pax6 is important but not absolutely essential for expression of the insulin gene in mice. The importance of Pax6 in human insulin-gene expression is

less certain, however, because the C2 element is not conserved in the human insulin-gene promoter.

Unidentified Factors: RIPE3b1

Immediately upstream of the E1 element lies the C1 element, a cytosine-rich sequence that is conserved in all of the mammalian insulin promoters. The C1 element is critically important for the function of both the human insulin and rat insulin II promoters (31,32,35,78–80). A protein complex found in β -cell nuclei, the RIPE3b1 complex binds specifically to the C1 element and has not been detected in other cell-types, including α -cells (35,81). Although it is known that the RIPE3b1 complex is composed of several proteins of similar molecular mass and that binding to the C1 element requires its phosphorylation, the protein has not been identified (82–84).

Unidentified Factors: Za1

Upstream of the A3 element in the human insulin promoter lies the negative regulatory element (NRE), which strongly inhibits insulin promoter function in β -cell tumor lines (32,85,86). The NRE also inhibits transcription when isolated from the insulin promoter and linked to a heterologous promoter in either β -cell or non- β cell tumor lines (32,85). It has been proposed that the NRE may modulate insulin promoter activity and help restrict insulin expression to the β -cell (85).

The NRE may not always function, however, simply as a silencer of transcription. Walker et al. (18), for example, found that removal of the NRE from the human insulin promoter had no significant effect on the promoter, and Clark et al. (85) found that isolated sequences within the NRE could activate transcription weakly. It is in primary cultured islets, however, that the NRE reveals its most remarkable activity. Removal of the NRE from the human insulin promoter causes a marked loss of activity in cultured fetal rat islet cells (80). Placed upstream of a minimal insulin promoter or a heterologous promoter, the NRE functions as a potent activator of transcription in both fetal and adult islets, whereas in the same constructs it strongly represses transcription in tumor cell lines from β -cells or non- β cells and in primary-cultured fibroblasts (86). Because it appears that the primary function of this region in normal β -cells *in vivo* is to activate transcription, this region has been renamed the Z element. Although a Z element–binding complex that correlates with the positive activity of the Z element can be detected in nuclear extracts from primary cultured islets (86), the proteins in this complex have not been identified.

The Insulin Promoter Transcription Complex

The linear view of the insulin promoter as a series of binding sites and binding proteins, as shown in Figure 4.2, fails to illustrate the complexity and dynamic character of the functioning promoter *in vivo*. Missing from this view is the added dimension provided by the interactions among the transcription factors, DNA structural proteins, co-activators and repressors, intracellular signaling molecules, and the RNA polymerase complex. This view also ignores the role of upstream factors that regulate the expression and function of these proteins. The promoter should be regarded as a large and fluid complex formed by interactions among many different proteins and the chromosome in dynamic equilibrium with forces acting from within and outside the cell.

In this perspective, the bipartite E-A combination represents the minimal functional component of the larger complex and demonstrates the underlying concept of cooperativity. Neither the E elements nor the A elements by themselves have any significant transcriptional activity in β -cells; but together they can dramatically boost the activity of a linked promoter in a β cell–specific fashion (87,88). The synergy between these elements results from interactions among the proteins that bind to them and non–DNA-binding transcriptional co-activators.

This cooperativity can be demonstrated when PDX1 is coexpressed along with either E47 or E47 plus neuroD1 in non- β -cells: activation of the E-A mini-enhancer depends on the combination of PDX1 bound to the A element and a bHLH dimer bound to the E element (89,90). In addition to both the E and A binding sites, cooperativity between PDX1 and the bHLH dimer requires the DNA-binding domains of all the proteins and the transcriptional activation domains of both PDX1 and at least one of the bHLH proteins (89–93).

Cooperativity results from interactions among the proteins at several levels (Fig. 4.3). First, the proteins cooperate at the level of DNA binding. Physical interaction among the DNA binding domains, the homeodomain of PDX1, and the bHLH domains of E47 and neuroD1/BETA2, stabilizes the complex of all three proteins on DNA. Although DNA binding affinity is increased, with purified proteins in vitro the relative increase in binding affinity is small (92). In vivo, however, the nuclear environment is very different, with differences in local concentrations of factors and the presence of many other proteins, all of which change the energetic equilibrium of DNA binding. In addition, chromatin structure is quite different from the purified oligonucleotides used to test DNA binding in vitro. Chromosome structure is controlled in vivo by the binding of histones and of small, abundant DNA-binding proteins, the high-mobility group (HMG) proteins.

The presence of these structural DNA-binding proteins changes the energetic cost of DNA-binding by the transcription factors (for a review, see reference 94). For example, in the presence of HMG I(Y), a small nonhistone DNA-binding protein that can bind to the A3/4 region of the insulin promoter, cobinding of PDX1 and the bHLH dimer is greatly favored *in vitro*. As a result, HMG I(Y) increases PDX-bHLH transcriptional synergy *in vivo*. In insect cells, where HMG I proteins are expressed at very low levels, PDX1 and the bHLH proteins cannot cooperatively activate the E-A mini-enhancer without the addition of HMG I(Y) (92).

At the next level of organization, the insulin promoter activation complex requires non-DNA-binding proteins that form a bridge between the proteins binding at the E and A sites and the basal transcriptional machinery. Just as interactions within the PDX1/bHLH/HMG I(Y) complex stabilize DNA binding and increase the occupancy of the E-A sites on the insulin promoter, multiple protein-protein contacts stabilize the interaction with the basal transcription machinery and ensure efficient transcription initiation. The grouping of transcription factors on adjacent DNA sites, as in the E-A mini-enhancers, creates clusters of protein interaction sites that cooperatively recruit or stabilize binding of the RNA polymerase II transcription initiation complex (95). Non-DNA-binding coactivators promote this process by linking the DNA-bound transcription factors with TFIID complex and the basal transcription machinery. The additional interactions provided by the co-activators provide critical stability and play a linchpin role in the formation and the function of the insulin promoter transcription-activation complex (Fig. 4.3). In support of this model, the E2A proteins, neuroD1, and PDX1 have all been shown to interact with the ubiquitous p300 co-activator (40,41,47,96,97).

If insulin-gene transcription depends on the presence of an active insulin promoter complex and the assembly of that complex depends on the proper interactions of multiple nuclear proteins, then the cell-type specificity of insulin-gene transcription is a product of the uniqueness of the set of proteins that compose the complex. According to this model, the absence of some subset of these proteins in other, non– β -cells, or the presence of proteins that interrupt the interactions that stabilize the complex would block formation of the complex and prevent insulin-gene transcription. The true explanation is not quite this simple, however, as demonstrated by the fact that mice lacking key components of the complex, PDX1, neuroD1, E2A, or HEB, can all continue to transcribe the insulin gene in β -cells (42,63,98). Apparently, the insulin-gene transcription complex has some inherent flexibility and redundancy.

Although the transcription complex certainly provides significant specificity, it cannot by itself provide an explanation for the strict restriction of insulin-gene transcription to the βcell. Negative regulation in non- β -cells plays a role as well. Non- β -cells contain proteins in their nuclei that interfere with formation of the insulin-gene transcription complex. For example, the homeodomain protein pbx can associate with PDX1 and alter its DNA-binding specificity, thereby preventing it from binding to the insulin promoter A sites (97,99,100). In addition, the physical state of the chromatin surrounding the insulin gene may silence the gene in non– β -cells. Modifications such as methylation or structural changes induced by histone binding can block access to the gene for binding by the transcription complex (101-103). Finally, it must be understood that not only does the physical state of the chromatin at the insulin promoter affect binding of the transcription complex but the proteins of the transcription complex can alter local histone acetylation and binding, thereby opening the chromatin structure of the promoter region and increasing access for the transcription complex. These interactions amplify the effect of small changes in functional levels of the transcription complex, producing a threshold for insulin-gene transcription.

Metabolic Regulation of Gene Expression

In their role as nutrient sensors and metabolic regulators, the islet cells need to alter gene expression in response to the metabolic state of the organism. The paradigm for how the islet cells achieve metabolic regulation of gene expression has been the regulation of the insulin gene by glucose.

Levels of insulin messenger \overline{RNA} (mRNA) increase in β -cells in response to glucose due to the combined effects of increased insulin-gene transcription, increased insulin pre-RNA splicing, and decreased insulin mRNA degradation (104–106). It has been proposed that the increase in transcription occurs within a few minutes of glucose stimulation (107), but because the halflife of insulin mRNA is 1 to 4 days (105), it is difficult to understand how this rapid change would significantly affect insulin production or secretion in response to a meal. More likely, changes in insulin-gene transcription modulate insulin production in response to long-term dietary changes.

The transcriptional activation induced by glucose in the β -cell is selective for the insulin gene and is due at least in part to activation of the insulin promoter and the E-A mini-enhancer (108) (Fig. 4.4). Glucose regulates the promoter through multiple effects on several of the proteins in the transcription activation complex (27,52,79,80,86,108–110). After glucose stimulation, PDX1 binding to the A elements acutely increases (55,56,109), due in part to phosphorylation of PDX1 through a pathway that involves phosphatidylinositol (PI) 3 kinase and the stress-activated protein kinase 2 (SAPK2) (55,111). Glucose also causes a shift in the cel-

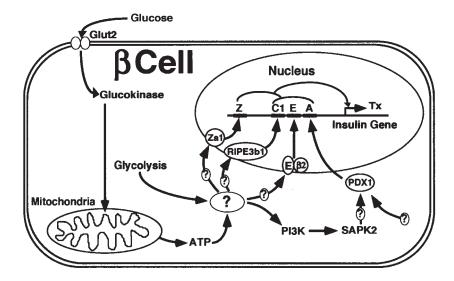

Figure 4.4. Proposed pathways for glucose regulation of insulin gene expression. *IE* represents E2A proteins, and β 2 represents the selectively expressed heterodimer partner neuroD1/BETA2. Question marks indicate unknown steps in the pathway or the probable intersection with other pathways. The two objects labeled *IE* and β 2 represent a dimer of the E47 and neuroD1/BETA2 bHLH proteins.

lular distribution of PDX1 to the nucleus (112–114), apparently secondary to its phosphorylation (112,114), and increases the activation potential of the PDX1 activation domain (115).

At the same time, glucose increases the binding of the bHLH dimer to the E elements (27), which in turn cooperate with the activated PDX1 bound at the A site to increase insulin-gene transcription. In addition, sequences outside the E-A elements also contribute to the transcriptional response to glucose, as demonstrated by increased binding of the Za1 (86) and RIPE3b1 (110) protein complexes in response to glucose. All of these effects then combine to produce the overall increase in insulingene transcription in response to glucose.

Glucose stimulates insulin-gene transcription indirectly through the end products of its catabolism (116). The rate-limiting step for glycolysis in β -cells is phosphorylation of glucose to glucose-6-phosphate. When the rate of glucose phosphorylation is increased by expressing high levels of hexokinase I in β -cells, glycolysis is accelerated and the insulin promoter is activated. The intermediates of glycolysis are required for this response (116). The intracellular signaling pathways through which glycolysis regulates the insulin-gene activation complex remain elusive, although it has been proposed that insulin secretion may feed back to activate insulin-gene transcription in the β -cell through its receptor, PI 3 kinase, and downstream signaling pathways (117,118).

Application to the Expression of Other Islet Genes

As our understanding of insulin-gene expression has expanded, it has become apparent that many of the lessons learned from studies of the insulin promoter can be applied to the broader problem of islet cell–specific gene expression. The general concept of cooperative protein interactions building an activation complex that is specific to a particular gene and cell type explains the specificity of other islet cell–specific promoters. In addition, many of the proteins that form these complexes are the same. For example, PDX1 binds and activates promoters from the β -cell genes islet amyloid polypeptide, GLUT2, and glucokinase (17,59,119–121) and the δ -cell gene somatostatin (51), as well as the insulin-gene promoter.

The glucagon-gene promoter provides an interesting comparison to the insulin-gene promoter (Fig. 4.5). Like the insulingene promoter, the glucagon-gene promoter depends on interactions among several sequence elements. The proximal G1 element is required for function of the promoter and restricts activity to the α -cell, but its activity depends on interactions with at least one of the more distal elements G2 and G3 (122–125), although more distal elements may play important roles as well (126). Like the insulin promoter, many of the sequences found in these elements function as binding sites for homeodomain and bHLH proteins (73,127–133).

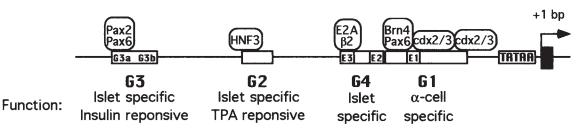

Figure 4.5. The rat glucagon-gene promoter with known sequence elements and binding factors. The boxes represent characterized sequence elements. The four interacting enhancer regions, G1–G4, are labeled below the boxes, and their functional roles are listed underneath. The cloned binding proteins are circled above the promoter. β_2 , neuroD1/BETA2.

The proximal G1 element contains several adjacent and overlapping binding sites. The pou-homeodomain transcription factor Brn4 binds to an A/T-rich sequence at the 5' end of the G1 element (133). Within the adult pancreas, Brn4 expression is restricted to the α -cells, and it can activate both an isolated glucagon-gene promoter in a G1-dependent manner (133) and the native glucagon gene (134). Activity of the G1 element also appears to involve two other homeodomain proteins: pax6, which binds to a sequence overlapping the one recognized by brn4, and cdx2/3, which binds to two sites on the 3' end of the G1 element (129,130,135–138). Pax6 and cdx2/3 then synergize in activating the promoter by cooperatively recruiting the p300 co-activator (136–138).

Full activation of the glucagon promoter results from higherorder interaction between the complex of proteins binding to the G1 element and the complexes on the G2, G3, and G4 elements, each of which depends on additional interactions among proteins binding within each element (71,72,122,123,131, 139–146). Similar to glucose regulation of the insulin promoter, this interdependence of discrete promoter elements and their cognate binding factors allows for regulation of the entire promoter through regulation of individual factors, as exemplified by the regulation of the G3 complex by insulin (143,147,148) and the G2 element by protein kinase C (141).

Upstream Genes in Differentiating and Mature Islet Cells

The preceding discussion yields a model for the expression of islet genes in which gene activation is achieved through multiple protein interactions that combine to produce a unique gene transcription complex on the promoter. Before an active complex can form, however, the genes encoding each of the proteins that comprise the complex must themselves be activated. Studies of the differentiation of islet cells from pluripotent progenitor cells have provided insight into the hierarchy of these factors and the cascade of gene expression events that lie upstream of the activation of the final differentiated genes such as insulin (Fig. 4.6). As a result, islet gene expression is regulated by an entire network of factors directly and indirectly involved in the formation of each gene transcription complex.

ISLET GENE TRANSCRIPTION AND TYPE 2 DIABETES MELLITUS

The determination that mutations in the genes encoding islet transcription factors can lead to diabetes mellitus in mice (Table 4.1) led to the consideration of these genes as candidates in genetic studies of type 2 diabetes mellitus in humans. Type 2 diabetes mellitus in humans is a strongly genetic disorder, but its inheritance is complex, and the identification of the contributing genes has been impeded by the non-Mendelian inheritance of the disease in most families. To simplify genetic studies, efforts to identify diabetes genes initially focused on families with an early onset and autosomal dominant form of the disease termed maturity-onset diabetes of the young (MODY). Of the five causative genes so far identified in families with MODY, four encode islet transcription factors: HNF4α (MODY1) (149), HNF1α (MODY3) (150), IPF1 (PDX1, MODY4) (151), and HNF1B (MODY5) (152). In addition, mutations in the coding sequence of isl1 and neuroD1 have been implicated in families with later-onset diabetes (153,154) (Table 4.1).

How do mutations in these genes cause diabetes mellitus? Even with the availability of mutant mouse lines, answering this question has not been simple. While it is tempting to speculate that these mutations cause diabetes mellitus by affecting the expression of a single key target gene such as insulin or GLUT2, the animal models suggest that the answer is more complex. Given the interdependence of the different islet transcription factors, it is not surprising to find that mutation of a single transcription-factor gene can impair the expression of many islet genes, including many that do not appear to be direct targets of the transcription factor (63,155–159). For that reason, the upstream regulators of islet differentiation and gene expression, the transcription factor genes such as *Nkx2.2*, *Nkx6.1*, *Pax4*, and *neurogenin3*, also

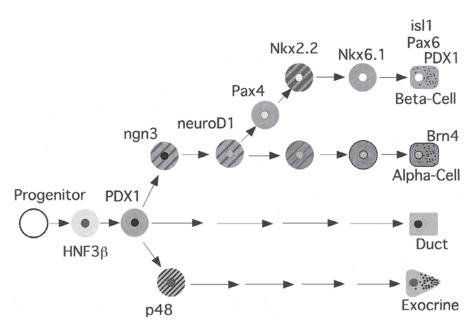

Figure 4.6. A simplified model for the role of islet transcription factors in endocrine differentiation in the developing pancreas. The proposed position for each transcription factor is based on its timing of expression, timing of predominant functional role, or both. Clearly, some factors function at several steps, but a single step is shown for simplicity.

TABLE 4.1. Islet Transcription Factors						
Factor	Family	Expression	Downstream islet genes	Mouse mutations ^a	Human mutations	References
Neurogenin 3	bHLH	Fetal pancreas and CNS	NeuroD1/BETA2, Pax4, Nkx2.2	Diabetes, no islet cells		(11,160–163)
NeuroD1/ BETA2	bHLH	Islet, gut endocrine cells, CNS	Insulin	Diabetes, decreased islet cells	Het: late-onset diabetes	(38–40,42,47,53)
PDX1/IPF1	Parahox homeodomain	α- and β-cells, duodenum and stomach	Insulin, IAPP, glucokinase, GLUT2	Pancreatic agenesis	Het: MODY4 Hom: pancreatic agenesis	(59–63, 119–121, 151, 164,165)
HB9	Parahox homeodomain	β-cells, gut, lymphoid, CNS	GLUT2	Dorsal pancreatic agenesis	Het: sacral agenesis	(166–168)
Pax2	Paired domain	Islet, urogenital tract and CNS	Glucagon	Defects in optic nerve, CNS and urogenital tract	Het: renal- coloboma syndrome	(169,170)
Pax4	Paired- homeodomain	Fetal pancreas and CNS	Pax4 (autorepression)	Decreased β- and α-cells	,	(171–173)
Pax6	Paired- homeodomain	Islet, gut endocrine cells, CNS	Glucagon, insulin, somatostatin	Decrease in all islet cells, decreased glucagon	Het: aniridia	(73,77,135)
Nkx2.2	NK- homeodomain	α-, β-, and PP cells and CNS	Nkx6.1, insulin, GLUT2, GK	Diabetes, no insulin		(10,54,174,175)
Nkx6.1	NK- homeodomain	β -cells and CNS	,	Decreased β-cells, postnatal lethal		(10,54,174,176)
Cdx2/3	Caudal- homeodomain	Islet and gut	Glucagon	Het: gut tumors Hom: embryonic lethal		(65,128–130,177)
Isl1	LIM- homeodomain	Islet and CNS	Somatostatin, glucagon	No islet cells, embryonic lethal		(9,64,154, 178–181)
Lmx1.1	LIM- homeodomain	β -cells and CNS	Insulin	Dreher: roof plate, cerebellum defects		(65,92,182)
Brn4	Pou- homeodomain	α -cells and CNS	Glucagon		Hom: congenital neurogenic deafness	(11,133,183)
HNF1α	Pou- homeodomain	Islet, liver, kidney	Pax4, Ngn3, GLUT2, Rat insulin I	Diabetes, impaired β-cell glucose sensing	Het: MODY3	(66,150,157,159, 171,184,185)
HNF1β	Pou- homeodomain	Islet, pancreatic duct, liver, kidney	Pax4	Embryonic lethal	Het: MODY5	(152,171,186,187)
HNF6	Cut- homeodomain	Pancreatic duct, liver	Neurogenin3	IGT, small islets		(185,188–192)
HNF3α HNF3β	Winged helix Winged helix	Islet, gut, liver Islet, pancreatic duct, gut, liver, CNS	Glucagon PDX1, neurogenin3	Hypoglycemia Embryonic lethal		(146,193) (156,185,190,192, 194–197)
HNF4α	Nuclear receptor	Liver, islet, kidney	HNF1α, glycolytic enzymes, Pax4	Embryonic lethal	Het: MODY1	(149,156,171, 198–200)

CNS, Central nervous system; het, heterozygous; hom, homozygous; MODY, maturity-onset diabetes of the young. ^aAll mouse phenotypes are for homozygous mutant animals unless stated otherwise.

should be considered candidate genes for genetic studies of type 2 diabetes mellitus.

Acknowledgments

I would like to thank the many members of the Rutter and German laboratories who contributed to the work discussed here. The work from our laboratory was supported by NIH grants DK-21344 and DK-48281.

SUMMARY 76

Insulin, the major hormonal regulator of glucose metabolism, was first isolated from pancreatic tissue in 1921 by Banting and Best (1). Shortly after the discovery of insulin, the impure extract was used experimentally to treat pancreatectomized dogs (2) and patients with diabetes mellitus (3). As soon as it became clear that the hormone was effective, both the amount of extract isolated and the degree of its purity were increased. Insulin was thus made available to patients with diabetes mellitus. The treatment of such patients underwent a remarkable revolution within 1 to 2 years of the initial discovery of insulin. However, many aspects of insulin biochemistry and chemistry were not understood until years later, and some of these topics remain as areas of intense investigation. This chapter will focus on the biosynthesis of insulin, from insulin gene to secretory granule; the chemistry and structure of insulin; and abnormalities in insulin structure that affect its action or biosynthetic processing.

INSULIN PRODUCTION

In mammals, expression of the insulin gene and insulin biosynthesis are restricted to the β -cells of the endocrine pancreas (4), with the possible exception of the yolk sac and fetal liver (5,6). This exquisite tissue selectivity is conferred upon the insulin gene by a complex interplay between upstream *cis*-elements (short DNA sequences) and cellular *trans*-acting factors (proteins) that bind to the DNA and regulate expression (refer to Chapters 2 and 4). The primary function of the pancreatic β -cell is the production, storage, and regulated secretion of insulin. Under normal circumstances, the β -cell maintains a condition such that there is always a readily available pool of insulin that can be rapidly secreted in response to a stimulus, such as an increase in blood glucose level. Any increase in insulin release is compensated for by a corresponding increase in insulin biosynthesis, so that β -cell insulin

stores are constantly maintained. Thus, the biosynthesis and processing of the insulin molecule along the secretory pathway of the β -cell is a highly regulated and dynamic process.

Translation of Preproinsulin and Conversion to Proinsulin

Although the two-chain structure of insulin had been known since 1955 (7), it was not until 1967 that Steiner et al. (8,9) first presented evidence for a single-chain biosynthetic precursor, proinsulin. The identification of a hormone precursor was profound for our understanding not only of insulin synthesis but also of protein synthesis in general. It is now evident that there is also a protein precursor for proinsulin, preproinsulin (10,11) (Fig. 5.1), with (for the human protein) the first 24 amino acids forming a signal peptide. The role of signal peptides in the translocation of nascent proteins to the lumen of the rough endoplasmic reticulum (RER) was first elucidated by Gunter Blobel and colleagues (12), and he was awarded the Nobel Prize for this work in 1999. As preproinsulin is synthesized, the signal peptide is bound by the signal-recognition particle (SRP), which in turn homes to the SRP receptor on the membrane of the RER (13). These events occur after the addition of the first 70 to 80 amino acids to the growing preproinsulin chain (14,15). The signal peptide is rich in hydrophobic residues, facilitating the penetration of the RER membrane. Penetration occurs rapidly, and the rest of the nascent preproinsulin molecule then crosses into the lumen of the RER. A signal peptidase within the RER causes cleavage of the signal peptide from preproinsulin to yield intact proinsulin. This proteolytic event arises for the most part cotranslationally, so that preproinsulin is a very minor constituent of the β -cell (16).

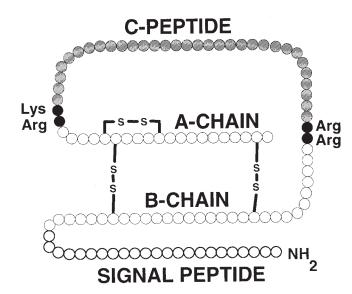

Figure 5.1. Preproinsulin. The initial, high-molecular-weight precursor of insulin consists of four distinct domains. The signal (or pre-) peptide occupies the first (amino-terminal) 24 residues (human preproinsulin) and is cleaved off within the lumen of the rough endoplasmic reticulum to produce proinsulin. Conversion of proinsulin to insulin arises at the pairs of basic residues linking the two insulin (A- and B-) chains to the C- (connecting) peptide, as depicted in Figure 5.3. The two insulin chains are joined together by two disulfide bridges. The molecular mass of insulin is approximately 5,800 daltons.

Regulation of Insulin Biosynthesis in the β-Cell

The rate of proinsulin biosynthesis is controlled by many factors, including nutrients, neurotransmitters, and hormones (17-20). The most physiologically relevant of these is glucose (21). The initial studies on the regulation of biosynthesis were limited to measuring the rate of incorporation of labeled amino acid into insulin or its precursors. The earliest of these studies, dating from the 1960s (22-26), showed that glucose specifically stimulated (pro)insulin biosynthesis in vitro above that of general protein synthesis in the β -cell. As for insulin secretion, the metabolism of glucose is necessary to generate intracellular signals to stimulate insulin biosynthesis (21,26-29). However, while the threshold concentration of glucose required to stimulate insulin secretion is 4 to 6 mM, that required to stimulate insulin biosynthesis is lower-between 2 and 4 mM (28-31). Maximum proinsulin biosynthesis is reached at a glucose concentration of 10 to 12 mM (21,28,29). As well as glucose (21,30,32-34), other sugars (21,23,27,35) and nutrients, including leucine (36), succinate (37), pyruvate (38), inosine, guanosine, adenosine, and ribose (30,39,40), are capable of stimulating insulin biosynthesis but are generally less effective than glucose. After exposure of pancreatic islet β -cells to a glucose stimulus, there is about a 20-minute lag period before there is any significant increase in proinsulin biosynthesis. By 60 minutes, the rate of proinsulin synthesis is stimulated 10- to 20-fold (28,29,41). Upon removal of the stimulus, downregulation of proinsulin biosynthesis is relatively slow, taking more than 1 hour to return to a basal rate (41).

Certain hormones also specifically stimulate insulin biosynthesis, such as growth hormone (42,43), glucagon (44), and glucagon-like peptide-1 (GLP-1) (45). Glucagon and GLP-1 stimulate insulin biosynthesis via a cyclic adenosine monophosphate (cAMP)-dependent pathway; and indeed, cAMP itself can potentiate glucose-induced proinsulin biosynthesis (30-32,44,46,47). As for insulin secretion, epinephrine inhibits glucose-induced insulin synthesis (46). Whereas somatostatin is a potent inhibitor of insulin secretion, it has no effect on proinsulin biosynthesis (48,49). Relevant to cytokine-mediated β -cell destruction in type 1 diabetes mellitus, it has been shown that interferons can inhibit insulin biosynthesis, but only at extremely high concentrations (50-52). Depending on the concentration used, interleukin-1 can either stimulate or inhibit insulin biosynthesis (52-54). The rate of proinsulin biosynthesis is also increased in pregnancy (55,56) and obesity (57,58) as well as during in vivo glucose infusions (59–61), but in these examples, it is in association with increased β -cell mass and islet hyperplasia. On the other hand, in other physiologic or pathophysiologic states, such as aging (62), some animal models of type 2 diabetes mellitus (63,64), or during starvation (38,55,65), there is a degree of inhibition of proinsulin synthesis. However, it is not entirely clear whether this is reflective of decreased β-cell mass

In general, nutrients that are efficiently metabolized in β cells stimulate insulin secretion and proinsulin biosynthesis at the translational level in parallel (19,20). This provides an ideal situation where insulin released from the β -cell is rapidly replenished at the biosynthetic level by the same stimulus. However, unlike the metabolic stimulus-response coupling for regulation of insulin secretion (refer to Chapter 6 and references 66–71), information regarding that for proinsulin biosynthesis is lacking. In all likelihood, beyond a requirement for glucose metabolism, the mechanism responsible for stimulus coupling of proinsulin biosynthesis differs from that for insulin secretion.

There are several lines of evidence to suggest this is so. Extracellular Ca²⁺ is essential for glucose-induced insulin release, but proinsulin biosynthesis is independent of Ca²⁺ (66,72). Likewise, inhibitors of Ca²⁺ calmodulin kinase activity (e.g., trifluoperazine) inhibit insulin release (73,74) but have no effect on proinsulin biosynthesis (75). In contrast, Mg²⁺ appears to be a requirement of proinsulin biosynthesis, but not necessarily of insulin release (47). Sulfonylureas, which close the β -cell K_{ATP}channel in a key step in signal transduction for glucose-induced insulin release (refer to Chapter 6) (69,71), are very effective at inducing insulin release but appear to have little effect on proinsulin biosynthesis (25,76,77). Likewise, diazoxide that keeps the β -cell K_{ATP}-channel open (78) inhibits insulin release (67) but not proinsulin biosynthesis (47). Long-chain fatty acids are marked potentiators of insulin release (79-81) but have a tendency to inhibit glucose-induced proinsulin biosynthesis (38,49). Protein kinase C has been involved in stimulus coupling for insulin secretion (82) but does not appear to be related to the specific regulation of proinsulin biosynthesis (38,49,83,84).

In the early 1970s, Permutt and Kipnis convincingly demonstrated that glucose regulation occurred at both the pretranscriptional and posttranscriptional levels (85-87) and that translation was affected by modulating initiation and, to a lesser extent, by the rate of elongation (87). Such translational regulation by glucose was confirmed by experiments using cell-free systems (88-90). Subsequent studies have found that short-term (less than 4 hours) glucose stimulation of pancreatic islets does not alter the total amount of preproinsulin messenger RNA (mRNA) in a β -cell, even though proinsulin biosynthesis is increased 10- to 20-fold (21,83,91–93). Moreover, short-term glucose-induced proinsulin biosynthesis is unaffected by inhibition of insulin gene transcription (28,85). Thus, short-term proinsulin biosynthesis is principally controlled by translational regulation of preexisting preproinsulin mRNA (19,76). Although total preproinsulin mRNA levels in the β -cell are unchanged, upon an increase in glucose level, preproinsulin mRNA is redistributed from a cytosolic storage pool to polysomes associated with the RER, the major site of proinsulin biosynthesis (4,91,93,94). This reaffirmed that glucose primarily influences the initiation phase of preproinsulin mRNA translation (95-98). The additional glucose-mediated regulation at the elongation phase of translation [below 3 mM glucose; see references (93,99)] and at SRP-SRPreceptor interaction (91,93) is likely adaptive to the primary regulation at the initiation phase of preproinsulin mRNA translation (91,93,100). For general protein synthesis, translational regulation occurs primarily at the initiation phase (98); however, glucose specifically stimulates proinsulin biosynthesis above that of general protein synthesis in the β -cell. Thus, translational control of proinsulin biosynthesis is a relatively exclusive mechanism (21,83,85,100). Although the details of this mechanism have yet to be defined, it is currently thought that there are specific elements within preproinsulin mRNA that control its rate of translation and consequently the biosynthesis of proinsulin (20,100,101). This is analogous to specific translational regulation of ferritin biosynthesis by iron (102).

Under normal physiologic circumstances, where a glucose stimulus lasts no longer than 2 to 3 hours, control of proinsulin biosynthesis is mediated entirely at the translational level (18,28,38,83,93). However, for prolonged exposure to glucose (greater than 4 hours), such as the hyperglycemia in animal models of non–insulin-dependent diabetes mellitus (NIDDM) (103,104), a degree of transcriptional regulation (59,64,105,106) and changes in mRNA stability (107) additionally contribute to the control of proinsulin biosynthesis. During starvation or prolonged hypoglycemia, levels of preproinsulin mRNA are markedly reduced (108,109), in turn reducing proinsulin biosynthesis (55,65). When animals are re-fed after a period of starvation, levels of preproinsulin mRNA rapidly return to normal, allowing proinsulin biosynthesis to recover (108).

Intracellular Trafficking of Proinsulin

From the moment of synthesis, insulin and its precursors, like all secretory proteins, are enveloped in a limiting membrane and as such are protected from the cytosol. The passage from one subcellular compartment to the next occurs by the successive budding and fusion of carrier vesicles, culminating in formation of the mature secretory granule and the ultimate fusion event, exocytosis (Fig. 5.2). These events, initially outlined in pioneering studies by Nobel laureate George Palade (110), provided the point of departure for Orci's seminal studies on the cell biology of the insulin-producing β -cell (4,111,112). Our understanding of these events, and in particular that of the regulated secretory pathway adopted by insulin and its precursors (113–116), has progressed, but remains incomplete in its fine molecular detail.

Once in the RER, proinsulin undergoes appropriate folding so that the disulfide linkage between the A- and B-chains of insulin are correctly aligned. Properly folded proinsulin is then delivered to the cis-Golgi apparatus from the RER in transport vesicles in an ATP-dependent process (117,118). The RER to *cis*–Golgi transport mechanism also requires integrity of the β cell's microtubular network (119), Ca2+ (120), guanosine triphosphate (120,121), and certain cytosolic protein factors (120–125). Trafficking of proinsulin from the stacks of *cis*—via the medial-to the trans-Golgi apparatus is mediated by vesicles reversibly encased by members of the COP family of coatomerproteins (118,126-128). Intercisternal transport between Golgi stacks also requires several cytosolic factors and various membrane proteins (118,120,125,126,129–134). Once delivered to the trans-Golgi network (TGN), proinsulin is separated from other secretory and integral membrane proteins destined for the constitutive pathway and from enzymes destined for lysosomes (116).

Sorting of Proinsulin to the Regulated Secretory Pathway

Secretion of insulin or other proteins can proceed through either constitutive or regulated pathways (113,135,136). All cells use the constitutive secretory pathway, both for secretion and to dispatch integral membrane proteins to their appropriate destinations. Only a few highly differentiated secretory cell types can store products in secretory granules and release them in response to a secretagogue, however. The β-cell is equipped with both these pathways but under normal circumstances directs proinsulin almost exclusively to the regulated pathway (137). The pattern of release using these two pathways is quite different (113). As its name implies, the constitutive pathway is not subject to control by secretagogues. It arises by the rapid transport of proteins from the trans-Golgi to the plasma membrane in small vesicles (transit time, approximately 10 minutes). For proteins inserted in the vesicle membrane (i.e., cell-surface receptors), fusion of the vesicle with the plasma membrane results in presentation to the extracellular environment, whereas proteins in solution in the transport vesicles are secreted.

The regulated pathway involves the selective packaging of secretory proteins (for the most part in the form of proproteins, and notably prohormones) into secretory granules, followed by

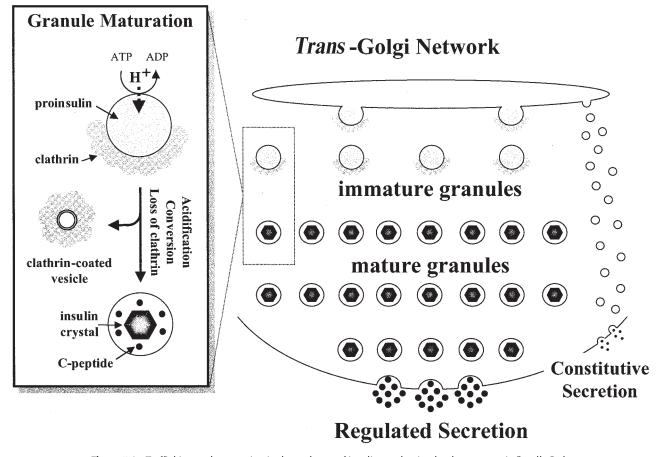

Figure 5.2. Trafficking and processing in the pathway of insulin production by the pancreatic β -cell. Only those steps arising after delivery of proinsulin from the rough endoplasmic reticulum to the *trans*-Golgi network are depicted. For clarity, some steps have been intentionally oversimplified and some critical processes omitted (e.g., granule degradation by crinophagy). The inset shows the major events involved in the maturation of the clathrin-coated, proinsulin-rich immature granule to the uncoated, insulin-rich mature granule. Clathrin-coated vesicles are presumed to bud from maturing granules and to be destined for the endosomal compartment (delivering their contents thereafter to lysosomes or the extracellular space). Little if any proinsulin is released via the constitutive pathway under normal circumstances. ATP, adenosine triphosphate; ADP, adenosine diphosphate.

secretion (exocytosis) in response to a stimulus. Active selection of proinsulin destined for granules is known to take place in the *trans*-most cisternae of the Golgi complex (138). The constitutive pathway, by contrast, is considered to be a default route, accepting any material in the *trans*-Golgi not previously singled out for shipment to a specific destination. In the rat, the sorting process has been shown to be remarkably effective, with more than 99% of newly synthesized proinsulin entering the regulated secretory pathway (137). If this is the case for primary β cells, sorting to granules appears to be less efficient in transformed cells (139).

The selection process for directing prohormones to granules is not well understood. There is morphologic evidence for an intimate association of proinsulin with the cisternal face of Golgi membranes, suggestive of the presence of receptors (140). If such receptors exist, their unequivocal identification remains elusive. Thus, the postulated role of carboxypeptidase E (also known as carboxypeptidase H), an enzyme involved in the trimming of prohormones following endoproteolytic cleavage (see below), as such a receptor (141–143) has been challenged both in general terms (144) and more specifically in the context of proinsulin sorting (145–147). An alternative sorting mechanism implicates selective protein aggregation in the TGN, leading to concentration/condensation in intimate association with the TGN membrane (116,148–150). It is proposed in this model mechanism that common physicochemical properties of secretory-granule proteins allow them to aggregate (or coaggregate) in the presence of an elevated Ca²⁺ concentration and a mildly acidic pH as encountered in the internal environment of the TGN (116,149–153) and that this event in itself promotes budding of a nascent granule. However, sorting by aggregation is likely to be a complex mechanism, considering that 50 to 100 β -granule proteins (154,155) must be coordinately delivered to the site of secretory granule biogenesis (59,154,156).

Regardless of the true TGN sorting mechanism, it is commonly supposed to be similar in all cells equipped with the regulated pathway. This conclusion is based in part upon the results of experiments in which cells are transfected with genes for foreign proteins. For example, AtT20 (pituitary corticotroph) cells can target foreign secretory peptides such as proinsulin (157) or growth hormone (158) as well as exocrine enzymes such as trypsinogen (159) to secretory granules. Furthermore, a protein normally destined for the constitutive pathway can be rerouted to secretory granules and regulated release if fused to the appropriate sequences of the growth-hormone molecule (160). The last experiment indicates that the targeting machinery must recognize functional domains on the secretory protein. By analogy, there must be functional domains on the proinsulin molecule allowing for its recognition and targeting to the regulated pathway (161). If so, they remain to be identified and characterized experimentally. Although a mutant proinsulin (with aspartate instead of histidine in position 10 of the B-chain) has been shown to be diverted from the regulated to the constitutive pathway (162,163), the reason is not clear. It could be due to perturbation to a "sorting domain," lack of coordination of Zn^{2+} needed for hexamerization [unlikely because another mutant proinsulin unable to form hexamers appears well sorted (164)], or to more esoteric reasons related to the enhanced binding of this particular mutant proinsulin to the insulin receptor (163,165).

The Clathrin-Coated, Immature Secretory Granule

The earliest detectable form of the secretory granule in β -cells is formed from regions of the *trans*-Golgi characterized by the presence of clathrin on their cytosolic face (166), and the immature granule similarly carries a partial coating of clathrin (111). Clathrin consists of two chains, which can associate to form a network of triskelions and cover membranes with a basket-like coat (167–169). The assembly of a clathrin coat depends on associated proteins, and coating of secretory granules involves the adaptor protein AP-1 (149,170) as well as ADP-ribosylation factor-1 (ARF-1) (170,171). It appears increasingly likely that clathrin is involved in the purging of unwanted proteins from granules during their maturation (see next section) rather than in the formation of the immature granule from the TGN (150).

Granule Maturation and Refinement of Granule Constituents

Maturation of the immature granule involves three parallel events: loss of clathrin, progressive acidification, and proinsulin conversion. The loss of clathrin is attributed to the budding of clathrin-coated vesicles from maturing granules (150), as first proposed by Orci (111). They are understood to take with them some soluble granule proteins, with insulin being retained ("sorting by retention") in the granule due to its crystalline state (see below) (172,173). This results in the purging of unwanted proteins that may have been erroneously introduced into the immature granule. A second mechanism, "sorting for exit," operates in parallel to this same end. This involves the selective binding of proteins to the intragranular aspect of mannose-6phosphate (and possibly other) receptors that participate in coordinating clathrin adaptors via their cytosolic domain. Lysosomal proteases are known to be bound in such a fashion, leading to their sequestration in clathrin-coated vesicles and consequent clearance from maturing granules (150,174,175).

The immature granule is itself mildly acidified, but as it matures and loses its clathrin coat, it becomes progressively more so, reaching a pH as low as 5.0 to 5.5 (176–178). Granule acidification is due to action of an ATP-dependent proton pump and is critical for proinsulin conversion (179).

Conversion of Proinsulin to Insulin

The conversion of proinsulin to insulin and C-peptide occurs in the immature, clathrin-coated secretory granule (4,176,177) and is outlined in Figure 5.3. There are two pairs of basic

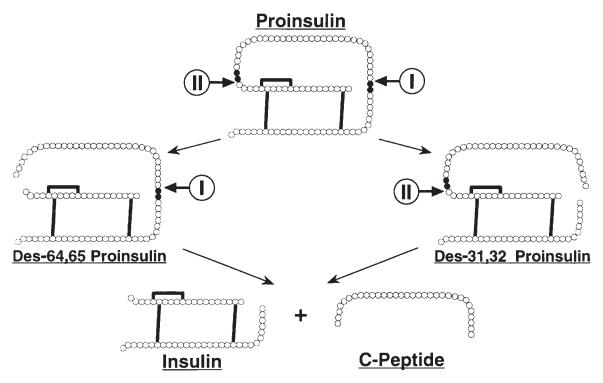

Figure 5.3. Conversion of proinsulin to insulin. Conversion occurs within acidifying secretory granules. The initial event is an endoproteolytic cut on the carboxyl-terminal side of one of the basic residues linking the insulin chains to the C-peptide (in humans, this initial cleavage event occurs predominantly at the B-chain/C-peptide junction). Two endopeptidases are involved: PC3 ("I" in figure), also known as PC1, and PC2 ("II" in figure); each is postulated to display a preference for just one site. The residual basic amino acids left at the carboxyl-terminus of the cleaved proinsulin intermediate are trimmed off by carboxypeptidase H (also known as carboxypeptidase E). These two sequential events lead to one of two proinsulin conversion intermediates: des-31,32-split proinsulin or des-64,65-split proinsulin. A further round of endoproteolytic cleavage and carboxypeptidase trimming of either intermediate generates insulin and C-peptide (as well as the four basic amino acids that originally linked C-peptide to the insulin chains).

residues at which the endoproteolytic conversion event occurs: Arg31-Arg32, linking the insulin B-chain to the C-peptide; and Lys64-Arg65, linking the C-peptide to the insulin Achain.

The Proinsulin-Processing Enzymes

Endoproteolytic peptide-bond cleavage of proinsulin occurs on the carboxyl side of Arg31, Arg32 and Lys64, Arg65, followed by exopeptidic removal of the newly exposed basic amino acids (180,181) (Fig. 5.3). The proinsulin-processing endopeptidase activity proved elusive and was not discovered until 20 years after that of proinsulin (182). Soon after, it was found that this activity actually consisted of two individual endopeptidases, then named type I and type II (183). Type I cleaved specifically at the Arg31, Arg32 site of proinsulin, and type II preferentially cleaved the Lys64, Arg65 site (Fig. 5.3) (183-187). Soon after, these endopeptidase activities were cloned and found to be members of a family of prohormone processing enzymes (188–191). The type I endopeptidase activity was equivalent to PC3 (also known as PC1) (192-195), and the type II endopeptidase activity was equivalent to PC2 (152,196-198). Cotransfection studies of proinsulin with PC3 and PC2 have confirmed these enzymes as the bona fide proinsulin-processing endopeptidase activities (199).

The third proteolytic enzyme involved in proinsulin processing is an exopeptidase, carboxypeptidase H (CPH) (180,181). CPH [also named CPE (200)] is a Ni²⁺-requiring exopeptidase with an acidic pH optimum (181). Once proinsulin has been cleaved by PC2 or PC3, CPH specifically and rapidly removes the exposed (C-terminal) basic amino acids (181,183,186).

Regulation of Proinsulin Conversion

PC2 and PC3 are Ca2+-dependent enzyme activities that display an acidic pH optimum of around 5 to 5.5 (183). Maximal activity of these enzymes is appropriately assured by the Ca²⁺-rich [1–10 mM free Ca²⁺; see reference (201)] and mildly acidic [pH 5.5; see reference (202)] internal milieu of an immature insulin secretory granule (183,185,194,195), which is also optimal for CPH activity (181). Because these [Ca²⁺] and acidic pH conditions are not encountered in the secretory pathway of the β -cell until the immature insulin secretory granule compartment is reached, it ensures that insulin is produced only in the intracellular β -granule compartment in which it is stored (183,203). As such, for full PC2, PC3, and CPH activity, activation of the secretory granule proton-pumping ATPase to generate an acidic pH (176,179,202) and Ca2+-translocation proteins to increase [Ca²⁺] (204) are key regulatory events for controlling proinsulin conversion.

Most members of the proprotein processing endopeptidase family undergo a zymogen-like autocatalytic cleavage activation (205–207). In pancreatic islets, PC2 and PC3 are synthesized initially as inactive proproteins that are subsequently cleaved by limited proteolysis (29,197,208–210). This processing of PC2 and PC3 precursors is thought to be initiated in the RER (152,211) and then completed in the TGN/immature granule compartment (152,211,212). This also ensures that the vast majority of proinsulin is converted to insulin in the secretorygranule compartment (4,203). While it is likely that proteolysis of proPC2 and proPC3 is an autocatalytic process, processing by other endoproteolytic activities has not been ruled out (152,207,211,212). Recently, it has been found that the proteolytic processing of proPC2 is more complex than originally thought because of the transient interaction between proPC2 and its chaperone, 7B2, that inhibits PC2 activity (213,214). Proteolytic cleavage of 7B2 results in subsequent PC2 activation in the *trans*–Golgi region of the secretory pathway (215,216). In part, this may account for the observation that PC2 traverses the secretory pathway more slowly than PC3 and proinsulin (152,208).

As previously outlined, proinsulin biosynthesis is stimulated by glucose at both translational and transcriptional levels (93,106,107). This places an obvious increased demand on the proinsulin conversion mechanism in β-cells. However, proinsulin conversion is adaptable to changes in glucose (217). In the short term (less than 2 hours), the biosynthesis of PC2 and PC3 is stimulated in parallel with that of proinsulin at the translational level (29,58,83). PC2 and PC3 gene expression is also coordinately regulated by long-term exposure to glucose (more than 12 hours) at the level of transcription, along with the preproinsulin gene (218). By contrast, the biosynthesis of CPH in β cells is not regulated by glucose at either the translational or the transcriptional level (28,83). However, this is believed to be of little consequence, since CPH is much more abundant in the insulin secretory granule compartment relative to PC2 and PC3 (188).

The Efficiency of Proinsulin Conversion

As previously mentioned, in a β -cell of a healthy rat (137), and it is assumed (although not yet demonstrated experimentally) in a healthy human being as well, almost all (more than 99%) newly synthesized proinsulin appears to be destined for secretory granules. Despite this remarkably efficient targeting, there is always a detectable level of proinsulin-like material in the circulation, as became apparent almost as soon as proinsulin had been identified as the immediate precursor of insulin (219-221). With the use of specific antibodies, it has been shown that this material consists not only of intact proinsulin but also of conversion intermediates (222), and this has been confirmed using the higher resolving power of high-performance liquid chromatography (223,224). The major intermediate encountered in the circulation, des-31,32-split proinsulin (223,224), results from cleavage at Arg31, Arg32 (the B-chain/C-peptide junction with trimming of the resulting Cterminal basic residues) leaving the C-peptide joined by its C-terminal extremity to the insulin A-chain (Fig. 5.3). In the fasting state in healthy individuals, proinsulin and this intermediate have been estimated to account for approximately 5% to 10% each of the total insulin-related material in the circulation (222-224). The other major conversion intermediate [des-64,65-split proinsulin (Fig. 5.3), cleaved and trimmed only at Lys64, Arg65, the C-peptide/A-chain junction] is present in much smaller amounts. The relative amounts of proinsulin, intermediates, and insulin in the peripheral circulation reflect not only rates of production by the pancreas but also rates of clearance. Proinsulin is cleared from the circulation less rapidly than insulin (primarily because the insulin receptor displays a lower affinity for proinsulin than for insulin) (225), which explains why the relative concentration of proinsulin in the periphery is higher than that encountered in the portal vein (222). Although the intermediate cleaved at Lys64, Arg65, between the A-chain and C-peptide, may be released in smaller amounts than the other intermediate (223,224), it is also cleared more rapidly (225), which will further reduce its relative concentration in the periphery. Notwithstanding, several lines of evidence have led to the idea that the processing of human proinsulin is sequential, where PC3 cleaves intact proinsulin at Arg31, Arg32 first to generate des-31,32-proinsulin (after CPH trimming), which is then processed by PC2 at

Lys64, Arg65 to generate the final products (after CPH trimming): insulin, C-peptide, and free basic amino acids (185,195,203,226). This preferred route of proinsulin conversion has been observed in human β -cells (227), confirming des-31,32-split proinsulin as the predominant conversion intermediate in humans.

Possible Physiologic Role of C-Peptide

Ever since proinsulin was identified as the biosynthetic precursor of insulin and its structure elucidated, its conversion was known to generate insulin and C-peptide in equimolar quantities. Although it was believed for many years that C-peptide was important only to ensure correct folding of proinsulin, more recent experiments suggest otherwise. C-peptide has thus been shown to exert direct effects on renal function (228,229), to augment glucose utilization (230,231), and to improve autonomic nervous function in insulin-dependent diabetes mellitus (IDDM) (232), as well as to exert direct effects on insulin secretion (233). All these effects could be mediated by a direct impact of C-peptide on Na⁺K⁺-ATPase activity in various tissues (231, 234,235). Such a physiologic role for C-peptide as a bioactive hormone is still the subject of intense study and debate. The field has been well reviewed by John Wahren, the scientist most responsible for renewed interest in this enigmatic partner of insulin (236-239), and his group, who have demonstrated specific binding of C-peptide to a putative membrane receptor (240), a hotly contested issue (241).

HYPERPROINSULINEMIA IN DISEASE STATES

Diabetes Mellitus

An increased ratio of proinsulin to insulin frequently is found in individuals with NIDDM (224,242–245) and in some individuals with recent-onset IDDM (246–248) and their nondiabetic twins (249) or siblings (250). Proinsulin levels have been found to predict development of NIDDM and as such must be the result (or reflection) of a very early defect in the course of the disease (251).

In most early studies, no attempt was made to distinguish between intact proinsulin and conversion intermediates. When this was achieved (224,243,252,253), des-31,32-split proinsulin was found to contribute significantly toward total "proinsulinrelated" immunoreactivity in persons with NIDDM just as in control subjects (see above).

The reasons for elevated ratios of proinsulin to insulin in persons with diabetes mellitus are not known (203,224,254,255). There are two alternative explanations currently under evaluation: (a) proinsulin conversion per se is impaired, and (b) granule turnover is so rapid that a significant amount of proinsulin is released before it can be converted. According to the first explanation, the conversion system (enzymes) itself is at fault. This should lead to an increase not only in the amount of unprocessed proinsulin that leaves the β -cell but also in the amount of any other proprotein normally cleaved within β-cells by the same processing machinery. This has yet to be documented. The second explanation, that hyperproinsulinemia is caused by increased turnover, is based on the suggestion that the rate of turnover of secretory granules might be such that the residence time of some proinsulin molecules within the granules (before release) would be too short to permit conversion. Such might be the case in NIDDM under conditions of increased insulin demand caused by insulin resistance in the face of a partially depleted population of β -cells.

Genetic Defects in Proinsulin Conversion Enzymes

Mice that are PC2-deficient have defective proinsulin processing and increased levels of the conversion intermediate des-31,32-proinsulin, consistent with preferential cleavage by PC2 at the Lys64, Arg65 site on proinsulin (256,257). It is intriguing that these mice have a phenotype of chronic fasting hypoglycemia and a reduced increase in blood glucose levels during an intraperitoneal glucose tolerance test (257). This is not due to increased insulin secretion but rather to a deficiency in circulating levels of glucagon (256,257). This underscores the fact that PC2 and PC3 are involved in the conversion of many other prohormones, in keeping with the limitation of their expression to neuroendocrine cell types (207,258). In mice lacking the PC2specific chaperone 7B2, no PC2 activity is detected and processing of islet prohormones is defective, resulting in a hypoglycemic, hyperproinsulinemic, and hypoglucagonemic phenotype (259), similar to that in the PC2-deficient mice (256, 257). However, unlike mice with the PC2 null phenotype, these mice also show markedly increased circulating adrenocorticotropic hormone and corticosterone levels, resulting in Cushing syndrome (259)

Deletion of the PC3 gene in mice results in an embryonic lethal phenotype. In humans, mutation in both alleles of the PC3 gene that results in negligible PC3 activity generates a complicated phenotype due to a generalized anomaly in prohormone processing (260). The patient presented with type 2 diabetes mellitus due to abnormal glucose homeostasis, elevated plasma proinsulin concentrations, but very low insulin levels, indicating a severe deficiency in proinsulin processing (260). In addition, marked obesity (developed in childhood), hypogonadotrophic hypogonadism, hypocortisolism, and increased propiomelanocortin concentrations were also apparent, emphasizing the role of PC3 in general neuroendocrine prohormone processing (260).

Obese Cpe(fat)/Cpe(fat) mice have been found to possess a CPH (CPE) mutation that reduces enzyme activity (145). Diarginyl insulin (with residual basic residues at the carboxylterminus of the B-chain) rather than insulin itself is the major processed product in β -cells of Cpe(fat)/Cpe(fat) mice, an expected consequence of the absence of active CPH (146). Cpe(fat)/Cpe(fat) mice are, furthermore, hyperproinsulinemic, indicating that loss of CPH activity in some as yet ill-defined fashion results in impaired proinsulin cleavage by PC2 and PC3 (145). As for PC2 and PC3, CPH does not exclusively process proinsulin, being involved in the trimming (subsequent to endoproteolytic cleavage) of many other prohormones in a variety of neuroendocrine cell types (200). The obese phenotype in the Cpe(fat)/Cpe(fat) mouse is not believed to be directly due to inefficient proinsulin processing but is more likely the result of inadequate production of α melanocyte-stimulating hormone due to defective POMC processing in the pituitary (261,262).

Insulinoma

Aside from the unregulated overproduction of immunoreactive insulin by insulinoma cells, these cells also are characterized by the disproportionate amount of proinsulin secretion (263–266). It is possible, on the basis of the results of studies on human insulinoma tissue (267) or on cell lines derived from animal insulinomas (139,268–270), that their unusually increased production of proinsulin reflects a partial diversion of proinsulin from the regulated to the constitutive pathway. Why such a diversion should be provoked by cellular trans-

formation is unclear. Certainly, tumor cells typically fail to express some of the differentiated features of the native parent cell. The failure to use the regulated pathway to full effect would be an example of such a lesion. Perhaps the need to synthesize unusual quantities of membrane and associated proteins to satisfy accelerated cell division leads to an impaired ability to satisfy luxury pathways such as granule formation. Amyloid deposits often are found in insulinoma tissue (271). As for amyloidosis in islets of individuals with NIDDM, insulinoma amyloidosis also may reflect increased production of pro–islet amyloid polypeptide (the biosynthetic precursor of islet amyloid polypeptide; see below) in association with the observed hyperproinsulinemia.

Other Protein Constituents of the β**-Granule**

Insulin, C-peptide, and related peptides contribute approximately 80% of the content of the insulin secretory granule protein (154,272) but are not the only proteins present [for a review, see (273)]. As just discussed, proinsulin conversion occurs in the granule itself, which means that the conversion enzymes, PC2, PC3, and CPH, also reside within this organelle. There is another processing enzyme present in β cell granules, peptidylglycine-amidating monooxygenase (PAM), which converts a peptide carboxyl-terminal glycine to an amide on certain granule peptides (273-275). Granule constituents are categorized into soluble and membrane-bound granule proteins (154). Proinsulin, insulin, C-peptide, and the conversion enzymes are all soluble components of a granule and as such are cosecreted in response to secretagogues (156,273,276–278). It should also be noted that the biosynthesis of the majority of insulin secretory granule proteins is translationally regulated in parallel to proinsulin (29,83,155) to replenish that lost in secretion.

Some of the soluble insulin secretory granule proteins deserve special mention. First, chromogranin A is found in secretory granules of many different secretory cell types, including β -cells (276,279,280). Chromogranin-A is actually a precursor proprotein that is proteolytically processed within the granule by PC2, PC3, and CPH to form a variety of peptides, including β -granin (280,281). Biologic function has yet to be assigned to any of these peptides. However, in the pig, an amidated peptide named pancreastatin is derived from chromogranin A (273,282). In the 1980s, pancreastatin generated some interest as a possible autocrine regulatory factor of insulin secretion, since it was found to inhibit the release of insulin from the β -cell (282,283). However, because of the lack of appropriate processing sites in the corresponding chromogranin A, pancreastatin is not produced in humans (or rodents), and this has downplayed its physiologic relevance (273).

Another insulin secretory granule protein of interest is islet amyloid polypeptide (IAPP) (also known as amylin or diabetes-associated peptide), which displays structural homology with calcitonin gene–related peptide (CGRP) [for reviews, see references (284–287)]. IAPP is generated by PC2/CPH-mediated proteolytic processing of a higher-molecular-weight precursor (pro-IAPP) (285,288,289), then amidated, presumably by PAM (285,286). There is considerable interest in IAPP, since it is the major constituent of islet amyloid deposits (271,286, 287,290,291). These deposits, first reported at the turn of the century, have been found in the pancreases of nearly all individuals with NIDDM (271,292) [and often in insulinoma tissue (271,293)] and are thought to be a major contributor to β -cell

dysfunction in NIDDM (254,286,287). Human IAPP can oligomerize to form insoluble fibrils that are characteristic of pancreatic amyloid deposits (294,295). Intriguingly, the varying primary structure of IAPP across mammalian species dictates whether or not it can form fibrils and amyloid deposits (286,290,296). Amyloid deposits are found surrounding islets only in diabetic humans, macaques, and cats, but not in rodents (286,296). However, overexpression of human IAPP in β-cells of transgenic mice can lead to formation of IAPP-fibrils and pancreatic amyloid plaques, accompanied by β-cell dysfunction and symptoms of NIDDM (297-299). In common with other soluble granule constituents, IAPP is cosecreted with insulin (277,278). IAPP has attracted attention because of its reported properties as a diabetogenic agent. IAPP has thus been indicated to inhibit insulin release in vitro (300) and to cause insulin resistance (301-303), although these effects are quite controversial (286,287,304,305). IAPP also exerts calcitonin-like effects, but this is probably due to its homology to CGRP (306,307). Despite much research, a convincing physiologic (rather than pharmacologic) function for IAPP remains to be clearly established (286,287). Moreover, it also remains to be shown whether IAPP amyloid formation contributes to the pathogenesis of NIDDM or is merely a consequence of the disease (281,287). Notwithstanding, IAPP, when injected as an adjunct to insulin, may help control glycemia and could thus prove of therapeutic value.

Several insulin secretory granule membrane proteins are also worthy of mention. First, there are the components of the proton-pumping ATPase responsible for lowering the intragranular pH (202,273). There also are certain proteins found in close association with the granule membrane and shown to be involved in promoting insulin exocytosis. These include vesicle-associated membrane protein 2 (VAMP-2) (308,309), synaptotagmin-III (310,311), and rab3A (312-314). Recently, two islet cell autoantigens for type 1 diabetes mellitus, ICA512/IA-2 (315-317) and phogrin (318), have been cloned and located to the insulin secretory granule membrane. Phogrin and ICA512 have homology to tyrosine phosphoprotein phosphatases but actually do not possess phosphatase activity (316–318). As such their biologic function is currently unknown. However, it is interesting that phogrin is phosphorylated in a Ca²⁺-dependent manner and thus may play a regulatory role in insulin secretory granule transport and/or exocytosis (319).

The Mature Granule and the Insulin Crystal

The combination of granule acidification and conversion of proinsulin to insulin provides the scenario for insulin crystallization within the mature granule. Insulin is known to be able to associate into dimers, and, in the presence of Zn²⁺, the dimers can associate to form hexamers (320) (Fig. 5.4). The Zn²⁺ is coordinated by the histidine residue at position 10 of the insulin B-chain. The Zn-hexamers can then pack together to form a crystal lattice. Crystallization depends on a very high local concentration of insulin and Zn²⁺, as well as an acidic milieu, with these conditions being satisfied within the granule (201,273,321). The dense core of the secretory granule observed by electron microscopy is thus taken to be an insulin crystal (119,320). C-peptide does not cocrystallize with insulin to any significant extent and is therefore excluded from the crystal to be found in the clear halo surrounding the dense core of granules (111,322) with other soluble granule constituents, such as PC2, PC3, chromogranin A, and IAPP (323).

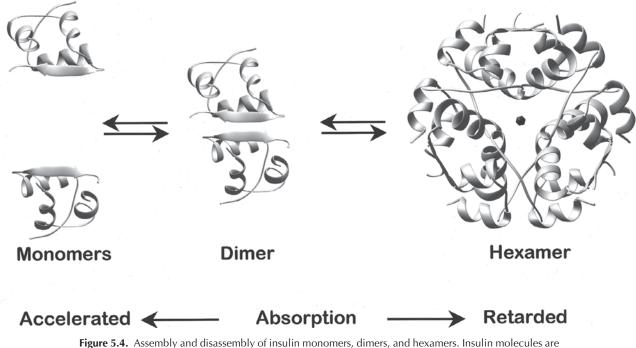

Figure 5.4. Assembly and disassembly of insulin monomers, dimers, and hexamers. Insulin molecules are modeled as ribbon diagrams depicting elements of secondary structure (α helices and β sheets). Monomeric insulins (lispro, aspart) are created by altering residues along the monomer/dimer interface to destabilize dimer formation. This accelerates absorption of the injected insulin. Hexamer formation is stabilized by substitutions in the long-acting insulin, glargine. Enhanced hexamerization retards absorption.

THE FATE OF THE MATURE SECRETORY GRANULE

Insulin is stored in the mature secretory granule until it is either released by exocytosis or degraded by crinophagy.

Transport of Insulin Secretory Granules to the Plasma Membrane

Before the release of insulin via exocytosis, an insulin secretory granule must be transported from an intracellular storage pool to the β -cell surface. The β -cell is polarized (4), and secretory granules appear to be delivered to a certain location on the β -cell plasma membrane (324,325). The directional transport of insulin secretory granules to the plasma membrane is likely mediated via an interaction with the β -cell cytoskeletal framework of microtubules and microfilaments (119,326–329). Granule movement along microtubules is most probably driven by microtubule-associated proteins and motors [e.g., kinesin and dynein (329–334)]. The role of microfilaments [which form a bundled network just beneath and parallel to the plasma membrane of the β -cell called a "cell-web" (335)] is not particularly clear, but they likely provide a proportion of motive force for the transport of insulin secretory granules along microtubules (119,335,336).

The Mechanism of Regulated Insulin Exocytosis

Insulin is stored in the secretory granules of the β -cell in the resting state and is not released from the β -cell to any great extent unless there is a specific signal that stimulates exocytosis (4,137). Insulin exocytosis is triggered by certain intracellular secondary signals, including an increase in cytosolic [Ca²⁺]_i (as outlined in Chapter 6), and also by several secretory granule, cytosolic, and plasma membrane proteins (337,338). The proteins involved in the mechanism of regulated insulin exocytosis are now becoming better understood, mostly from analogies to the mechanism of synaptic vesicle exocytosis in neurons (312,339–342).

In essence, insulin exocytosis involves docking of the insulin secretory granule with the plasma membrane and subsequent fusion, processes accounted for by the so-called SNAREhypothesis (118,122,337,338). According to this theory, members of a family of secretory granule proteins called v-SNAREs (vesicle-soluble N-ethylmaleimide attachment protein receptors) specifically associate with cognate members of a family of plasma membrane proteins, called target-SNAREs (t-SNAREs). The synaptobrevin family of proteins have been identified as v-SNAREs on secretory vesicles (341,343-345), and the syntaxin family (339,341,343,346,347) and synaptosome-associated protein 25 (SNAP-25, which should not be confused with SNAPs, the soluble NSF attachment proteins) have been identified (132, 343,348,349) as plasma membrane t-SNAREs. VAMP-2, located on insulin secretory granules, is the v-SNARE (308,309,350), and SNAP-25 (350,351) plus syntaxin 1a, 4, and 5 are the t-SNAREs (309,352,353) implicated for insulin exocytosis in β -cells. Syntaxin and SNAP-25 associate with each other to form a high-affinity binding site for VAMP (345). Binding of VAMP to syntaxin/ SNAP-25 forms a stable core complex (345,354), allowing a secretory granule to dock with the plasma membrane (341,343). This complex then acts as a receptor for a cytosolic protein, α -SNAP (soluble NSF attachment proteins) (122,132,341,343,349,354), shown to be present in β -cells (355). The α -SNAP association with the complex then promotes association of another cytosolic protein, NSF [N-ethylmaleimide sensitive factor (122, 341,343,349,354), also present in β-cells (355)]. A VAMP/ syntaxin/SNAP-25/ α -SNAP/NSF complex is then formed (341, 354). Upon ATP hydrolysis, catalyzed by an intrinsic ATPase activity of NSF, there is dissociation of this "pre-exocytotic" com-

plex that promotes membrane fusion between the insulin secretory granule and plasma membranes, thus enabling the granule content to be expelled into the surrounding milieu (341,343,354). The involvement of the SNARE complex in regulated insulin exocytosis has recently been highlighted, in that the VAMP/syntaxin/SNAP-25 interaction dissociates during the first phase of glucose-induced insulin exocytosis (356).

However, although the SNARE hypothesis forms a central basis for hormone-regulated exocytosis (122,341,343,349, 357-359), it also applies to most generic vesicular transport membrane fusion events in the cell (339,349), including unregulated constitutive exocytosis (122). While SNARE proteins are an essential part of the mechanics of insulin exocytosis (337,338), the SNARE hypothesis does not account for the tight control of regulated insulin exocytosis (343,349,357,359). As such, other protein factors that interact with SNARE proteins in a regulated manner likely control the insulin exocytotic mechanism (337,338,343,349). For example, a family of secretory granule proteins, named synaptotagmins, act as Ca2+ sensors for Ca²⁺-dependent regulated exocytosis (343,360,361). It has been proposed that synaptotagmins bind to the VAMP/SNAP-25/syntaxin core complex under resting circumstances at low $[Ca^{2+}]_{i}$, preventing α -SNAP binding. However, when $[Ca^{2+}]_{i}$ increases in response to a stimulus, synaptotagmin dissociates from the complex, allowing α -SNAP/NSF association, formation of the VAMP/SNAP-25/syntaxin/α-SNAP/NSF complex, and commitment to membrane fusion and exocytosis (343,362). In β -cells, the synaptotagmin-III isoform is found on insulin secretory granules (310,338) and has been postulated to play a regulatory role in controlling insulin exocytosis (310,311). Another example is munc-18, a cytosolic protein that, under resting circumstances, associates with syntaxin, preventing the formation of the VAMP/SNAP-25/syntaxin complex and hence the docking of secretory granules (343,362,363). It is believed that a protein kinase C (PKC)-mediated phosphorylation of munc-18 takes place at a "predocking" step, analogous to

synaptic vesicle exocytosis in neurons (364), that results in munc-18/syntaxin dissociation and then allows VAMP/SNAP-25/syntaxin association and secretory granule docking to proceed. Such phosphorylation of munc-18 in β -cells could account in part for a role of PKC in regulating insulin secretion (365,366). One should be aware that synaptotagmin-III and munc-18 represent just two exemplar β -cell proteins that may control the mechanism of insulin exocytosis and that several other factors should also be considered (337,338).

Degradation of Insulin Stores in the β-Cell (Crinophagy)

If not released, insulin can be degraded within the β -cell (367,368). Degradation arises by the fusion of granules with lysosomes (369), an event referred to as crinophagy and that was first shown to occur in pituitary mammotrophic cells (370) and pancreatic β -cells (371). Degradation seems to act in concert with biosynthesis and release to regulate the amount of insulin housed in the β -cell at a given time (367,368). Although the factors regulating crinophagy are not understood, it has been found that when insulin release is inhibited, degradation increases and vice versa (367,368,372,373). Insulin is degraded only slowly, even after its introduction into lysosomes (369,372,374). This is thought to be due to the stability of the insulin crystal in lysosomes, which display an acidic milieu similar to that of the secretory granule. By contrast, both proinsulin and C-peptide (neither of which exists in the crystal state within granules) are degraded rapidly within β -cells (369,372,374).

INSULIN STRUCTURE

Amino Acid Sequence

Although insulin was recognized to be a protein shortly after its discovery (375), the elucidation of its primary structure

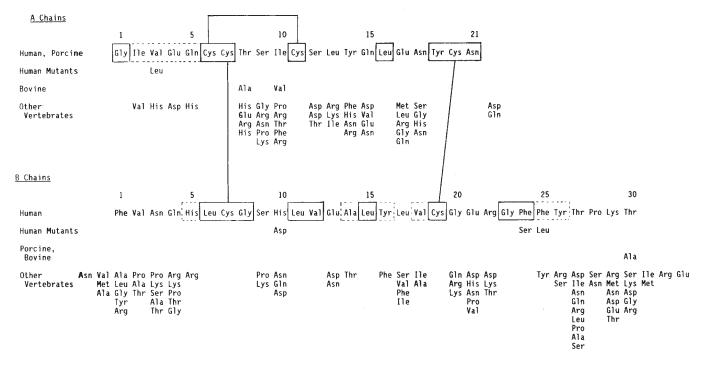

Figure 5.5. Amino acid sequences of therapeutic and mutant human insulins and substitutions occurring in other vertebrate insulins. Solid lines denote disulfide bonds; solid and dashed boxes surround invariant and highly homologous residues, respectively.

came many years later with the development by Sanger and coworkers of methods to determine primary sequences of proteins (7,376). In fact, insulin was the first protein to have its entire primary sequence determined (for which Frederic Sanger received the 1958 Nobel Prize in Chemistry). Figure 5.5 compares the primary sequences of insulins from different animal species. Known insulins are composed of two polypeptide chains that are linked to one another by disulfide bonds. The A- and B-chains of human, porcine, and bovine insulins, like those of most other vertebrate insulins, are composed of 21 and 30 amino acids, respectively. The two peptide chains are covalently linked to one another by two cystine disulfides, one between CysA7 and CysB7 and the other between CysA20 and CysB19. An additional intrachain disulfide connects cysteines A6 and A11. Insulin structure is highly conserved in vertebrate evolution (377). Regions of invariability include the positions of cysteines that form the disulfide bridges, the amino- and carboxyl-terminal regions of the A-chain, and certain hydrophobic residues at the carboxyl-terminus of the Bchain (19,76). Mutations and chemical modifications at invariant or highly conserved positions generally diminish or abolish receptor binding potency and biologic activity, emphasizing the importance of these positions in either creating or maintaining a three-dimensional surface suitable for receptor recognition (378-380).

Three-dimensional Structure of Insulin

The pioneering studies of the x-ray diffraction patterns of insulin crystals, conducted simultaneously by Dorothy Hodgkin (Nobel Prize for Chemistry in 1964) and coworkers (381,382) and the Peking Insulin Structure Group (383), have been the cornerstone for relating the structure and function of insulin. The crystal structure of insulin has been refined to a resolution of 1.5 Å (384). Within each unit cell of two zinc insulin crystals, six insulin molecules compose a hexamer around two zinc atoms; three HisB10 residues (Fig. 5.4) chelate each zinc atom. Two zinc insulin hexamers can be subdivided into three equivalent dimers, with each dimer being composed of two insulin molecules of similar but not identical structure. The hydrophobic core of the insulin monomer is composed of invariant and highly conserved residues, including leucine residues A16, B6, B11, and B15, the A6-A11 cystines, the TyrA19 ring, IleA2, and AlaB14, supporting the notion that core structure must be maintained for insulin action. These core residues with hydrophobic side chains contact additional, more peripheral nonpolar residues, including ValA3, LeuA13, ValB12, ValB18, CysB19, and PheB24, which in turn contact the remaining nonpolar residues (PheB1, ValB3, LeuB17, and PheB25). The more peripheral nonpolar residues that are exposed partially on the monomer surface contribute to the surfaces of insulin involved in protein-protein interactions, including the dimer and hexamer interfaces and possibly the receptor-binding surface as well (378,380,384). Residues from both A- and B-chains comprise the hydrophobic core of insulin and the various binding surfaces. The A-chain forms two helical segments (A1-A8 and A13-A19), which are connected by a turn; the B-chain contains two regions of extended chain (B1-B8, B21-B30) connected by a region of α -helix (B9–B19). The two chains are connected to one another covalently by cystine disulfides (A7-B7, A20-B19), and the overall structure is stabilized by interchain hydrogen bonds (A11-B4, A6-B6, A21-B23, and A19-B25) and ionic interactions between the N-terminus of the A-chain and the C-terminus of the B-chain.

Proinsulin Structure

Structural studies by two-dimensional nuclear magnetic resonance imaging indicated that the insulin portion of proinsulin is similar to that of insulin, whereas the C-peptide portion of proinsulin appears to be unstructured (226). However, there are some perturbations in the insulin moiety of proinsulin that are reverted by cleavage between the A-chain but not by cleavage between the B-chain and C-peptide (226). To account for the reduced biologic potency of proinsulin (385), it has been suggested that the C-peptide obscures a portion of the receptorbinding surface of insulin (386) or, alternatively, prevents movement of the carboxyl-terminus of the B-chain during binding (387). Unlike insulin, the sequence of which is highly conserved, the sequences of the C-peptide portions of different proinsulins show little homology (19). These C-peptides differ markedly both in length and amino acid composition, suggesting that the C-peptide composition itself is not very important. It has been thought that the C-peptide moiety of proinsulin acts as a tether between the A- and B-chains of insulin to guarantee appropriate folding and disulfide pairing during the biosynthetic process (19). However, recent reports suggest that C-peptide might have an endocrine function of its own (388). As previously mentioned, however, the physiologic relevance remains controversial.

Mutant Insulins and Proinsulins

Mutations in the coding sequences of the insulin gene can lead to production of structurally abnormal insulin molecules (389,390). Three different altered forms of insulin with low biologic potency have been associated with diabetes mellitus: PheB25Leu (391,392), PheB24Ser (393,394), and ValA3Leu (395) substitutions. While additional, apparently unrelated, probands have been found who produce the same abnormal insulins from identical insulin gene mutations (396-398), no additional abnormal insulins have yet been identified, although they surely exist. These patients and their families define a clinical syndrome, the insulinopathies, which are characterized by high circulating levels of insulin and a frequent association with mild carbohydrate intolerance (390,398-400). Affected individuals can be distinguished from patients with type 2 diabetes mellitus by a normal or slightly impaired sensitivity to exogenous insulin despite unusually high levels of their own circulating insulin (399). Hyperinsulinemia in these patients is not explained by the presence of circulating antibodies or elevated levels of counterregulatory hormones. In fact, each of these patients produces normal and abnormal forms of insulin in equivalent amounts (391). The more potent normal insulin is cleared more rapidly, resulting in accumulation of the abnormal insulin and in a dramatic degree of hyperinsulinemia. The amounts of normal bioactive insulin in the circulation of these patients are actually inappropriately low, resulting in the observed impaired glucose tolerance and diabetes (395,400).

Mutations in the insulin gene can also result in impaired processing of proinsulin to insulin. Individuals with hyperproinsulinemia caused by impaired processing, like individuals with abnormal insulins, may exhibit carbohydrate intolerance, but not necessarily. For two of the cases studied, large amounts of an insulin molecule with C-peptide still attached at the Achain/C-peptide junction were found in the circulation. In both cases, impaired processing was due to the mutation of arginine within the Lys64-Arg65 endopeptidase cleavage sequence (401–403).

A third case of familial hyperproinsulinemia results from a HisB10Asp mutation (404,405). It is surprising that a defect in

proinsulin structure distant from the paired basic cleavage sites prevents processing. However, transfection of the mutated gene into cells and expression in transgenic mice (163,406) both show that significant proportions of the mutated hormone are secreted from cells via the constitutive pathway. Because proinsulins have substantially less biologic potency than the corresponding insulin molecules, and as much of insulin and proinsulin clearance occurs by receptor-mediated pathways, the proinsulin molecules are cleared more slowly and accumulate in the circulation of affected individuals. The proteolytic product of HisB10Asp proinsulin is HisB10Asp insulin, which unlike other abnormal insulins, exhibits enhanced receptor binding affinity (406,407).

Therapeutic Insulins

Historically, insulin for treating patients with diabetes mellitus was isolated from animals, primarily pigs and cows. However, the human insulin produced today with recombinant DNA methods has the identical sequence and chemical composition as insulin produced in the human pancreas. Use of the human hormone provides a theoretical advantage of lower immunogenicity, compared with use of animal insulins that have slightly different sequences. The use of recombinant techniques to produce insulin also provides the opportunity to modify the insulin sequence to alter both its biologic activity and pharmacokinetic properties. This opportunity has recently been realized, and several modified insulin analogues are available either for clinical use or in clinical trials (408,409).

At the concentrations used for its storage in vials before injection, insulin self-associates to form hexamers. Dissociation of the hexamers into biologically active monomers is slow at the site of injection, and rates of absorption and entry into the circulation are slow because the hexameric complexes are large and diffuse slowly. Insulin monomers, being smaller, diffuse much more rapidly. The rationale for creating fast-acting insulin analogues is based on the desire to decrease the tendency to self-associate but to retain normal receptor binding affinity (Fig. 5.4). This has been accomplished with lispro (Eli Lilly) and aspart (Novo Nordisk) insulins. Positions B28 and B29 of human insulin are proline and lysine, respectively. These residues are reversed in the sequence of insulin-like growth factor 1 (IGF-1), a closely related growth factor that does not selfassociate. Thus lispro insulin contains Lys-Pro at the B28-B29 positions, which decreases its tendency to self-associate and increases its rate of absorption following subcutaneous injection. Aspart insulin contains aspartic acid at the B28 position in place of proline. This region at the carboxyl-terminus of the insulin B-chain participates in self-association. The presence of an acidic side chain at this site, and hence a negative charge, diminishes self-association because of charge repulsion. Both lispro and aspart insulins display a rapid onset and a short duration of action, which better matches blood glucose excursions following meals.

Long-acting insulins may be most useful for reducing blood glucose levels during nocturnal periods of fasting, particularly for suppressing hepatic glucose production after 2:00 a.m. to 3:00 a.m. Insulin glargine (Aventis) contains two modifications relative to native human insulin. The addition of two basic arginine residues to the carboxyl-terminus (to create ArgB31 and ArgB32 positions not normally present) shifts the isoelectric point of the protein from a pH of 5.4 to pH 6.7. This renders the molecule more soluble at acidic pH and less soluble at neutral pH. Because the analogue is stored at acidic pH, a second substitution was needed to avoid the undesirable deamidation of asparagine A21 that occurs at low pH. Replacement of AsnA21 with glycine avoids this problem and is otherwise well tolerated. Injected as a clear solution at acidic pH (4.0), insulin glargine forms a microprecipitate at the physiologic pH of the subcutaneous space, which delays its dissolution and absorption from the site of injection. Another method for creating long-acting insulin is linking it covalently to a fatty acid rather than modifying its primary sequence. Insulin detemir (NN304 from Novo Nordisk) is made by acylating the LysB29 side chain of des-B30 insulin with tetradecanoic acid. This modification promotes binding to serum albumin and consequently increases the half-life of insulin at the site of injection and in the circulation. Receptor binding affinities of lispro, aspart, and glargine insulins roughly match that of native human insulin, whereas detemir insulin binds with slightly reduced affinity.

SUMMARY

From the initial seconds of the biosynthesis of its early precursor, preproinsulin, to its release or degradation within the β -cell, insulin is always protected from the cytosol by a limiting membrane. Insulin release reflects a well-orchestrated series of events involving the successive budding, directed movement, and fusion of transport vesicles or granules and intravesicular proteolytic conversion events. The three-dimensional structure and physicochemical properties of insulin and its precursors play an intimate role in this series of events, just as they do for the biologic activity of these molecules.

Under physiologic conditions, the concentration of blood glucose fluctuates only in a narrow range despite alternations in periods of food intake and fasting. This stability is due to a remarkably efficient hormonal system that exerts opposite effects on the organs of glucose storage and production. Whereas several hormones can prevent dangerous declines in blood glucose concentrations by stimulating glycogenolysis and gluconeogenesis, insulin secretion by β -cells of the islets of Langerhans is the only efficient means by which the organism can decrease the blood glucose concentration. Any alteration in the β -cell functioning has thus a profound impact on glucose homeostasis: excessive secretion of insulin causes hypoglycemia, and insufficient secretion leads to diabetes mellitus. It is therefore not surprising that insulin secretion is subject to tight control. This control is ensured by glucose itself and by an array of metabolic, neural, hormonal, and sometimes pharmacologic factors, which necessitates rapid integration by β -cells of a host of signals generating intracellular messengers.

Stimulus-secretion coupling in β -cells is astonishingly complex and still incompletely understood despite continuous investigation. However, its main features are beginning to appear clearly enough to gain wide acceptance. Only these major characteristics will be discussed here, leaving issues that are too controversial and specialized for more specific review articles. Because this chapter is devoted to normal stimulussecretion coupling, I have given preference to publications of studies performed with normal β -cell models and limited those of studies using insulin-secreting cell lines that often show abnormal properties. Although *in vitro* studies of normal adult human islets are still few, they indicate that the information gained from animal experiments can be extrapolated in large part to humans. Only functionally important specificities of the human β -cell will thus be highlighted.

IDENTIFICATION OF GLUCOSE BY β-CELLS

In most secretory cells, extracellular stimuli bind to membrane receptors and activate stereotyped transduction pathways that eventually trigger specific responses. The existence in the plasma membrane of β -cells of a glucoreceptor that would trigger insulin secretion upon binding of glucose itself has been considered but could never be proved. On the other hand, compelling evidence indicates that glucose must be metabolized by β -cells to induce insulin secretion. Small interferences with glucose metabolism have repercussions on insulin secretion, whereas marked interferences with insulin secretion may be without effect on glucose metabolism in β -cells. The experimental work on which this "fuel-concept" of insulin secretion is based has been discussed in detail in several review articles (1–8).

 β -Cells detect blood glucose variations and adjust the rate of insulin secretion to these variations through changes in their metabolism. This ability rests on a peculiar biochemical organization that is summarized in Figure 6.1.

1. In rodent β -cells, as in hepatocytes, glucose entry is mediated by the high-capacity, low-affinity ($K_m \sim 17$ mM) glucose

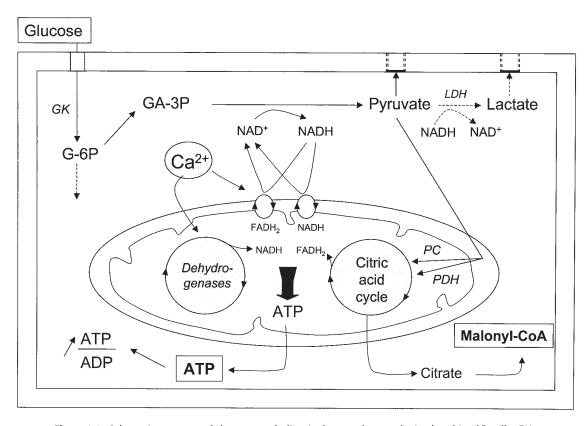

Figure 6.1. Schematic summary of glucose metabolism in the cytoplasm and mitochondria of β -cells. GK, glucokinase; LDH, lactate dehydrogenase; PDH, pyruvate dehydrogenase; PC, pyruvate carboxylase; G-6P, glucose-6-phosphate; GA-3P, glyceraldehyde-3-phosphate; NAD⁺ and NADH, oxidized and reduced nicotinamide adenine dinucleotide, respectively; FADH₂, reduced flavin adenine dinucleotide; ATP, adenosine triphosphate; ADP, adenosine diphosphate; CoA, coenzyme A.

transporter GLUT2 (9,10). In human β -cells, GLUT2 is less extensively expressed, and GLUT1 predominates (11,12). Nevertheless, whatever the proportion of the different transporters, glucose transport is always efficient enough to permit rapid equilibration between the intracellular and extracellular concentrations of glucose (13,14). The rate of glucose transport exceeds the rate of glucose utilization and is, therefore, not limiting (10,15,16).

- 2. Phosphorylation of glucose into glucose-6-phosphate is catalyzed by a glucokinase (GK hexokinase IV) similar (15 amino acids shorter) to that present in hepatocytes (17,18). The same gene is controlled by two distinct promoters, permitting differential regulation of the expression-positively by insulin and negatively by glucagon in the liver and positively by glucose in β -cells. The characteristics of GK, a K_m between 6 and 10 mM, sigmoidal dependency on its substrate concentration, and lack of inhibition by its product (glucose-6-phosphate), make it a suitable glucose sensor (15). The view that GK is the flux-determining step of glucose metabolism in β -cells is supported by the fact that its activity is lower than that of the other potentially regulatory enzymes of glycolysis and closely matches glucose usage (10,15,16). Mutations of the GK gene result in the production of either hypoactive isoforms of the enzyme in patients with maturity-onset diabetes of the young (MODY-2) (19) or hyperactive isoforms in glucokinase-linked hyperinsulinemia and hypoglycemia (20). Expression of these mutants in insulin-secreting cell lines produced the expected decreasing and increasing effects on glucose metabolism and insulin secretion (21). Whereas the important role of GK is admitted unanimously, the concept that the enzyme is the sole regulator of glycolysis in β -cells remains disputed (22). The contribution of a high-affinity hexokinase has often been considered, but recent experiments have cast doubt on the presence of this enzyme in β -cells (23).
- 3. Under physiologic conditions, dephosphorylation of glucose-6-phosphate by glucose-6-phosphatase, storage of glucose as glycogen, and transformation of glucose to sorbitol are quantitatively small (4,5,16,22,24). They play no significant role in the control of normal β -cell function. Glucose metabolism through the pentose phosphate pathway does not exceed 5%, and its relative contribution decreases as the glucose concentration is increased. This pathway also is thought to be unimportant for the control of insulin secretion. Glycolysis is the major route of glucose metabolism in β -cells.
- 4. β-Cells contain the muscle (PFK1-M) and cerebral (PFK1-C) isoforms of phosphofructokinase (25). The characteristics of the enzyme and of its regulators indicate that PFK adjusts its rate of phosphorylation to that of glucokinase (15,16). Normal β -cells hardly express lactate dehydrogenase (24,26), and plasma membrane monocarboxylate transporters (for lactate and pyruvate) are present in only low amounts (26,27), so that pyruvate generated by glycolysis is channeled (>90%) to the mitochondria. However, the low activity of lactate dehydrogenase is insufficient to regenerate enough oxidized nicotinamide adenine dinucleotide (NAD⁺) to sustain a high glycolytic flux. Reoxidation of NADH is thus achieved by two mitochondrial electron shuttles that are unusually active in β -cells: the glycerol-3-phosphate shuttle and the malateaspartate shuttle (7,26,28,29). The two shuttles appear to be at least partially redundant but, together, play an essential role in β -cell function (30,31).
- 5. Within mitochondria, pyruvate is transformed approximately equally into acetyl coenzyme A (CoA) by pyruvate dehydrogenase and into oxaloacetate by pyruvate carboxy-

lase (32,33). Acetyl CoA is then used by the citric acid cycle, with formation of NADH and reduced flavin adenine dinucleotide (FADH₂), which together with NADH and FADH₂ issued from the activity of the shuttles previously described, transfer electrons to the electron-transport chain. This eventually results in hyperpolarization of the mitochondrial membrane and generation of adenosine triphosphate (ATP) (34). The high activity of pyruvate carboxylase in β -cells is unusual for a non-gluconeogenic, non-lipogenic tissue. The enzyme serves to fill the citric acid cycle with intermediates (anaplerosis) (35), which allows some of these intermediates to exit from the mitochondria without compromising the cycle function. These compounds can then be used as precursors of amino acids (24) or, in the case of citrate, produce putative second messengers such as malonyl CoA (36) (see below).

- 6. When the concentration of glucose is raised, the acceleration of glucose oxidation is greater than that of glycolysis (22). This remarkable feature is attributed to the activation of mitochondrial dehydrogenases. Three of these, pyruvate dehydrogenase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase, are activated by the increase in mitochondrial Ca²⁺ that follows the increase in cytoplasmic Ca²⁺ induced by glucose (37) (see below). A fourth dehydrogenase, the FAD-linked mitochondrial glycerol 3-P-dehydrogenase, the key enzyme of the glycerol phosphate shuttle (see point 4 above), is also Ca²⁺-sensitive, but its activation is achieved by the increase in cytoplasmic Ca²⁺.
- 7. The major consequence of this original biochemical organization of β -cells is that the ATP/adenosine diphosphate (ADP) ratio increases with the glucose concentration (38). It is important to emphasize how this situation is exceptional. Thus, most cells, including glucagon-secreting α -cells, adapt their metabolism to maintain a constant ATP/ADP ratio when the concentration of glucose changes (39). The glucose-induced variations in ATP/ADP ratio observed in purified β -cells or in whole islets take place in the cytoplasm. They are often underestimated because of a partial masking by a stable pool of nucleotides within insulin granules, occur over a wide range of glucose concentrations and are rapid, preceding any increase in cytoplasmic [Ca²⁺]_i (38,40,41). All these characteristics support the proposal that adenine nucleotides serve as second messenger in stimulus-secretion coupling.

This metabolic recognition of glucose by β -cells is then coupled to the process of insulin secretion through the operation of two pathways: a triggering pathway and an amplifying pathway (42). Their major steps are schematized in Figure 6.2.

THE TRIGGERING PATHWAY OF GLUCOSE-INDUCED INSULIN SECRETION

Cytoplasmic Ca²⁺ as Triggering Signal

Direct evidence that cytoplasmic Ca^{2+} triggers exocytosis of insulin granules was obtained from experiments using β -cells of which the plasma membrane was permeabilized. In these cells, the membrane potential is dissipated and the cytosolic concentration of small molecules (e.g., Ca^{2+} , ATP) can be controlled. An increase in free $[Ca^{2+}]_i$ induced insulin release independently from any other change (43,44). More recently, exocytosis of insulin granules was estimated by measuring the capacitance of voltage-clamped single β -cells: increases in capacitance reflect increases in plasma membrane surface caused by the fusion of secretory granules. This technique confirmed that Ca^{2+} directly triggers exocytosis (45,46). Although progressive desensitiza-

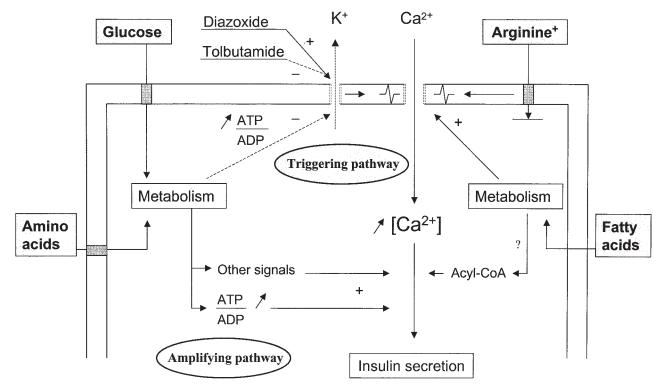

Figure 6.2. Schematic representation of the triggering and amplifying pathways of the stimulation of insulin secretion by glucose, and of the mode of action of other nutrients: +, stimulation; – inhibition; ATP, adenosine triphosphate; ADP, adenosine diphosphate; CoA, coenzyme A.

tion to Ca^{2+} occurs in these preparations, imposed oscillations of $[Ca^{2+}]_i$ were able to entrain oscillations of insulin secretion in permeabilized cells (47), indicating that Ca^{2+} has a minute-to-minute triggering role.

Experiments using permeabilized insulin-secreting cells (47) and capacitance measurements in β -cells (48) have shown that stable derivatives of guanosine triphosphate (GTP) can increase insulin release in a truly Ca²⁺-independent manner. In intact rat islets, a Ca²⁺-independent pathway of glucose-induced insulin secretion could be unmasked by strong and combined activation of protein kinases A and C (49). However, the significance of this pathway is unclear (50). Under physiologic conditions, glucose increases the cytoplasmic free Ca²⁺ concentration ([Ca²⁺]_i) in β -cells, and all maneuvers interfering with this increase impair the stimulation of insulin secretion. Although the sequence of events leading to insulin secretion may include Ca²⁺-independent steps, the physiologic regulation by glucose is achieved through a Ca²⁺-dependent pathway.

How can cytoplasmic $[Ca^{2+}]_i$ serve as triggering signal? Unstimulated β -cells maintain $[Ca^{2+}]_i$ between 50 and 100 nM by several mechanisms: a low permeability of the plasma membrane to Ca²⁺, pumping of Ca²⁺ into the endoplasmic reticulum by a sarco(endo)plasmic reticulum Ca²⁺-ATPase (SERCA) (51,52), and extrusion of Ca²⁺ across the plasma membrane by a calmodulin-sensitive Ca²⁺-ATPase (53,54) and an Na⁺/Ca²⁺ countertransport driven by the electrochemical gradient for Na⁺ (55). There thus exist large gradients of Ca²⁺ concentration between the cytoplasm and either the lumen of the endoplasmic reticulum or the extracellular medium. Opening of Ca²⁺ channels in the plasma membrane (e.g., by depolarization) or in the endoplasmic reticulum membranes (e.g., by inositol trisphosphate) allows rapid movements of Ca²⁺ down the electrochemical gradient and causes increases in cytoplasmic [Ca²⁺]_i.

How Does Glucose Increase $[Ca^{2+}]_i$ in β -Cells?

Mobilization of Ca²⁺ from intracellular stores is the major mechanism by which many stimuli increase $[Ca^{2+}]_i$ in electrically non-excitable cells. β -Cells are electrically excitable, and mobilization of intracellular Ca²⁺ by glucose has never been demonstrated by direct measurements in normal β -cells. Although Ca²⁺ handling by intracellular organelles contributes to the fine regulation of $[Ca^{2+}]_i$ during glucose stimulation (56,57), Ca²⁺ influx through voltage-operated Ca²⁺ channels is indisputably the major determinant of the glucose-induced $[Ca^{2+}]_i$ increase (Fig. 6.2).

When the extracellular concentration of glucose increases, β cell metabolism accelerates (Fig. 6.1). One of the earliest consequences is a decrease in the K⁺ conductance of the plasma membrane (58–60). It is due to the closure of the K⁺ channels that determine the resting potential of β -cells, the ATP-sensitive K⁺ channels (K⁺-ATP channels) (61,62). These channels are tetramers of a complex of two proteins: a high-affinity sulfonylurea receptor (SUR 1) and an inwardly rectifying K⁺ channel (Kir 6.2) (63–65). The pore of the channel is formed by the four subunits of Kir 6.2 to which ATP binds to close the channel. The four subunits of SUR 1 mediate the opening property of Mg²⁺-ADP and endow the channel with sensitivity to pharmacologic agents such as sulfonylureas and diazoxide that respectively close and open the channel (Fig. 6.2).

The decrease in K⁺ conductance produced by glucose allows a background current of a yet unidentified nature to move the membrane potential away from the equilibrium potential for K⁺, that is, to depolarize the membrane (Fig. 6.3). In a mouse β cell, within an intact islet, the resting potential is about -65 mV in the presence of a non-stimulatory glucose concentration (3 mM). When the concentration of glucose is increased to 10 mM,

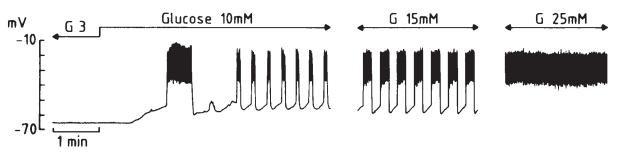

Figure 6.3. Changes in the membrane potential of a mouse β -cell induced by successive increases in the concentration of glucose in the perifusion medium. The three recordings were obtained in the same cell. (Adapted from Henquin JC. Les mécanismes de contrôle de la sécrétion d'insuline. *Arch Int Physiol Biochim* 1990;98:A61-A80, with permission.)

the membrane depolarizes by about 15 mV, to reach the threshold potential for opening of voltage-operated Ca²⁺ channels (66). Depending on the species, these voltage-operated Ca²⁺ channels are predominantly or exclusively of the L-type (67,68). Their opening allows the influx of Ca²⁺, which manifests itself as a rapid depolarization to a plateau potential on which a burst of Ca²⁺ action potentials appears. The electrical activity then suddenly stops and the membrane repolarizes. The membrane potential then starts to oscillate, thus producing rhythmic openings of Ca²⁺ channels and Ca²⁺ influx. As the glucose concentration increases, the phases of depolarization and Ca2+ influx become longer and the intervals become shorter (Fig. 6.3). The membrane eventually remains persistently depolarized at the plateau potential and exhibits continuous electrical activity. This characteristic pattern has been studied primarily in vitro (66) but is also observed when the membrane potential of β -cells is recorded in vivo (69).

Attributing the electrical properties of β -cells only to K⁺-ATP channels and voltage-operated Ca²⁺ channels is an oversimplification imposed by the objectives of this chapter. The electrogenic sodium pump and a number of voltage-dependent and voltage-independent ionic channels also participate in the fine tuning of the glucose-induced electrical activity, which is still only partly understood (66,68,70,71). Whether the changes in the ATP/ADP ratio suffice to explain the influence of glucose on the β -cell membrane potential is also uncertain. The fact that the ratio gradually changes between 0 and 20 mM glucose (38) makes the hypothesis at least plausible. Functionally, the decrease in ADP (which acts on SUR 1) is probably more important than the increase in ATP. Other metabolic regulators of the membrane potential have been proposed, but none of these suggestions has gained wide acceptance (63–65).

Characteristics of the Increase in [Ca²⁺]_i Produced by Glucose

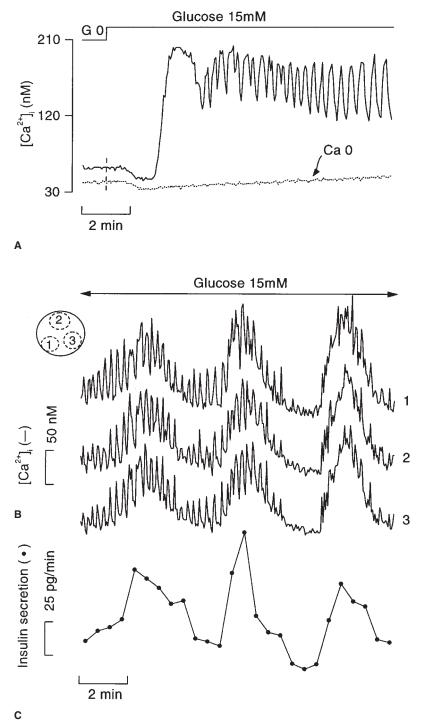

In the presence of a non-stimulatory concentration of glucose, β -cell [Ca²⁺]_i is low and stable. Upon stimulation with high glucose, [Ca²⁺]_i changes in three stages (Fig. 6.4A). A small decrease occurs initially, reflecting cytoplasmic Ca²⁺ pumping into the endoplasmic reticulum (72). This Ca²⁺ sequestration might be promoted by the increase in ATP/ADP ratio (73), but its functional significance is unknown. The subsequent [Ca²⁺]_i increase displays a biphasic pattern. An initial large and sustained increase is followed by a nadir and then by oscillations that persist as long as the glucose stimulation is continued. These changes in [Ca²⁺]_i are superimposable on those of the membrane potential (compare Fig. 6.4A and Fig. 6.3) (74,75). The initial decrease in [Ca2+]i occurs during progressive depolarization from the resting to the threshold potential, but the two events do not seem to be causally related (76). In contrast, the long first phase of the [Ca²⁺]_i increase and the subsequent oscillations not only coincide with but are caused by the influx of Ca²⁺ brought about by the changes in membrane potential. The mechanisms of the oscillations in β -cell membrane potential (66,68,70,71) and [Ca²⁺]_i (77–79) during steady-state stimulation with glucose remain controversial. They seem to result from a complex interplay between oscillations in metabolic signals and the coordinated opening and closing of ionic channels with distinct timeand voltage-dependent properties. Ca2+-independent, intrinsic oscillations of glucose metabolism (77), Ca²⁺-induced acceleration of ATP production (80), and Ca²⁺-induced stimulation of ATP consumption (40) have been proposed. The variability of these oscillations (period from 20 seconds to 4 minutes) between preparations adds to the complexity. Sometimes, glucose-induced electrical activity and [Ca²⁺]_i oscillations are characterized by a double periodicity in which rapid oscillations are superimposed on slower ones (Fig. 6.4B). It is not unusual that, in the same islet, the oscillatory pattern spontaneously changes from regular, fast oscillations into mixed or slow oscillations. Cyclic adenosine monophosphate (cAMP) increases the rhythm and regularity of the oscillations.

Figure 6.4A also shows that glucose does not increase $[Ca^{2+}]_i$ in the absence of extracellular Ca^{2+} . This is also true when, in the presence of extracellular Ca^{2+} , Ca^{2+} influx is impeded by blocking the voltage-operated Ca^{2+} channels or by preventing the glucose-induced depolarization with diazoxide (see below).

Activation of an Effector System by Ca²⁺

Insulin is stored in large dense core vesicles. Its secretion in the extracellular space of the islets occurs by a process of regulated exocytosis (81) that involves several steps: recruitment of the granules, followed by their docking, priming, and eventual fusion with the plasma membrane. Extensive description of these complex stages can be found in specialized review articles (82,83).

The importance of the cytoskeleton has been established by the use of drugs capable of interfering with the function of its distinct elements (84,85). The cytoskeleton, composed of microfilaments, microtubules, and intermediary filaments (vimentin, cytokeratin), ensures the transport of the secretory granules to the plasma membrane. Upon β -cell stimulation, tubulin polymerizes to form microtubules that can guide the granules toward the sites of exocytosis. Polymerization of globular actin with formation of microfilaments also occurs. Actin filaments may both facilitate and impede (cortical network) the access of

secretory granules to the plasma membrane. Ca^{2+} -calmodulin protein kinase II (Cam-kinase II), associated with the secretory granules, appears to play an important role in this mobilization of the granules from the Golgi to the exocytotic sites (86). The activation of Cam-kinase II by the increase in $[Ca^{2+}]_i$ that glucose and other secretagogues produce correlates well with insulin secretion. Myosin light-chain kinase also is implicated in granule movements by modulation of actin-myosin interactions (87).

The docking step corresponds to the targeting of the secretory vesicle to the plasma membrane (82,83). It is achieved by the pairing of cognate proteins present on the vesicle membrane

Figure 6.4. Glucose-induced changes in cytoplasmic free Ca^{2+} ([Ca^{2+}]₁) in intact mouse islets. **A:** After an initial period of perifusion without glucose (G 0), the islet was stimulated with 15 mM glucose. The medium contained 2.5 mM or 0 mM CaCl₂. **B:** [Ca^{2+}]_i and insulin secretion were measured simultaneously in the same mouse islet during continuous stimulation with 15 mM glucose. Traces 1–3 correspond to the [Ca^{2+}]_i signal recorded in the different regions of the islet schematically identified in the upper left corner. They show the excellent synchrony of both slow and rapid oscillations of [Ca^{2+}]_i. The lower line shows that insulin secretion (sampling every 30 seconds) oscillates in phase with the slow [Ca^{2+}]_i oscillations. A higher sampling rate would be necessary to show that the fast [Ca^{2+}]_i oscillations also trigger oscillations of insulin secretion (experiments performed by M. A. Ravier).

(v-SNARE, e.g., synaptobrevin) and the plasma (target) membrane (t-SNARE, e.g., syntaxin). This assembly then recruits several cytoplasmic proteins to reorganize in a multimeric complex through an ATP-dependent process (priming). Finally, Ca²⁺ acts on yet other proteins of the vesicle membrane, among which synaptotagmin is predominant, to induce the fusion of the two membranes. Eventually, the granule content, i.e., insulin, C peptide, other proteins, and nucleotides, is released outside the β -cell.

GTP-binding proteins also control the process of exocytosis (82,83), but it is unclear whether these serve a regulatory role in glucose-induced insulin secretion. As already mentioned,

experiments using permeabilized insulin-secreting cells (47) or β -cells patch-clamped in the whole-cell mode (48) (to control the cytosolic composition) have shown that insulin release can be induced by GTP, independently of $[Ca^{2+}]_i$ changes. The Gprotein involved in this stimulation often is referred to as G_E (for exocytosis), but its nature is unknown. Heterotrimeric Gproteins can influence insulin secretion independently of their role in membrane receptor–activated signal transduction (88). $G_{\alpha i}$ or $G_{\alpha 0}$ mediate an inhibitory effect that abolishes the action of Ca^{2+} (89,90). It has been suggested that the protein phosphatase calcineurin is implicated in this inhibition, but the hypothesis has not been confirmed.

In addition to Cam-kinase II, two other protein kinases have a marked influence on the effector system. The cAMP-dependent protein kinase A and the Ca²⁺-and phospholipid-dependent protein kinase C strongly amplify the action of Ca²⁺ on exocytosis. Their targets are not known (see below).

Consensus Model of the Triggering Pathway

The entry of glucose in β -cells by facilitated diffusion being not rate limiting, changes in the extracellular (blood) glucose concentration are immediately transduced into changes in β -cell metabolism. The tight coupling between glycolysis and mitochondrial metabolism results in rapid and marked changes in the ATP/ADP ratio that then control K⁺-ATP channels in the plasma membrane. These channels serve as transducers of biochemical into biophysical signals. Thus, their closure by an increase in the ATP/ADP ratio leads to membrane depolarization and opening of voltage-operated Ca²⁺ channels. The ensuing Ca²⁺ influx raises [Ca²⁺]_i, which eventually activates an effector system responsible for the exocytosis of insulin granules (Fig. 6.2).

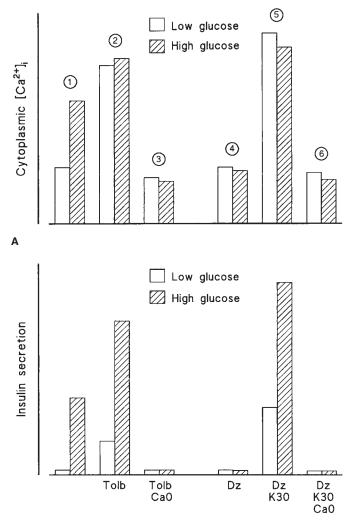

THE AMPLIFYING PATHWAY OF GLUCOSE-INDUCED INSULIN SECRETION

In addition to the generation of a triggering signal, an increase in $[Ca^{2+}]_{i}$, glucose-induced insulin secretion involves the generation of signals that amplify the action of Ca^{2+} on the exocytotic process (42) (Fig. 6.2). This concept was established by experiments showing that glucose can still increase insulin secretion when K⁺-ATP channels cannot be closed (91–93) or are already completely closed (94–96).

Identification of the Pathway

In a control medium, a high glucose concentration increases $[Ca^{2+}]_i$ in β -cells (triggering signal) and stimulates insulin secretion. In a low glucose medium, tolbutamide mimics the effects of glucose. When the drug is used at a maximally effective concentration that closes all K⁺-ATP channels (Fig. 6.2), it increases $[Ca^{2+}]_i$ more than does high glucose but has a less potent effect on insulin secretion (Fig. 6.5). Increasing the glucose concentration under these conditions considerably amplifies insulin secretion without affecting $[Ca^{2+}]_i$. However, glucose does not have this effect when the tolbutamide-induced $[Ca^{2+}]_i$ increase has been prevented by omission of extracellular Ca^{2+} .

When K⁺-ATP channels are opened by diazoxide (Fig. 6.2), a high glucose concentration is unable to increase $[Ca^{2+}]_i$ and stimulate insulin secretion because it cannot depolarize the β cell membrane (Fig. 6.5). An increase in $[Ca^{2+}]_i$ can, however, be induced, even in a low glucose environment, by depolarizing the membrane with high extracellular K⁺. This is followed by a

В

Figure 6.5. Demonstration of the existence of two pathways of control of insulin secretion by glucose. The figure is based on data obtained with mouse islets. Changes in cytoplasmic free Ca^{2+} ($[Ca^{2+}]_i$) (A) and in insulin secretion (B) under the following conditions are shown: (1) In control medium, high glucose raises cytoplasmic [Ca2+]i and stimulates insulin secretion. (2) Blockade of all K⁺-ATP channels by a high concentration of tolbutamide (Tolb) in low glucose mimics both effects of high glucose alone, but the stimulation of secretion is smaller in spite of a larger rise in $[Ca^{2+}]_i$. High glucose does not affect $[Ca^{2+}]_i$ but markedly increases insulin secretion. (3) The effects of tolbutamide and glucose are abolished when [Ca2+]i cannot be increased because of omission of extracellular Ca2+. (4) Opening of K+-ATP channels by diazoxide (Dz) prevents the stimulatory effects of high glucose on $[Ca^{2+j}]_i$ and insulin secretion. (5) Depolarization with high K⁺ strongly increases $[Ca^{2+j}]_i$ and induces insulin secretion in low glucose. High glucose markedly amplifies the secretory response without changing $[Ca^{2+}]_i$. (6) The effects of high K⁺ and glucose are abrogated when $[Ca^{2+}]_i$ cannot be raised because of omission of extracellular Ca2+. In conclusion, glucose stimulates insulin secretion by increasing [Ca2+]i (triggering pathway as shown in 1), and by increasing the efficacy of Ca2+ on exocytosis (amplifying pathway as shown in 2 and 5).

stimulation of insulin secretion simply because a triggering signal has been produced. Increasing the concentration of glucose in the presence of high K⁺, while K⁺-ATP channels are held open by diazoxide, leads to a marked increase in insulin secretion without any further increase in $[Ca^{2+}]_i$ (Fig. 6.5). Again, these effects of glucose require that $[Ca^{2+}]_i$ be increased, because they are abolished by omission of extracellular Ca²⁺.

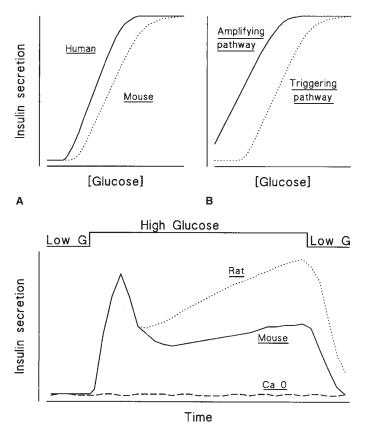

Direct comparisons of the relationships between insulin secretion and $[Ca^{2+}]_i$ under various conditions have established beyond doubt that glucose amplifies insulin secretion by increasing the efficacy of cytosolic Ca²⁺ in the secretory process (42,96,97).

Mechanisms of the Amplifying Pathway

The amplifying pathway requires the metabolism of glucose by β -cells (91). The second messenger has not been identified with certainty, but good correlations exist between the ATP/ADP ratio and glucose-induced insulin secretion through this pathway (38,92). Moreover, several experimental approaches have established that ATP influences insulin secretion at steps distal to the increase in [Ca²⁺]_i (98–100). There is also good evidence that cAMP-dependent protein kinase A and diacylglycerol-activated protein kinase C are not involved (92,101,102). Whether long-chain acyl CoAs participate in this effect is still disputed (101,103). More complete discussion of this question can be found elsewhere (42).

Hierarchy between the Triggering and Amplifying Pathways

Under control conditions, the concentration dependency of glucose-induced insulin secretion displays a sigmoidal shape (Fig.

С

Figure 6.6. Concentration dependence and kinetics of glucose-induced insulin secretion *in vitro*. **A:** The relationship between the glucose concentration and insulin secretion is sigmoidal; it is shifted to the left in humans as compared with the curve in mice; the curve would be intermediate in the rat. **B:** The triggering and amplifying pathways of glucose control of insulin secretion show distinct dependences on the glucose concentration. **C:** An abrupt increase in the glucose concentration triggers a biphasic secretion of insulin. During second phase, the rate of secretion increases more in the rat than in the mouse. Insulin secretion is not stimulated in the absence of extracellular Ca²⁺ (Ca 0).

6.6A). A similar relationship characterizes generation of the triggering signals, electrical activity, and increase in [Ca2+]i by glucose (104-106). The threshold corresponds to the glucose concentration required to depolarize the $\hat{\beta}$ -cell membrane to the potential where voltage-operated Ca2+ channels start to open and the triggering signal thus starts to be produced. In contrast, the concentration dependency of the amplifying pathway, which can be established when the triggering signal is kept constant by high K⁺ in the presence of diazoxide, is hyperbolic and shifted to the left (Fig. 6.6B). Low concentrations of glucose are thus able to influence insulin secretion, but their influence manifests itself only when a triggering signal has been produced. The similarity of the concentration dependencies of glucoseinduced triggering signal and secretory response establishes a clear hierarchy between the two pathways: The amplifying pathway remains functionally silent as long as the triggering pathway has not depolarized the membrane and increased [Ca²⁺]_i, but its role is essential to optimize the secretory response to the triggering signal (42). This hierarchy ensures that no insulin is inappropriately secreted in the presence of low glucose. It may be altered when the function of K+-ATP channels is perturbed by genetic alterations or by long-acting sulfonylureas (42).

OTHER PUTATIVE MESSENGERS IN THE β -CELL RESPONSE TO GLUCOSE

As previously discussed, changes in the cytoplasmic ATP/ADP ratio in β -cells are currently thought to be the major coupling factor between glucose metabolism and the biophysical events leading to the generation of the triggering signal. There is also evidence for a role of the ATP/ADP ratio in the amplification pathway (Fig. 6.2). Over the years, however, many other messengers have been considered to play a role in the β -cell secretory response to glucose.

Metabolic Factors

The hypothesis that a specific intermediate of glucose metabolism (e.g., of glycolysis) is directly involved in triggering secretion was abandoned when it became evident that fuel secretagogues metabolized through distinct pathways have largely similar effects.

Reduced pyridine nucleotides (NADPH and NADH) are unlikely to be an essential triggering signal but may play a modulatory role (e.g., by changing the thiol-disulfide equilibrium in various proteins) (107). Fuel-induced insulin secretion is associated with a more reduced state of the cytosol of β -cells (2,108,109).

The GTP/GDP ratio in islet cells increases in parallel with the ATP/ADP ratio upon stimulation with glucose (38,110). This parallelism probably reflects the high activity of the islet nucleotide-diphosphate kinase (111). There exists a good correlation between glucose-induced insulin secretion through either pathway and the GTP/GDP ratio (38), but a specific role of changes in GTP or GDP in stimulus-secretion coupling remains disputed (110,112).

A mitochondrial factor distinct from ATP has been suggested to control exocytosis of insulin granules together with Ca²⁺ and ATP. The proposal that this factor might be glutamate (113) has been challenged (114).

Although protons are produced during glucose metabolism, the cytosolic pH of glucose-stimulated β -cells increases slightly (115) because of the operation of an HCO₃⁻/Cl⁻ exchanger (116). It is possible that this small alkalinization modulates insulin secretion (117).

Malonyl Coenzyme A and Long-Chain Acyl Coenzyme A

The anaplerotic characteristics of glucose metabolism in β -cells lead to the formation of excess citrate that exits mitochondria to serve as a precursor of malonyl CoA in the cytoplasm (36) (Fig. 6.1). Malonyl CoA then inhibits carnitine palmitoyl transferase I and reduces fatty acid uptake by mitochondria, which explains the inhibition by glucose of the oxidation of endogenous (and exogenous) fatty acids (118,119). The result is an increase in cytosolic long-chain acyl CoAs that are proposed to serve as effector signal molecules (36). Because long-chain acyl CoAs open K⁺-ATP channels (120), they cannot underlie generation of a triggering signal by membrane depolarization. Longchain acyl CoA seems to increase the efficacy of Ca²⁺ on exocytosis (121). This attractive model has, however, been challenged by the demonstration that glucose-induced insulin secretion does not correlate with the extent to which lipids are either oxidized or esterified (122). Other signaling functions of glucose-regulated anaplerosis are currently being investigated (123).

Cyclic Adenosine Monophosphate

Glucose increases the concentration of cAMP in β-cells slightly (124), probably secondarily to the increase of $[Ca^{2+}]_i$ and the activation of adenylate cyclase by a Ca2+-calmodulin protein kinase (125). Several phosphodiesterases (PDE) that degrade cAMP are present in β -cells, but the PDE 3 isoform is predominant both quantitatively and functionally (126,127). There is no doubt that an increase in cAMP concentration in β -cells is not a sufficient signal to trigger insulin secretion, but it can amplify the response to various secretagogues. Whereas the role of this amplification during hormonal stimulation of β-cells is well established (see below), its role during stimulation by glucose alone is much less clear. Experiments with isolated β-cells suggest that a minimal concentration of cAMP is necessary for normal stimulation of insulin secretion by glucose (128), and hormones that increase cAMP levels have been suggested to increase the glucose competence of poorly responsive β -cells (129). In contrast, inhibitors of protein kinase A do not impair the effect of glucose in intact islets (130).

Inositol Phosphates and Diacylglycerol

Glucose stimulates both the synthesis and hydrolysis of phospholipids in β -cells (131–134). However, the breakdown of phosphatidylinositol 4,5-bisphosphate and accumulation of inositol 1,4,5-trisphosphate are not primary signals but rather consequences of the increase in $[Ca^{2+}]_i$ (133,134). The acceleration of phospholipid turnover by glucose may serve to optimize the potentiation of insulin secretion by agonists acting via phospholipase C–linked receptors (see below).

Glucose stimulates de novo synthesis of diacylglycerol in β cells. However, this diacylglycerol is richer in palmitate and poorer in arachidonate than is the diacylglycerol generated by hydrolysis of preexisting glycerolipids and does not significantly increase the total mass of diacylglycerol in islet cells (135). This may explain why glucose is usually (136–138), although not consistently (139,140), found not to translocate and activate protein kinase C in β -cells. It is possible that activation of protein kinase C (by diacylglycerol or another stimulator) contributes to the second phase of insulin secretion in certain species (102), but the bulk of the evidence indicates that its role in glucose-induced insulin secretion is not a major one.

Arachidonic Acid and Other Lipid Derivatives

Glucose stimulation of islet cells increases the release of arachidonic acid from phospholipids. However, decisive arguments that arachidonic acid itself plays a role in stimulus-secretion coupling are still missing (132,138,141). On the other hand, metabolites of arachidonic acid could modulate glucoseinduced insulin secretion. The latter is decreased by prostaglandins and increased by certain products formed by lipoxygenation. It has been suggested that phosphatidic acid, formed by activation of phospholipases or by de novo synthesis from glucose, and lysophospholipids formed by activation of phospholipase A₂, might be involved in glucose-induced insulin secretion (138). In no case, however, have the reported effects of these substances carried conviction that their role is critical in stimulus-secretion coupling.

GENERAL CHARACTERISTICS OF GLUCOSE-INDUCED INSULIN SECRETION

Links between Insulin Synthesis and Secretion

The mechanisms of insulin biosynthesis and of its regulation by glucose are dealt with in detail in Chapter 5.

Short-term control of insulin secretion does not depend on insulin synthesis. Pancreatic insulin stores largely exceed the maximal secretory rates (~5% of insulin content per hour). The inhibition of insulin secretion that follows blockade of protein synthesis in β -cells does not reflect requirement of insulin synthesis (142) but results from the loss of other proteins with a short half-life (143). The first alteration is a rapid (1 to 2 hours) impairment of the action of Ca²⁺ on exocytosis followed by a delayed (>5 hours) decrease in the production of the triggering signal (143). Insulin synthesis and secretion can also be dissociated under several conditions. In contrast to glucose and other fuel secretagogues that stimulate both processes, several agents (e.g., arginine, acetylcholine, and hypoglycemic sulfonylureas) increase insulin secretion without increasing its synthesis (2,144). It also is possible to abolish the effects of glucose on secretion without affecting those on synthesis (e.g., by omitting extracellular Ca²⁺) (2,144).

Insulin synthesis and secretion are, however, not completely independent events. Under certain circumstances, isolated islets release newly synthesized insulin in preference to older stored hormone (145). This may indicate that insulin granules do not undergo exocytosis at random but that a subpopulation of newly formed granules is "marked" to be released rather than to be stored (146). The mechanisms of this marking are not known. Alternatively, the phenomenon of preferential release of newly formed insulin could be due to β -cell heterogeneity within the islets (147). If the rise in glucose concentration recruits the same β -cells to synthesize (148) and to release insulin, and if these cells have low stores of preformed insulin, an apparent preferential secretion of newly formed insulin may be measured.

Kinetics

Insulin secretion depends not only on the ambient concentration of glucose but also on the rate of change of this concentration. When the glucose level increases slowly, the rate of insulin secretion increases in parallel. However, when the concentration of glucose is abruptly increased and then maintained at a high level, insulin secretion follows a biphasic time course (Fig. 6.6C). A nadir and a slowly rising second phase follow a rapid peak (first phase). This pattern, first described in the perfused rat pancreas (149), is commonly observed *in*

vitro. It is not seen *in vivo* when the plasma glucose concentration progressively increases after a meal or even after an oral glucose load, but it can be produced by a rapid increase in plasma glucose during intravenous glucose infusion (150). This ability of β -cells to respond rapidly to glucose is thought to be essential for optimal glucose homeostasis. The loss of this ability has long been considered an early sign of β -cell dysfunction characteristic or even predictive of type 2 diabetes mellitus (150,151).

Numerous hypotheses have been put forward to explain the biphasic time course of glucose-induced insulin secretion. Because the glucose dependency of the two phases is similar *in vitro* (152) and *in vivo* (150), there is no evidence that distinct initial steps in glucose recognition are involved. Early suggestions that the nadir between the two phases is due to a negative feedback exerted by insulin secreted during the first phase or to partial inhibition by somatostatin have been abandoned (152,153). The concept that the first phase reflects release of preformed insulin and that the second phase reflects release of newly synthesized insulin is also not correct (152).

According to a "storage-limited" model (152,153), two compartments of insulin granules could exist, the smaller one, in proximity to the plasma membrane, being readily released and responsible for the first phase. The existence of distinct subsets of granules is supported by experiments monitoring insulin release as capacitance changes in single, voltage-clamped β cells (154,155). It has been suggested that the pool of readily releasable granules is composed of those insulin granules that can be immunoprecipitated by an antibody directed to syntaxin, a plasma membrane protein (156). However, functional evidence indicates that only a fraction of the docked granules is readily releasable (155). This model implies that the second phase reflects the energy-dependent mobilization of granules from a reserve to the readily releasable pool.

According to a "signal-limited" model (153,157), changes in the magnitude or effectiveness of the triggering signal produced by glucose could underlie the biphasic response. Evidence supporting this hypothesis is accumulating. The increase in β -cell [Ca²⁺]_i produced by glucose is biphasic (74,75), and no first phase of secretion occurs when [Ca²⁺]_i does not abruptly increase. However, no gradual increase in [Ca²⁺]_i occurs during sustained glucose stimulation (74,75). Therefore, the slowly increasing second phase of secretion (which is more pronounced in the rat than in the mouse) (Fig. 6.6C) does not depend simply on the concentration of cytoplasmic Ca²⁺ but probably also involves an increase in the efficacy of the Ca²⁺ signal (42,102,158). There is good evidence that the amplifying pathway is implicated, but it is still unclear whether the enlargement of the pool of releasable insulin granules results from a mobilization of granules toward the sites of exocytosis or from a modification of the properties of already adequately situated granules.

Biphasic insulin secretion is not specific to glucose. It can also be induced by other fuel stimuli (159,160). Moreover, the kinetics of the secretory response may be influenced by the concentration of the applied stimulus and by the prevailing concentration of glucose. For instance, the common idea that sulfonylureas simply trigger a first phase of insulin secretion (149) holds true only for stimulation by high concentrations of the drugs in low-glucose environments. When used at a low concentration and in the presence of glucose, sulfonylureas induce a sustained secretion of insulin (161,162). These are further arguments supporting the conclusion that the kinetics of insulin secretion does not depend simply on the existence of different pools of insulin granules. Either model is probably insufficient. Biphasic secretion of insulin requires immediately releasable and mobilizable granules *and* adequate temporal and quantitative changes in both triggering and amplifying signals. It is also unlikely that an empty pool of releasable granules can explain the lack of first phase in patients with type 2 diabetes mellitus (150,151). If this were the case, why should non-glucose stimuli cause immediate insulin secretion (163,164)? The defect is more likely due to the inability of glucose to induce a rapid increase in $[Ca^{2+}]_i$ in these diseased β -cells.

Concentration Dependency: Recruitment and Increase in the Individual Responses

As previously mentioned, the relationship between the extracellular glucose concentration and the rate of insulin secretion *in vitro* is sigmoidal (1) (Fig. 6.6A). In isolated rat islets or in the perfused rat pancreas, the threshold concentration is around 5 to 6 mM and half-maximal and maximal responses are observed at 9 to 11 mM and 15 to 20 mM, respectively. This relationship is shifted slightly to the left in human islets and to the right in mouse islets, which corresponds well with the differences in blood glucose concentration between the three species. It is also important to bear in mind that circulating nutrients other than glucose, hormones, and neurotransmitters shift the dose-response relationship to glucose to the left *in vivo* (see below).

The sigmoidal shape of the dose-response curve has been attributed to a gaussian distribution of the thresholds for β -cell stimulation (128). Increasing the concentration of glucose would thus recruit more and more β -cells to secrete insulin. Functional heterogeneity between β -cells has been directly demonstrated *in vitro* by measuring (with the reverse hemolytic plaque assay) insulin secretion from single β -cells obtained by dispersion of rat islets (165). The number of secreting cells increases as the concentration of glucose is increased (166,167). The alternative possibility is that the response of each individual cell increases with the concentration of glucose. It has indeed been demonstrated that glucose causes a dose-dependent increase in [Ca²⁺]_i (106) and in insulin release (166,167) in single isolated β -cells.

The key question is whether the heterogeneity of individual isolated β -cells persists within the islets of Langerhans in which β-cells are preferentially interconnected by gap junctions made of connexin 36 (168). This intercellular coupling and paracrine influences may erase the individual differences to constitute a functionally homogeneous population. Thus, in contrast to the heterogeneous responses produced in isolated β-cells, glucose induces uniform metabolic (NADPH autofluorescence) (169), electrical (69,71,170), and $[Ca^{2+}]_i$ responses (74,75) in β -cells residing within intact islets. The homogeneity and synchrony of complex [Ca²⁺]_i changes in different regions of an islet are illustrated in Figure 6.4. Recruitment of β -cells can be detected in islets or clusters, but it occurs over a narrow range of glucose concentrations (106). There is no doubt that the triggering signal is not generated in an all-or-none manner; its amplitude increases with the glucose concentration. It is also well established that the secretory performance is greatly improved when contacts are established between β -cells (128,171,172). Through the electrical coupling, the most active β -cells of an islet can entrain the less active ones to generate an increase in $[Ca^{2+}]_i$. Nevertheless, there is indirect evidence that not all β -cells within intact islets secrete insulin at the same rate (173,174). This heterogeneity of secretion in face of a homogeneous triggering signal could be due to a variable production of the amplifying signals (106).

Oscillations

Insulin secretion is pulsatile even during stimulation by a stable concentration of glucose. Simultaneous measurements of [Ca²⁺]_i and secretion in single mouse islets have shown that [Ca²⁺]_i oscillations are synchronous in all regions (β -cells) of the islet (74,75) and that each oscillation is accompanied by an oscillation of insulin secretion (175-177). This is illustrated in Figure 6.4 for the slow oscillations but holds true for the fast oscillations, whose detection requires a high temporal resolution (175). The synchrony between [Ca²⁺]_i and insulin secretion oscillations persists under a variety of experimental conditions (175,178), indicating that the islet behaves as a functional syncytium. Whereas it is widely agreed that $[Ca^{2+}]_i$ oscillations in β cells induce pulses of insulin secretion, the possibility that pulsatile insulin secretion occurs in the absence of $[Ca^{2+}]_i$ oscillations in β -cells is debated (97,179,180). Although metabolic oscillations could theoretically drive oscillations of secretion through the amplifying pathway, their power is definitely less than that of [Ca²⁺]_i oscillations (180). It is much more plausible that metabolic oscillations generate oscillations of membrane potential and hence of $[Ca^{24}]_i$. The latter (triggering pathway) then induce oscillations of exocytosis, the amplitude of which may be increased by metabolism itself (amplifying pathway). The primum movens is a metabolic oscillation, but the minute-to-minute regulator is [Ca²⁺]_i.

In healthy human subjects, plasma insulin concentration oscillates at low and high frequencies (181,182). Low-frequency oscillations with a period of about 120 minutes are usually considered to result from feedback loops linking glucose and insulin (183). High-frequency oscillations have a period of 5 to 8 minutes, which is closer to but still substantially longer than the period of the electrical and $[Ca^{2+}]_i$ oscillations in individual islets. Recordings of the β -cell membrane potential within islets of living mice have shown an excellent synchrony between β -cells within the same islet but a lack of synchrony between islets (69). There is at present no evidence that extrinsic signals coordinate the functioning of all islets to generate oscillations of plasma insulin concentration. How these are produced is still unclear.

What can be the functional reasons of the oscillatory behavior of β -cells? The production of pulsatile insulin secretion and oscillations of plasma insulin is the most obvious answer. However, there could also be advantages for the β -cell itself: Oscillations of the signal permit a finer regulation than an amplitudemodulated, sustained signal; oscillations of $[Ca^{2+}]_i$ also may serve to regulate functions other than secretion; oscillations of $[Ca^{2+}]_i$ are less costly for maintenance of cell homeostasis and prevent potentially damaging effects of long-lasting sustained elevations of $[Ca^{2+}]_i$.

THE PREEMINENT ROLE OF GLUCOSE IN THE CONTROL OF INSULIN SECRETION

On the basis of *in vitro* experiments, the numerous agents that increase insulin secretion have traditionally been subdivided into two broad categories: the initiators or primary stimuli that are able to increase insulin secretion in the absence of any other stimulatory agent and the potentiators or secondary stimuli that are ineffective alone but increase insulin secretion in the presence of an initiator, particularly glucose (3). It is, however, essential to emphasize that glucose is by far the most important controller of insulin secretion. One may even consider glucose as the only physiologic initiator of insulin secretion in adult mammals. This concept is illustrated schematically in Figure 6.7.

When insulin secretion is studied *in vitro* with isolated islets or the perfused pancreas and an artificial balanced-salt solution, a stimulatory effect of glucose can already be measured at concentrations within the physiologic range (depicted in hatched area in Fig. 6.7A). In contrast, other initiators, such as amino acids or drugs (e.g., sulfonylureas), must be used at concentrations well above the physiologic or therapeutic range to induce insulin secretion (Fig. 6.7B). Hormones are not initiators; they have no effect when used alone. However, when the incubation or perfusion medium contains a physiologic concentration of glucose, insulin secretion can be increased by amino acids, hormones, or drugs at physiologic or therapeutic concentrations (184–186) (Fig. 6.7B). Glucose thus confers to otherwise ineffective or weakly effective agents the ability to increase insulin

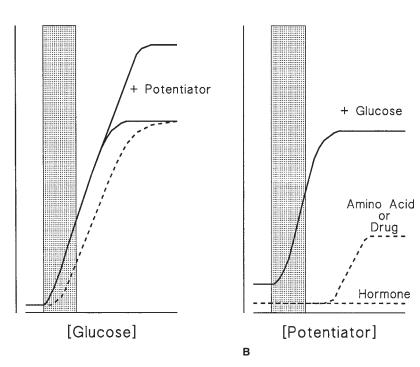

Figure 6.7. Concentration dependence of insulin secretion induced by glucose (**A**) or amino acids, drugs or hormones (**B**). Hatched areas correspond to the range of physiologic or therapeutic concentrations of the test substance. Broken lines show the effect of the test substance alone. Solid lines show the effect of glucose in the presence of a physiologic or therapeutic concentration of a potentiator (**A**) or the effect of an amino acid, a drug, or a hormone in the presence of a physiologic concentration of glucose (**B**). Depending on its mode of action, a potentiator may shift the dose-response curve to glucose to the left or increase the maximum response.

secretion, even at low concentrations, a property known as the "permissive action of glucose." If, on the other hand, the medium contains amino acids, hormones, or a drug at physiologic or therapeutic concentrations (potentiator in Fig. 6.7A), the dose-response curve of glucose-induced insulin secretion is shifted to the left. Depending on the mode of action of the potentiator, the sensitivity or the maximum response to glucose, or both, can be increased.

These apparently complex properties can easily be understood by considering how each agent affects the triggering and amplifying pathways. Initiators are those substances that can produce a triggering signal, a rise in $[Ca^{2+}]_i$, independently of glucose. Non-metabolized agents such as sulfonylureas or arginine belong to that category when they are used at high concentrations, but their effect on insulin secretion is usually small or transient because the efficacy of Ca^{2+} on exocytosis is poor in the absence of an amplifying signal (42). When these agents are used at lower concentrations, they become potentiators. They no longer depolarize the β -cell membrane enough to open voltage-dependent Ca^{2+} channels. However, their small effect on the membrane potential is sufficient to increase Ca^{2+} influx and $[Ca^{2+}]_i$ in the presence of a threshold or stimulatory concentration of glucose (187).

Purely potentiating agents do not induce a triggering signal in the absence of glucose but may increase the insulinotropic action of the latter in different ways. The metabolism of a substrate by β-cells may be insufficient to produce enough ATP to depolarize the membrane to the threshold potential at which Ca²⁺ channels open. Ca²⁺ influx, and hence insulin release cannot be stimulated. In the presence of glucose, however, the substrate potentiator increases β -cell metabolism, as if the concentration of glucose had been raised; hence, the larger secretory response. This type of potentiating action has been well characterized for fructose (22) and can probably also explain the potentiation by other fuels, with the reservation that the metabolic usage of different types of substrates is not always simply additive (4). Another mechanism characterizes the action of hormones that may produce a potent amplifying signal such as cAMP but remain ineffective on insulin secretion until a triggering signal has been produced by glucose (or by another initiator).

It is thus evident that the permissive action of glucose (188,189) depends on the β -cell membrane potential. The depolarization induced by glucose permits the small depolarizing action of the potentiators to activate further Ca²⁺ channels (187). However, the amplifying action of glucose augmenting the efficacy of Ca²⁺ also plays a critical role (42).

With this background in mind, it is easy to understand how changes in the glucose concentration below the threshold value measured *in vitro* can influence β -cell function *in vivo*. A small decrease in plasma glucose concentrations (e.g., during fasting) prevents inappropriate insulin secretion in response to non-glucose stimuli. On the other hand, relatively small increases in plasma glucose concentrations (e.g., after meals) lead to larger insulin responses than those expected from dose-response curves defined *in vitro* because of the greater effect of non-glucose stimuli. The marked glucose dependency of the action of various stimuli on β -cells is thus an essential safeguard against both hypoglycemia and hyperglycemia (Fig. 6.7).

THE β -CELL RESPONSE TO NUTRIENTS OTHER THAN GLUCOSE

Sugars and Derivatives

Glucose is the sole sugar of physiologic importance for the control of insulin secretion. Fructose is metabolized slowly by β -

cells and causes a modest increase in insulin secretion when it is used at nonphysiologic concentrations and in the presence of glucose (potentiation) (3,22,190). Galactose is not metabolized by β-cells and does not affect insulin secretion. In vitro, mannose, glyceraldehyde, dihydroxyacetone, and N-acetylglucosamine can increase insulin secretion. The coherent picture that has emerged from a number of studies is that the insulin-releasing capacity of all sugars and derivatives correlates well with their rate of metabolism in β -cells (2,190,191). Their effects are mediated by both the triggering and amplifying pathways. Exogenous pyruvate and lactate are poor insulin-secretagogues even in high concentrations because they are not well taken up and therefore cannot readily be metabolized by β -cells (27,192). Their metabolism by whole islets takes place in non-\beta-cells which, unlike β -cells, possess plasma membrane transporters for monocarboxylic acids. This also explains why the membrane permeant phenyl-pyruvate is a considerably more potent insulin secretagogue than pyruvate (193).

Amino Acids

The ability of amino acids to increase insulin secretion depends to a marked extent on the ambient concentration of glucose (184) (Fig. 6.7B). At a physiologic concentration, individual amino acids are ineffective, but their combination in proportion to their plasma concentrations is stimulatory (194,195). Their combined action probably involves both metabolic and biophysical mechanisms (Fig. 6.2). Thus, studies using high concentrations of individual amino acids have clearly shown that they distinctly affect stimulus-secretion coupling.

Leucine alone is able to increase insulin secretion, albeit weakly, in the absence of glucose. It is considerably more potent in the presence of glutamine, which itself is ineffective alone. These properties can be explained by changes in β -cell metabolism (196,197). Leucine is degraded by a branched-chain keto acid dehydrogenase to produce acetyl CoA, which is then used by the citric acid cycle. Glutamine is transformed into glutamate by a phosphate-dependent glutaminase. In the presence of leucine, an allosteric activator of glutamate dehydrogenase, glutamate is metabolized into α -ketoglutarate, which eventually fuels the citric acid cycle. Leucine and, even more so, the combination of leucine and glutamine increase the ATP/ADP ratio (92) and stimulate insulin secretion by activating triggering and amplifying pathways similar to those set in motion by glucose (105,198,199) (Fig. 6.2). It is the activation of glutamate dehydrogenase, with subsequent acceleration of the metabolism of endogenous amino acids, that explains the ability of a non-metabolized leucine derivative (BCH, or 2-endoaminonorbornane-2-carboxylic acid) to increase insulin secretion (196,197). Glutamate dehydrogenase may also be indirectly regulated by glucose metabolism (200). Certain mutations of the gene coding for glutamate dehydrogenase increase the activity of the enzyme and provide an explanation for the inappropriate secretion of insulin in the syndrome of leucine-induced hypoglycemia (201).

Alanine is metabolized slowly in islet cells (202) and increases insulin secretion only weakly (203). This effect, which requires the presence of glucose, is probably due to the cotransport of alanine with Na⁺ in β -cells (204). The resulting small depolarization slightly augments Ca²⁺ influx and hence the triggering signal [Ca²⁺]_i.

Arginine and other cationic amino acids are only poorly metabolized in islet cells (202,205). Their mode of action markedly differs from that of nutrients that serve as fuels for β -cells. They depolarize the β -cell membrane because of their transport in the cell in a positively charged form (198,206). The

Fatty Acids

There is wide, albeit incomplete (209), agreement that fatty acids do not acutely increase insulin secretion in the presence of low concentrations of glucose (210–212). This may probably be explained by the fact that fatty acids, although well oxidized by βcells (118,119), do not increase the ATP/ADP ratio and, therefore, do not depolarize the membrane and increase $[Ca^{2+}]_i$ (212). In the presence of stimulatory concentrations of glucose, fatty acids potentiate Ca^{2+} influx possibly by an action on Ca^{2+} channels. The resulting increase in the triggering signal certainly contributes to the increase in insulin secretion that fatty acids produce under these conditions. However, production of an amplifying signal, long-chain acyl CoAs, also is involved (Fig. 6.2). Thus, malonyl-CoA issued from glucose metabolism (Fig. 6.1) inhibits carnitine palmitoyltransferase 1 and thereby prevents long-chain acyl CoA entry and oxidation in mitochondria (36).

ulation of insulin secretion by the amino acid (207,208).

No qualitative differences appear to exist between the effects of saturated, monounsaturated, and polyunsaturated fatty acids, which, however, display distinct potencies (palmitate > stearate ~ oleate > linoleate) (213). It is also evident that the acute effects of fatty acids on β -cell function depend on the unbound fraction rather than on the total concentration. This must be remembered when evaluating the physiologic relevance of *in vitro* studies (213).

Ketone Bodies

Acetoacetate and β -hydroxybutyrate are oxidized by islet cells and slightly increase insulin secretion, at least when used in high concentrations and when the medium also contains glucose (118,214). The available evidence suggests that the effects of ketone bodies on insulin secretion are due to their metabolic degradation in β -cells (214). It is uncertain that these effects observed *in vitro* ever occur *in vivo*, even for maintaining minimum insulin secretion during prolonged fasting.

PHARMACOLOGIC CONTROL OF INSULIN SECRETION

A number of drugs are used in therapeutics with the specific aim of increasing insulin secretion in patients with type 2 diabetes mellitus or, much more rarely, of decreasing insulin secretion in patients suffering from hyperinsulinemic hypoglycemia. Other drugs are used for different purposes but exert side effects in β -cells. Finally, many pharmacologic compounds serve as tools for the study of stimulus-secretion coupling *in vitro*. Only those drugs with a therapeutic potential will be discussed in this section, which is subdivided by site of action rather than by drug family (Fig. 6.8).

Stimulators of Metabolism

No drugs capable of accelerating glucose metabolism have been identified, but synthetic derivatives of glucose or other nutrients that are actively metabolized in β -cells are currently being tested as potential insulin secretagogues (215).

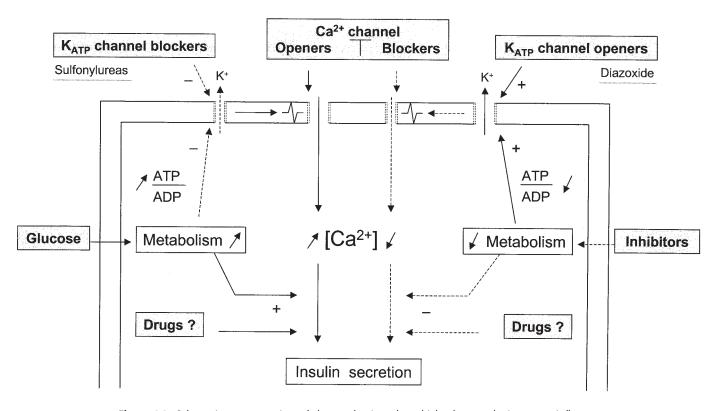

Figure 6.8. Schematic representation of the mechanisms by which pharmacologic agents influence insulin secretion: +, stimulation; –, inhibition; ATP, adenosine triphosphate; ADP, adenosine diphosphate.

K⁺-Adenosine Triphosphate–Channel Blockers

Hypoglycemic sulfonylureas, commonly used in the treatment of patients with type 2 diabetes mellitus, increase insulin secretion by closing K+-ATP channels. This closure does not involve a change in β -cell metabolism but is the result of a direct interaction with SUR 1, the regulatory subunit of the channel (63-65,216) (Fig. 6.8). The ensuing membrane depolarization opens voltage-operated Ca2+ channels, promotes Ca²⁺ influx, and increases [Ca²⁺]_i (75,162,217). Sulfonylureas thus mimic the biophysical effects of glucose that lead to the production of the triggering signal. All sulfonylureas have a similar mode of action but differ by their affinity for SUR 1. In general, those compounds with the highest affinity for the receptor (glibenclamide >> tolbutamide) show the greatest potency but also the poorest reversibility on the stimulation of insulin secretion (217,218). For example, at equipotent concentrations, tolbutamide has a rapid, stable, and rapidly reversible effect on insulin secretion, whereas glibenclamide exerts a slow, progressively increasing and slowly reversible action. It is also important to bear in mind that sulfonylureas are tightly bound to albumin and that their therapeutic free concentrations are much lower than the free concentrations used in many in vitro studies.

Non-sulfonylurea compounds usually derived from glibenclamide (219), the "glinides," have recently become available for the treatment of patients with type 2 diabetes mellitus. The glinides also close K⁺-ATP channels by binding to SUR 1 (220). In contrast, several imidazoline compounds, including blockers of α_2 -adrenoceptors, block the channel by directly closing the pore formed by Kir 6.2 (221,222). Basically, all these substances increase insulin secretion by the same mechanism as sulfonylureas. Some imidazoline compounds may have additional, yet unidentified, sites of action (223–225).

Many other drugs block K⁺-ATP channels in β -cells (226), and the increase in insulin secretion that they may produce explains the hypoglycemic episodes complicating their clinical use; this is the case for quinine (227) and certain antiarrhythmic agents (228).

Inhibitors of Metabolism

Several substances can interfere with glucose metabolism and, therefore, inhibit secretion of insulin by decreasing both the triggering and amplifying signals (Fig. 6.8). Such substances are used *in vitro* as tools to study stimulus-secretion coupling. It is unlikely that therapeutically useful drugs exert such a side effect.

K⁺-Adenosine Triphosphate–Channel Openers

Diazoxide inhibits insulin secretion by opening K⁺-ATP channels (229,230). This opening does not involve a decrease in β -cell metabolism but results from a direct interaction with SUR 1 (Fig. 6.8). The ensuing membrane repolarization closes voltage-operated Ca²⁺ channels, diminishes Ca²⁺ influx, and inhibits insulin secretion (75). Diazoxide thus counteracts the generation of the triggering signal by glucose and other secretagogues that close K⁺-ATP channels. It is, therefore, understandable that the *genuine* effect of arginine, which acts independently of these channels (Fig. 6.2), is not inhibited by diazoxide *in vivo* (231) and *in vitro* (232). However, one effect of diazoxide is largely misunderstood. The drug can also decrease the insulin-releasing action of agents that do not close K⁺-ATP channels when these agents are tested in the presence of subthreshold concentrations of glucose. The explanation is that the depolarizing

action of these agents (with the exception of high extracellular K^+), hence their effect on $[Ca^{2+}]_i$, is diminished when the membrane conductance is increased by opening of K^+ -ATP channels. In other words, diazoxide counteracts the permissive effect of glucose previously described.

Openers of K⁺-ATP channels in vascular smooth muscle cells are currently developed as antihypertensive agents (233). The risk that they inhibit insulin secretion is small because the selected drugs have a higher affinity for SUR 2A (the smooth muscle isoform) than SUR 1 (the β -cell isoform).

Ca²⁺-Channel Openers and Blockers

Blockage of voltage-dependent Ca²⁺ channels by dihydropyridines (e.g., nifedipine) or phenylalkylamines (e.g., verapamil) inhibits Ca^{2+} influx in β -cells (67,68) and, therefore, antagonizes the ability of glucose and other depolarizing agents to increase [Ca²⁺]_i (234) (Fig. 6.8). This explains why these drugs nonselectively inhibit the secretion of insulin induced by those agents whose effect depends on Ca2+ influx, regardless of the mechanisms of depolarization (232). In vivo, Ca2+-channel blockers have no or little deleterious influence on insulin secretion and glucose homeostasis (235). There also exist dihydropyridine derivatives that do not block Ca²⁺ channels but act as agonists at the channel level. They are ineffective in unstimulated β -cells, when the membrane potential is high and the voltage-dependent Ca²⁺ channels are closed, but they increase Ca²⁺ influx and insulin secretion in the presence of glucose (226). Unfortunately, these drugs lack a sufficient tissue selectivity to be used as antidiabetic agents.

Drugs Modulating the Amplifying Pathway

Indirect evidence indicates that the amplifying action of glucose is defective in patients with type 2 diabetes mellitus (236). Drugs correcting this defect could thus be useful. It has been suggested that sulfonylureas also amplify the action of Ca^{2+} on exocytosis of insulin granules (237–239), but this view has been challenged (240,241). No currently available drug exerts such an effect to an extent that is significant and beneficial for the patients. Agents aimed at these distal steps of stimulus-secretion coupling may be developed in the future; those that have been proposed thus far (242) appear to be phosphodiesterase inhibitors producing their effect by increasing cAMP in β -cells. The optimal drug should, however, not be so potent that it reverses the normal hierarchy between the triggering and amplifying pathways (42).

Pharmacologic agents may interfere with insulin secretion by acting on the effector system (e.g., the cytoskeleton) (85). However, no therapeutically useful drug is known to impair the amplifying pathway specifically. The proposal that diazoxide interferes with the action of Ca^{2+} is not grounded (240).

NEUROHORMONAL AMPLIFICATION OF INSULIN SECRETION

Insulin secretion is also subject to autocrine, paracrine, neurocrine, and endocrine influences (90,243–245). The list of hormones and neurotransmitters that may modulate the insulinotropic action of glucose and other nutrients is long and easily confusing because of species differences and uncertainties about the physiologic relevance of some of the effects observed with *in vitro* models. It is particularly difficult to establish whether paracrine interactions observed in isolated

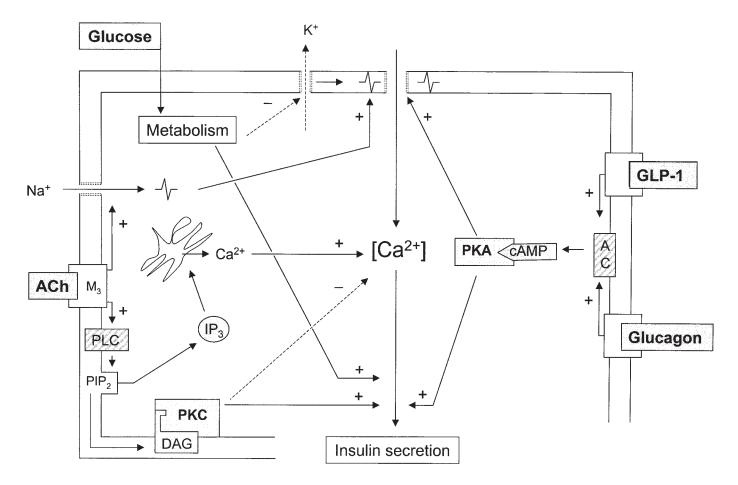

Figure 6.9. Schematic representation of the major mechanisms by which neurotransmitters and hormones amplify insulin secretion: +, stimulation; –, inhibition; ACh, acetylcholine; M₃, muscarinic receptor of the M₃ type; PLC, phospholipase C; PIP₂, phosphatidylinositol 4,5-bisphosphate; IP₃, inositol 1,4,5-trisphosphate; DAG, diacylglycerol; PKC, protein kinase C; GLP-1, glucagon-like peptide 1 (7–36 amide); AC, adenylate cyclase; PKA, protein kinase A.

islets or dispersed cells really occur *in situ* when secreted products are rapidly cleared by the circulation. In addition, many of these putative regulatory peptides can act on receptors other than their own when they are used, as they often are *in vitro*, at supraphysiologic concentrations.

Neurohormonal agents bind to membrane receptors and activate transduction pathways that are generally not specific to β -cells, but their effects on insulin secretion are tightly conditioned by the prevailing glucose concentration. The major intracellular messengers that amplify insulin secretion are cAMP, inositol phosphates, and diacylglycerol (Fig. 6.9).

The Cyclic Adenosine Monophosphate–Protein Kinase A Pathway

Adenylate cyclase, which synthesizes cAMP from ATP, is linked to several membrane receptors by a stimulatory subtype G_s of the GTP-binding proteins (G-proteins). Once formed, cAMP binds to its target, protein kinase A (PKA), of which the type I and type II isoforms are present in β -cells (137). This binding to the regulatory subunits of the kinase releases the catalytic subunits that catalyze the phosphorylation of distinct proteins, the nature of which has only been partially identified.

Several mechanisms underlie the amplification of insulin secretion by cAMP (125,131,246). The two major ones are

depicted in Figure 6.9. Probably by phosphorylating the α_1 subunit of the voltage-operated Ca²⁺ channels (247), PKA slightly increases Ca²⁺ influx triggered by primary secretagogues such as glucose or tolbutamide (248,249) and hence augments the increase in [Ca²⁺]_i that they produce (131,180). A second, quantitatively more important, mechanism is an amplification of the action of Ca²⁺ on exocytosis. This has been demonstrated by the use of permeabilized (43,137) or voltage-clamped (250) β-cells, in which cAMP increases the amount of insulin secreted in response to a fixed [Ca²⁺]_i. The protein or proteins mediating this effect are not known. It is also unclear whether PKA modulates the action of Ca²⁺ itself or increases the pool of releasable insulin granules or even mediates all cAMP effects. In summary, cAMP potentiates glucose-induced insulin secretion by increasing the triggering signal and by amplifying its efficacy (Fig. 6.9).

The Phosphoinositide–Protein Kinase C Pathway

β-Cells are equipped with different types of receptors that are linked to a phospholipase C-β (PLC-β) by a G-protein of the G_q subtype. On activation of the receptor, the enzyme is stimulated to split phosphatidylinositol 4,5-bisphosphate, a phospholipid present in small amounts in the plasma membrane, into inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (133, 251) (Fig. 6.9).

Diacylglycerol, which is liposoluble, remains in the plasma membrane, to which it causes translocation of its target, protein kinase C (PKC) (136,252), of which the α -isoform predominates in β -cells (137). This translocation, which also requires Ca²⁺ and phosphatidylserine, activates the kinase, which can then phosphorylate proteins, the nature of which is incompletely known. One of these is the myristoylated alanine-rich C kinase substrate, a protein that binds actin and Ca2+-calmodulin and that has been implicated in vesicle transport (137). The result of these phosphorylations is a sensitization of the releasing machinery to Ca²⁺ (43,253). Experiments using phorbol esters, which activate PKC directly, have shown that this pathway does not increase Ca²⁺ influx and even lowers [Ca²⁺]_i in normal β -cells (180,249,254), probably by accelerating extrusion of the ion from the cell. Pure activation of the PLC pathway thus potentiates insulin secretion by amplifying the action of the triggering signal (Fig. 6.9).

IP₃, which is hydrosoluble, diffuses in the cytoplasm and binds to receptors present on the membranes of the endoplasmic reticulum, in which Ca2+ is present in high concentration because of its active pumping by a Ca²⁺-ATPase (SERCA pump). IP₃ binding results in the opening of channels through which Ca^{2+} diffuses from the organelle to the cytoplasm (255) (Fig. 6.9). The consequence is an increase in $[Ca^{2+}]_i$ that usually displays two phases: an initial large peak followed by a smaller sustained elevation. The latter not only reflects intracellular Ca²⁺ mobilization, it also depends on Ca²⁺ influx through voltage-independent Ca2+ channels (controlled by the repletion state of intracellular Ca2+ stores) and through voltage-dependent Ca²⁺ channels (256,257). Actually, the amplitude and pattern of the [Ca²⁺]_i change are very much dependent on the ambient glucose concentration. In the context of this chapter, one should simply bear in mind that activation of PLC potentiates insulin secretion by both increasing the triggering signal (via IP₃) and amplifying its action (via diacylglycerol).

Physiologic Amplifiers of Insulin Secretion

Glucagon-like peptide-1 [7–36 amide] (GLP-1) is a product of post-translational processing of proglucagon in L-cells from the mucosa of the ileum and colon (244,258).

Glucose-dependent insulinotropic polypeptide (GIP, also known as gastric inhibitory polypeptide) is synthesized by the enteroendocrine K-cells from the duodenojejunal mucosa (244).

These two hormones are important players in the "enteroinsular axis." They are released after nutrients are ingested and probably are responsible for the "incretin" effect, that is, the larger increases in plasma insulin levels observed for a given increase in plasma glucose levels when the sugar is absorbed orally rather than administered intravenously (259-261). In humans, the role of GLP-1 is probably more important than that of GIP. GLP-1 and GIP act on G-protein-coupled specific receptors in β -cells (262). They do not affect insulin secretion in the presence of low glucose concentrations but markedly increase it in the presence of threshold or stimulatory glucose concentrations. This amplification is mediated through the cAMP-protein kinase A pathway. Glucose-dependent inhibition of K+-ATP channels has also been reported (129,263) but is not unanimously accepted (264,265). GLP-1 is currently being evaluated as an antidiabetic agent to increase insulin secretion by mechanisms different from those of sulfonylureas (266).

Amplification of insulin secretion through the phosphoinositide–protein kinase C pathway is physiologically relevant for acetylcholine and cholecystokinin.

Acetylcholine is released by parasympathetic nerve endings in the islets during both the cephalic and intestinal phases of feeding (245). It acts on muscarinic receptors of the M_3 type (267). The effects of acetylcholine are more complex in β -cells than in many other cells (257). In addition to activating PKC (see above), the neurotransmitter activates a phospholipase A₂. More surprisingly, it depolarizes the β -cell membrane by increasing its conductance to Na⁺. In the presence of glucose or another primary secretagogue, this additional depolarization augments Ca²⁺ influx through voltage-operated Ca²⁺ channels (Fig. 6.9).

Cholecystokinin (CCK) is released from the duodenum and proximal jejunum during meals but acts primarily as a neuro-transmitter at peptidergic synapses present in the islets (245,261). It activates specific (CCK-A) receptors in β -cells (268).

Putative Amplifiers of Insulin Secretion

Glucagon raises cAMP levels in β -cells and amplifies the secretion of insulin induced by various primary secretagogues (124,125). This effect, which is mediated by specific glucagon receptors (not by cross-reaction with GLP-1 receptors) (262), is clear for exogenous glucagon (269), but it is not certain that glucagon released by α -cells of the islets exerts any paracrine action on the neighboring β -cells (270).

Catecholamines have the net effect of inhibiting insulin secretion through α_2 -adrenoceptors, but β -adrenergic agonists (stimulating cAMP formation) increase plasma insulin levels *in vivo* (245). They have, however, little or no effect *in vitro*. Functional studies with purified islet cells have suggested that rat β -cells are devoid of β -adrenergic receptors (271). Human β -cells could possess β_2 -adrenoceptors (272), but the inhibitory effect of catecholamines remains predominant.

Pituitary adenylate cyclase-activating polypeptide (PACAP), vasoactive intestinal polypeptide, and gastrin-releasing peptide are present in nerve fibers of the pancreas (245,273,274). By activating specific receptors in β -cells, they amplify glucose-induced insulin secretion (245,261). PACAP is particularly potent and acts through the cAMP pathway, as does vasoactive intestinal peptide, whereas gastrin-releasing peptide activates the PLC pathway (245,275). The physiologic importance of these peptides in the control of β -cell function is still unclear.

Vasopressin and oxytocin increase glucose-induced insulin secretion *in vitro* through a stimulation of phosphoinositide metabolism (276,277). This effect does not occur at physiologic concentrations of the hormones in plasma but is compatible with a local control of β -cell function by vasopressin and oxytocin, which are present in the pancreas (278).

The purine nucleotides ATP and ADP amplify insulin secretion, at least in certain species, by activating extracellular P2Ypurinergic receptors in β -cells (279). It is unclear whether ATP, present in secretory granules and released with insulin during exocytosis (280), exerts a direct stimulatory influence on β -cell function by this mechanism. ATP may indeed be rapidly degraded by ecto-ATPases, and adenosine inhibits insulin secretion by acting on A₁ receptors.

Glutamate, at micromolar concentrations, increases insulin secretion from the perfused rat pancreas in a glucose-dependent manner. The effect is mediated by an ionotropic glutamate receptor of the AMPA subtype (281) that has been shown to be present and functional in β -cells by molecular, immunocytochemical, and electrophysiologic techniques (282,283).

NEUROHORMONAL ATTENUATION OF INSULIN SECRETION

Cellular Mechanisms

Attenuation of insulin secretion may be mediated by various types of membrane receptors, which exert their effects by multiple similar mechanisms, the exact nature and relative contribution of which are not completely established (90) (Fig. 6.10).

These receptors are linked to the adenylate cyclase by a pertussis toxin-sensitive, inhibitory subtype (Gi or Go) of the G-proteins. Activation of the receptor thus leads to a decrease in the concentration of cAMP in β -cells, with consequences opposite to those described above for an increase in cAMP. This mechanism, however, cannot fully account for the attenuation of secretion (125,284). Activation of the receptor also causes partial repolarization of the β -cell membrane, by a mechanism that is still disputed. There is good evidence that opening of K⁺ channels is involved (285,286), but it has not been conclusively established whether these are the ATP-sensitive K⁺ channels or other K⁺ channels (287,288). Direct inhibition of Ca2+ channels has also been envisaged. This partial repolarization of the β-cell membrane reduces the influx of Ca²⁺ through voltage-dependent Ca²⁺ channels and thus leads to a small decrease of [Ca²⁺]_i that is, however, insufficient to account for the abrogation of secretion (175) (Fig. 6.10). Experiments using permeabilized β -cells (289,290) or single β -cells voltage-clamped in the whole-cell mode (240,241,291), in which the composition of the cytoplasm can be controlled, have established the existence of an inhibitory step distal to the generation of cellular messengers (Ca²⁺, cAMP, diacylglycerol). It involves an heterotrimeric GTP-binding protein implicated in the exocytotic process (290) (see above).

Physiologic Attenuators of Insulin Secretion

These complex mechanisms underlie the physiologically relevant decreases in insulin secretion brought about by catecholamines, galanin, and somatostatin (Fig. 6.10). Catecholamines are released during exercise and under stress conditions by the adrenal medulla (epinephrine) or by sympathetic nerve terminals in the pancreas (norepinephrine) (245). They exert their inhibitory effect by activating α_2 -adrenoceptors (α_{2a} and α_{2c} subtypes) in β -cells (292,293).

Galanin is a 29-residue peptide that is also released by sympathetic nerve endings in the pancreas (294) and acts on specific receptors in β -cells (295).

Somatostatin-28 is released by the gut during absorption of fat-rich meals (296), whereas somatostatin-14 is secreted by islet δ -cells. Somatostatin-28 preferentially binds to β -cells, which express the somatostatin receptor type 5 (297). It is a more potent inhibitor of insulin secretion than is somatostatin-14 (298), which predominantly inhibits glucagon secretion by acting on a receptor type 2 (297). Paracrine control of β -cell function by somatostatin-14 is probably less important than previously thought.

Leptin produced and secreted by adipocytes has generally, although not consistently, been found to inhibit insulin secretion (299,300). Its mode of action differs from that of the previous inhibitors. Upon binding of leptin to its receptor in β -cells, a janus-tyrosine kinase (JAK-2) is activated, which in turn activates phosphoinositide 3-kinase (PI 3-kinase). The final events causing inhibition of insulin secretion are still debated but seem to involve an activation of phosphodiesterase 3B with ensuing decrease in cAMP (301) and an opening of K⁺-ATP channels with subsequent membrane repolarization (300,302).

Putative Attenuators of Insulin Secretion

Several other hormones or neuropeptides may attenuate insulin secretion. However, the physiologic relevance of the effects

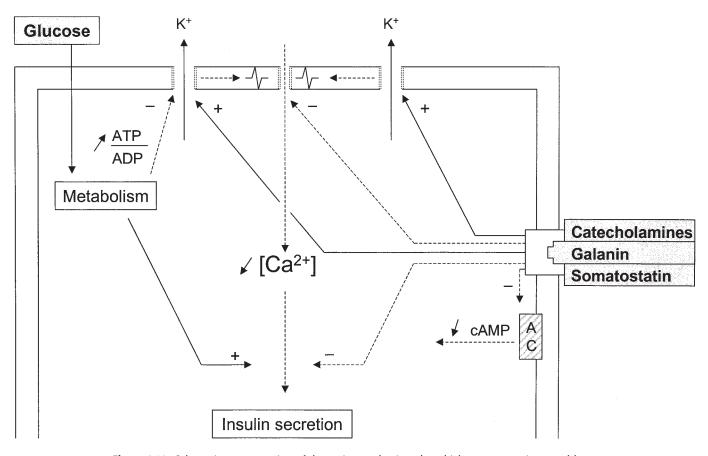

Figure 6.10. Schematic representation of the major mechanisms by which neurotransmitters and hormones attenuate insulin secretion; +, stimulation; –, inhibition; ATP, adenosine triphosphate; ADP, adenosine diphosphate; AC, adenylate cyclase.

observed *in vitro* has yet to be established, and the cellular mechanisms involved are largely unknown.

Insulin-like growth factor-1 (IGF-1) inhibits glucose- and arginine-induced insulin secretion from the perfused rat pancreas (303). This effect occurs at physiologic concentrations, is probably mediated by specific receptors for IGF-1 in β -cells (304), and might involve activation of phosphodiesterase 3B with a subsequent decrease of cAMP (127).

Pancreastatin is a 49-residue peptide produced by proteolytic cleavage of chromogranin A (305,306). It is released by β cells in parallel with insulin and also by α - and δ -cells. Exogenous pancreastatin causes a modest inhibition of insulin secretion induced by glucose and other secretagogues, but it is unclear whether endogenous pancreastatin causes autocrine inhibition of β -cells (305).

Opioid peptides have inhibitory and stimulatory effects on insulin secretion, depending on the agent used (β -endorphin, type of enkephalin) and on the concentration (307). This may be due to the existence of various types of opioid receptors in β -cells (308).

Calcitonin gene–related peptide (CGRP) is a 37-residue peptide present in intrapancreatic nerve fibers and in δ -cells of the islets (309). Exogenous CGRP inhibits stimulated insulin secretion by decreasing cAMP formation in β -cells.

Islet amyloid polypeptide (IAPP, also known as amylin) is a 37-residue peptide structurally related to CGRP. It is synthesized in β -cells (310) and is secreted with, but in much smaller amounts (<1%), than insulin (311). IAPP in high concentrations has been reported to inhibit insulin secretion (312), but this effect is unlikely to have any physiologic significance (313).

Prostaglandin E2 inhibits glucose-induced insulin secretion by a receptor-mediated, pertussis-toxin–sensitive mechanism (314). Whether prostaglandins are physiologic regulators of β cell function remains unclear. It is particularly intriguing that only cyclooxygenase type 2 (normally induced by inflammatory events) is expressed in islets (315).

DELAYED CHANGES IN INSULIN SECRETION

Time-Dependent Potentiation

Previous exposure of β -cells to a stimulatory concentration of glucose increases insulin secretion in response to a subsequent challenge by glucose or another secretagogue (153,316,317). This phenomenon has been called "priming," "memory," or "time-dependent potentiation." Its amplitude increases with the magnitude and duration of the first exposure to glucose and decreases with the length of the interval between the end of the first and the start of the second stimulation. Time-dependent potentiation requires glucose metabolism, does not involve cAMP, is not clearly dependent on Ca²⁺, and does not require exocytosis of insulin granules. It is perhaps linked to phosphoinositide metabolism (102,153,316,317).

A related phenomenon has been called "proemial sensitization." It consists of the enhancement of the β -cell response to glucose by a previous exposure to a neurotransmitter (acetylcholine) or a hormone (cholecystokinin) under conditions in which the latter agents have little or no effect on insulin secretion (318). It has been ascribed to a persistent translocation of protein kinase C to the plasma membrane, where the enzyme can be readily activated by the rise in cytoplasmic Ca²⁺ that occurs on glucose stimulation. This phenomenon could be important to the optimization of the β -cell response to nutrients during a meal (319). Hormones such as GLP-1, GIP, and glucagon might also keep β -cells in a "glucose-competent state" by maintaining adequate cAMP concentrations.

Desensitization

Prolonged stimulation of β -cells with a high concentration of glucose leads to a progressive decrease in the rate of insulin secretion *in vitro*. The phenomenon is already observed after 3 to 4 hours and, at that stage sometimes called the "third phase" (320), does not reflect exhaustion of insulin granules. The underlying mechanisms are still unclear and probably involve time- and Ca²⁺-dependent decreases in the generation of metabolic signals and efficacy of the triggering signal on the exocytotic process.

 β -Cell "desensitization" is best known as a refractory state induced by prolonged exposure (a few days) to high glucose concentrations; it precedes or is associated with poorly reversible β-cell dysfunctions known as "glucose toxicity" (321). However, β-cell refractoriness has often been misinterpreted. It is usually identified as an abnormally small increase in insulin secretion when the preparation is challenged by an acute rise of glucose from expectedly unstimulatory to stimulatory concentrations. This stereotyped approach fails to disclose a marked leftward shift of the dose-response curve, which indicates that the sensitivity to glucose is increased. In fact, β -cells are hypersensitive, not desensitized, to glucose (322-324). This hyperresponsiveness of the β -cells is supported by the observed changes in their membrane K⁺ conductance (325). The decrease in the amplitude of the absolute (not fractional) insulin response may be explained by the depletion of the insulin stores. Moreover, a higher proportion of proinsulin is secreted than under control conditions (326).

A similar phenomenon of desensitization can be observed with agents other than glucose (327). After 1 to 2 days of islet exposure to fatty acids, insulin secretion is increased in low glucose and decreased in high glucose (328,329). Whether this reflects changes in glucose metabolism is still debated. Prolonged exposure to glibenclamide also alters the β -cell response to glucose, mainly by preventing the sugar from influencing the membrane potential and changing the triggering signal $[Ca^{2+}]_i$ (330). Here again, the dose responsiveness to glucose is shifted to the left, while the maximum response is decreased.

LONG-TERM INFLUENCES ON INSULIN SECRETION

Neonatal Maturation

Numerous in vitro studies have shown that fetal and neonatal islets secrete insulin at a lower rate than do adult islets. The response to glucose is particularly poor, in contrast to that to other secretagogues such as amino acids (331,332). The most striking feature of the functional maturation that β -cells undergo during the perinatal period is the acquisition of a normal responsiveness to glucose in terms of both magnitude and kinetics (332,333). A defect in generation of cAMP has often been thought to contribute to the poor secretory response of fetal and neonatal β-cells, but stimulation of PKA and PKC pathways increases glucose-induced insulin secretion without leading to the appearance of an adult-type, biphasic pattern of release (334). Patch-clamp recordings have shown that K+-ATP channels are present in fetal $\beta\mbox{-cells}$ and normally respond to tolbutamide and diazoxide but that they are not closed by glucose (335). Consistent with these findings, glucose, unlike effective insulin secretagogues, does not raise [Ca2+]i in fetal islets (336). The available evidence indicates that the inability of glucose to induce insulin secretion from fetal and neonatal β-cells is due to an immature metabolism with insufficient production of ATP, hence an inability to produce a triggering signal.

Whether the glucokinase is the site of this immaturity is still disputed (337,338).

Aging

The contribution of impairment in insulin secretion to the deterioration of glucose tolerance with aging is unclear (339,340). It is difficult to isolate the impact of physiologic aging from that of aging-associated diseases. Even *in vitro* studies are fraught with difficulties that explain the major controversies surrounding the specific effects of age on β -cell function (341,342). Impairments of the individual β -cell or islet responses have often been reported. They include diminished insulin secretion associated with or caused by small and inconsistent defects in insulin biosynthesis, glucose metabolism, ionic fluxes, and adenylate cylase activity. At the level of the whole pancreas, however, the insulin secretion capacity does not seem to be altered, possibly because of a compensatory increase in the β -cell mass (343).

Starvation

During starvation, basal plasma insulin levels are lowered and the β -cell secretory response to glucose is impaired. Many *in* vitro studies have shown that glucose-induced insulin secretion is more severely altered than the secretion induced by other fuel or non-fuel secretagogues (344,345). This selective change is generally attributed to a decreased glycolytic rate in β -cells (344,346), which largely, though not exclusively, results from a lower glucokinase activity (5,6,22). Thus, starvation lowers the levels of glucokinase mRNA (347,348) and glucokinase protein (22) in islet cells. During starvation, β -cells also rely on fuels other than glucose, particularly free fatty acids, whose plasma concentration is elevated. It has been proposed that operation of a glucose–fatty acid cycle in β -cells impairs mitochondrial glucose metabolism, and hence insulin secretion, by decreasing the activity of pyruvate dehydrogenase (349). Starvation also reduces the ability of glucose to shift the metabolism of fatty acids from oxidation to esterification in islets (119), an abnormality that could contribute to the alteration of β -cell function, since its correction by 2-bromostearate (an inhibitor of fatty acid oxidation) restores glucose-induced insulin secretion (119). In contrast, positive effects of fatty acids are suggested by experiments showing that a decrease in their concentrations with nicotinic acid in fasted rats impairs the ability of glucose to induce insulin secretion from the pancreas subsequently isolated from these fasted animals (350). Unexpectedly, when studied in vivo, β -cells of 48 hour-fasted mice show electrical activity at plasma glucose concentrations that are not stimulatory in living fed mice (351). This paradoxical hyperresponsiveness of the fasted β -cells, which could be ascribed to the high circulating levels of free fatty acid, contrasts with the expectedly low plasma levels of insulin; electrical activity and insulin secretion are thus dissociated. Low concentrations of cAMP usually are found in islets from fasted animals and may contribute to the low insulin secretory responses (345,346). mRNA levels of the voltage-dependent Ca²⁺ channels are also reduced (348), but it is not known whether Ca²⁺ currents are similarly affected.

Exercise Training

Exercise training increases peripheral insulin sensitivity and lowers plasma insulin levels (352) by decreasing the magnitude without affecting the frequency of insulin secretion pulses (353). Isolated islets and the perfused pancreas obtained from trained rats exhibit a diminished glucose- or arginine-induced insulin secretion (354,355). A decrease in islet glucokinase mRNA has been found in islets from trained rats (356), but it is uncertain whether this explains the lower insulin responses, because such islets were found to metabolize glucose at a rate similar to that of islets from sedentary animals (354).

Pregnancy and Lactation

To meet the increased insulin demands during pregnancy, β cells proliferate, leading to an increased islet size and total mass, and undergo several functional adaptations (357). The major change is an enhancement of glucose-induced insulin secretion with a lowering of the threshold glucose concentration (358,359). It is attributed to the combined increases of glucose metabolism, cAMP concentration, and gap-junctional coupling in β -cells and is compensated for by an increase in insulin synthesis (357–360). Both dietary (increase in food consumption) and hormonal (prolactin and placental lactogen) factors are involved in this functional adaptation of β -cells (357,361).

Plasma glucose and insulin concentrations are relatively low during lactation. Islets from lactating rats have been found to secrete less insulin than islets from nonlactating animals during *in vitro* stimulation with glucose or leucine (362). This decrease in β -cell secretory activity is paradoxically associated with increased activity of adenylate cyclase, protein kinase A, and protein kinase C and increased oxidation of glucose and leucine (362). The β -cell coupling is also increased in islets from lactating rats (363). It should be noted, however, that the suggestion that β -cells of lactating rats have an intrinsically low secretory activity has been challenged (364).

Hormones

Growth-hormone deficiency is associated with decreased plasma concentrations of insulin (365). Glucose metabolism and glucose-induced insulin secretion are lower in islets from hypophysectomized rats than in islets from control animals (366). In most *in vitro* studies, however, growth hormone has no acute impact on β -cell function (367), whereas delayed stimulation of β -cell growth, insulin biosynthesis, and insulin release is well established. These effects appear to be due to a direct action of growth hormone on somatogenic and lactogenic receptors in β -cells (368) rather than to an indirect action mediated by IGF-1 that also stimulates β -cell proliferation (369) but inhibits insulin secretion.

Thyroid hormones in excess decrease the insulin content of the pancreas (370), perhaps by decreasing levels of proinsulin mRNA (371). They also cause a slight and delayed inhibition of insulin secretion in response to glucose but not to other secretagogues in the rat (370). Thyroid hormones do not acutely influence β -cell function (370,372)

Rats deficient in 1,25-dihydroxyvitamin D_3 show impaired insulin secretion *in vivo* and *in vitro* (373). This defect probably reflects both direct effects of the hormone on β -cells and metabolic abnormalities (e.g., hypocalcemia, poor growth) associated with its deficiency. Vitamin D_3 has usually (374), but not always (375), been found to increase insulin secretion *in vitro*. Both genomic and nongenomic pathways have been implicated.

Glucocorticoids indirectly increase insulin secretion through their effects on glucose production and their antagonism of insulin action (370). Paradoxically, their direct effect on β -cells is inhibitory (376,377). This inhibition, mediated by a genomic action, results not from an alteration in glucose recognition or in

triggering signal generation but from a decrease in the efficacy of Ca^{2+} on the exocytotic process (376).

Note: The final writing of this chapter was completed in February 2001.

INSULIN SECRETION IN OBESITY AND INSULIN RESISTANCE 114	

The classic experiments of Von Mering and Minkowski at the turn of the last century demonstrating that pancreatectomy in dogs resulted in hyperglycemia (1) focused attention on the important role of the pancreas in maintaining glucose homeostasis *in vivo*. Banting and Best (2), by reversing this hyperglycemia with internal secretions of the pancreas, confirmed the belief that the islets of Langerhans were the key cells within the pancreas responsible for maintaining normal blood glucose levels. Although the isolation and purification of insulin rapidly followed, many years passed before sensitive techniques for evaluating β -cell function were devised. Because these techniques are critical to the analysis of insulin secretion *in vivo*, they will be discussed at the outset.

METHODS OF QUANTITATING β -CELL FUNCTION

The development of a sensitive radioimmunoassay for the measurement of insulin levels was the first major advance in our attempts to understand how the β -cell functions *in vivo* (3). For many years afterward, the measurement of peripheral levels of insulin was the gold standard used to evaluate β -cell secretory activity (4–8). This approach, however, is limited by the fact that 50% to 60% of the insulin produced by the pancreas is extracted by the liver without ever reaching the systemic circulation (9,10). While these problems can, in fact, be overcome by hepatic vein catheterization allied to intraportal infusion of insulin, these techniques can only be applied in an investigational setting and, even then, are only of value under steady-state conditions (11). The standard radioimmunoassay for the measurement of insulin concentrations is also limited by its inability to distinguish between endogenous and exogenous insulin, making it ineffective as a measure of endogenous β -cell reserve in the insulin-treated diabetic patient. The problem is further compounded by the development in many of these patients of antibodies to insulin, which interfere in the interpretation of serum levels of immunoreactive insulin. Although insulin-specific assays have been developed, another disadvantage of the conventional insulin radioimmunoassay is its inability to distinguish between levels of circulating proinsulin and true levels of circulating insulin.

Following the discovery of proinsulin, the single-chain precursor of insulin (12), and the identification of the biosynthetic pathway of insulin within the β -cell (13), β -cell secretory products in addition to insulin were found in the circulation. These included proinsulin, proinsulin conversion intermediates (split proinsulins), and connecting-peptide (C-peptide) (see Chapter 5). Within the islet cells, proinsulin undergoes cleavage at the Golgi apparatus (14), a reaction that leads to the formation of insulin, C-peptide, and two pairs of basic amino acids. Insulin is subsequently released into the circulation at concentrations equimolar to those of C-peptide (13–15). In addition, small amounts of intact proinsulin and proinsulin conversion intermediates are released. Although these molecules constitute 20% of the total circulating

insulin-like immunoreactivity (16), they are much less potent than insulin biologically. It has been estimated that the biologic potency of proinsulin in vivo is only 10% of that of insulin (17,18), whereas the potency of split proinsulin is between that of proinsulin and insulin (19,20). The low concentrations of proinsulin and split proinsulins in serum, however, ensure that in vivo, under normal physiologic conditions, their effects are negligible. In contrast to insulin and proinsulin, C-peptide has no known conclusive effects on carbohydrate metabolism (21,22). It has recently been suggested that it may stimulate Na+/K+-ATPase and endothelial nitric oxide synthase activities, resulting in a number of biologic activities, including augmented blood flow in skeletal muscle and skin, diminished glomerular hyperfiltration, reduced urinary albumin excretion, and improved nerve function in patients with type 1 diabetes mellitus who lack C-peptide, but not in healthy subjects (23). It has therefore been proposed that replacement of C-peptide together with insulin may prevent or retard the progression of the long-term complications of diabetes mellitus (24,25). Unlike insulin, C-peptide is not extracted by the liver (10,26,27) and is excreted almost exclusively by the kidneys. Its plasma half-life of approximately 30 minutes (28) contrasts sharply with that of insulin, which is approximately 4 minutes.

Because C-peptide is secreted in equimolar concentrations with insulin and is not extracted by the liver, many investigators have used levels of C-peptide as a marker of β -cell function. While C-peptide levels are usually measured in plasma, C-peptide levels in urine have also been used to evaluate endogenous insulin secretion (29-32). This approach is limited, however, because the fraction of the secreted C-peptide that appears in the urine varies considerably among subjects and even in the same subject studied on different occasions (33). The use of plasma C-peptide levels as an index of β -cell function is dependent on the critical assumption that the mean clearance rates of C-peptide are constant over the range of C-peptide levels observed under normal physiologic conditions. This assumption has been shown to be valid for both dogs and humans (10,34), and this approach can be used to derive rates of insulin secretion from plasma concentrations of C-peptide under steady-state conditions (34). However, because of the long plasma half-life of C-peptide, under non-steady-state conditions (e.g., following a glucose infusion), peripheral plasma levels of Cpeptide do not change in proportion to the changing insulin secretory rate (34,35). Thus, under these conditions, insulin secretion rates are best calculated with use of the two-compartment model initially proposed by Eaton and coworkers (36). This approach involves nonlinear least-squares regression analysis of C-peptide

decay curves to derive model parameters in individual subjects. Once the fractional rate constants and distribution volume are known, the peripheral concentrations of C-peptide can be analyzed mathematically and the corresponding secretion rates derived. Estimates of the secretion rate of insulin in human subjects by this method are quite accurate—reportedly $98\% \pm 3\%$ of the actual rate as rates of insulin secretion are increasing and $100\% \pm 2\%$ as they are decreasing (34). Similar findings have been reported for dogs (37). Modifications to the C-peptide model of insulin secretion have recently been introduced. This approach combines the minimal model of insulin action with the two-compartment model of C-peptide kinetics and allows insulin secretion and insulin sensitivity to be derived following either the intravenous or the oral administration of glucose (38–41).

Rates of insulin secretion have also been measured by calculating the difference between arterial and hepatic venous Cpeptide and by multiplying this difference by the estimated hepatic plasma flow (42,43), an approach designed to overcome the inherent difficulty of performing portal venous cannulation in humans. Rates of insulin secretion determined by this method are similar to those obtained with other methods, but the technique is invasive and by its nature can only be applied in an investigational setting.

In summary, under steady-state conditions, levels of C-peptide in whole plasma provide an accurate index of the insulin secretory rate, while under non–steady-state conditions, rates of β -cell secretion of insulin can be derived more accurately and easily from mathematical analysis of peripheral C-peptide concentrations with use of a two-compartment model. In interpreting the validity of experimental results evaluating insulin secretion *in vivo*, one should always take into account the limitations of the method used to assess β -cell function.

REGULATION OF INSULIN SECRETION

Carbohydrate Nutrients

The most important physiologic substance involved in the regulation of insulin release is glucose (44–46). The effect of glucose on the β -cell is dose-related. Dose-dependent increases in concentrations of insulin and C-peptide and in rates of insulin secretion have been observed following oral and intravenous glucose loads, with 1.4 units (~50 µg) of insulin, on average, being secreted in response to an oral glucose load as small as 12 g (42,47–49) (Fig. 7.1). The insulin secretory response is greater

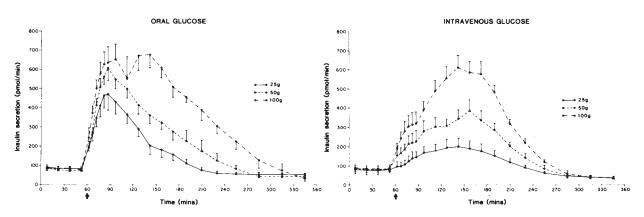

Figure 7.1. Insulin secretory responses to graded glucose doses following oral (**left**) and intravenous (**right**) administration. (From Tillil H, Shapiro ET, Miller MA, et al. Dose-dependent effects of oral and intravenous glucose on insulin secretion and clearance in normal humans. *Am J Physiol* 1988;254: E349–357, with permission. Copyright © 1988 by the American Physiological Society.)

after oral than intravenous glucose administration (49–52). Known as the incretin effect (48,53), this enhanced response to oral glucose has been interpreted as an indication that absorption of glucose by way of the gastrointestinal tract stimulates the release of hormones and other mechanisms that ultimately enhance the sensitivity of the β -cell to glucose (see discussion on hormonal factors below and Chapter 12). In a study involving nine normal volunteers who received a glucose infusion at a rate designed to achieve levels previously attained following an oral glucose load, the amount of insulin secreted in response to the intravenous load was 26% less than that secreted in response to the oral load (52).

Insulin secretion does not respond as a linear function of glucose concentration. The relationship of glucose concentration to the rate of insulin release follows a sigmoidal curve, with a threshold corresponding to the glucose levels normally seen under fasting conditions and with the steep portion of the doseresponse curve corresponding to the range of glucose levels normally achieved postprandially (54–56). The sigmoidal nature of the dose-response curve has been attributed to a gaussian distribution of thresholds for stimulation among the individual β -cells (56–58).

When glucose is infused intravenously at a constant rate, an initial biphasic secretory response is observed that consists of a rapid, early insulin peak followed by a second, more slowly increasing, peak (44,59,60). The significance of the first-phase insulin release is unclear but may reflect the existence of a compartment of readily releasable insulin within the β-cell or a transient increase and decrease of a metabolic signal for insulin secretion (61). Despite early suggestions to the contrary (62,63), a subsequent study has demonstrated that the first-phase response to intravenous glucose is highly reproducible within subjects (64). Following the acute response, a second phase of insulin release occurs that is directly related to the level of glucose elevation. In vitro studies of isolated islet cells and the perfused pancreas have identified a third phase of insulin secretion commencing 1.5 to 3.0 hours after exposure to glucose and characterized by a spontaneous decline in secretion to 15% to 25% of the amount released during peak secretion-a level subsequently maintained for more than 48 hours (65-68).

The effects of a variety of other sugars, sugar derivatives, and sugar alcohols on the β -cell have also been examined (69). D-glucose, D-mannose, D-glyceraldehyde, dihydroxyacetone, D-glucosamine, *N*-acetylglucosamine, fructose, and galactose have all been shown to be stimulators or potentiators of insulin secretion *in vitro*. *In vivo* studies in dogs and humans suggest that xylitol and sorbitol also enhance β -cell function.

The insulin secretory response to glucose exhibits anomeric specificity, the α -anomer being a more potent stimulator of insulin release than the β -anomer (70). Similar results have been obtained with mannose (71). Because α -anomers are more readily metabolized by the glycolytic pathway than are β -anomers (72,73), it has been suggested that the metabolism of glucose and mannose within the β -cell is a prerequisite for the production of intracellular signals that trigger insulin release in response to these secretagogues. In support of this suggestion is the observation that mannoheptulose, an inhibitor of the glycolytic enzyme glucokinase, blocks the insulin secretory response to glucose. Similarly, iodoacetate, an inhibitor of glyceraldehyde dehydrogenase, blocks the β -cell response to hexoses (74).

Noncarbohydrate Nutrients

Amino acids have been shown to stimulate insulin release in the absence of glucose, the most potent secretagogues being the essential amino acids leucine, arginine, and lysine (75,76). The effects of arginine and lysine on the β-cell appear to be more potent than those of leucine. Although the effects of amino acids on insulin secretion are independent of concomitant changes in glucose levels, the effects are potentiated by glucose (76–78). The response of the islet cells to a series of amino acid metabolites has also been evaluated. Phenylpyruvate, α-ketoisocaproate, α-keto-β-methylvalerate, and α-ketocaproate are potent stimulators of insulin release, and most are effective in the absence of glucose (69,79).

In contrast to amino acids, various lipids and their metabolites appear to have only minor effects on insulin release in vivo. Although carbohydrate-rich fat meals stimulate insulin secretion, carbohydrate-free fat meals have minimal effects on β -cell function (80). Ketone bodies and short- and long-chain fatty acids have been shown to acutely stimulate insulin secretion both in isolated islet cells and in humans (81–85). The effects of elevated free fatty acids in the insulin secretory responses to glucose are related to the duration of the exposure. Zhou and Grill first suggested that long-term exposure of pancreatic islets to free fatty acids inhibited glucose-induced insulin secretion and biosynthesis (86). This observation has been confirmed in rats (87). In humans, it was demonstrated that the insulin resistance induced by an acute (90-minute) elevation in free fatty acids was compensated for by an appropriate increase in insulin secretion (88). Following chronic elevation of free fatty acids (48 hours), the β -cell compensatory response for insulin resistance was not adequate. Additional studies have demonstrated that the adverse effects of prolonged elevations in free fatty acids on glucose-induced insulin secretion are not seen in individuals with type 2 diabetes. On the basis of these results, it appears that elevated free fatty acids may contribute to the failure of β -cell compensation for insulin resistance.

Hormonal Factors

The release of insulin from the β -cell following a meal is facilitated by a number of gastrointestinal peptide hormones, including glucose-dependent insulinotropic peptide (GIP), cholecystokinin, and glucagon-like peptide-1 (GLP-1) (53,89-96) (see Chapter 12). These hormones are released from intestinal endocrine cells postprandially and travel in the bloodstream to reach the β -cells, where they act through second messengers to increase the sensitivity of these islet cells to glucose. In general, these hormones are not of themselves secretagogues, and their effects are only evident in the presence of hyperglycemia (89-91). The release of these peptides may explain why the modest postprandial glucose levels achieved in normal subjects in vivo have such a dramatic effect on insulin production whereas similar glucose concentrations in vitro elicit a much smaller response (96). Similarly, this so-called incretin effect could account for the greater β -cell response observed following oral as opposed to intravenous glucose administration. Whether impaired postprandial secretion of incretin hormones plays a role in the inadequate insulin secretory response to oral glucose and to meals in impaired glucose tolerance (IGT) or diabetes mellitus is controversial (97–104), but pharmacologic doses of these peptides may have future therapeutic benefits. Subcutaneous administration of GLP-1, the most potent of the incretin peptides, lowers glucose levels in patients with type 2 diabetes by stimulating endogenous insulin secretion and perhaps by inhibiting glucagon secretion and gastric emptying (105,106). Because of the short half-life of GLP-1, however, its longer-acting analogue, exendin-4, has greater therapeutic promise (107). Treatment with supraphysiologic doses of GIP during hyperglycemia has been shown to augment insulin secretion in normal (108,109) but not in diabetic humans

(100,109). Although cholecystokinin has the ability to augment insulin secretion in humans, whether it is an incretin at physiologic levels has not been firmly established (110–113). Its effects are also seen largely at pharmacologic doses (114).

The postprandial insulin secretory response may also be influenced by other intestinal peptide hormones, including vasoactive intestinal polypeptide (115), secretin (116–119), and gastrin (116,120), but the precise role of these hormones remains to be elucidated.

The hormones produced by pancreatic α - and β -cells also modulate insulin release. While glucagon has a stimulatory effect on the β -cell (121), somatostatin suppresses insulin release (122). It is currently unclear whether these hormones reach the β-cell by traveling through the islet-cell interstitium (thus exerting a paracrine effect) or through islet-cell capillaries. Indeed, the importance of these two hormones in regulating basal and postprandial insulin levels under normal physiologic circumstances is in doubt. Other hormones that exert a stimulatory role on insulin secretion include growth hormone (123), glucocorticoids (124), prolactin (125-127), placental lactogen (128), and the sex steroids (129). While all of the above hormones may stimulate insulin secretion indirectly by inducing a state of insulin resistance, some also may act directly on the β -cell, possibly to augment its sensitivity to glucose. Thus, hyperinsulinemia is associated with conditions in which these hormones are present in excess, such as acromegaly, Cushing syndrome, and the second half of pregnancy. Furthermore, treatment with placental lactogen (130), hydrocortisone (131), or growth hormone (131,132) is effective in reversing the reduction in insulin response to glucose that is observed in vitro after hypophysectomy. Although hyperinsulinemia following an oral glucose load has been observed in patients with hyperthyroidism (133,134), the increased concentration of immunoreactive insulin in this setting may reflect elevations in serum proinsulin rather than a true increase in serum insulin (135).

Neural Factors

The islets are innervated by both the cholinergic and adrenergic limbs of the autonomic nervous system. While both sympathetic and parasympathetic stimulation enhance secretion of glucagon (136,137), the secretion of insulin is stimulated by vagal nerve fibers and inhibited by sympathetic nerve fibers (136–141). Adrenergic inhibition of the β -cell appears to be mediated by the α -adrenoceptor, since its effect is attenuated by the α -antagonist phentolamine (137) and reproduced by the α_2 agonist clonidine (142). There is also considerable evidence that many indirect effects of sympathetic nerve stimulation play a role in regulation of β -cell function via stimulation or inhibition of somatostatin, β_2 adrenoceptors, and the neuropeptides galanin and neuropeptide Y (143). Parasympathetic stimulation of islets results in stimulation of insulin, glucagon, and pancreatic polypeptide directly and via neuropeptides vasoactive intestinal peptide, gastrin-releasing polypeptide, and pituitary adenylate cyclase-activating polypeptide (143). In addition, sensory innervation of islets may contribute to the regulation of insulin secretion. Sensory nerves have been shown to contain calcitonin gene-related peptide (144-146), which may play a inhibitory role, and substance P, whose role is not clearly defined (147,148). The importance of the autonomic nervous system in regulating insulin secretion *in vivo* is unclear. Studies in animals (149,150) and humans (151,152) have emphasized the importance of the cephalic phase of insulin release-that occurring at the sight, smell, and expectation of food-in regulating the postprandial glucose response. It has been suggested that this reflex, which is under vagal control (96,153), may have a

key role in minimizing the early increase in glucose levels following meals (152). Because cholinergic agonists increase the response of the β -cell to glucose *in vitro* (154), this may be the mechanism by which vagal stimulation achieves its effect. Decreased glucose tolerance following vagotomy has been reported in human subjects (155,156) and following islet denervation in rats (157,158), whereas the insulin secretory response to meals is delayed in patients who have undergone pancreatic transplantation (159). However, many of these patients remain euglycemic without therapy after transplantation (159-162). Therefore, the importance of the parasympathetic nervous system in maintaining glucose tolerance is unclear. For similar reasons, doubts exist about whether the sympathetic nerve fibers innervating the islets exert a major influence on the basal or postprandial insulin secretory responses. Sympathetic innervation of islets likely accounts for the inhibition of insulin secretion and increased glucagon secretion during exercise and in response to hypoglycemia (163-166). Similarly, inhibition of insulin secretion mediated by the sympathetic nervous system may account in part for the deteriorating glycemic control reported in individuals with diabetes mellitus who are under severe stress (138,167). The relative contributions of the sympathetic and parasympathetic innervation of the pancreas to the hyperinsulinemia of obesity have been studied, but no consistent differences from lean subjects have been found (168-172).

The neural effects on β -cell function cannot be entirely dissociated from the hormonal effects, since some of the neurotransmitters of the autonomic nervous system are in fact hormones. Furthermore, the secretion of insulinotropic hormones such as GIP and GLP-1 postprandially has been shown to be under vagal (173,174) and adrenergic (175,176) control.

TEMPORAL PATTERN OF INSULIN SECRETION

It has been estimated that, in any 24-hour period, 50% of the total insulin secreted by the pancreas is secreted under basal conditions, and the remainder is secreted in response to meals (177,178). The estimated basal insulin secretion rates typically range from 18 to 32 units per 24 hours (0.7 to 1.3 mg) (34,36,42, 177). Moreover, the secretion of insulin is pulsatile, with major pulses being observed every 1.5 to 2 hours (178-182) (Fig. 7.2). These ultradian pulses are present in the basal state but are amplified postprandially (178,179). These pulses have also been observed in subjects receiving glucose intravenously (180,182), suggesting that they are not dependent on food ingestion and are not generated by intermittent absorption of nutrients from the gut. Furthermore, they do not appear to be related to fluctuations in glucagon or cortisol levels (180). Many of these insulin and C-peptide pulses are synchronous with pulses in glucose levels (178,180,182). The ability of an exogenous oscillatory glucose infusion to entrain these pulses in insulin secretion has been shown to indicate normal β -cell function (see Fig. 7.9) (183-185). Experimental evidence from studies of animals and humans suggests that superimposed on these large-amplitude ultradian pulses are more rapid oscillations in β-cell activity that occur at a periodicity of 8 to 16 minutes (186-192). These rapid oscillations in insulin and C-peptide levels do not appear to be coupled as tightly as the ultradian pulses to changes in glucose levels (189,191,193,194). The frequency of these rapid oscillations varies from study to study, and wide variability among subjects is seen even within studies. Accordingly, the physiologic significance of these rapid oscillations in the peripheral circulation is unclear. Although the amplitude of the rapid oscillations is very low in the peripheral circulation, it is much greater in the portal circulation (Fig. 7.3), where these

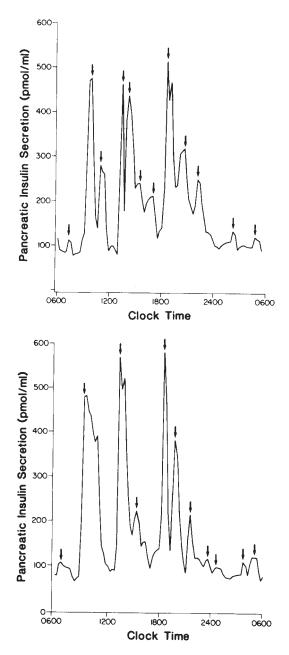

Figure 7.2. Two 24-hour profiles of insulin secretion from normal-weight subjects. Meals were eaten at 0900, 1300, and 1800. Statistically significant pulses of secretion are shown by the arrows. (From Polonsky KS, Given BD, Van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. *J Clin Invest* 1988;81: 442–448, with permission.)

rapid oscillations may have an important biologic function (194). In this regard, it is possible that the liver responds more favorably to insulin delivered in a pulsatile fashion than to insulin delivered at a constant rate (195–197).

Circadian variations in the secretion of insulin have also been reported. When insulin secretory responses are measured during a 24-hour period during which subjects receive three standard meals, the maximal postprandial responses are observed after breakfast (6,178,198). These findings are mirrored by the results of studies in which subjects were tested for oral glucose tolerance at different times of the day and were found to exhibit maximal insulin secretory responses in the morning and lower responses in the afternoon and evening (199–201). These diurnal differences also are noted in tests for

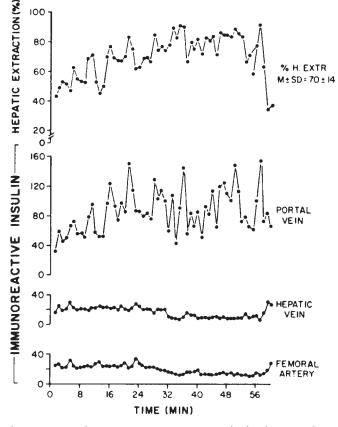

Figure 7.3. Simultaneous minute-to-minute insulin levels in portal vein, hepatic vein, femoral artery, and derived hepatic insulin extraction in one dog. Because of substantial hepatic extraction of insulin, pulsatility in posthepatic circulation is markedly dampened. (From Jaspan JB, Lever E, Polonsky KS, Van Cauter E. In vivo pulsatility of pancreatic islet peptides. *Am J Physiol* 1986;251:E215–E226, with permission. Copyright © 1986 by the American Physiological Society.)

intravenous glucose tolerance. Furthermore, although ultradian glucose and insulin oscillations are closely correlated during a constant 24-hour glucose infusion, the nocturnal rise in mean glucose levels is not accompanied by a similar increase in the insulin secretory rate (182). It has been postulated that these diurnal differences may reflect a diminished responsiveness of the β -cell to glucose in the afternoon and evening (201).

INSULIN SECRETION FOLLOWING EXERCISE

The effects of exercise on β -cell function have also been evaluated extensively. Individuals who exercise regularly have reduced fasting levels of insulin and C-peptide (202–204) and also exhibit a reduction in the release of these hormones following a carbohydrate load. This reduction has been seen following a 100-g oral glucose load (205,206) and during hyperglycemic clamping, during which reductions in both first-phase and second-phase secretory responses have been described (202–204,207). Despite these changes, these subjects have normal or even improved glucose tolerance (203,207), consistent with the observation that insulin sensitivity is improved in those who exercise regularly as measured during hyperinsulinemic euglycemic clamping (203,207).

Altered β -cell responses to glucose are apparent even after short periods of exercise and have been observed in individuals subjected to as little as 1 hour of exercise 24 hours before being tested for oral glucose tolerance (208). Similarly, even in well-

trained athletes, insulin responses to glucose increase dramatically within 2 weeks of cessation of exercise (202). In this latter study, rates of glucose disposal both before and after cessation of exercise were similar, supporting the view that those who exercise regularly are more sensitive to the action of insulin. The altered β -cell responses to glucose observed in athletic subjects may therefore be a compensatory response to the increased sensitivity to insulin in the periphery. Whatever the mechanism, lack of exercise could be a key factor in the pathogenesis of the insulin resistance associated with aging, because fasting insulin levels and insulin secretory responses to glucose in athletes older and younger than 60 years are similar, the responses in both groups being lower than the corresponding responses in young untrained subjects (205).

INSULIN SECRETION IN THE ELDERLY

Peripheral insulin resistance, impaired glucose tolerance, and postprandial hyperinsulinemia are metabolic changes associated with aging (209-211). Although insulin secretion may be reduced in aging rats (212-214), the results of studies of elderly human subjects have conflicted-with increased, normal, and decreased β -cell responses having been reported (215–217). These discrepancies may be, in part, a reflection of the indirect methods used to quantitate insulin secretion in some of these studies. In experiments that used a direct approach to quantitation of insulin secretory rates from peripheral C-peptide levels by means of the two-compartment model (36), ten elderly subjects demonstrated enhanced insulin secretion under basal conditions, with an accentuation of this response seen postprandially (218). Plotted as a percentage of the basal secretory rate, the secretory response to meals in these elderly subjects was no different from that of younger controls. However, when glucose levels are matched during hyperglycemic clamping, the insulin secretory response-although normal in absolute terms-is disproportionately low in the elderly patients, especially when viewed in relation to the degree of insulin resistance associated with aging. Thus, while elderly subjects have enhanced rates of insulin secretion, the β -cell responses are lower than those predicted when one takes into account the insulin insensitivity associated with this population subgroup. Diminished insulin clearance does not appear to be a contributory factor to the observed hyperinsulinemia in the elderly (218,219).

INSULIN SECRETION IN OBESITY AND INSULIN RESISTANCE

The insulin resistance of obesity is characterized by hyperinsulinemia (220-224). Hyperinsulinemia in this setting reflects a combination of increased insulin production (222,225) and decreased insulin clearance (222-226), but most evidence suggests that increased insulin secretion is the predominant factor (227,228). Both basal and 24-hour insulin secretory rates are three to four times higher in obese subjects and are strongly correlated with body mass index. Insulin secretory responses to intravenous glucose have been studied in otherwise healthy insulin-resistant subjects in comparison to insulin-sensitive subjects by means of a graded glucose infusion (228,229). Figure 7.4 depicts insulin concentrations and insulin secretion rates at each level of plasma glucose achieved, thereby constructing a glucose-insulin or glucose-insulin secretion rate dose-response relationship. Both insulin concentrations and insulin secretion rates are increased in insulin-resistant subjects, resulting from a combination of increased insulin secretion and decreased insulin clearance. For each level of glucose, insulin secretion rates are higher in the insulin-resistant subjects, reflecting an adaptive response of the β -cell to peripheral insulin resistance. Similar compensatory hyperinsulinemia has been demonstrated with other clinical techniques, such as the frequently sampled intravenous glucose tolerance test in obesity and other insulin-resistant states such as late pregnancy (230,231).

The temporal pattern of insulin secretion is unaltered in obese subjects as compared with normal subjects. In the obese, basal insulin secretion accounts for 50% of the total daily production of insulin and secretory pulses of insulin occur every 1.5 to 2 hours (178,227). However, the amplitude of these pulses postprandially is greater in obese subjects. Nevertheless, when these postprandial secretory responses are expressed as a percentage of the basal secretory rate, the postprandial responses in obese and normal subjects are identical (Fig. 7.5). These findings suggest that

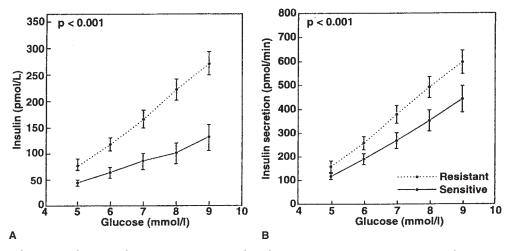

Figure 7.4. Plasma insulin concentrations **(A)** and insulin secretion rates **(B)** in response to molar increments in the plasma glucose concentration during the graded glucose infusion in the insulin-resistant *(dashed line)* and insulin-sensitive *(solid line)* groups. (From Jones CNO, Pei D, Staris P, Polonsky KS, Chen YDI, Reaven GM. Alterations in the glucose-stimulated insulin secretory dose-response curve and in insulin clearance in nondiabetic insulin-resistant individuals. *J Clin Endocrinol Metab* 1997;82: 1834–1838, with permission. Figure 7.5. Mean 24-hour profiles of insulin secretion rates in normal and obese subjects (*top*). The hatched areas represent ± SEM. The curves in the lower panel were derived by dividing the insulin secretion rate measured in each subject by the basal secretion rate derived in the same subject. Mean data for normal and obese subjects are shown. (From Polonsky KS, Given BD, Van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. *J Clin Invest* 1988;81:442–448, with permission from the American Society of Clinical Investigation.)

the increase in insulin secretion in the obese is due not to a hyperresponsiveness to secretory stimuli but rather to the presence of an abnormally large functional β -cell mass. This suggestion is consistent with both the earlier pathologic observations of Ogilvie, who described an increased number of islet cells in obese subjects (232), and with animal studies, which confirm the presence of a compensatory increase in β -cell mass in obese insulinresistant fatty rats that maintain normal glucose tolerance (233). Rapid oscillations in insulin secretion that occur every 10 to 12 minutes and are similar to those in nonobese subjects have also been found in obese patients, although of an amplitude that tended to be lower than that of the corresponding pulses in the nonobese (191). It appears, therefore, that the normal regulatory mechanisms controlling insulin secretion in nonobese controls are also operative in hyperinsulinemic obese subjects and that β cell function is intrinsically normal in this setting.

INSULIN SECRETION IN TYPE 2 DIABETES MELLITUS

Owing to the common finding of obesity and insulin resistance in type 2 diabetes mellitus, these patients are often hyperinsulinemic but have a degree of hyperinsulinemia inappropriately low for the prevailing glucose concentrations. Nevertheless, many of these patients have sufficient β -cell reserve to maintain a euglycemic state by dietary restriction with or without therapy with an oral agent. It is generally agreed that defects in the β-cell superimposed on a background of insulin resistance converge to cause type 2 diabetes (234-238). In an animal model of type 2 diabetes mellitus, in which obesity, insulin resistance, and hyperinsulinemia are present before the inevitable development of diabetes mellitus, inadequate expansion of β-cell mass is implicated as a significant causative factor (233). Autopsy studies in diabetic humans are consistent with this observation (239–241). Alterations in β -cell gene expression also may play a role (242). Clinically, these patients demonstrate virtually absent first-phase insulin and C-peptide responses to intravenous glucose, a reduced second-phase response (77, 243-246) (Fig. 7.6), and marked flattening of the glucose-insulin secretion dose-response curve (184). This attenuated β -cell response is not confined to glucose; diminished responses to nonglucose secretagogues such as arginine and isoproterenol have also been observed, although the reduction is of a lesser magnitude (77,243). In vitro studies using the isolated perfused pancreas have emphasized the importance of hyperglycemia in the mediation of these changes (247,248). However, the abnormal first-phase response to intravenous glucose persists in patients whose diabetic control has been markedly improved (243,244), further supporting the presence of an intrinsic defect in the β -cell in patients with type 2 diabetes mellitus.

Many studies have examined the effects of type 2 diabetes mellitus on levels of proinsulin in serum. These studies have consistently demonstrated elevated levels of proinsulin in association with increases in the molar ratio of proinsulin to insulin (249–254), suggesting that the β -cells of patients with type 2 diabetes mellitus release an excess of immature secretory granules into the circulation. The amount of proinsulin produced in these patients appears to be related to the degree of glycemic control rather than to the duration of the diabetic state. In one series, proinsulin levels contributed almost 50% of the total insulin immunoreactivity in patients with type 2 diabetes mellitus who had marked hyperglycemia (254). Because conventional assays of levels of immunoreactive insulin also measure levels of proinsulin (253), it is possible that the hyperinsulinemia reported in many studies of patients with type 2 diabetes mellitus to some degree represents hyperproinsulinemia rather than true hyperinsulinemia. In support of this view, studies using a sensitive insulin assay that did not cross-react with proinsulin report that insulin levels in both obese and nonobese patients with type 2 diabetes mellitus are lower than those in weight-matched control subjects, although when insulin levels are measured with a conventional insulin assay, differences between patients with diabetes mellitus and control subjects are less apparent (253-255). Furthermore, patients with diabetes in one series had elevated levels of both circulating proinsulin and 32-33 split proinsulin (a proinsulin conversion intermediate molecule) (253).

Abnormalities in the temporal pattern of insulin secretion in patients with type 2 diabetes mellitus have also been demonstrated. In contrast to normal subjects, who secrete equal

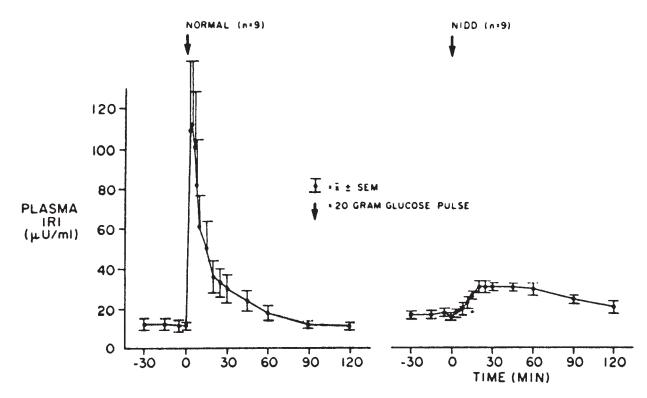

Figure 7.6. Insulin release in response to the intravenous administration of glucose in normal subjects and in patients with non–insulin-dependent diabetes mellitus. Note the lack of first-phase insulin response in the diabetic subjects. (From Pfeifer MA, Halter JB, Porte D Jr. Insulin secretion in diabetes mellitus. *Am J Med* 1981;70:579–588. Copyright 1981 with permission from Elsevier Science.)

amounts of insulin basally and postprandially in a given 24hour period, patients with type 2 diabetes mellitus secrete a greater proportion of their daily insulin under basal conditions (256). This reduction in the proportion of insulin secreted postprandially appears to be related in part to a reduction in the amplitude of the secretory pulses of insulin that occur after meals rather than to a reduction in the number of pulses. The rapid oscillatory pattern of insulin production by the $\beta\mbox{-cells}$ is also altered in patients with type 2 diabetes mellitus, who exhibit cycles that are shorter and more irregular than the persistent, regular, rapid oscillations present in healthy subjects (189). The slower ultradian oscillations of insulin secretion described above, which are "entrainable" by exogenous oscillatory glucose infusion in normal subjects, are severely disrupted in diabetic patients, with a nearly complete lack of coordination between pulses of glucose and insulin secretion (257). The effects of therapy on β -cell function in patients with type 2 diabetes mellitus have also been investigated. While interpretation of the results frequently is limited because β -cell function was not always studied at comparable glucose levels before and during therapy (258), the majority of the studies indicate that improvements in diabetic control are associated with an enhancement of β -cell secretory activity (244,259–263). This increased endogenous production of insulin appears to be independent of the mode of treatment and shows a particular association with increases in the amount of insulin secreted postprandially (244,263). The enhanced β -cell secretory activity following meals reflects an increase in the amplitude of existing secretory pulses rather than an increased number of pulses (263). Despite improvements in glycemic control, β -cell function is not normalized with therapy (244,261,263), suggesting that

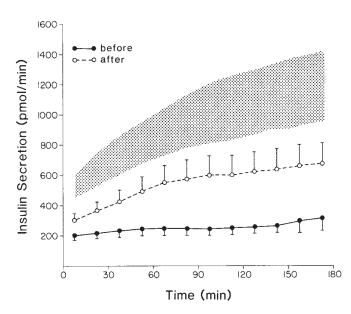

Figure 7.7. Insulin secretion rates (\pm SEM) during hyperglycemic clamping at 300 mg/dL (16.7 mmol/L) in patients with non–insulin-dependent diabetes mellitus before and during therapy with glyburide. The shaded area represents the secretion rates (\pm SEM) in a group of nondiabetic subjects. (From Shapiro ET, Van Cauter E, Tillil H, et al. Glyburide enhances the responsiveness of the β -cell to glucose but does not correct the abnormal patterns of insulin secretion in noninsulin-dependent diabetes mellitus. *J Clin Endocrinol Metab* 1989;569:571–576, with permission. Copyright 1989. The Endocrine Society.)

there may be a persistent intrinsic defect in the β -cell in patients with type 2 diabetes mellitus (Fig. 7.7).

INSULIN SECRETION IN IMPAIRED GLUCOSE TOLERANCE

Insulin secretion in subjects with IGT (2-hour glucose >140 mg/dL or 7.8 mmol/L after oral glucose challenge) has been studied to determine at what point measurable defects in β -cell function occur in the deterioration of glucose tolerance. When insulin responses to oral glucose or meals are measured over a range of glucose tolerance, they are found to be highest in subjects with IGT as compared with weight-matched glucose-tolerant controls and diabetic subjects (264). Despite elevated absolute insulin and insulin secretion in IGT, early defects in βcell function intermediate between normal and diabetic subjects are observed, suggesting that IGT is truly a "prediabetic" state. Detailed study of insulin secretion in patients with IGT has demonstrated consistent quantitative and qualitative defects in this group. During oral glucose tolerance testing, there is a delay in the peak insulin response (265-267). The glucoseinsulin secretion dose-response relationship is flattened and shifted to the right (Fig. 7.8), and first-phase insulin responses to an intravenous glucose bolus are consistently decreased in relationship to ambient insulin sensitivity (184,268). Further, there are abnormalities in first-phase insulin secretion in firstdegree relatives of patients with type 2 diabetes mellitus who exhibit only mild intolerance to glucose (269) and an attenuated insulin response to oral glucose in normoglycemic co-twins of patients with type 2 diabetes mellitus (270). This pattern of insulin secretion during the so-called prediabetic phase also is seen in subjects with IGT in whom type 2 diabetes develops later (78,271,272) and in normoglycemic obese subjects with a recent history of gestational diabetes mellitus (273), another group at high risk for type 2 diabetes mellitus (274). Abnormalities in β -cells may therefore precede the development of overt type 2 diabetes mellitus by many years.

The temporal pattern of insulin secretory responses is altered in IGT in a manner similar to but not as pronounced as that seen

Figure 7.8. in diabetic subjects described previously. There is a loss of coordinated insulin secretory responses during oscillatory glucose infusion, indicating that the ability of the β -cell to appropriately sense and respond to parallel changes in the plasma glucose level is impaired (Fig 7.9) (185). Abnormalities in rapid oscillations of insulin secretion have also been observed in first-degree relatives of patients with type 2 diabetes mellitus who have only mild glucose intolerance (275), further evidence suggesting that abnormalities in temporal pattern of β -cell function may be an early manifestation of β -cell dysfunction preceding the development of type 2 diabetes mellitus. Because an increase in serum proinsulin is seen in subjects with diabetes mellitus, the contribution of proinsulin to the hyperinsulinemia of IGT has been questioned. The hyperinsulinemia of IGT has not been found to be accounted for by an increase in proinsulin, although elevations in fasting and stimulated proinsulin or proinsulin/insulin ratios have been found by many, although not all, investigators (252,254,264, 276-278). Correlation of increased proinsulin levels in IGT as a predictor of future conversion to diabetes mellitus has also been observed (279-281).

INSULIN SECRETION IN TYPE 1 DIABETES MELLITUS

In contrast to patients with type 2 diabetes, patients with type 1 diabetes mellitus are insulin-deficient and have practically no β -cell response to glucose and nonglucose stimuli (243). However, the initial period following diagnosis often is associated with an improvement in glucose tolerance to a degree permitting the

maintenance of normoglycemia for a self-limiting duration in some patients in the absence of any definitive therapy (282). This so-called honeymoon period is associated with increases in the C-peptide and insulin responses to glucose (8,283-286). Although the secretory capacity of β -cells is improved during this period, it is still less than that observed in healthy subjects. A qualitative defect also is present and is manifested in serum by an increased molar ratio of proinsulin to C-peptide (287-289). Thus, during the honeymoon phase, in addition to secreting less insulin, the pancreas releases greater quantities of immature β -cell granules into the circulation. The subsequent and inevitable deterioration in glycemic control that heralds the end of the honeymoon period is preceded by a gradual reduction in the secretory capacity of the β -cell (8). The assessment of β-cell function in patients with recently diagnosed type 1 diabetes mellitus may be of clinical relevance, in view of the evidence suggesting that the degree of residual β -cell function at this stage is an important prognostic indicator of which patients are most likely to benefit from a period of immunosuppression (290 - 292).

The β -cell secretory responses during the period before the onset of type 1 diabetes mellitus are also of interest. Studies in normoglycemic, islet cell antibody-positive monozygotic twins in which one twin is already insulinopenic have demonstrated a progressive diminution in the first-phase insulin response to glucose over a number of years before the development of overt diabetes mellitus (293). During this "early" diabetic phase, the β-cell response to other secretagogues, including arginine, tolbutamide, and glucagon, is also impaired, but to a much smaller extent (239). In the future, this identification of β -cell dysfunction in response to intravenous glucose in those at high risk for the development of type 1 diabetes mellitus some years before clinical onset may be of value therapeutically in preventing the onset of type 1 diabetes mellitus in susceptible individuals. Several trials have been designed to determine whether type 1 diabetes mellitus can be prevented in predisposed individuals. The European Nicotinamide Diabetes Intervention Trial (ENDIT) involves the random allocation of patients with type 1 diabetes mellitus to nicotinamide or placebo (294). In the United States, the Diabetes Prevention Trial (DPT-1) (295) recently demonstrated that low-dose parenteral insulin administration failed to delay the onset or progression of type 1 diabetes mellitus.

A number of studies evaluating β -cell function in the transplanted pancreas have been performed (159-162,296,297). Because many of those patients who have undergone pancreatic transplantation remain euglycemic without therapy during the posttransplantation period, the β -cell appears to be functional despite denervation. However, marked alterations in the temporal pattern of insulin secretion have been reported. Although the overall daily number of insulin secretory pulses is not altered following transplantation, basal insulin secretion accounts for up to 75% of the total insulin produced by these patients in a given 24-hour period. Postprandial insulin responses are therefore markedly attenuated (160). Detailed analysis of these postprandial secretory pulses suggests that they are both reduced in amplitude and occur later after meals. This latter factor supports the view that the cephalic phase of insulin secretion mediated by the vagus is an important component of the prompt insulin response to meals usually observed in normal subjects (96,152). In addition to quantitative abnormalities in insulin secretion, qualitative defects in the transplanted β -cell have also been reported, with increased ratios of proinsulin to C-peptide under fasting conditions and a further accentuation of these abnormalities in the postprandial period (161).

INSULIN SECRETION IN PATIENTS WITH INSULINOMA

In the diagnosis of insulinoma, a detailed knowledge and a correct interpretation of the β -cell secretory responses are critical. In distinguishing hypoglycemia caused by an islet cell tumor from hypoglycemia caused by other factors, the measurement of plasma levels of insulin alone may not be sufficient. Under normal physiologic circumstances, β-cell secretion is reduced as glucose levels fall. The hypoglycemia seen in patients with an insulinoma, however, is characterized by low glucose levels with inappropriate levels of insulin (which may be normal or elevated) (298,299). Although hypoglycemia induced by the surreptitious administration of insulin may also be associated with hyperinsulinemia, C-peptide levels will be elevated in patients with an insulinoma whereas administration of exogenous insulin usually suppresses the release of C-peptide from the β -cell (300). Moreover, patients with an insulinoma release a greater proportion of proinsulin into the circulation (301,302). This latter factor could prove to be important in distinguishing patients with an insulinoma from those rare patients with hypoglycemia caused by surreptitious ingestion of oral hypoglycemic agents. Thus, the simultaneous measurement of proinsulin, insulin, and C-peptide levels can be of value in excluding or confirming the presence of an insulinoma in patients who present with hypoglycemia.

EFFECT OF DRUGS ON INSULIN SECRETION

Many pharmacologic agents other than hypoglycemic agents alter insulin secretion in vivo. In many instances, the effects of these agents on insulin secretion are associated with a deterioration in glucose tolerance. Some of these agents (e.g., phenytoin, verapamil, diazoxide, pentamidine) exert direct effects on the β -cell to suppress insulin release (303–306). The indirect effects of other drugs may be mediated through alterations in insulin sensitivity (e.g., glucocorticoids) or through potassium depletion (e.g., thiazides), which secondarily alters the resting membrane potential of the β -cell (307,308). Still other pharmacologic agents modulate both insulin secretion and insulin action. Both α - and β -adrenoceptor antagonists are included in this category. Indeed, the effects of this group of drugs on the rapid insulin secretory oscillations (those that occur every 8 to 16 minutes) have also been characterized. α-Adrenoreceptor blocking agents appear to enhance insulin secretion by increasing the amplitude of these rapid pulses, whereas the reduced insulin secretory response in patients receiving aadrenergic antagonists appears to be in part a reflection of a smaller pulse amplitude (192). Neither α - or β -adrenoceptor antagonists alter the frequency of these rapid oscillations. Other pharmacologic agents that affect both insulin secretion and insulin action include clonidine, prazosin, the benzodiazepine and phenothiazine groups of drugs, and the opiates. In relation to the latter, hyperglycemia has been observed in subjects receiving morphine (309) and hyperinsulinemia has been reported in heroin addicts, who also demonstrate insulin secretory responses to intravenous glucose lower than those in age- and weight-matched control subjects (310). New-onset diabetes mellitus, even diabetic ketoacidosis, has been observed in patients taking clozapine and olanzapine, novel antipsychotic agents, but the underlying mechanism is not yet understood (311-315).

CONCLUDING REMARKS

The study of insulin secretion in vivo is greatly facilitated by a clear knowledge of the biosynthetic pathway of insulin within the β -cell and of the factors regulating insulin production and clearance from the circulation. In many clinical situations, the simultaneous measurement of proinsulin and C-peptide levels provides information on β -cell secretory function not possible to obtain by measurement of insulin levels in isolation. In interpreting the concentrations of these peptides, it is necessary to take into account the age and weight of the subjects as well as the glucose level at the time of sampling. The presence of any factor likely to alter insulin sensitivity should also be noted. While glucose is the key stimulus regulating insulin secretion in vivo, other nutrients, as well as neural and hormonal factors, interact to modify this response, thus helping to maintain glucose levels within the physiologic range during fasting and postprandial states. This complex regulatory system is disrupted in the early stages of type 1 diabetes mellitus before absolute insulinopenia develops and also in type 2 diabetes mellitus. In both cases, the β -cell is unable to respond appropriately to the prevailing glucose concentration. Future studies of β -cell secretory function *in vivo* are likely to concentrate on the secretory defects present in the β -cell early in the evolutionary phase of diabetes mellitus before the clinical manifestations become apparent. The study of β -cell function and reserve during this period could make a major contribution to our understanding of the pathogenesis of diabetes mellitus and may ultimately lead to the development of suitable approaches for its prevention.

BASIC PRINCIPLES

Fuel Reservoirs

Humans have a constant requirement for energy but eat only intermittently. To cope with this problem, we usually ingest food in excess of the immediate caloric needs of our vital organs and store the extra calories in the form of hepatic and muscle glycogen, adipose tissue triglyceride, and to a certain extent, tissue protein. In turn, during starvation and in response to various stresses, we break down these fuel reservoirs to provide energy for organ metabolism and function (Fig. 8.1).

The two principal circulating fuels in humans, glucose and free fatty acids (FFAs), are stored intracellularly as glycogen and triglycerides, respectively. The largest reservoir of glycogen (300 to 500 g) is skeletal muscle (1). However, the principal reservoir of glycogen from which free glucose can be released into the circulation is the liver (Table 8.1) (1). The major site of triglyceride storage is adipose tissue. Adipose tissue triglyceride is the most efficient form of energy storage in humans. Triglyceride contains 9.5 kcal per g and the average caloric content of an adipocyte, including its cytosol, is approximately 8 kcal per g (2). In contrast, glycogen contains 4 kcal per g. Furthermore, because 3 mL of water is needed to maintain the intracellular osmolality of each gram of glycogen *in vivo* (3), in

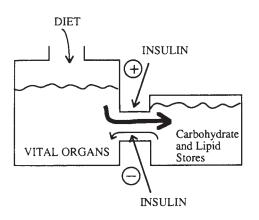

reality glycogen provides only 1 kcal per g. Thus, if the 15 kg of adipose tissue triglyceride in a normal 70-kg man were replaced with an equicaloric quantity of glycogen, the individual would weigh an additional 120 kg!

Body protein, although of considerable mass (Table 8.1), is not, strictly speaking, a fuel reservoir. Protein molecules serve specific roles in maintaining organ structure and function and are less expendable than glycogen or triglycerides. On the other hand, a portion of body protein (e.g., some of the contractile protein of muscle as well as other proteins in liver and muscle) is degraded during starvation and other periods of stress and provides amino acid substrate for gluconeogenesis.

The Brain and Other Vital Organs

The brain has a continuous need for fuel but stores almost no energy as glycogen or fat. Instead, it uses glucose derived from the liver either directly from glycogen or indirectly from other fuel reservoirs through gluconeogenesis. The brain does not use FFAs directly. During prolonged starvation, however, it is able to use energy derived from FFAs after their conversion to ketone bodies. Other vital organs, such as liver, heart, and skeletal muscle, also have a continuous requirement for fuels (Table 8.2), but unlike the brain, these organs can utilize fatty acids directly to meet their energy needs (1,3). <u>FED</u>

STARVATION

Carbohydrate and Lipid Stores Counter-Insulin Hormones -Glucagon -Catecholamines -Growth Hormone (adipose)

-Glucocorticoids

Figure 8.1. Fuel homeostasis in humans. In the fed state, fuels in excess of the needs of vital organs are stored in carbohydrate and lipid reservoirs (i.e., as glycogen and triglycerides and to some extent as protein). During starvation, these stores are broken down to provide fuel for other organs. Changes in circulating levels of insulin and counterinsulin hormones modulate these transitions.

Hormonal Regulators of Fuel Homeostasis

Energy reservoirs in humans are built up and broken down in response to hormonal messages. The principal hormonal messenger is insulin. In the fed state, insulin levels increase, promoting glycogen synthesis in liver and muscle, lipid formation in adipocytes, and amino acid uptake and protein synthesis in most cells. In the postabsorptive state, during starvation and in response to many stresses, decreased insulin levels contribute to glycogen breakdown, lipolysis, hepatic ketogenesis, and decreased synthesis and increased degradation of protein. In the latter situations, a major role of insulin is to act as a restraint on these catabolic events (Fig. 8.1).

Multiple hormones counter the effects of insulin. Glucagon stimulates glycogenolysis, gluconeogenesis, and ketogenesis in the liver (4–7). Glucagon also can stimulate lipolysis in adipose tissue, although the physiologic relevance of this latter effect is unclear. Catecholamines have effects similar to those of glucagon on the liver and are key regulators of lipolysis in adipose tissue and glycogenolysis in muscle and other tissues. In general, the counterinsulin hormones (also called counterregulatory hormones) liberate energy from fuel reservoirs by actions opposite to those of insulin (Fig. 8.1). However, not all of the actions of these counterinsulin hormones are catabolic. For instance, growth hormone, although catabolic in the sense that it stimulates lipolysis in adipose tissue, also has significant anabolic effects and enhances cell growth (8). Similarly, glucagon has the anabolic property of stimulating amino acid uptake by the liver (6). The potential roles of leptin and other hormones

TABLE 8.1. Fuel Reservoirs in Humans			
Source	g	kcal	
Liver glycogen	75	300	
Muscle glycogen	400	1,600	
Blood glucose	20	80

Protein	6,000	24,000	
Data are estimates for an overnight-fasted man weighing 70 kg.			

released by the adipocyte in regulating fuel homeostasis will be discussed in the section on adipose tissue.

Nonhormonal Regulation of Fuel Homeostasis

Although fuel homeostasis has been classically envisaged in the context of its regulation by hormones, changes in the concentrations of the fuels themselves may also play a direct role. Thus, increases in circulating glucose levels have been shown to diminish hepatic gluconeogenesis and glycogenolysis and enhance glycogen synthesis independent of their effects on hormone secretion (9,10). In addition, FFAs have been shown to stimulate hepatic gluconeogenesis; indeed recent studies suggest that much of the antigluconeogenic action of insulin in humans and other mammals may be secondary to its antilipolytic action on the fat cell (11).

Glucose Homeostasis

A principal objective of the interplay between insulin and the counterinsulin hormones in humans is the maintenance of normoglycemia. The concentration of glucose in the circulation is more closely controlled than that of any other fuel. Thus, plasma glucose levels are maintained between 4 and 7 mM in normal humans despite varying rates of glucose utilization (Table 8.3), whereas levels of FFAs and ketone bodies may range 10-fold to more than a 100-fold, respectively (12,13). Prevention of hypoglycemia is important because central nervous system (CNS) function is impaired at low plasma glucose concentrations. Likewise, significant hyperglycemia resulting in glycos-uria causes a loss of fuel and may contribute to the complica-

TABLE 8.2. Typical Daily Fuel Requirements of Liver, Muscle, and Brain of a Physically Active, Normally Fed Human

Organ	Fuel	~kcal/d
Liver	Amino acids, fat, glucose	280
Muscle	Glucose, fat	880
Brain	Glucose	480

TABLE 8.3.Rates of Glucose Utilization in the Fed and Fasted State				
	G	Glucose utilization (g/d)		
Tissue	12-h fast	8-d fast	Marathon run	
Brain Muscle	120 30	45 Very low	120 500	

tions of diabetes mellitus. Whether plasma glucose levels modestly above or below the "normal" range are undesirable remains to be determined.

Insulin lowers plasma glucose levels both by stimulating glucose uptake into muscle and adipose tissue and by inhibiting hepatic glycogen breakdown and gluconeogenesis. The different counterinsulin hormones balance these effects of insulin in order to maintain normoglycemia. Thus, glucagon, epinephrine, and norepinephrine are released into the circulation in response to hypoglycemia (7) and during stresses such as exercise, when glucose utilization is altered by other factors (14,15). In addition to stimulating hepatic glycogenolysis and gluconeogenesis, the catecholamines inhibit insulin-stimulated glucose utilization in muscle and promote lipolysis in adipose tissue (16), thereby providing tissues with an alternative fuel to glucose. Glucocorticoids also are released into the circulation in increased quantities in response to hypoglycemia and other stresses (14,15). Glucocorticoids appear to be necessary for the mobilization of energy stores by catecholamines and glucagon; however, their role may be permissive rather than regulatory (17).

FIVE PHASES OF FUEL HOMEOSTASIS

Immediately after a carbohydrate or mixed meal has been ingested, the concentrations of insulin, glucose, and glucagon in

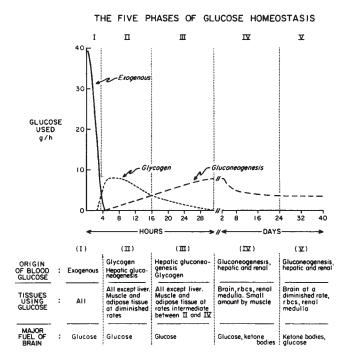

Figure 8.2. The five phases of glucose homeostasis. The figure depicts rates of glucose utilization and the source of glucose entering the circulation in a 70-kg man who ingests 100 g of glucose and then fasts for 40 days.

plasma favor fuel storage. Once absorption of the ingested food is complete, the concentrations of these and other hormones and substrates change, causing a shift from energy storage in fuel reservoirs to energy mobilization. Further alterations in fuel homeostasis occur with more prolonged food deprivation. These changes can be broken down into five phases on the basis of the source and quantity of glucose entering the circulation. Figure 8.2 illustrates these changes in a hypothetical human who ingests 100 g of glucose and then begins a prolonged fast (13).

Fed State

During the first few hours after a carbohydrate meal, glucose absorbed from the gastrointestinal tract provides for the metabolic needs of the brain and other organs (Fig. 8.2, phase I). The absorbed glucose in excess of these needs is used to rebuild fuel reservoirs in liver, muscle, fat, and presumably in other tissues (Fig. 8.3). In this setting, plasma insulin levels are high, plasma glucagon levels are low, and glycogen synthesis is stimulated in liver and muscle. Approximately 75 g of carbohydrate is stored as glycogen in liver, and 300 to 500 g is stored in muscle in a human who has fasted overnight (1) (Table 8.1).

As noted earlier, the major form of lipid storage in humans is triglyceride and the major site for triglyceride storage is adipose tissue (2). Smaller amounts of triglyceride are stored in muscle, liver, and other tissues. Triglycerides also are present in

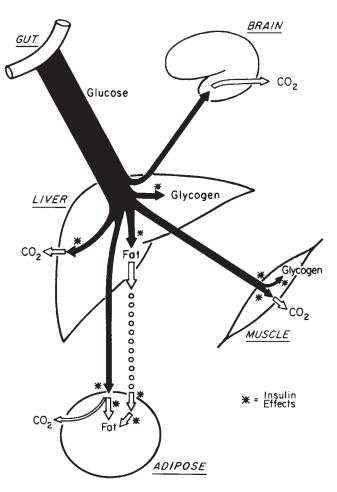

Figure 8.3. Fuel metabolism during a carbohydrate meal. Soon after the ingestion of carbohydrate, insulin levels rise and stimulate the uptake of glucose. Glucose is the major oxidative fuel of all major tissues at this time. Glucose that is present in excess of the oxidative needs of tissues is stored as glycogen or lipid. Asterisks indicate steps enhanced by insulin.

130 JOSLIN'S DIABETES MELLITUS

the circulation as constituents of lipoproteins. However, the major circulating lipid fuels are the FFAs. After a carbohydrate meal, high concentrations of insulin favor the use of both glucose and lipoprotein triglycerides for triglyceride synthesis in adipose tissue.

In addition to promoting the synthesis of glycogen and triglycerides in the fed state, insulin inhibits the breakdown of these fuel reservoirs (18) (i.e., it is anticatabolic). The concentrations of insulin that inhibit lipolysis appear to be lower than those that stimulate glucose transport in muscle. Presumably, it is for this reason that patients with mild type 2 diabetes and glucose intolerance are hyperglycemic in the absence of significant elevations of plasma FFAs or ketone bodies.

Early Starvation

With the decrease in plasma insulin and the increase in plasma glucagon that accompany an overnight fast, fuel homeostasis shifts from energy storage to energy production (Fig. 8.4). At this stage, glucose no longer enters the circulation from the gastrointestinal tract but is derived principally from the breakdown of liver glycogen and, via gluconeogenesis, from lactate, amino acids, and glycerol, a process that takes place predominantly in the liver (1) but that also occurs in the kidney (19) and intestines (20). In addition, circulating FFAs, derived from the hydrolysis of adipocyte triglycerides, become a major source of

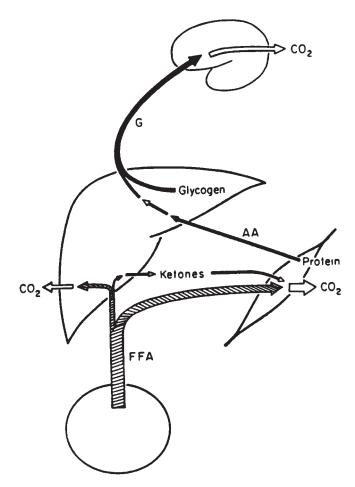

Figure 8.4. Fuel metabolism after an overnight fast (postabsorptive). After approximately 12 hours of starvation, insulin concentrations have returned to basal levels and glucose (G) entering the circulation is derived from both hepatic glycogen and gluconeogenesis. Free fatty acids (FFA) produced from adipocyte lipolysis have become a principal fuel for skeletal muscle. AA, amino acids.

fuel (21). As will be discussed later, by using FFAs, muscle and liver decrease their oxidation of glucose as a fuel, thereby conserving it for the brain.

MOBILIZATION OF CARBOHYDRATE AND LIPID STORES

In the earliest phase of starvation (i.e., the postabsorptive state), hepatic glycogen is a major source of the glucose entering the circulation and remains so for 12 to 24 hours (22,23). Glucagon seems to be necessary for hepatic glycogenolysis during this period, although an increase in the level of plasma glucagon does not appear to be the primary stimulus (24-26). After an overnight fast, the average rate of glucose utilization by a healthy human is approximately 7 g per hour (Table 8.3) (1). By extrapolation, the 70 to 80 g of glycogen present in the liver can provide glucose to the brain and peripheral tissues for 12 to 16 hours. Two events allow the maintenance of blood glucose levels beyond this time: (a) Muscle and other tissues begin to oxidize lipid-derived fuels in place of glucose, and (b) hepatic gluconeogenesis, which is also stimulated by fatty acids, replaces glycogenolysis as the principal source of glucose entering the circulation (Fig. 8.4). As will be discussed later, glycogen breakdown in muscle does not yield significant quantities of free glucose, and after an overnight fast, gluconeogenesis by the kidney is of minor importance.

Two factors stimulate the breakdown of adipocyte triglyceride during starvation. First, the concentration of circulating insulin diminishes and, consequently, triglyceride synthesis is decreased and lipolysis is enhanced (2,27). Second, norepinephrine is released from sympathetic nerve endings and directly stimulates lipolysis by raising levels of cyclic adenosine monophosphate (cAMP) in adipocytes (2,27). Epinephrine, which is secreted from the adrenal medulla, appears to play a lesser role. The mechanisms by which FFAs are released into the circulation are discussed in the section "Adipose Tissue." The principal users of FFAs during the early phases of starvation are skeletal muscle and liver.

GLUCONEOGENESIS

Because the brain is unable to use FFAs as a fuel, it must continue to use glucose during the early phases of starvation. Gluconeogenesis is an important source of the glucose that enters the circulation even after an overnight fast (28) and becomes the major source as hepatic glycogen stores become depleted (Fig. 8.2, phase III) (23). Gluconeogenesis is responsible for approximately 35% to 60% of the hepatic glucose output after an overnight fast (12 to 15 hours postabsorptive) and for more than 97% of the output by 60 hours of starvation (23,29,30). At 60 hours, glucose production is limited not by the enzymatic capacity of the liver but by the concentration of gluconeogenic substrate in the circulation (31). During the early phases of starvation, the two principal gluconeogenic precursors are lactate and alanine (Table 8.4) (17,32–34).

TABLE 8.4.	Gluconeogenic Substrates in	1		
Humans Starved for 24 Hours				

Substrate	Amount generated (g/d)
Lactate	60
Amino acids except alanine	25
Alanine only	25
Glycerol	14
Pyruvate	5
Total	129

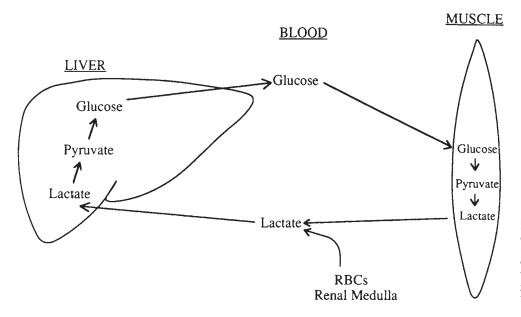

Figure 8.5. The Cori cycle. Lactate derived from glycolysis in skeletal muscle, red blood cells (RBCs), renal medulla, and other tissues is taken up by the liver, which uses it to synthesize glucose. The glucose can then be reused by these same tissues.

Lactate comprises 50% of the gluconeogenic substrate of liver in a human who has fasted overnight and is the major gluconeogenic substrate throughout starvation (Table 8.4) (32). When glucose cannot be metabolized beyond pyruvate in peripheral tissues, much of the pyruvate is reduced to lactate, which is then released into the circulation (Fig. 8.5). In red blood cells and renal medulla, this reduction occurs because there are no mitochondria in which pyruvate can be oxidized. In muscle and other tissues, lactate and pyruvate are released during starvation because the activity of pyruvate dehydrogenase, the enzyme that decarboxylates pyruvate to form acetyl coenzyme A (CoA), is decreased (35). For the most part, lactate generated from glucose in this way is taken up by the liver and reconverted to glucose by the gluconeogenic pathway (33). This recycling of glucose between liver and peripheral tissues via lactate is referred to as the Cori cycle.

A second major group of gluconeogenic substrates is the amino acids. Skeletal muscle is the principal reservoir of amino acids in humans (34). During early starvation, however, the gut and liver also appear to be important sources of the amino acids entering the circulation (36). A major stimulus to protein catabolism (both decreased synthesis and increased degradation) during starvation is the decrease in plasma insulin concentrations (37–39). Glucagon stimulates protein degradation in liver, and glucocorticoids inhibit protein synthesis in muscle and other tissues (34). Although increases in the plasma levels of these counterinsulin hormones almost certainly play a role in modulating protein catabolism in stressful states (e.g., diabetic ketoacidosis and trauma), their concentrations are not dramatically altered during starvation, and their role here is thought to be limited.

The principal amino acids released into the circulation from muscle are alanine and glutamine (Fig. 8.6). Most of the alanine

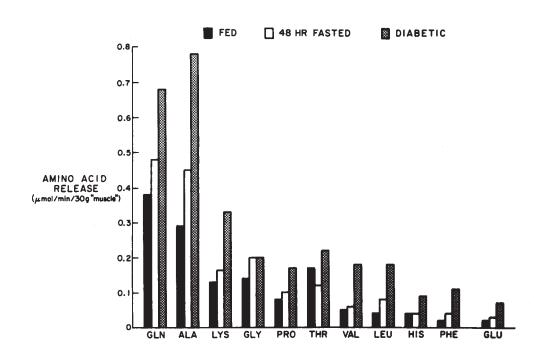

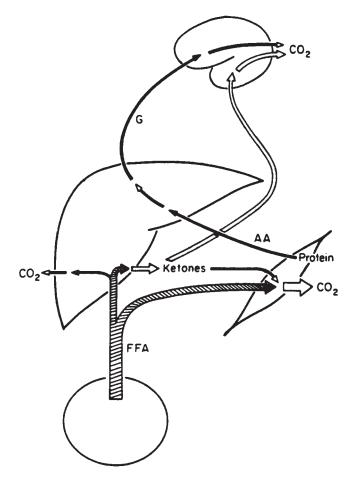

Figure 8.6. Release of amino acids from hind limb muscle of fed, fasted, and streptozotocin-diabetic rats perfused with an amino acid–free medium. The amino acids released in greatest amount are glutamine and alanine. In humans, the pattern of amino acid release is similar except that glutamine is taken up from the circulation.

is taken up directly by the liver, whereas glutamine is metabolized in the gastrointestinal tract, which can use it for gluconeogenesis and to generate alanine (20), and by the kidney, where it is the principal gluconeogenic substrate (19) as well as a major source of the NH₃ used for neutralizing acid in urine. Glutamine and alanine, despite comprising only 15% to 20% of muscle protein (34,39–41), account for 50% of the amino acids released by muscle because these amino acids can be generated from other constituents in muscle as well as from the degradation of protein. Alanine is formed by the transamination of pyruvate by alanine aminotransferase and glutamine by the amidation of glutamate by free ammonia, a reaction catalyzed by glutamine synthetase (41).

The rate of release of alanine increases markedly during starvation and other states of insulin deficiency (34,42). Despite this, the concentration of alanine in plasma is usually diminished in these situations because its uptake by the liver is stimulated to an even greater extent. Since the interorgan relationships of alanine are very much like those of lactate, a "glucose–alanine cycle" similar to the Cori cycle has been proposed (22). Impaired release of alanine from muscle has been postulated as a contributor to impaired gluconeogenesis and hypoglycemia in patients with uremia, maple syrup urine disease, and ketotic hypoglycemia of infancy and in starved women during pregnancy (43).

The other major gluconeogenic substrate is glycerol, which is derived principally from the hydrolysis of adipose tissue triglyceride. In nondiabetic subjects, the rate with which glycerol appears in the circulation correlates with adipose mass (44) and increases during starvation. Glycerol comprises about 10% of total gluconeogenic substrate during early starvation and a much higher percentage during prolonged starvation, when gluconeogenesis from amino acids is markedly diminished (see below).

Prolonged Starvation

KETONE BODIES AND THE BRAIN

With the prolongation of starvation, several events occur that limit the need for gluconeogenesis and thereby conserve body protein (Fig. 8.7). The first of these, as already noted, is an increase in the reliance of muscle and other peripheral tissues on lipid-derived fuels: initially FFAs and later both FFAs and the ketone bodies, acetoacetate and β -hydroxybutyrate. The second is a change in the fuels used by the brain. During early starvation, the CNS continues to use glucose as its exclusive fuel. However, as starvation is prolonged, plasma levels of the ketone bodies increase to values even greater than the level of glucose (Fig. 8.8). Under these circumstances, the brain, or at least parts of it, increases its use of these lipid-derived fuels (1, 45,46). A third factor could be a decrease in plasma leptin, which by diminishing sympathetic nervous system activity, would diminish the basal metabolic rate.

Ketone bodies are produced from acetyl-CoA via the β -oxidation of fatty acids in the liver (Fig. 8.9). This process, termed ketogenesis, is enhanced by glucagon and inhibited by insulin. In contrast to long-chain FFAs, the ketone bodies are watersoluble and cross the blood–brain barrier via specific carrier proteins (47–49). Furthermore, the activity of these carriers is increased in physiologic states associated with sustained hyperketonemia such as diabetic ketoacidosis and starvation (50,51). These physiologic adaptations enhance the use of ketone bodies in place of glucose by the brain and diminish the need to degrade proteins for gluconeogenesis. It is because of

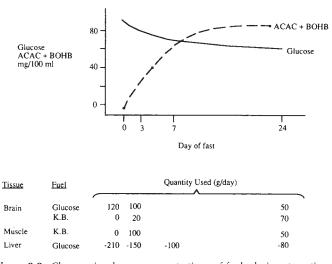

Figure 8.7. Fuel metabolism during prolonged starvation. As fasting continues, insulin levels remain suppressed and the principal source of hepatic glucose (G) production is gluconeogenesis. Skeletal muscle continues to use free fatty acids (FFA) for fuel but also uses ketone bodies produced in the liver. Ketone bodies may also be used by the brain. AA, amino acids.

Figure 8.8. Changes in plasma concentrations of fuels during starvation. Blood glucose concentrations decrease during the first 7 days of a fast but then remain relatively stable. As glucose utilization decreases, the concentration and use of ketone bodies increases. After a week of starvation, the concentration of ketone bodies in blood is equal to or greater than the glucose level. K.B., ketone bodies; ACAC, acetoacetate; BOHB, β -hydroxy-butyrate.

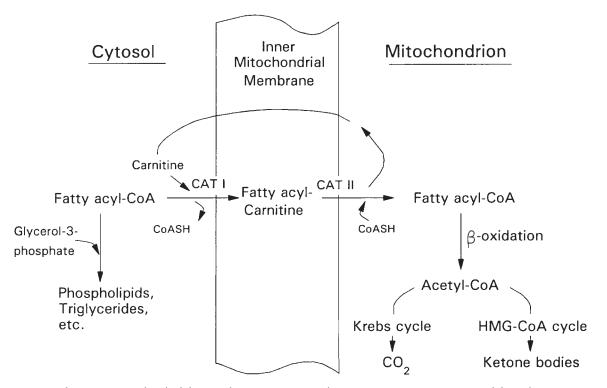

Figure 8.9. Mitochondrial fatty acid transport. Fatty acyl–coenzyme A (CoA) is transported from the cytosol into mitochondria by a series of steps that involves carnitine acyltransferase (CAT) I and II and a carnitine acyltranslocase (not shown). When rates of fatty acid transport into liver mitochondria are high, the hepatocyte obtains most of its fuel needs from the β -oxidation of the fatty acyl-CoA and the Krebs (tricarboxylic acid) cycle is inhibited. By generating malonyl-CoA, an inhibitor of CAT I, insulin inhibits fatty acid transport into mitochondria and, secondarily, ketogenesis. Glucagon has the opposite effect. HMG-CoA, 3-hydroxy-3-methyl glutaryl coenzyme A.

these adaptations that humans of normal weight are able to survive fasts of up to 60 to 70 days.

Hormonal Controls

GLUCONEOGENESIS AND PROTEIN CATABOLISM

The decreased use of glucose by the brain during prolonged starvation is accompanied by a diminished rate of gluconeogenesis in the liver (Fig. 8.2 and Table 8.3). The latter appears to be due to decreases in protein catabolism and secondarily to the release of gluconeogenic amino acids (mostly alanine) from muscle (21,34). Some studies suggest that these adaptations in protein metabolism are related to the increased use of lipid fuels during prolonged starvation (33,52,53). Whatever the mechanism, as one proceeds from early to prolonged starvation, urinary excretion of nitrogen decreases from 12 g per day to 3 to 4 g per day, indicating a decrease in protein catabolism from 75 g per day to 12 to 20 g per day (1).

The relative contribution of the kidney to gluconeogenesis increases from 5% to 10% after an overnight fast to 50% after 3 to 4 weeks of starvation (1,53). However, in absolute amounts, renal production of glucose is still much lower than hepatic production of glucose after 1 to 2 days of fasting. The increase in renal gluconeogenesis during prolonged starvation is linked to an increase in NH₃ generation from glutamine.

Unlike amino acids, the relative importance of glycerol as a gluconeogenic precursor increases during prolonged starvation. This reflects the fact that the release of glycerol from fat is approximately 14 g per day and remains nearly constant during early and late starvation (53). After several weeks of starvation, gluconeogenesis from glycerol hypothetically provides upwards of half of the glucose oxidized by the brain.

The gradual decrease in plasma insulin modulates the orderly breakdown of fuel reservoirs during the early phases of starvation. However, during prolonged starvation, the decreases in protein degradation and in the use of glucose and ketone bodies in muscle (see section titled "Muscle") occur in the absence of further changes in plasma insulin level. Some studies suggest that a decrease in thyroid hormone activity contributes to these adaptations (54). Presumably, the low levels of insulin during prolonged starvation are needed for these adaptations to occur. Thus, patients without any insulin (e.g., during diabetic ketoacidosis) have an impaired ability both to limit the breakdown of their fuel reservoirs and to use glucose and ketone bodies in peripheral tissues. The precise connection between the presence of insulin and these adaptations remains to be determined.

Recent studies suggest that another factor that plays a role in the adaptation of fuel homeostasis during starvation is leptin. As will be discussed in more detail in the next section, during periods of calorie deprivation when plasma insulin levels and adipocyte lipid stores are low, the release of leptin from adipose tissue diminishes, leading to an altered release of neuropeptide Y (NPY) and other CNS peptides and secondarily to a decrease in activity in the sympathetic nervous system. Although the precise interrelation of this chronic regulation of fuel metabolism to that modulated by insulin and counterinsulin hormones is only partially understood, it is highly likely that leptin plays a significant role in the adaptation of mammals to prolonged starvation (55,56).

HORMONE–FUEL INTERRELATIONS AT AN ORGAN LEVEL

Adipose Tissue

THE ADIPOCYTE IN METABOLIC REGULATION

While the adipocyte has classically been viewed as a storage depot for metabolic fuel in the form of lipid, it is now clear that the fat cell plays a central role in the endocrine regulation of energy homeostasis (57). Adipocytes not only respond to numerous hormones to regulate the storage and release of lipids but also secrete hormones (such as leptin, summarized above) that act to control energy balance and endocrine function throughout the rest of the body (57–59). The adipocyte also secretes a number of other protein factors, including resistin (also known as Fizz3) (60); tumor necrosis factor- α (TNF- α), an inflammatory cytokine (61); and Acrp30 (or adiponectin and adipoQ) (62), that may regulate insulin sensitivity elsewhere in the body. Although it was initially suggested that resistin increases with increasing adiposity and plays a role in insulin resistance associated with obesity, a number of subsequent

studies failed to support this notion (60,63,64), and more research is necessary to determine the physiologic function of resistin. TNF- α mediates elements of insulin resistance and type 2 diabetes syndromes in some mouse models of obesity and diabetes, although the relevance of TNF-a to obesity and insulin resistance in humans remains unclear (61). In contrast to resistin and TNF-α, Acrp30 appears to mediate insulin sensitization (62). Acrp30 is an adipocyte-derived complement-related protein that is secreted as a high-order multimeric complex. Its production by adipocytes is decreased in obesity and other states of insulin resistance, and exogenously increased levels of this protein enhance numerous insulin actions. Although a great deal remains to be learned about Acrp30 (e.g., the identity of the functional proteolytic product, receptor identity) (62,65), this molecule currently commands a great deal of attention as an insulin sensitizer.

INSULIN ACTION IN ADIPOCYTES

In general, the hormones that regulate energy storage and release in adipocytes are similar to those that regulate these events throughout the body (Figs. 8.10 and 8.11). Insulin pro-

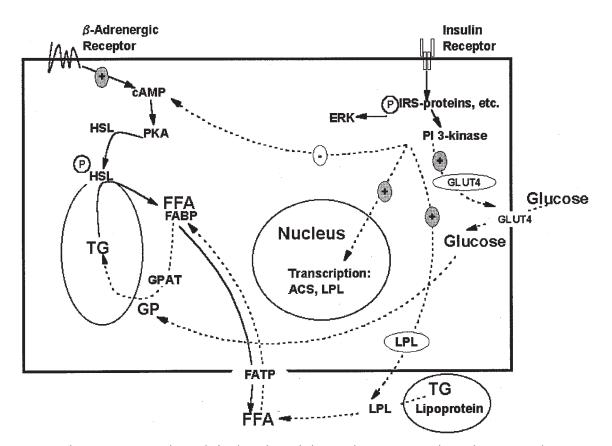

Figure 8.10. Hormonal control of triglyceride metabolism in adipose tissue: signaling and transcriptional events. Insulin stimulation activates its receptor, resulting in the phosphorylation (P) of insulin-receptor substrate (IRS)–proteins and the activation of the extracellular signal–regulated (ERK) kinase and phosphoinositide (PI) 3–kinase pathways. These signals stimulate the movement of GLUT4 from intracellular vesicles to the cell membrane, where they facilitate the uptake of glucose, which is broken down into glycerol-3-phosphate (GP). Insulin also increases the transcription of genes, such as that for lipoprotein lipase (LPL); LPL is secreted from the cell, where it mediates the breakdown of triglyceride (TG) in lipoproteins into free fatty acids (FFAs). FFAs are taken into and moved through the cell by fatty acid–transport and fatty acid–binding proteins (FATP and FABP, respectively). Insulin stimulates the action of glycerol phosphate acyltransferase (GPAT), which mediates the production of intracellular TG from FFA and GP. Receptor binding by counterregulatory hormones such as norepinephrine triggers the accumulation of cyclic adenosine monophosphate (cAMP) and the activation of protein kinase A (PKA), which mediates the prosphorylation of hormone-sensitive lipase (HSL) and its translocation to the lipid droplet, where it mediates the breakdown of TG to FFAs. FFAs are transported through and out of the cell by FABP and FATP. Insulin inhibits the action of HSL by impairing the accumulation of cAMP.

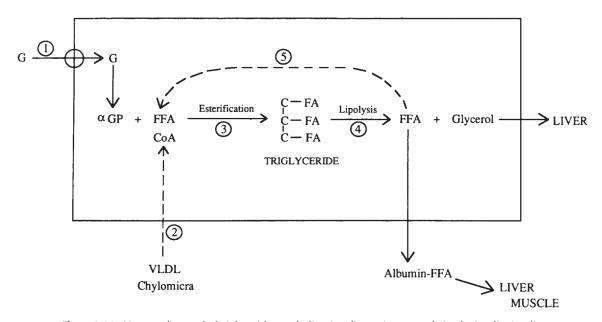

Figure 8.11. Hormonal control of triglyceride metabolism in adipose tissue: regulation by insulin. Insulin stimulates accumulation of triglycerides (TG) by enhancing glucose (G) transport and causing the generation of α -glycerophosphate (α -GP) (1), activating lipoprotein lipase (LPL) (2) and glycerol-3-phosphate (GP) acyltransferase (3), and inhibiting hormone-sensitive lipase (HSL) (4). By virtue of its effects on 1 and 3, insulin also stimulates the reesterification of free fatty acids (FFAs) (5) derived from lipolysis of intracellular TG. Hormones, such as norepinephrine, stimulate lipolysis by activating adenyl cyclase and secondarily HSL. Insulin also acts by countering the effects of these hormones. FFAs released from the adipocytes are carried complexed to albumin in the circulation. Principal sites of FFA utilization include muscle and liver (see Fig. 8.12). The glycerol released during lipolysis is not metabolized in the adipocytes, which lack glycerol kinase. Most of this glycerol appears to be used by the liver for gluconeogenesis. VLDL, very-low-density lipoprotein.

motes the uptake of metabolites such as glucose and lipids and their storage as triglyceride. Insulin mediates its effects in adipose and other tissues by binding a cell-surface insulin receptor, activating the tyrosine kinase in the intracellular portion of the receptor (66). The activated insulin receptor then recruits and phosphorylates downstream intracellular substrates, such as the insulin-receptor substrate (IRS)-proteins and Shc. These molecules in turn activate two main intracellular signaling pathways: the phosphoinositide (PI) 3-kinase regulated pathway, and the ras-mitogen-activated protein (MAP) kinase pathway. The counterregulatory hormones, such as catecholamines, oppose the effects of insulin and mediate breakdown and release of stored fats (67,68). In general, the counterregulatory hormones act via seven-transmembrane receptors coupled to heterotrimeric G proteins to stimulate adenylyl cyclase, increasing intracellular levels of cAMP and activating protein kinase A (PKA).

Insulin acts at several levels to promote energy storage. Insulin increases uptake of glucose from the extracellular space by promoting the movement of the insulin-responsive glucose transporter (GLUT4) to the cell surface to increase the rate of glucose flux into the cell (69). Insulin drives the metabolism of glucose to form glycerol 3-phosphate and increases the activity of glycerol phosphate acyltransferase; coupled with the increased FFA uptake also mediated by insulin, the net result is increased triglyceride storage. Insulin increases uptake of FFA by increasing the synthesis and secretion of lipoprotein lipase (LPL) (70,71); LPL degrades triglycerides and phospholipids in adipocyte-bound lipoproteins to FFA. FFAs are then shuttled into the adipocyte by simple diffusion (71a) and/or by specialized fatty acid–transport proteins (FATPs) and fatty acid– binding proteins (FABPs) (72–75), then coupled to CoA by acyl-CoA synthetase (ACS), and finally esterified with glycerol to form triglycerides. Insulin generally acts to increase the production of these and other proteins involved in lipid storage in adipocytes (71,76). Inhibitor studies suggest that most of these effects of insulin require the action of PI 3–kinase but not the ras \rightarrow MAP kinase pathway (66,77).

NUCLEAR FACTORS IN ADIPOCYTE FUNCTION

The lipid storage function of insulin acts in concert with a number of important nuclear factors that have recently been described. Adipocyte differentiation and determination factor-1/steroid response element binding protein (ADD/SREBP) mediates transcription in response to low levels of cholesterol and other lipids in adipocytes as well as in hepatocytes (78,79). ADD/SREBP is synthesized as an integral membrane protein that is retained in the endoplasmic reticulum (ER). Low cellular levels of cholesterol and other lipids result in the movement of the membrane-bound ADD/SREBP to the Golgi, where it is proteolytically cleaved and released from the membrane. Dissociation from the ER/Golgi allows ADD/SREBP to translocate to the nucleus and increase the transcription of a number of genes required for the synthesis of cholesterol, fatty acids, and triglycerides. The peroxisome proliferator-activator receptor-y (PPAR- γ) is a so-called orphan nuclear receptor that promotes the differentiation of adipocytes and increases the expression of proteins involved in insulin-stimulated lipid storage, including FATPs, FABPs, ACS, and GLUT4 (80-82). While the endogenous ligand for PPAR-y remains unknown, the insulin-sensitizing antidiabetic thiazolidinedione compounds act by stimulating PPAR-γ-mediated transcription.

CONTROL OF HORMONE-SENSITIVE LIPASE BY COUNTERREGULATORY HORMONES

The hormone-sensitive lipase (HSL)-mediated breakdown of lipids is one of the best-characterized pathways downstream of counterregulatory hormones such as catecholamines. Although other neutral lipid lipases exist, HSL is the only hormone-regulated neutral lipid lipase (83). HSL is a neutral lipid esterase that mediates the regulated step of triglyceride hydrolysis by removing the first fatty acid moiety from the triglyceride. After generating FFA from triglycerides, FABPs and FATPs transport the FFA through the cytoplasm and out of the cell (73-76). During counterregulatory hormone signaling, PKA mediates the serine phosphorylation of HSL; this phosphorylation event does little to alter the assayable activity of the enzyme, however (84-86). Instead, serine phosphorylation of HSL mediates the translocation of HSL in complex with a protein known as lipotransin from the cytosol to the lipid droplet. Access to the lipid droplet may be increased by the PKA-mediated phosphorylation of the perilipin protein that coats the droplet and by the subsequent dissociation of perilipin from the droplet (87-89). Insulin decreases the phosphorylation of HSL, probably by decreasing intracellular levels of cAMP via increases in phosphodiesterases, but perhaps also by increasing phosphatase activity toward HSL (90,91).

Muscle

FIBER TYPES

Muscle comprises approximately 40% of body mass in a man of normal weight. It accounts for 20% to 30% of the body's consumption of oxygen at rest and for up to 90% during exercise (92). Muscle fibers in the rat are classified as slow-twitch red (type 1), fast-twitch red (type 2a), and fast-twitch white (type 2b) according to their contractile characteristics and their capacity for oxidative metabolism (93,94). The same fiber types are found in human muscle (93). In general, the red fibers have a high oxidative capacity and oxidize fatty acids and other fuels in addition to glucose. White fibers have a lesser ability to oxidize fuels and generate a greater portion of their adenosine triphosphate (ATP) from glycolysis. With respect to exercise, white fibers are those recruited principally during brief periods of intense exercise such as sprinting or weight lifting and red fibers are those recruited during endurance-type activities of low-tomoderate intensity such as walking and running (22,93,95).

All of the fiber types in muscle respond to insulin. However, red fibers have a greater number of insulin receptors (96) and GLUT4 glucose transporters (97) than do white fibers. In addition, muscles rich in red fibers have more capillaries per mass (93,95), which could enhance diffusion of insulin and glucose from the plasma to the muscle cell (98). Perhaps for all of these reasons, glucose uptake in red muscle is more sensitive to insulin than is white muscle both *in vivo* and *in vitro* (99–101). Physical training, which causes white fibers to assume some of the characteristics of red fibers, is associated with an increase in their GLUT4 content (102,103).

FUEL RESERVOIRS

Glycogen

Glycogen in muscle is synthesized from circulating glucose after meals and exercise and is broken down during exercise and starvation. Glycogenolysis in muscle does not result in the release of free glucose into the circulation, since muscle cells are deficient in glucose-6-phosphatase. As a result, the 300 to 500 g of carbohydrate stored as glycogen in muscle is used solely for its own energy needs and for generating lactate and other gluconeogenic substrates for the liver (Fig. 8.12).

The importance of glycogen as a fuel in contracting muscle is underscored by the association of glycogen depletion with the phenomenon of "hitting the wall" in runners (104). Likewise, patients with McArdle syndrome, a hereditary deficiency of muscle phosphorylase, are unable to maintain high-energy phosphate stores during exercise (105). During starvation, mus-

A. After a carbohydrate meal (high insulin)

B. After 24-28 hrs. of starvation (low insulin)

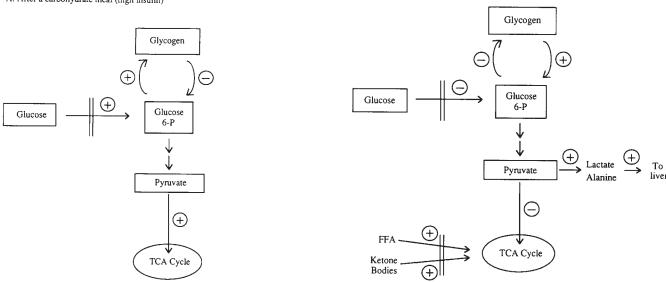

Figure 8.12. Muscle fuel metabolism. **A:** After a carbohydrate meal (high insulin), glucose uptake by the muscle is increased. Within the cell, glycogen synthesis is increased, as is use of glucose by the tricarboxylic acid (TCA) cycle. **B:** After 24 to 48 hours of starvation, glucose uptake by muscle is inhibited and glycogen is broken down. Pyruvate dehydrogenase is inhibited, and pyruvate is converted to lactate and, to a lesser extent, alanine. The + symbols indicate steps enhanced and the – symbols indicate steps diminished in comparison to rates following an overnight fast.

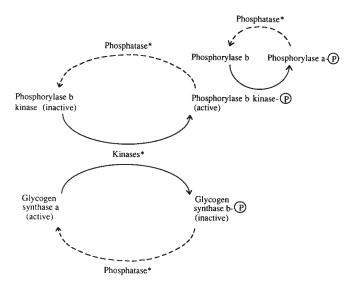

Figure 8.13. Regulation of glycogen synthase and phosphorylase in skeletal muscle. Asterisks, reactions affected by insulin; P, phosphate that alters activity.

cle glycogen in normal individuals diminishes by approximately 33% after 2 to 3 days and then remains constant as muscle switches over more completely to a lipid fuel economy (3,20). During early starvation (phases I and II) and exercise, a considerable portion of the lactate, pyruvate (about 0.1 as much as lactate), and alanine released by muscle is presumably derived from the breakdown of glycogen (34).

The regulation of glycogen synthesis and degradation in muscle by insulin is similar to its regulation of adipocyte triglyceride. Insulin stimulates glycogen synthesis by enhancing glucose transport and activating (dephosphorylating) a key regulatory enzyme, glycogen synthase (106) (Fig. 8.13). Likewise, insulin concurrently diminishes the breakdown of glycogen by inhibiting the conversion (phosphorylation) of phosphorylase *b* to phosphorylase *a* (107). These effects of insulin are thought to be mediated by specific phosphatases that both acti-

vate glycogen synthase and eventually inhibit phosphorylase b kinase and possibly by the inhibition of a kinase (glycogen synthase kinase 3) that, when active, phosphorylates and inhibits glycogen synthase (108). After exercise, glycogen synthesis is also increased (see Chapter 38), although the responsible mechanism may be different. Catecholamines and exercise per se stimulate the breakdown of muscle glycogen (Fig. 8.14). As in adipose tissue, catecholamines (epinephrine) act by increasing cAMP and secondarily by increasing cAMP-dependent protein kinase, which in turn activates (phosphorylates) phosphorylase b kinase (20,109,110).

Lipids

Red muscle fibers, in particular, store some energy as triglycerides, and triglyceride hydrolysis may provide a significant portion of their fuel needs during exercise (111). The question of whether the synthesis and breakdown of triglycerides are regulated in muscle by the same mechanisms as in adipose tissue has not been intensively studied. The activities of lipoprotein lipase in muscle and adipose tissue go in opposite directions during feeding and starvation, suggesting differences between the two tissues with respect to their use of circulating triglycerides (112). A particularly intriguing observation is the strong association of increases in intramuscular triglycerides and insulin resistance (113,114).

Protein

The synthesis and degradation of protein in muscle also are regulated by insulin. Insulin promotes protein synthesis in the fed state and probably acts as a brake on protein degradation during starvation. The mechanisms by which insulin acts on protein metabolism are more complex than those by which it acts on carbohydrate and fat metabolism and have been reviewed elsewhere (115).

Fed State and Starvation

Following a carbohydrate meal or insulin administration, glucose derived from the circulation is the principal oxidative fuel of muscle (116). During early starvation, however, it is placed in this role by fatty acids (116,117) (Fig. 8.12B). As noted earlier, this transition to lipid fuels conserves glucose for use by the

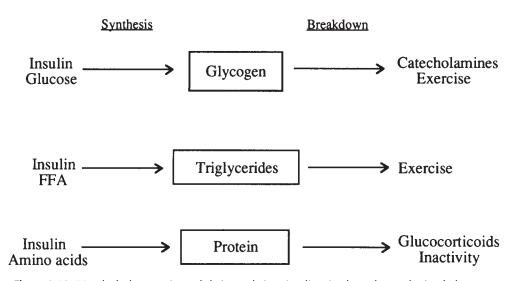

Figure 8.14. Muscle fuel reservoirs and their regulation. Insulin stimulates the synthesis of glycogen, triglycerides, and protein. The breakdown of glycogen and triglycerides is stimulated by catecholamines and by exercise. The breakdown of protein is enhanced by glucocorticoids and inactivity. FFA, free fatty acids.

138 JOSLIN'S DIABETES MELLITUS

brain and conserves protein by reducing the need for gluconeogenesis. The precise mechanism by which these events are modulated has not been resolved but is almost certainly related initially to a decrease in circulating levels of insulin to values lower than those in the fed state. Among the changes attributable to the decreased levels of insulin during starvation are (a) diminished glucose transport into muscle; (b) higher plasma levels of FFA; (c) inhibition of pyruvate dehydrogenase in muscle, resulting in a decrease in glucose oxidation and an increase in release of lactate and pyruvate and, secondarily, of alanine; and (d) decreased levels of malonyl-CoA, an inhibitor of carnitine palmitoyltransferase I (CPTI, also referred to as CAT1), which controls the oxidation of fatty acids in muscle and other tissues by regulating the transport of long-chain fatty acyl CoA into the mitochondria (Fig. 8.9). Recent studies have demonstrated that the concentration of malonyl-CoA increases substantially after 1 to 2 hours of refeeding following a fast and that this correlates closely with a decrease in fatty acid oxidation (119).

Another group of fuels used by muscle during starvation is the ketone bodies. Acetoacetate and β -hydroxybutyrate are oxidized by muscle more or less as a function of their concentration in plasma. In rats starved for 48 hours (120) and in humans starved for 1 to 2 weeks (121), the metabolism of these ketone bodies may account for upwards of 70% of the oxygen consumed by muscle. A role for insulin in regulating the utilization of ketone bodies by muscle has been suggested by studies in rats (122) and humans (123,124).

Exercise and Adenosine Monophosphate–Activated Protein Kinase

Exercise can increase oxygen consumption by muscle in excess of 10-fold and, depending on its intensity and duration, may increase both fatty acid and glucose oxidation. It has long been appreciated that the increase in glucose oxidation is the result of increases in glucose transport, glycogenolysis, glycolysis, activation of pyruvate dehydrogenase, and changes in intracellular Ca²⁺ and adenine nucleotides. Recent studies have linked the increase in fatty acid oxidation, at least in part, to activation of an AMP-activated protein kinase (AMPK). Studies in humans and experimental animals have shown that the activity of AMPK is increased within seconds or minutes of the onset of exercise (muscle contraction) and that the activated AMPK phosphorylates acetyl-CoA carboxylase (125,126), which it inhibits, and malonyl-CoA decarboxylase, which it activates (127), leading to a decrease in malonyl-CoA. Abundant evidence suggests that this results in an increase in fatty acid oxidation. It is interesting that treatment with a cell-permeable AMPK-activator, AICAR, also activates glucose transport in the muscle cell, and when administered in vivo for several days or longer, increases the expression of the GLUT4, hexokinase 1 and 2, and several mitochondrial enzymes. In other words, it mimics many (although not all) of the effects of exercise, suggesting that activation of AMPK may be an integral component of both the acute- and long-term response of the muscle cell during physical activity. Interestingly, it has recently been shown that the action of the antidiabetic drug metformin (127a) and the adipocyte hormone adiponectin (127b,c) might be mediated by AMPK.

Liver

The liver is the key regulatory site of glucose homeostasis. Blood glucose levels are maintained in a narrow range in great measure because the liver is able to take up glucose in the fed state and to release it in varying amounts into the circulation during starvation, exercise, and other situations in which the ratio of insulin to counterinsulin factors is decreased (Fig. 8.14). Although the liver does not play a key role in determining the rate at which FFAs enter the circulation, it does appear to play a major role in the disposition of FFAs. Thus, the liver can oxidize FFAs for its own energy needs or production of ketone bodies or it can utilize FFAs for the synthesis of triglycerides and phospholipids, which it can export as constituents of verylow-density lipoprotein (VLDL).

FED STATE

High levels of circulating insulin and decreased levels of glucagon, such as occur after a carbohydrate meal, stimulate glycogen synthase and inhibit glycogen phosphorylase in the liver (18,128). These changes in insulin and glucagon also inhibit hepatic gluconeogenesis (25,26,129). However, gluconeogenesis does not appear to cease immediately but may continue for several hours after the termination of a fast with a meal. This persistence of gluconeogenesis after a meal may allow hepatic glycogen synthesis to continue when glucose absorption by the gut is no longer in excess of the needs of other organs. According to this glucose paradox hypothesis (130), dietary glucose is metabolized initially to pyruvate or lactate in peripheral cells; the liver then takes up these gluconeogenic precursors and resynthesizes glucose-6-phosphate, which can be used to synthesize glycogen. Studies in humans suggest that glucose is incorporated into glycogen by this indirect route as well as by the classical direct pathway (131,132). Studies using ¹³C nuclear magnetic resonance (NMR) spectroscopy suggest that glucose conversion to glycogen via the direct pathway predominates immediately after a standard meal (132).

STARVATION

As starvation proceeds through its different phases (Fig. 8.2), the liver releases fuels into the circulation by three distinct processes: glycogenolysis, gluconeogenesis, and ketone body formation. The breakdown of glycogen in the liver is essentially regulated by insulin and counterinsulin hormones in a manner analogous to that in skeletal muscle (128). A major difference between the two tissues, as previously stated, is that liver can generate free glucose, which is released into the circulation, because of the presence of glucose-6-phosphatase. Another difference is that a primary stimulus of hepatic glycogenolysis is glucagon, which does not act on muscle.

Binding of glucagon to its receptor activates adenylyl cyclase in liver, producing cAMP from ATP (133). Besides initiating glycogenolysis, an increase in liver cAMP suppresses glycogen synthesis and increases gluconeogenesis (4,22,128,133). As noted earlier, liver glycogenolysis is critical in meeting the body's energy requirements in the early stages of starvation. Between one third and two thirds of the glucose released by the liver after an overnight fast is derived from hepatic glycogen (23). Several inherited metabolic disorders of glycogen storage or breakdown have been described. These include von Gierke disease (type I glycogen storage disease), in which glucose-6phosphatase is deficient and the liver cannot release free glucose into the circulation; Hers disease (type VI glycogen storage disease), in which liver glycogen phosphorylase is absent; and Cori disease (type III glycogen storage disease), in which the debranching enzyme that hydrolyzes the 1,6 linkage of the glycogen molecule is absent (134).

GLUCONEOGENESIS

In humans, the maintenance of euglycemia during starvation depends on the ability of the liver to synthesize glucose from nonhexose precursors (i.e., gluconeogenesis) (Table 8.4 and Fig. 8.15). The molecular mechanisms regulating gluconeogenesis (22,129,135) and the disorders of this pathway in humans have been reviewed elsewhere (13,34,129). Gluconeogenesis uses

8: HORMONE–FUEL INTERRELATIONSHIPS: FED STATE, STARVATION, AND DIABETES MELLITUS 139

many of the enzymes involved in glycolysis but requires unique enzymes to circumvent the reactions catalyzed by glucokinase, phosphofructokinase, and pyruvate kinase (Fig. 8.15). As with glycogenolysis, glucagon is a major positive hormonal modulator of gluconeogenesis and insulin is the primary inhibitor. Catecholamines also stimulate gluconeogenesis and may be the principal positive regulator in some patients with long-standing type 1 diabetes in whom glucagon secretion is impaired (7). Glucocorticoids appear to play an important permissive role, since the stimulation of gluconeogenesis by glucagon and catecholamines is diminished in their absence (17).

FORMATION OF KETONE BODIES

Synthesis of ketone bodies occurs almost exclusively within the liver. Mitochondrial acetyl-CoA produced from oxidation of fatty acids either can combine with oxaloacetate and enter the tricarboxylic acid (TCA) cycle or can be used for the synthesis of acetoacetate and β -hydroxybutyrate within the mitochondrion (22,135–138). When rates of FFA–CoA uptake by mitochondria are high, much of the energy needs of the liver are generated by their β -oxidation to acetyl-CoA. Under these conditions, acetyl-CoA preferentially enters the pathway for ketone-body formation and its oxidation in the TCA cycle is diminished (Fig. 8.9). The high ratio of glucagon to insulin and the increase in intrahepatic fatty acids during prolonged starvation stimulate the enzyme CPTI, which is located within the outer leaflet of the inner mitochondrial membrane (Fig. 8.9) (137,138) and is rate-limiting for fatty acid oxidation.

INTERRELATIONS BETWEEN FATTY ACID AND GLUCOSE METABOLISM AND INSULIN RESISTANCE

Glucose in the presence of insulin inhibits the oxidation of fatty acids in muscle, liver, the pancreatic β -cell, and undoubtedly

other tissues. Conversely, elevated levels of fatty acids can inhibit the oxidation of glucose. From a functional perspective, such increases in plasma levels of FFA have been linked to events such as the stimulation of hepatic gluconeogenesis and ketogenesis and the maintenance of the low but finite rate of insulin secretion during starvation. The notion that high plasma levels of FFA could also contribute to the insulin resistance (defined as a decrease in the biologic effect of the hormone) in diabetes and obesity was initially given credibility by the studies of Randle et al. (139,140) that led them to propose the existence of a glucose-fatty acid cycle. The Randle mechanism was worked out in a preparation of isolated perfused rat heart, and although it has been difficult to apply it to other tissues, recent studies have strongly suggested a link between abnormalities in fatty acid metabolism and insulin resistance. Thus, the administration of lipids to prevent decreases in plasma FFA levels during an infusion of insulin and glucose (euglycemic-hyperinsulinemic clamp) has been shown to diminish the ability of insulin to increase glucose uptake by muscle and to diminish its production by liver in humans and experimental animals (141,142). Likewise, a close association between insulin resistance (assessed by the clamp procedure) and intramuscular triglycerides, quantified by NMR imagery, has been reported by several groups (113,114). Concurrently, studies in rodents have found that insulin resistance in skeletal muscle in a wide variety of conditions is characteristically associated with increases in the concentrations of malonyl-CoA, long-chain fatty acyl-CoA, diacylglycerol, and triglycerides and alterations in the distribution and activation of certain protein kinase C isoforms (143). Figure 8.16 depicts how increases in PKC activity and other factors linked to insulin resistance (see Chapter 24) might arise in this setting. The possible linkage of this or a similar mechanism to obesity and to the disordered function and metabolism of other tissues in individuals with type 2 diabetes and obesity has been discussed elsewhere (144). An attractive feature of this mechanism is that it could explain why exercise, acting through AMPK, could attenuate insulin resistance and exert effects on multiple tissues.

TYPE 1 DIABETES MELLITUS

The hormone-fuel interrelationships described in healthy humans are abnormal in patients with untreated type 1 diabetes because of the lack of insulin. The precise manifestations of this lack depend on its severity. During the period before the onset of overt type 1 diabetes and during the "honeymoon" phase following its diagnosis, patients may have sufficiently high plasma levels of insulin to maintain a normal fasting concentration of glucose (145,146). Hyperglycemia may be manifest only postprandially, when higher rates of insulin secretion are required to maintain euglycemia. As β-cell destruction progresses, plasma insulin levels fall even during the fasted state, hepatic glucose production increases, and the patient requires insulin therapy (146,147). With more severe insulin deficiency, plasma FFA levels increase in response to enhanced lipolysis, and plasma triglyceride levels may increase because of a decrease in lipoprotein lipase activity (see discussion of lipoprotein lipase in the section titled "Adipose Tissue").

The most extreme form of poorly controlled type 1 diabetes is diabetic ketoacidosis (see Chapter 53). Here the deficiency of insulin and/or the increase in counterinsulin hormones are sufficiently severe to increase glycogen, protein, and lipid catabolism well beyond the fuel needs of the patient. Furthermore, the ability of peripheral tissues to utilize glucose and ketone bodies is impaired and large quantities of these fuels are lost in the

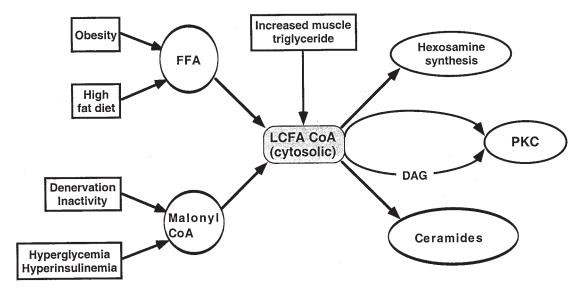

Figure 8.16. Hypothetical interrelations between concentration of cytosolic long-chain fatty acid (LCFA)–coenzyme A (CoA) and development of insulin resistance in muscle. According to this scheme, free fatty acids (FFAs) increase the concentration of LCFA-CoA by mass action and hyperglycemia (in the presence of insulin) by generating malonyl-CoA, which inhibits entrance of LCFA-CoA into mitochondria. By generating α -glycerophosphate, hyperglycemia will also increase fatty acid esterification. Insulin resistance could result from effects on diacylglycerol (DAG)–protein kinase C (PKC) signaling, ceramide synthesis, and so forth. See text for details.

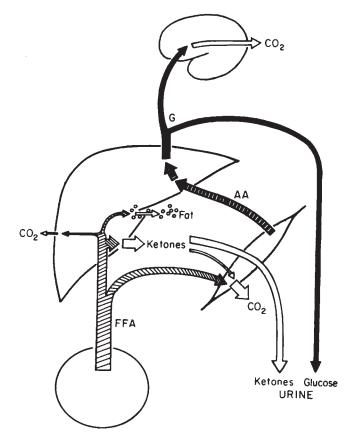

Figure 8.17. Diabetic ketoacidosis. Restraint on catabolism by insulin is lost, and lipolysis, ketogenesis, gluconeogenesis, and protein catabolism are enhanced. In addition, the utilization of ketone bodies and glucose by muscle is impaired. Studies in experimental animals suggest that ketone bodies may be used as a fuel for the brain in this state. G, glucose; AA, amino acids; FFA, free fatty acids.

urine. Some of the metabolic differences between diabetic ketoacidosis and prolonged starvation, in which plasma levels of FFA and ketone bodies are also elevated, are illustrated in Fig. 8.17.

TYPE 2 DIABETES MELLITUS

Whereas the metabolic derangements in type 1 diabetes are readily explained by a lack of insulin, the basis for the metabolic abnormalities in type 2 diabetes is less clear. Nonetheless, type 2 diabetes can be separated into stages according to hormone-fuel interrelationships (Fig. 8.18). An increasing body of evidence suggests that an early abnormality in this disorder is hyperinsulinemia, which is associated with insulin resistance (148-150). Initially, these patients are similar to obese nondiabetic adults, in that they are hyperinsulinemic but usually have normal or near-normal glucose tolerance (Fig. 8.18). In addition, they frequently have higher-than-normal plasma triglyceride levels and elevated blood pressure. Some of them have an upper body (android) pattern of fat distribution with increased intraabdominal fat even if they are not grossly obese (151,152). Current thinking holds that such individuals go on to develop overt type 2 diabetes, hypertension, certain dyslipidemias, and premature atherosclerotic vascular disease, singly or in combination, depending on their genetic makeup and environmental factors such as diet and physical activity (153-155). The insulinresistant state that antedates these disorders has been referred to as metabolic obesity, the metabolic syndrome, or syndrome X (153)

Type 2 diabetes appears to develop in patients with acquired (diet- or obesity-related) and genetically programmed insulin resistance when the pancreatic β -cells are no longer able to produce enough extra insulin to maintain normoglycemia (155). Changes in plasma insulin and glucose in type 2 diabetes can be depicted, on the basis of published data (148–150), as occurring

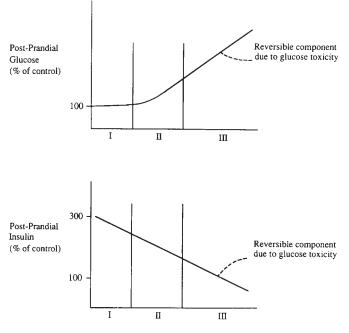

Figure 8.18. Hypothetical changes in postprandial glucose and insulin levels during the evolution of type 2 diabetes mellitus.

in three phases (Fig. 8.18). In phase I, glucose levels are normal but only because hyperinsulinemia compensates for the insulin resistance in muscle, liver, and possibly other tissues. In phase II, insulin levels are somewhat diminished but are generally still higher than those in individuals of normal weight who are not diabetic. On the other hand, the insulin levels in phase II are no longer sufficient to enhance glucose utilization by muscle and/or to restrict hepatic glucose production, and postprandial glucose levels are increased as a result. Finally, in phase III, plasma insulin levels fall even further and overt hyperglycemia occurs both in the fed and fasted states. The inability of the β cell to secrete insulin at a higher rate indefinitely may therefore determine those who ultimately develop type 2 diabetes. Conversely, the ability of some individuals to maintain hyperinsulinemia might distinguish those who will remain euglycemic and obese. One would predict from this paradigm that therapies designed to diminish insulin resistance and lessen the stress on the β -cell (i.e., diet and regular exercise and insulinsensitizing drugs) would prevent or at least retard the development of type 2 diabetes (156,157). Thus, it is noteworthy that a lower incidence of progression from impaired glucose tolerance to overt diabetes has recently been reported in individuals undergoing lifestyle modification programs consisting of diet and exercise (158,159) or treatment with metformin (159a). For a more complete discussion of the pathogenesis of type 2 diabetes, see Chapters 24 and 25.

Although the paradigm shown in Figure 8.18 may serve as a model for type 2 diabetes, it provides no insight into either its etiology or its development. Attempts have been made to identify the initial site of insulin resistance. When evaluated with the euglycemic insulin clamp technique, which measures glucose disposal during a continuous infusion of insulin (160), patients with both type 2 diabetes and obesity have been shown to have a significant defect in glucose uptake in skeletal muscle (158), a decrease in glycogen synthesis by muscle (160,161), and an increase in lactate production (161). A decrease in glycogen content has also been observed in skeletal muscle of some patients with type 2 diabetes (162). Some studies suggest that a

primary event may be an impairment in the activation of glycogen synthase by insulin in skeletal muscle (163–166). However, investigations in which NMR spectroscopy was used indicate that levels of glucose-6-phosphate and free glucose in muscle are lower in patients with type 2 diabetes than in nondiabetic control subjects during a hyperglycemic–hyperinsulinemic clamp (167), suggesting that a defect in glucose uptake in these individuals is at the level of glucose transport. Yet another metabolic change in muscle in patients with type 2 diabetes is a decrease in pyruvate dehydrogenase activity (168). This presumably contributes to the decrease in glucose oxidation and the increase in muscle lactate release in these individuals. Thus, the mechanisms responsible for the initial insulin resistance in muscle, liver, and adipose tissue and the defect in insulin secretion remain to be absolutely identified.

In addition to the initial site of insulin resistance, the factors that worsen insulin sensitivity and promote transition from one phase to another are not well known. Hyperglycemia may worsen insulin resistance, a phenomenon termed glucose toxicity (169, 170). Persistent hyperglycemia has been shown to inhibit both insulin-stimulated glucose transport and glycogen synthesis in muscle and glucose-mediated insulin secretion (171, 172). In partially pancreatectomized and other rats with hyperglycemia and insulin resistance, increases in insulin sensitivity and the amount of GLUT4 have been shown to occur when the glucose level was made to fall by increasing glycosuria (171, 172). Glycosuria was increased with the use of phloridzin, an inhibitor of renal tubular glucose transport.

Rather than a single specific aberration, type 2 diabetes may prove to be the result of multiple defects in insulin action and insulin secretion. In addition, type 2 diabetes in obese patients may not be due to the same underlying processes as in nonobese patients. In these two groups of patients, the contributions of fasting hyperglycemia (usually attributed to increased hepatic glucose production) and postprandial increases in glucose concentration may also be different. In addition, the abnormalities present in the early stages of type 2 diabetes when blood glucose levels are minimally elevated may not correlate with the factors that perpetuate and worsen the hyperglycemia as time progresses. Interpretation of published studies of fuel homeostasis in patients with type 2 diabetes has been made difficult by the variations in the severity and duration of the diabetes and the unknown impairment of insulin sensitivity. Studies yielding conflicting results may ultimately be reconciled once the magnitude of insulin resistance and impaired insulin secretion has been considered.

A UNIFYING HYPOTHESIS OF TYPE 2 DIABETES 163

More than 18 million people in the United States have diabetes mellitus, and about 90% of these have the type 2 form of the disease. In addition, between 17 and 40 million people have insulin resistance, impaired glucose tolerance, or the cluster of abnormalities referred to variably as the metabolic syndrome, the dysmetabolic syndrome, syndrome X, or the insulin resistance syndrome (1). In all of these disorders, a central component of the pathophysiology is insulin resistance, i.e., reduced responsiveness to insulin in tissues such as muscle, fat, and liver. In

type 2 diabetes, the β -cell can no longer secrete sufficient insulin to compensate for insulin resistance, leading to relative insulin deficiency. Insulin resistance is also closely linked to other common health problems, including obesity, polycystic ovarian disease, hyperlipidemia, hypertension, and atherosclerosis. In this chapter, we will attempt to dissect the complexity of the molecular mechanisms of insulin action with a special emphasis on those features of the system that are subject to alteration in type 2 diabetes and other insulin-resistant states.

GLUCOSE HOMEOSTASIS AND INSULIN RESISTANCE

Despite periods of feeding and fasting, in healthy individuals plasma glucose remains in a narrow range between 4 and 7 mM (70 to 120 mg/dL). This tight control of glucose concentration is determined by a balance between glucose absorption from the intestine, glucose production by the liver, and glucose uptake from the plasma (reviewed in detail in Chapters 8, 13 to 16, 24) (Fig. 9.1). In tissues such as muscle, fat, and liver, glucose uptake and/or storage is regulated by insulin, whereas insulin has no apparent role in stimulating glucose metabolism in tissues such as brain, kidney, and erythrocytes. In addition to promoting glucose utilization, insulin inhibits both basal and glucagon-stimulated hepatic glucose production, thus serving as the primary regulator of blood glucose concentration during fasting. Insulin also has a general anabolic role promoting the storage of substrates in fat, liver, and muscle by stimulating lipogenesis and glycogen and protein synthesis; inhibiting lipolysis, glycogenolysis and protein breakdown; and stimulating cell growth and differentiation. In type 1 diabetes, the autoimmune destruction of the pancreatic β -cell leads to severe insulin deficiency with unrestrained hepatic glucose output, unrestrained lipolysis, and increased ketogenesis. In type 2 diabetes, insulin resistance in muscle, adipose tissue, and liver combined with a relative failure of the β -cell leads to increased glucose levels and a variable cluster of metabolic alterations in lipid and protein metabolism. Insulin resistance in patients with type 2 diabetes is usually defined by defects in insulinstimulated glucose transport, glycogen synthesis, and glucose oxidation, but other pathways of metabolism are clearly

altered. The most characteristic feature of the β -cell failure is a specific defect in glucose sensing characterized by loss of firstphase insulin secretion in response to a glucose stimulus, while response to other secretagogues is normal or only mildly depressed.

The control of blood glucose depends upon the balance between glucose production by the liver and glucose utilization by insulin-dependent tissues, such as muscle and fat, and insulin-independent tissues, such as the brain. In mammals, up to 75% of insulin-dependent glucose disposal occurs in skeletal muscle (2-6). This preeminence of muscle, however, has recently been challenged by the finding that mice with a muscle-specific knockout of the insulin receptor exhibit minimal abnormalities in glucose tolerance (7). Adipose tissue accounts for only a small fraction (5% to 15%) of insulin-stimulated glucose disposal. Despite this, knockout of the insulin-sensitive glucose transporter in fat leads to impaired glucose tolerance, apparently by inducing insulin resistance in muscle and liver through a yet undetermined mechanism (see the section Lessons from Knockout Mice about Insulin Action and Insulin Resistance below). Adipose tissue also plays a special additional role in glucose homeostasis through its release of free fatty acids, tumor necrosis factor- α (TNF- α) leptin, Acrp30/adiponectin, and other adipokines that have been shown to contribute to insulin action and insulin resistance (8-12). Furthermore, both obesity (increased fat mass) and lipoatrophy (decreased fat mass) cause insulin resistance and predisposition to type 2 diabetes (13–16).

The liver does not exhibit insulin-stimulated glucose uptake but plays a major role in glucose homeostasis, especially in the fasting state (17). When insulin levels are low, the liver releases glucose into the blood as a result of glycogenolysis

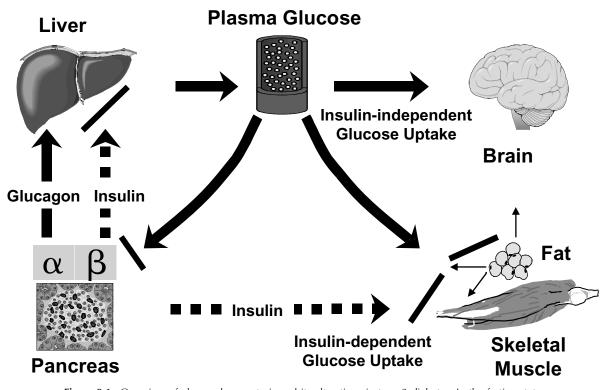

Figure 9.1. Overview of glucose homeostasis and its alterations in type 2 diabetes. In the fasting state, glucose is produced by the liver and utilized by insulin-independent tissues, such as the brain, and insulin-dependent tissues, such as fat and muscle. The balance of glucose production and utilization is controlled by many hormones, but the most important is insulin. In type 2 diabetes, there is insulin resistance in muscle, fat, and liver and relative insulin deficiency.

and gluconeogenesis, providing substrate for tissues with obligate glucose requirements. In the fed state, when insulin levels are high, glucose in the liver is converted to glycogen. Recent studies using knockout and other technologies suggest that insulin action in other tissues, including brain and β -cells, although not major sites of insulin-stimulated glucose uptake, may also play important roles in glucose homeostasis and metabolism (18,19) (see below).

PROXIMAL SIGNALING PATHWAYS

The Insulin Receptor and Its Substrates

The insulin receptor is a tetrameric protein consisting of two α subunits and two β -subunits that belongs to a subfamily of receptor tyrosine kinases that also includes the insulin-like growth factor-1 (IGF-1) receptor and an orphan receptor called the insulin receptor–related receptor (IRR) (20,21) (Fig. 9.2). Each of these receptors is the product of a separate gene in which the two subunits are derived from a single-chain precursor or proreceptor that is processed by a furin-like enzyme to give a single α - β subunit complex (22,23). Two of the α - β dimers then undergo disulfide linkage to form the tetramer.

The insulin receptor is widely distributed throughout the body, including in tissues classically regarded as "responsive" and "nonresponsive" to insulin. Recent studies suggest that the receptor in most of these tissues has an important functional role, but in some cases this may relate to actions other than the control of glucose or lipid homeostasis. For example, in ovarian granulosa cells, insulin signaling is coupled to regulation of estrogen/androgen balance (24), whereas the role of the insulin receptor in the endothelial cell may be to promote vasodilatation (25,26) or transcytosis of the insulin molecule from the intravascular space to the interstitial space and its target tissues (27–30); in neural or endocrine cells, insulin may have a role regulating hormone production, secretory function, or signal sensing (see below).

Functionally, the insulin receptor behaves as a classical allosteric enzyme in which the α -subunit inhibits the tyrosine kinase activity intrinsic to the β -subunit. Insulin binding to the α -subunit, or removal of the α -subunit by proteolysis or genetic deletion, leads to a derepression, i.e., activation, of the kinase activity in the β -subunit. Following this initial activation, there is transphosphorylation of the β -subunits, i.e., one subunit phosphorylates the other, leading to a conformational change and a further increase in activity of the kinase domain (31,32). The $\alpha\text{-}\beta$ heterodimers of the insulin, IGF-1, and the IRR receptiontors can form functional hybrids in which occupancy of one receptor's binding domain leads to activation of the other receptor in the heterodimer by this transphosphorylation process. Likewise, a dominant-negative form of one of these receptor subtypes can inhibit the activity of the other receptors by forming heterodimers (33). This may explain in part why individuals with mutations in the insulin receptor exhibit both insulin resistance and growth retardation (33).

The insulin/IGF-1 signaling system is evolutionarily very ancient. Homologues of the insulin/IGF-1 receptor have been identified in *Drosophila*, *Caenorhabditis elegans*, and even metazoan marine sponges of the phylum Porifera that date back over 500 million years (34). In the lower organisms, this system uses many of the same downstream signals used in mammalian cells, i.e., phosphatidylinositol 3-kinase (PI 3-kinase)/ Akt/forkhead transcription factors, and may also be involved

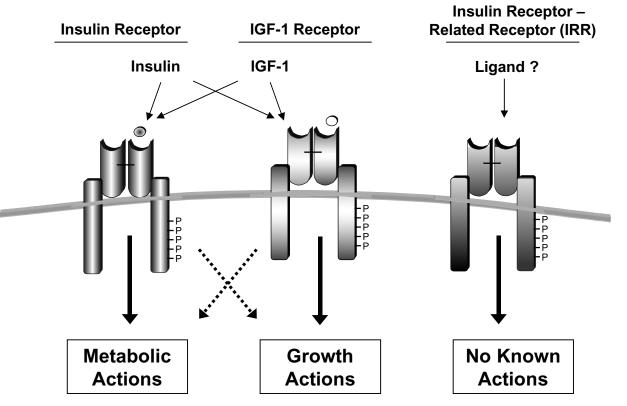

Figure 9.2. The insulin-receptor family, which includes the insulin receptor, the insulin-like growth factor-1 (IGF-1) receptor, and the insulin receptor–related receptor.

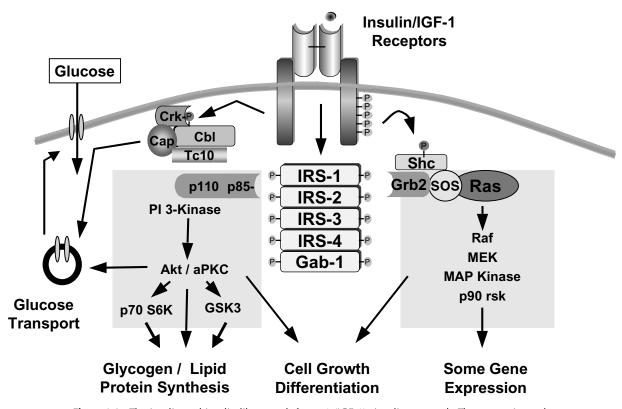

Figure 9.3. The insulin and insulin-like growth factor-1 (IGF-1) signaling network. The two major pathways are the phosphatidylinositol 3-kinase (PI 3-kinase) pathway and the Ras-mitogen-activated protein (MAP) kinase pathway. The PI-3 pathway is the major pathway leading to the metabolic actions of insulin.

in regulation of metabolism (35,36). In *Drosophila*, the insulinsecreting cells are neurons. Ablation of these cells results in changes in the major circulating carbohydrate in flies, trehelose (37). In *C. elegans*, a major effect of the insulin/IGF system is on aging, such that animals with mutations of the receptor that reduce insulin action live much longer than normal animals, whereas mutations in other parts of the pathway may reverse this longevity (38). It is interesting that chronic food restriction and leanness, which are associated with lower circulating insulin levels, increase longevity in rodents (39). This raises a number of interesting questions about the association of hyperinsulinemia and insulin resistance with conditions that shorten life span in humans, such as obesity, diabetes, and accelerated atherosclerosis.

At least nine intracellular substrates of the insulin and IGF-1 receptor tyrosine kinases have been identified (Figs. 9.3 and 9.4). Four of these belong to the family of insulin/IGF-1 receptor substrate (IRS) proteins (40-44). These IRS proteins are characterized by the presence of both pleckstrin homology (PH) and phosphotyrosine binding (PTB) domains near the N-terminus that account for the high affinity of these substrates for the insulin receptor and up to 20 potential tyrosine phosphorylation sites spread throughout the center and C-terminal region of the molecule. The molecular mass of IRS proteins ranges from 60 to 180 kDa. IRS-1 and IRS-2 are widely distributed, whereas IRS-3 and IRS-4 have more limited distributions. IRS-3 is most abundant in adipocytes, and its mRNA is also detected in liver, heart, lung, brain, and kidney (43,45-47). In contrast, the levels of mRNA for IRS-4 are very low, but are detectable, in fibroblasts, embryonic tissues, skeletal muscle, liver, heart, hypothalamus, and kidney (44). Interestingly, in humans the IRS-3 gene appears to be nonfunctional, leaving only IRS-1, -2, and -4 (48). Other direct substrates of the insulin/IGF-1 receptor kinases include Gab-1 (49), p62^{dok} (50), Cbl (51), and the various isoforms of Shc (52,53). Following insulin stimulation, the receptor directly phosphorylates most of these substrates on multiple tyrosine residues. The phosphorylated tyrosines in each of these substrates occur in specific sequence motifs and once phosphorylated serve as "docking sites" for intracellular molecules that contain SH2 (Src-homology 2) domains (44,54). Thus, the insulin-receptor substrates function as key intermediates in insulin-signal transduction.

The SH2 proteins that bind to phosphorylated IRS proteins fall into two major categories. The best studied are adapter molecules, such as the regulatory subunit of PI 3-kinase or the molecule Grb2, which associates with SOS to activate the Ras-mitogen-activated protein (MAP) kinase pathway (54–57). The other major category of proteins that bind to IRS proteins are enzymes, such as the phosphotyrosine phosphatase SHP2 (58,59) and cytoplasmic tyrosine kinases, such as Fyn. A few proteins that bind to phosphotyrosines in the IRS proteins do not contain known SH2 domains; these include the calcium adenosine triphosphatases (ATPases) SERCA 1 and 2 and the SV40 large T antigen (60,61). These pathways are discussed in more detail on page 153.

IRS proteins also undergo serine phosphorylation in response to insulin and other stimuli. In general, serine phosphorylation appears to act as a negative regulator of insulin signaling by decreasing tyrosine phosphorylation of IRS proteins, as well as by promoting interaction with 14-3-3 proteins (62). A number of different intracellular enzymes have been suggested as being involved in this serine phosphorylation, including

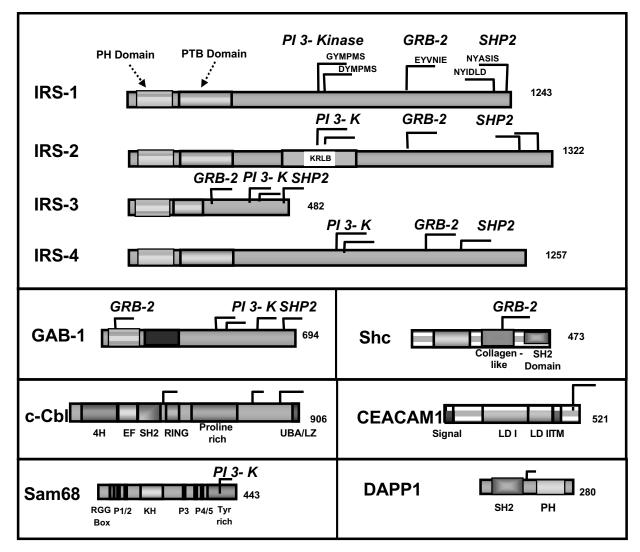

Figure 9.4. The family of insulin-receptor substrates (IRS). The functional domains and major tyrosine phosphorylation sites of each protein are indicated. PH, pleckstrin homology; PTB, phosphotyrosine; PI 3-kinase, phosphatidylinositol 3-kinase.

some in the insulin-signaling pathway, such as Akt (63), JNK kinase (64), and PI 3-kinase (which also has serine kinase activity) (65), thereby providing a form of autoinhibition of signaling, and others that mediate the effects of some inhibitors of insulin action, such as the inhibitor kappa B kinase β (IKK β) (66,67).

Although the IRS proteins are highly homologous and possess many similar tyrosine phosphorylation motifs, recent studies in knockout mice and knockout cell lines suggest that the various IRS proteins serve complementary rather than redundant roles in insulin and IGF-1 signaling (Fig. 9.5). The IRS-1 knockout mouse exhibits IGF-1 resistance as manifested by prenatal and postnatal growth retardation, as well as insulin resistance, primarily in muscle and fat, resulting in impaired glucose tolerance (68-70). IRS-2 knockout mice also exhibit insulin resistance, but primarily in the liver, and have defects in growth in only selected tissues of the body, including certain regions of the brain, β -cells, and retinal cells (71,72). Likewise at the cellular level, IRS-1 knockout preadipocytes exhibit defects in differentiation (73,74), whereas IRS-2 knockout preadipocytes differentiate normally but fail to respond to insulin-stimulated glucose transport (75).

The β-cell compensatory responses of the IRS knockout mice also differ. In the IRS-1 knockout, although there is some element of β -cell dysfunction, there is sufficient islet hyperplasia such that the animals develop only mildly impaired glucose tolerance. In the IRS-2 knockout mouse, there is a decrease in islet mass due to altered β -cell development. The combination of multifactorial insulin resistance and decreased β-cell mass leads to the development of early-onset diabetes in IRS-2^{-/-} mice (71), although the frequency of this phenotype varies considerably in different laboratories (72). By contrast, IRS-3 knockout mice have normal growth and metabolism, whereas IRS-4 knockout mice exhibit only minimal abnormalities in glucose tolerance (76,77). It is interesting that when IRS-1-deficient mice are crossed with IRS-3-deficient mice to produce a double knockout, the resultant animals exhibit severe hyperglycemia and marked lipoatrophy, indicating that, at least in adipocytes, there is at least some compensation of these two substrates (78).

The differential roles of the IRS proteins may be due to differences in tissue distribution, subcellular localization, and intrinsic activity of the proteins. IRS-1 and IRS-2 are widely distributed, whereas IRS-3 is limited largely to the adipocyte and brain and IRS-4 is expressed primarily in embryonic tissues or

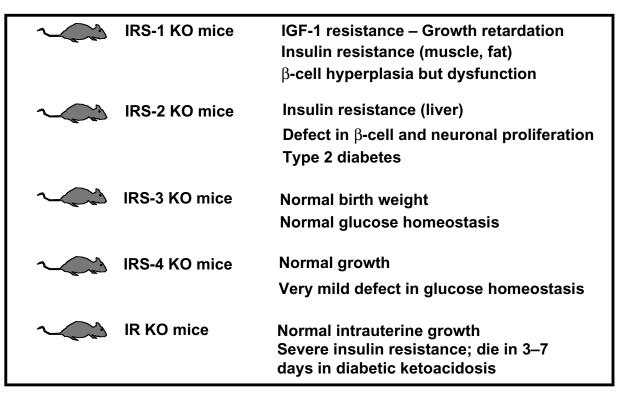

Figure 9.5. Phenotypes of the insulin receptor (IR) and insulin receptor substrate (IRS) knockout (KO) mice. IGF-1, insulin-like growth factor-1.

cell lines (see above). Furthermore, IRS-1 is more closely associated with low-density microsomes, whereas IRS-2 is found in low-density microsomes and in the cytosol (79). IRS-3 is associated more with the plasma-membrane fraction in rat adipocytes (80). In some studies, IRS-1 and IRS-3 appear to translocate to the nucleus (81,82), and IRS-3 has been suggested to possess DNA-binding activity (82).

Turning off the Insulin Signal

Unlike the prolonged actions of steroid and thyroid hormones, insulin action on glucose homeostasis demands a rapid on-andoff response to avoid the dangers of hypoglycemia. Several different mechanisms play a role in turning off the insulin signal (Fig. 9.6). First, insulin may simply dissociate from the receptor and be degraded. Following dissociation of the ligand, phosphorylation of the insulin receptor and its substrates is rapidly reversed by the action of protein tyrosine phosphatases (PTPases). Several PTPases have been identified that are capable of catalyzing dephosphorylation of the insulin receptor in vitro or in vivo, and some are even upregulated in insulinresistant states (83-86). Most attention has focused on the cytoplasmic phosphatase PTP-1b. Disruption of the gene encoding this enzyme in mice produces increased insulin-dependent tyrosine phosphorylation of the insulin receptor and IRS proteins in muscle and leads to a state of improved insulin sensitivity (87). PTP-1b knockout mice are also resistant to diet-induced obesity, suggesting an effect of PTP-1b deletion in the brain, with subsequent changes in energy uptake and expenditure. This is opposite the effect of knockout of insulin receptor in the brain (18) (see page 163).

Several other mechanisms may also be involved in turning off the insulin signal in normal or pathologic states. The insulin receptor itself may be internalized and undergo degradation (88,89). As noted above, serine phosphorylation of the insulin receptor and its substrates also inhibits insulin action (90,91). Finally, the phosphorylated receptor may interact with proteins in the cell that block insulin action. This latter mechanism has recently been observed for the SOCS (suppressors of cytokine signaling) proteins in the case of the insulin resistance associated with inflammation and obesity (92).

Phosphatidylinositol 3-Kinase and Downstream Targets

The first SH2 domain protein identified as interacting with IRS-1 was the regulatory subunit of the class Ia form of PI 3-kinase. This enzyme plays a pivotal role in the metabolic and mitogenic actions of insulin and IGF-1 (93,94). Thus, inhibitors of PI 3-kinase or transfection with dominant-negative constructs of the enzyme blocks virtually all of the metabolic actions of insulin, including stimulation of glucose transport, glycogen synthesis, and lipid synthesis. The enzyme itself consists of a regulatory and a catalytic subunit. Activation of the catalytic subunit depends on interaction of the two SH2 domains in the regulatory subunit with specific tyrosine-phosphorylated motifs in the IRS proteins of the sequence pYMXM and pYXXM (95,96).

At least eight isoforms of the regulatory subunits of PI 3kinase have been identified (Fig. 9.7). These are derived from three genes and alternative splicing (97–99). p85 α and p85 β represent the "full-length" versions of the regulatory subunits and contain an SH3 domain, a bcr homology domain flanked by two proline-rich domains, two SH2 domains [referred to as the Nterminal (nSH2) and C-terminal (cSH2) domains)], and an inter-SH2 (iSH2) domain containing the p110 binding region (99). The shorter versions of regulatory subunits, AS53 (also known as p55 α) (100,101) and p50 α (97,101), are splicing variants

9: MECHANISM OF INSULIN ACTION; GLUCOSE AND LIPID METABOLISM REGULATION 151

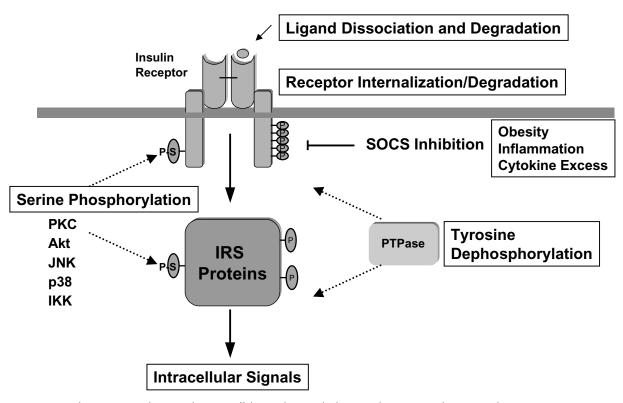

Figure 9.6. Mechanism of turning off the insulin signal. These mechanisms are also activated in a variety of acquired insulin-resistant states. SOCS, suppressors of cytokine signaling; IRS, insulin-receptor substrate; PTPase, protein tyrosine phosphatases.

derived from the same gene encoding $p85\alpha$ (*Pik3r1*) (97). They share the common nSH2-iSH2-cSH2 with p85α but lack the Nterminal half containing the SH3 domain, N-terminal prolinerich domain, and bcr domain and in its place have unique Nterminal sequences consisting of 34 amino acids and 6 amino acids, respectively. Another small version of the regulatory subunit, $p55^{\tilde{P}IK}$, is very similar in structure to $p55\alpha/AS53$ but is encoded by a different gene (102). Of these isoforms, $p85\alpha$ is predominantly and ubiquitously expressed and is thought to be the major response pathway for most stimuli (94,99); however, the splice variants, $p55\alpha/AS53$ and $p50\alpha$, have high levels of potency for PI 3-kinase signaling (100,101,103) and appear to play specific roles in some selected tissues (97,100,101) or in particular states of insulin resistance (104,105). The exact role of the different regulatory subunits of PI 3-kinase in insulin action is unclear. Knockout mice with a disruption of all three isoforms of *Pik3r1* gene die within a few weeks of birth, indicating the importance of $p85\alpha$ and its spliced variants in normal growth and normal metabolism (106). By contrast, mice lacking only the full-length version of $p85\alpha$ (107) or only the shorter spliced forms (107a) can grow to adulthood and exhibit improved insulin sensitivity. One explanation for the increased sensitivity in both cases is the improved stoichiometry of insulin-signaling proteins in the cell (108). Thus, it appears that under normal conditions the concentration of regulatory subunits is in excess of that of the catalytic subunits and phosphorylated IRS proteins. This leads to the binding of free monomeric (and thus catalytically inactive) forms of regulatory subunit to phosphorylated IRS proteins and blocking of the binding of the active heterodimer. Mice with a heterozygous knockout Pik3r1 gene also have improved stoichiometry of interaction between the regulatory and catalytic subunits. This results in improved sensitivity to insulin and IGF-1 and even protects mice with genetic insulin resistance from developing diabetes (109). Likewise, cell lines derived from heterozygous *Pik3r1*-gene knockout embryos exhibit increased insulin/IGF-1 signaling (108).

The exact mechanisms by which PI 3-kinase transmits the insulin signal appear to be multiple (94,99). PI 3-kinase itself catalyzes the phosphorylation of phosphoinositides on the 3position to PI-(3)P, PI-(3,4)P₂, and PI-(3,4,5)P₃ (also known as PIP₃). These lipids bind to the PH domains of a variety of signaling molecules and alter their activity or subcellular localization. Three major classes of signaling molecules are regulated by PI 3-phosphates: the AGC superfamily of serine/threonine protein kinases; guanine nucleotide exchange proteins of the Rho family of guanosine triphosphatase (GTPase); and the TEC family of tyrosine kinases, including BTK and ITK. PI 3-kinase also activates the mTOR/FRAP pathway and activates phospholipase D, leading to hydrolysis of phosphatidylcholine and increases in phosphatidic acid (PA) and diacylglycerol (DAG). Insulin also activates the enzyme glycerol-3-phosphate acyltransferase, which increases de novo synthesis of PA and DAG by PI 3-kinase-independent mechanisms.

The best characterized pathway involves the AGC kinase known as PDK1. This enzyme is one of the two serine kinases that phosphorylate and activate the serine/threonine kinase Akt (also known as PKB). Akt/PKB is thought to play an important role in the transmission of insulin's metabolic pathways by phosphorylating glycogen synthase kinase-3 (110), and either directly or indirectly the forkhead (FOXO) transcription factors and the cyclic AMP regulatory element binding protein CREB (111–114). However, studies using inhibitors and activators of Akt have not uniformly inhibited or mimicked insulin actions (113). Part of the variability may relate to

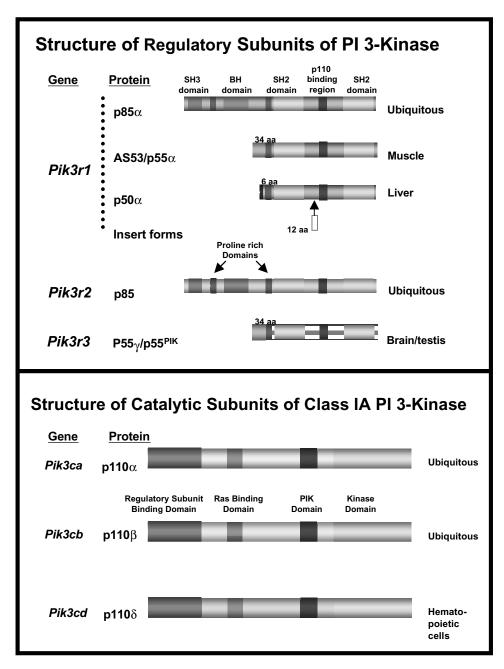

Figure 9.7. The structures of the regulatory and catalytic subunits of phosphatidylinositol 3-kinase (PI 3-kinase).

the fact that there are three isoforms of Akt/PKB (115). Although the major form, Akt1, is clearly important for cell survival and growth, recent data have suggested that Akt2 may be more important in mediating insulin action, at least in the liver (116). Other AGC kinases that are downstream of PI 3kinase are the atypical forms of protein kinase C (PKC), including PKC ζ and PKC λ . Both Akt and the atypical PKCs appear to be required for insulin-induced glucose transport (117). Stable expression of a constitutively active, membrane-bound form of Akt in 3T3L1 adipocytes results in increased glucose transport and persistent localization of GLUT4 to the plasma membrane (118). Conversely, expression of a dominant-interfering Akt mutant inhibits insulin-stimulated GLUT4 translocation. Likewise, overexpression of PKC ζ or λ results in GLUT4 translocation (119,120), whereas expression of a dominantinterfering PKC λ blocks the action of insulin (121). PKC ζ has been shown to phosphorylate IRS-1 and thus to serve as a

potential negative feedback regulator of insulin/IGF signaling (122).

It is important to keep in mind that, although less well studied, PI 3-kinase also has protein kinase activity and that both the regulatory and catalytic subunits of PI 3-kinase possess domains capable of interacting with other signaling proteins. The p85 regulatory subunits possess an SH3 domain, a bcr homology region that interacts with CDC42 and Rac, and two proline-rich regions for which the interacting partners have not yet been defined (99,123). PI 3-kinase also may interact with the PI 5'-kinase PIK-fyve (124) and some G-protein–coupled proteins (125); thus, this enzyme may contribute to insulin signaling in multiple ways.

It should be clear from the above discussion that turning off insulin signaling also involves reducing the level of PIP₃ in the cell. This is achieved through the activity of PIP₃ phosphatases, such as PTEN (126) and SHIP2 (127). PTEN dephosphorylates phosphoinositides on the 3'-position, thus lowering the level of the second messengers. SHIP2 is a 5'-phosphoinositide phosphatase. Disruption of the gene encoding this enzyme yields mice with increased insulin sensitivity (127).

The c-Cbl–Associated Protein/Cbl Pathway and Lipid Rafts

Although PI 3-kinase activity is clearly necessary for insulinstimulated glucose uptake, several lines of evidence suggest that additional signals may also be required. Indeed, other hormones or growth factors that activate PI 3-kinase, such as platelet-derived growth factor (PDGF) and interleukin-4, do not stimulate glucose transport (51). Likewise, addition of a PIP₃ analogue alone in some studies has no effect on glucose transport (128). In addition, two naturally occurring insulin-receptor mutants that appear to be fully capable of activating PI 3-kinase are unable to mediate full insulin action (129).

Recent studies have suggested that the PI 3-kinaseindependent pathway might involve the tyrosine phosphorylation of the Cbl protooncogene (51,130) (Fig. 9.3). This phosphorylation requires the presence of another protein that recruits Cbl to the insulin receptor, the adapter protein APS. In most insulin-responsive cells, Cbl is associated with the adapter protein CAP (c-Cbl-associating protein), which binds to prolinerich sequences in Cbl through its C-terminal SH3 domain (51). CAP expression correlates well with insulin responsiveness, and its expression is increased by treatment of cells with insulin-sensitizing thiazolidinediones (51). CAP belongs to a family of adapter proteins that contain a sorbin homology (SoHo) domain. This allows CAP to interact with one of the components of the lipid raft domain of the plasma membrane, a protein called flotillin. Expression of CAP mutants that cannot bind to Cbl or flotillin inhibit Cbl translocation and insulin-stimulated glucose uptake (51). The translocation of phosphorylated Cbl also recruits the adapter protein CrkII to the lipid raft, which in turn interacts with the guanyl nucleotide exchange protein C3G. C3G catalyzes the exchange of GTP for GDP on TC10, resulting in the activation of this Gprotein. TC10 has been suggested to provide the second signal to GLUT4 translocation (131), although the nature of this signal is still unclear.

The Ras–Mitogen-Activated Protein Kinase Cascade and mTOR

The second major pathway activated by insulin is the Ras-MAP kinase cascade. Following the tyrosine phosphorylation of one of the IRS proteins or the alternative substrate Shc, there is binding of the adapter protein Grb2, which in turn recruits the guanyl nucleotide exchange protein SOS to the plasma membrane, thus activating Ras (56,132). Full activation of Ras by insulin requires stimulation of the tyrosine phosphatase SHP2, which also interacts with insulin-receptor substrates such as Gab-1 and IRS1/2 (133). Once activated, Ras operates as a molecular switch, converting upstream tyrosine phosphorylations into a second serine kinase cascade, via the stepwise activation of Raf, the MAP kinase-kinase MEK, and the MAP kinases themselves, ERK1 and ERK2 (134). The MAP kinases, such as ERK1 and 2, can phosphorylate substrates in the cytoplasm or translocate into the nucleus and catalyze the phosphorylation of transcription factors, such as p62^{TCF}, initiating a transcriptional program that leads the cell to commit to a proliferative or differentiative cycle. Blockade of the Ras-MAP kinase pathway with dominant-negative mutants or pharmacologic inhibitors can prevent the stimulation of cell growth by insulin but has no

effect on any of the anabolic or metabolic actions of the hormone (134).

Yet another component of insulin signaling involved in protein synthesis/degradation and interaction with nutrient sensing is the protein kinase mTOR (mammalian target of rapamycin). mTOR is a member of the PI 3-kinase family but serves primarily as a protein kinase. Stimulation of mTOR appears to involve PI 3-kinase as well as another signal (135,136). mTOR itself helps regulate the mRNA translation via phosphorylation and activation of the p70 ribosomal S6 kinase (p70 S6 kinase), as well as the phosphorylation of the eIF-4E inhibitor, PHAS1 or 4E-BP1 (137). p70 S6 kinase phosphorylates ribosomal S6 protein, thus activating ribosome biosynthesis and increasing translation of mRNAs with a 5'-terminal oligopyrimidine tract. Phosphorylation of PHAS-1 by mTOR results in its dissociation from eIF-2, allowing cap-dependent translation of mRNAs with a highly structured 5'-untranslated region. Although the mechanism of activation of mTOR remains unclear, it appears to require the presence of amino acids and thus may also serve as a nutrient sensor (138).

REGULATION OF GLUCOSE TRANSPORT

The classical effect of insulin on glucose homeostasis is its ability to stimulate glucose transport in fat and muscle. This occurs via a translocation of GLUT4 glucose transporters from intracellular sites to the plasma membrane (Fig. 9.8). The GLUT4 protein consists of 12 transmembrane helices with a characteristic C-terminal tail containing two adjacent leucine residues commonly found in proteins that undergo regulated trafficking. In the basal state, GLUT4 continuously recycles between the cell surface and various intracellular compartments. The GLUT4 vesicle is highly specialized and appears to form from a sorting endosomal population. Insulin markedly increases the rate of GLUT4-vesicle exocytosis and slightly decreases the rate of internalization of the GLUT4 protein. Although the exact domains of the protein involved in localization and trafficking remain controversial, the C- and N-terminal tails of the protein, both of which are oriented on the cytoplasmic side of the vesicle, appear to be required (139). It is likely that the GLUT4 vesicle moves along microtubule tracks to the cell surface, perhaps via kinesin motors (140). These vesicles then fuse with the plasma membrane, allowing for the extracellular exposure of the GLUT4 protein.

Recent evidence also suggests that the actin cytoskeleton plays a critical role in insulin-stimulated GLUT4 translocation. Insulin has been shown to cause a remodeling of actin filaments just below the plasma membrane in a variety of cellular systems, with an induction of actin polymerization and membrane ruffling (141,142). This effect on ruffling is likely to reflect polymerization and depolymerization beneath the membrane, involving lamellipodia and/or filopodia formation. Actindepolymerizing agents, such as cytochalasin D and the actin monomer-binding toxins latrunculin A and B, inhibit insulinstimulated GLUT4 translocation (143). The C-terminal tail of GLUT4 in adipocytes has been shown to indirectly interact with F-actin by binding to the glycolytic enzyme aldolase, suggesting a homeostatic mechanism in which glucose metabolism might feedback regulate GLUT4 translocation along the actin cytoskeleton (144).

The docking and fusion of the GLUT4 vesicle at the plasma membrane are subject to regulation by insulin. This involves a series of proteins termed the SNARE proteins. The v-SNARE protein VAMP2 is present on GLUT4-containing vesicles and appears to physically interact with its t-SNARE

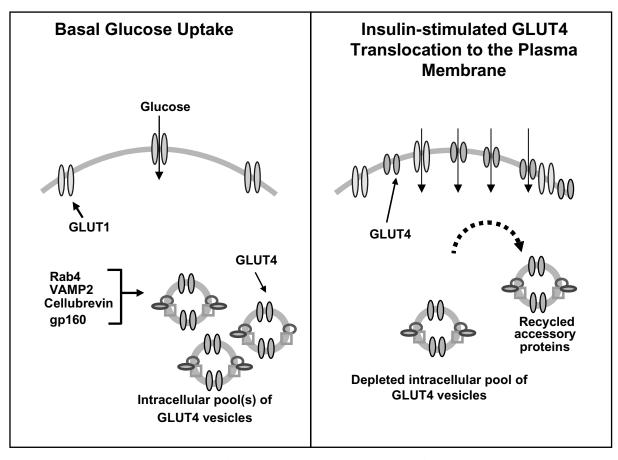

Figure 9.8. The regulation of glucose transport by insulin stimulation of GLUT4 translocation.

counterpart syntaxin 4 during GLUT4-vesicle docking and fusion with the plasma membrane (145), although neither SNARE protein appears to be a direct target of insulin action. However, the SNARE accessory proteins Synip and Munc18c may be involved in the control of GLUT4 docking and fusion in an insulin-dependent, PI 3-kinase–independent manner (146). One interesting possibility is that the PI 3-kinase–independent arm of insulin action may be directed at the docking and fusion step of GLUT4 regulation.

REGULATION OF GLUCOSE AND LIPID SYNTHESIS, UTILIZATION, AND STORAGE

Glucose Oxidation and Storage

Upon entering the muscle cell, glucose is rapidly phosphorylated by hexokinase and either stored as glycogen via the activity of glycogen synthase or oxidized to generate adenosine triphosphate (ATP) synthesis via enzymes such as pyruvate kinase. In the liver and adipose tissue, glucose can also be stored as fat. Some of the enzymes involved in glycolysis, as well as in glycogen and lipid synthesis, are regulated by insulin via changes in their phosphorylation state due to a combination of protein kinase inhibition and phosphatase activation. In addition, some of these enzymes are regulated at the transcriptional level.

Insulin stimulates glycogen accumulation through a coordinated increase in glucose transport and glycogen synthesis. Activation of glycogen synthase involves the promotion of its dephosphorylation via both the inhibition of kinases that can phosphorylate glycogen synthase, such as PKA or GSK3 (137,147), and the activation of phosphatases that dephosphorylate glycogen synthase, such as protein phosphatase 1 (PP1) (148). This process is downstream of PI 3-kinase and involves Akt phosphorylation of GSK-3. This inactivates GSK-3, resulting in a decrease in the phosphorylation of glycogen synthase and an increase in its activity state. However, the inhibition of GSK-3 is not sufficient for full activation of glycogen, because GSK-3 does not phosphorylate all of the residues of glycogen synthase that are dephosphorylated in response to insulin (137).

Activation of PP1 correlates well with changes in glycogen synthase activity (148). However, insulin does not appear to globally activate PP1 but rather to activate specific pools of the phosphatase localized on the glycogen particle. The compartmentalized activation of PP1 by insulin is due to glycogentargeting subunits that serve as "molecular scaffolds," bringing together the enzyme with its substrates glycogen synthase and glycogen phosphorylase in a macromolecular complex (149). Four different proteins (G_M, G_L, PTG, and R₆) have been reported to target PP1 to the glycogen particle. Overexpression of these scaffolding proteins in cells or in vivo by adenovirusmediated gene transfer results in a dramatic increase in basal cellular glycogen levels (150). Furthermore, glycogen stores in cells overexpressing PTG are refractory to breakdown by agents that raise intracellular cyclic adenosine monophosphate (cAMP) levels, suggesting that PTG locks the cell into a glycogenic mode (149). The mechanism by which insulin activates glycogen-associated PP1 remains unknown. Although it had been proposed that activation of MAP kinase leads to the phosphorylation of the targeting protein G_M and the subsequent release of inhibition of the enzyme by insulin, blockade of this pathway had no effect on the activation of glycogen synthase by insulin and mutation of the identified phosphorylation sites did not impair insulin action. However, inhibitors of PI 3-kinase can block activation of PP1 by insulin, indicating that PIP₃-dependent protein kinases are involved.

Regulation of Gluconeogenesis

Insulin inhibits the production and release of glucose by the liver and, to a lesser extent, by the kidney by blockade of gluconeogenesis and glycogenolysis. Insulin achieves these effects by directly controlling the activities of a subset of metabolic enzymes via the process of phosphorylation and dephosphorylation described above, as well as by regulation of the expression of a number of genes encoding hepatic enzymes. Insulin dramatically inhibits the transcription of the gene encoding phosphoenolpyruvate carboxylase (PEPCK), the rate-limiting step in gluconeogenesis. The hormone also decreases transcription of the genes encoding fructose 1,6-bisphosphatase and glucose 6-phosphatase and increases transcription of those encoding glycolytic enzymes such as glucokinase and pyruvate kinase and lipogenic enzymes such as fatty acid synthase and acetyl CoA carboxylase.

Several transcription factors play a role in this insulinmediated regulation (Fig. 9.9). Hepatic nuclear factor-3 (HNF3) and HNF4 both appear to be involved in regulation of the PEPCK gene, which is the rate-limiting enzyme of gluconeogenesis (151). Sterol regulatory element-binding protein-1c (SREBP-1c) is regulated by insulin in its phosphorylation and may play a role in the effect of insulin on PEPCK gene transcription (152). The forkhead transcription factor FKHR (now known as FOXO1) also appears to be involved in the regulation of PEPCK and glucose 6-phosphatase, because both PEPCK and glucose 6phosphatase contain putative FKHR binding sites in their promoter sequences, and overexpression of FKHR in hepatoma cells markedly increases the expression of the catalytic subunit of glucose 6-phosphatase (153). Recently, Yoon et al. (154) showed that both HNF4 and FOXO1 may be modified in their activity by a single co-activator known as PGC-1. PGC-1 levels are increased in insulin-deficient and insulin-resistant diabetes. This creates an attractive hypothesis by bringing together multiple regulators under one common master regulator.

Although there is no doubt that insulin plays a key role in the regulation of the enzymes of gluconeogenesis, insulin can also indirectly influence glucose metabolism. This occurs via changes in the availability of substrates for gluconeogenesis that are being released from muscle and fat (155,156). Thus, when insulin levels are low, there is a breakdown of muscle protein and adipocyte triglycerides, leading to increased levels of gluconeogenic substrates such as alanine and free fatty acids. Careful physiologic experiments in the dog that included time courses and dose responses of insulin action have suggested that under some circumstances this indirect pathway may be the major pathway of insulin regulation of gluconeogenesis (155,156). However, recent experiments with mice with a genetic knockout of the insulin receptor in liver indicate that the direct pathway is more important in that species (157). In any case, in humans the indirect pathway may contribute to the

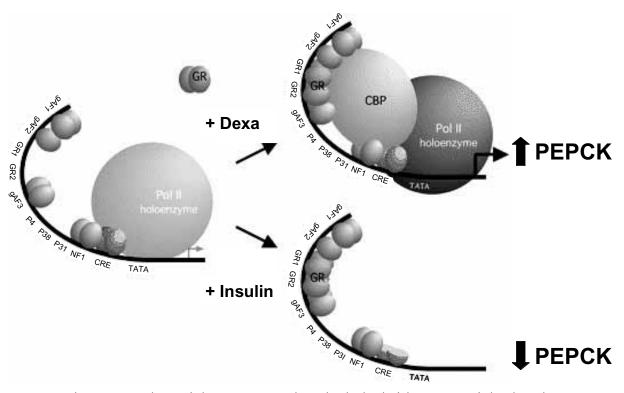

Figure 9.9. Regulation of gluconeogenesis at the molecular level of the promoter of phosphoenolpyruvate carboxylase (PEPCK), the rate-limiting enzyme in gluconeogenesis. (Adapted from Duong DT, Waltner-Law ME, Sears R, et al. Insulin inhibits hepatocellular glucose production by utilizing liverenriched transcriptional inhibitory protein to disrupt the association of CREB-binding protein and RNA polymerase II with the phosphoenolpyruvate carboxykinase gene promoter. *J Biol Chem* 2002;277: 32234–32242.)

pathogenesis of diabetes, especially in individuals with central obesity, because visceral fat is less sensitive than subcutaneous fat to insulin inhibition of lipolysis, resulting in direct flux of fatty acids derived from these fat cells through the portal vein to the liver.

Regulation of Lipogenesis and Lipolysis

As is the case with carbohydrate metabolism, insulin also promotes the synthesis of lipids and inhibits their degradation. Recent studies suggest that many of these changes also might require an increase in levels of the transcription factor SREBP1-c (158-160). Dominant-negative forms of SREBP1 can block expression of these gluconeogenic and lipogenic genes (159), and overexpression of SREBP-lc can increase their expression (161). Interestingly, hepatic SREBP levels are increased in rodent models of lipodystrophy, and this is associated with coordinated increases in fatty acid synthesis and gluconeogenesis, mimicking the phenotype observed in genetic models of obesity-induced diabetes. These observations led Shimomura et al. (161) to speculate that increased expression of SREBP-1c might lead to the mixed insulin resistance observed in the diabetic liver, with increased rates of both gluconeogenesis and lipogenesis. The pathways that account for the changes in SREBP1-c expression lie downstream of the IRS/PI 3-kinase pathway.

In adipocytes, glucose is stored primarily as lipid. This is the result of increased uptake of glucose and activation of lipid synthetic enzymes, including pyruvate dehydrogenase, fatty acid synthase, and acetyl CoA carboxylase. Insulin also profoundly inhibits lipolysis in adipocytes, primarily through inhibition of the enzyme hormone-sensitive lipase. This enzyme is acutely regulated by control of its phosphorylation state, activated by PKA-dependent phosphorylation, and inhibited owing to a combination of kinase inhibition and phosphatase activation. Insulin inhibits the activity of the lipase primarily via reductions in cAMP levels due to the activation of a cAMP-specific phosphodiesterase in fat cells (162).

WHAT CAUSES INSULIN RESISTANCE?

Defining Insulin Resistance and the Sites of Insulin Resistance

Insulin resistance is said to exist any time a normal amount of insulin produces a less than normal biologic response (163). Insulin resistance can be further divided into states in which there is a rightward shift in the dose response to the hormone but the maximal response remains normal (decreased insulin sensitivity) or states in which the dose response is normal but the maximal response is decreased (decreased responsiveness), or a combination of the two (Fig. 9.10). Insulin resistance is extremely common, occurring both in disease states such as type 2 diabetes, obesity, hypertension, polycystic ovarian disease, and a variety of genetic syndromes and in physiologic conditions such as puberty and pregnancy (164,165). Insulin resistance also is present in many states of stress, in association with infection, and secondary to treatment with a variety of drugs, particularly glucocorticoids.

From a molecular perspective, insulin resistance can occur at multiple levels and be either acquired or genetic. Prereceptor insulin resistance is rare today but formerly was exemplified by patients with high levels of circulating antibodies to insulin that blocked binding of the ligand to its receptor and by patients with what appeared to be increased subcutaneous degradation of injected insulin (166). Insulin resistance at the level of the receptor may be the result of genetic alterations in receptor expression or structure, secondary changes in receptor activity due to serine phosphorylation, or downregulation of receptor concentration. At the postreceptor level, insulin resistance can occur almost anywhere on one of the common or branched pathways of insulin signaling.

In the most common states of insulin resistance, there appear to be defects at multiple levels. For example, in type 2 diabetes, there are decreases in receptor concentration, in receptor kinase activity, in the concentration and phosphorylation of IRS-1 and IRS-2, in PI 3-kinase activity, and in glucose-transporter

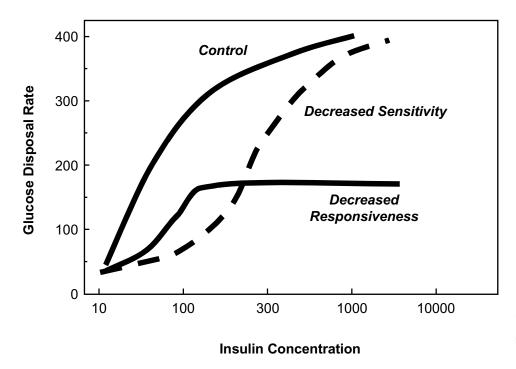

Figure 9.10. Types of insulin resistance. (Adapted from Kahn CR. Insulin resistance, insulin insensitivity, and insulin unresponsiveness: a necessary distinction. *Metabolism* 1978;27:1893–1902.)

Insulin resistance differentially affects the PI 3-kinase and MAP kinase-mediated signaling in human muscle. *J Clin Invest* 2000; 105:311–320.)

translocation and defects in activity of intracellular enzymes (3,167). Interestingly, in type 2 diabetes, there does not appear to be a reduction in insulin action on the MAP kinase pathway (Fig. 9.11). This blockade of the PI 3-kinase pathway with continued MAP kinase signaling might account for some of the detrimental effects of the chronic hyperinsulinemia on the vasculature (164).

Genetic Forms of Insulin Resistance

Insulin resistance due to genetic defects in insulin-receptor expression or sequence is relatively rare but represents the most severe forms of insulin resistance. In humans, these may present as several different disease syndromes, including two congenital diseases termed leprechaunism and the Rabson-Mendenhall syndrome, in which there is insulin resistance, intrauterine and postnatal growth retardation, and other developmental defects; and the type A syndrome of insulin resistance that appears in childhood, adolescence, or early adulthood (165,168). These are discussed in more detail in Chapter 28.

Although there is some correlation between the severity of the genetic defect in receptor function and the severity of the clinical presentation, the correlation is relatively weak, indicating that other genetic or acquired factors can modify the insulin-resistant state significantly (169). Interestingly, none of these diseases matches the phenotype of the insulin-receptor knockout mouse, which shows normal intrauterine growth but develops diabetic ketoacidosis in the first few days of life and dies (170). This difference in behavior may represent differences in the role of the insulin receptor in different species or the state of development of the human versus that of the mouse at birth. Alternatively, the mutant receptors may produce more complex disease phenotypes as a result of formation of hybrids with IGF-1 or other receptors that also interfere with their function.

Acquired Forms of Insulin Resistance

Acquired forms of insulin resistance may occur as a result of multiple mechanisms (Fig. 9.6). The first of these to be described was that of insulin-receptor downregulation (171,172). In this situation, mild hyperinsulinemia that occurs in response to tissue insulin resistance results in an increase in internalization and degradation of the insulin receptor. This occurs to some extent in the most common insulin-resistant states, i.e., obesity and type 2 diabetes. Recent studies have also shown that hyperinsulinemia can lead to downregulation of insulin-receptor substrates, producing an even greater decrease in insulin signaling (104,173–175). In both humans and rodents, the levels of insulin receptor and IRS-1 in some tissues can each be reduced by more than 50% in some of these insulin-resistant states. Most of the changes in the insulin receptor and its substrates are due to increased protein turnover, but there may also be an element of downregulation at the transcriptional level, especially for IRS-2.

In addition to downregulation, there may be many other factors that contribute to acquired insulin resistance. As noted above, in hyperinsulinemic and other insulin-resistant states, there is increased serine phosphorylation of the receptor and its substrates (174,176). This leads to decreased kinase activity of the receptor and decreased tyrosine phosphorylation of the receptor substrates. Several different serine kinases have been implicated in this serine phosphorylation, including Akt, various isoforms of PKC, and the stress-induced MAP kinases (p38 and JNK) and IKB kinase (64,67,177). The upstream stimulators of these kinases may also be multiple. For example, in obesity and type 2 diabetes, there are increased levels of circulating free fatty acids (FFAs), and in obesity, adipose tissue makes and releases a number of other factors, including TNF- α , leptin, various complement-related peptides, and two recently discovered hormones, resistin and adiponectin (also called Acrp30 and AdipoQ) (see below). Another class of proteins that can act as inhibitors of insulin signaling are the SOCS proteins (92,178,179). These certainly play a role in stress-induced states, such as that created by injection of bacterial lipopolysaccharide, and perhaps in obesitylinked insulin resistance. These SOCS proteins act to inhibit insulin signaling by binding to the phosphorylated insulin receptor and inhibiting phosphorylation of the IRS proteins.

Role of Free Fatty Acids and Intracellular Triglycerides in Insulin Resistance

Circulating FFAs are elevated in many insulin-resistant states and have been suggested to play a central role in the pathogenesis of the insulin resistance. Physiologic increases in plasma FFA levels have been shown to cause insulin resistance by several mechanisms in both diabetic subjects and obese, nondiabetic subjects. FFAs inhibit insulin-stimulated glucose uptake at

158 JOSLIN'S DIABETES MELLITUS

the level of glucose transport and/or phosphorylation, inhibit insulin-stimulated glycogen synthesis, and inhibit insulinstimulated glucose oxidation (180–182). As noted above, FFAs might have a special role in the insulin resistance associated with central obesity. Since central adipocytes are more resistant to insulin inhibition of lipolysis, there is an increased delivery of FFAs to the liver. This leads to increased accumulation of triglycerides that could also contribute to increased hepatic glucose output, reduced hepatic extraction of insulin, and hepatic insulin resistance. In experimental lipid-induced insulin resistance, insulin-stimulated IRS-1 phosphorylation and IRS-1– associated PI 3-kinase activity is also reduced. There is also an increase in membrane-bound, i.e., activated, PKC0 that may serve as a mediator of the insulin resistance by increased serine phosphorylation of the insulin receptor and/or IRS-1 (183).

A common link between increased levels of FFAs and the insulin resistance in type 2 diabetes, obesity, and syndrome X could be accumulation of triglycerides in muscle. Recent studies using magnetic resonance spectroscopy have demonstrated that at least some of the lipid accumulation is inside the myocyte itself (184,185). Factors leading to the accumulation of triglycerides are not clear, but it has been speculated that the triglyceride is derived from elevated levels of both circulating FFAs and triglycerides and is also the result of reduced muscle fatty acid oxidation. Whatever the mechanism, there is a close correlation between muscle triglyceride content and wholebody insulin resistance. The notion of a glucose-fatty acid cycle (Randle cycle) has been hypothesized for 40 years as a mechanism by which glucose might autoregulate its own use (186). It is likely that cytosolic accumulation of the long-chain fatty acyl CoAs is involved in the altered insulin signaling. Several

mechanisms have been implicated in the inhibition of insulin signaling, including increased serine phosphorylation of the insulin receptor and its substrates or direct inhibition of enzymes such as glycogen synthase. Insulin sensitizers, such as the PPAR γ agonists, reduce muscle lipid accumulation and increase insulin sensitivity. Other potent systemic lipid-lowering agents, such as PPAR α agonists (e.g., fibrates) or antilipolytic agents (e.g., nicotinic acid analogues), might also improve insulin sensitivity by this mechanism.

Transgenic mice with muscle- and liver-specific overexpression of lipoprotein lipase have recently been developed to help define the roles of muscle FFAs and triglycerides in insulin resistance. Muscle-specific lipoprotein lipase-deficient mice have a threefold increase in muscle triglyceride content and exhibit insulin resistance due to decreases in insulin-stimulated glucose uptake in skeletal muscle and insulin activation of IRS-1-associated PI 3-kinase activity (187). Mice with overexpression of lipoprotein lipase in the liver have increased triglyceride content in the liver and exhibit insulin resistance due to an impaired ability of insulin to suppress endogenous glucose production, along with defects in insulin activation of IRS-2-associated PI 3-kinase activity (187). In both tissues, these defects in insulin action and signaling are associated with increases in intracellular fatty acid-derived metabolites, such as diacylglycerol and fatty acyl CoA.

The Fat Cell as a Secretory Cell and Insulin Resistance

Over the past several years, it has become clear that the adipocyte plays a role in insulin resistance not only by storing

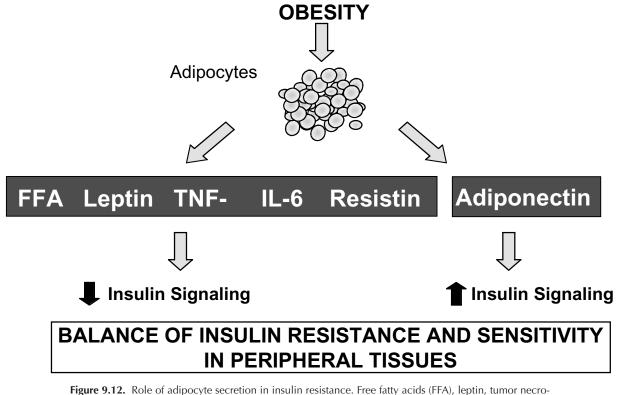

Figure 9.12. Kole of adipocyte secretion in insulin resistance. Free fatty acids (FFA), leptin, tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), and resistin are substrates and adipokines released by fat that increase insulin resistance. Adiponectin, also known as ACRP 30, decreases insulin resistance and increases insulin sensitivity.

fat but also as a secretory cell producing several cytokines and hormones, as well as releasing FFAs (Fig. 9.12). The first of the cytokines to be described as being increased in fat cells of obese animals and humans was TNF- α (188,189). TNF- α could lead to insulin resistance by increasing serine phosphorylation of IRS-1 and decreasing insulin-receptor kinase activity (190). This mechanism is clearly important in rodents, in which anti–TNF- α reagents significantly improve insulin resistance (188). However, the importance of this mechanism in humans is much debated, and limited studies of anti-TNF reagents have shown little or no effect on the insulin-resistant state (191).

Leptin is a member of the cytokine family of hormones that is produced by adipose tissue and acts on receptors in the central nervous system and other sites to inhibit food intake and promote energy expenditure (192,193). Leptin has been shown to interfere with insulin signaling systems *in vitro* (12,194); however, it is not clear if leptin has anti-insulin effects *in vivo*. Indeed, in states of severe leptin deficiency, such as in the ob/ob mouse or several genetic models of lipoatrophic diabetes, administration of exogenous leptin improves glucose tolerance and insulin sensitivity (195). This appears to be primarily the result of an action of leptin at the liver to increase insulin sensitivity, an effect that might be direct or centrally mediated.

Adiponectin (also called Acrp30, adipoQ, APM-1, and GBP28) is a peptide of 247 amino acids that possesses a collagenous domain at the N-terminus and a globular domain that shares significant homology with subunits of complement factor C1q. The expression of adiponectin is highly specific to adipose tissue. Adiponectin is among the most abundant proteins in adipocytes, is secreted into the bloodstream, and is present at very high circulating concentrations (196,197). Several recent studies have pointed to a potentially important role of adiponectin in the insulin resistance of obesity (198,199). First, expression of adiponectin mRNA is decreased in obese humans and mice and in some models of lipoatrophic diabetes (196). Acute treatment of mice with the globular head domain of Acrp30 significantly decreased the elevated levels of plasma FFAs and caused weight loss in mice consuming a highfat diet. Administration of adiponectin to obese mice also decreases insulin resistance and triglyceride content of muscle and liver. Moreover, insulin resistance in lipoatrophic mice is completely reversed by the combination of physiologic doses of adiponectin and leptin, but only partially by administration of either adiponectin or leptin alone (196). Administration of adiponectin/Acrp30 also lowers glucose levels in normal mice and mouse models of type 1 diabetes, such as NOD mice and streptozotocin-treated mice (200). Recent genome-wide scans have mapped a susceptibility locus for type 2 diabetes and metabolic syndrome to chromosome 3q27, a region where the gene encoding adiponectin is located (196,201). These data suggest that decreased levels of adiponectin are important factors in the insulin resistance of obesity and lipoatrophy and that replacement of adiponectin might provide a novel treatment for some insulin-resistant states.

Resistin is the most recently discovered peptide hormone secreted by adipocytes (202). Resistin belongs to a family of tissue-specific secreted proteins termed resistin-like molecules (RELMs) and the FIZZ (found in inflammatory zone) family (203). Initial studies suggested that resistin levels were increased in both genetic and acquired obesity in mice and reduced by antidiabetic drugs of the thiazolidinedione class. Further, administration of antibody to resistin appeared to improve blood glucose levels and insulin action in mice with

diet-induced obesity (202,204). Moreover, insulin-stimulated glucose uptake by adipocytes was enhanced by neutralization of resistin and reduced by resistin treatment. Others have not confirmed these initial studies, finding that resistin expression is significantly decreased in the white adipose tissue of several different models of obesity, including the ob/ob, db/db, tub/tub, and KKA(y) mice, as compared with their lean counterparts (205). Furthermore, treatment of both ob/ob mice and Zucker diabetic fatty rats with several different classes of PPARy agonists resulted in an increase in resistin expression. The potential role of resistin is further complicated by the fact that the human homologue has relatively poor sequence homology and little difference has been detected in resistin expression by normal, insulin-resistant, or type 2 diabetic subjects (206). Other recent studies have suggested alternative roles for resistin as an adipose sensor for the nutritional state of the animals and an inhibitor of adipocyte differentiation (207).

LESSONS FROM KNOCKOUT MICE ABOUT INSULIN ACTION AND INSULIN RESISTANCE

As noted above, the ability to create genetic knockout of insulin-signaling proteins has allowed us to define the roles of the insulin receptor and its substrates in both whole animals and in cells derived from these animals. The technique of homologous recombination gene targeting has been used to create and characterize mice lacking each of these insulin-signaling proteins. A number of these are described above. In addition, combinatorial knockouts have been produced, both in the homozygous and heterozygous states, as well as tissue-specific knockouts, and these also have provided important insights into the mechanisms of insulin action and the nature of insulin resistance in each tissue.

Mice with Compound Defects

The creation of polygenic models of diabetes was begun by breeding mice heterozygous for deletion of the insulin receptor (IR) with mice heterozygous for deletion of IRS-1 to produce double-heterozygote knockout mice (208). In contrast to the single-heterozygote knockout mice, which appear normal, the IR/IRS-1 double-heterozygote knockout mice manifested marked insulin resistance, with a 10-fold increase in circulating insulin levels and a 5- to 30-fold increase in β -cell mass. Despite this islet hyperplasia, ~50% of these mice developed diabetes by 4 to 6 months of age.

These compound-heterozygote animals have several features of interest. First, despite the genetic nature of the insulin resistance, these mice, like humans, develop diabetes with delayed onset. Second, the 50% incidence of diabetes indicates a marked synergism (epistasis) between the IR defect (which leads to diabetes in <10% of mice) and the IRS-1 defect (which never leads to diabetes). Finally, on a mixed genetic background, only ~50% of the mice develop diabetes, indicating that an additional gene or genes present in the background of these mice contribute to or protect them from the development of diabetes.

Recently, these studies have been extended to produce even more complex compound heterozygous animals and to explore the role of genetic background in the diabetic state. For example, IR/IRS-1/IRS-2 triple-heterozygote knockout mice have been created and shown to have severely impaired glucose tolerance and a doubling of the incidence of diabetes as compared with the double heterozygotes (209). By contrast, IR/IRS-1/p85

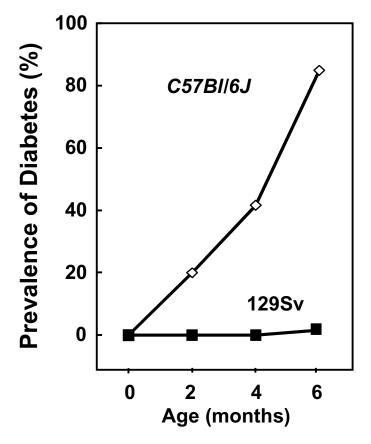

Figure 9.13. Impact of genetic background on the development of type 2 diabetes in mice with genetic insulin resistance. Genetic insulin resistance was created by breeding mice with heterozygous defects in both insulin receptor and insulin-receptor substrate 1 (IRS-1) onto two different genetic backgrounds of mice. On the C57Bl/6J background, about 90% of mice become diabetic within 6 months. On the 129Sv background, fewer than 2% become diabetic at 6 months or even at 18 months. (Redrawn from the data of Kulkarni RN, Almind K, Goren HJ, et al. Impact of genetic background on development of hyperinsulinemia and diabetes in insulin receptor/insulin receptor substrate-1 double heterozygous mice. *Diabetes* 2003;52: 1528–1534.)

triple-heterozyote knockout mice are less severely affected than the IR/IRS-1 double-heterozygote knockout mice owing to the beneficial effect of reduced p85 levels on insulin resistance (109). The phenotype of mice doubly heterozygous (DH) for IR and IRS-1 varies depending on the genetic background (210) (Fig. 9.13). Thus, DH mice on the C57B1/6J background have a high incidence of diabetes (85% at 6 months of age), whereas the 129Sv strain does not develop diabetes, despite the genetic defects in insulin signaling. DBA mice with the DH mutation show intermediate levels of hyperglycemia and hyperinsulinemia. This illustrates the importance of genetic modifiers of the diabetic state that exist in mice and humans. Genome-wide scans in these mice have identified four loci on three chromosomes that contribute to this difference (211).

CREATION OF TISSUE-SPECIFIC KNOCKOUTS

Two approaches applying mouse genetics have been used to address the role of insulin-receptor signaling in specific tissues. One has used mice that express a dominant-negative mutant of the insulin receptor under control of a tissue-specific promoter, such as the muscle creatine kinase (MCK) or GLUT4 promoters (212,213), and the other has created tissue-specific knockouts using the Cre-*loxP* system to disrupt the insulin-receptor gene in various tissues of the mouse (214). The latter is based on the use of the bacteriophage recombinase Cre to conditionally inactivate genes in mice in which *loxP* sites flanking some critical element have been introduced (215). *LoxP* sites are bacterial DNA sequences of 34 base pairs (bp) that allow for directional recombination of two segments of DNA, eliminating the DNA in between. For tissue-specific knockout of the insulin receptor, *loxP* sites were introduced

around exon 4, because deletion of this exon by the Cre recombinase would cause a major deletion and frameshift mutation with a premature stop of translation at amino acid 308 of the insulin-receptor protein. Mice carrying the IRlox allele could then be bred with a number of different cre-mice to produce a variety of tissue-specific knockouts of the insulin receptor, depending on the nature of the Cre-transgenic mice with which they are bred. For example, breeding mice carrying the IRlox allele with an MCK promoter-Cre mouse would produce a muscle-specific knockout of the insulin receptor (MIRKO) mouse, use of an albumin-Cre mouse would produce a liverspecific insulin-receptor knockout (LIRKO), and use of a P2-Cre mouse would produce a fat-specific insulin-receptor knockout (FIRKO) (Fig. 9.14). This technique has also been used in a more limited way to study the role of GLUT4 in specific tissues (216,217).

MUSCLE-SPECIFIC INSULIN-RECEPTOR KNOCKOUT MOUSE

Because muscle accounts for a large fraction of postprandial glucose uptake and is a site of insulin resistance early in the prediabetic state (218–220), the first tissue-specific knockout to be created was a muscle-specific insulin-receptor knockout. This was created using a Cre transgenic mouse with an MCK gene as promoter/enhancer. The MIRKO mice demonstrated almost complete and specific ablation of insulin-receptor expression in muscle, whereas insulin-receptor expression was unaltered in other tissues. Surprisingly, despite the virtual lack of insulin signaling in muscle, the MIRKO mice were able to maintain euglycemia up to at least the age of 20 months. Moreover, plasma insulin concentrations and insulin tolerance tests were indistinguishable between animals of each group.

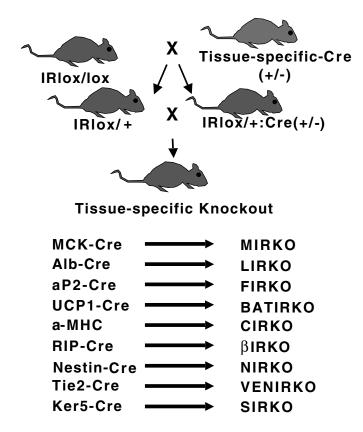

Figure 9.14. Generation of tissue-specific insulin receptor knockout mice using the Cre-lox technology. Mice carrying two alleles of the insulin receptor flanked with lox sites (IRlox/lox) are bred with mice carrying the Crerecombinase driven by a tissue-specific promoter. After two rounds of breeding, tissue-specific knockout mice are generated. The details of each of the tissue specific knockouts are discussed in the text. MIRKO, muscle-specific insulin-receptor knockout; LIRKO, liver-specific insulin-receptor knockout; FIRKO, fat-specific insulin-receptor knockout; CIRKO, cardiac-specific insulinreceptor knockout; VENIRKO, vascular endothelial cell insulinreceptor knockout; SIRKO, skin-specific insulin-receptor knockout.

On euglycemic clamp studies, however, the rates of insulinstimulated whole-body glucose uptake were decreased in MIRKO mice, with a 74% decrease in insulin-stimulated muscle glucose transport. What was unexpected, however, was the threefold increase of insulin-stimulated glucose transport in adipose tissue in MIRKO mice. Thus, insulin resistance in muscle produced a shift of substrate to adipose tissue that resulted in increased adipose-tissue mass, hypertriglyceridemia, and a modest increase in FFAs, all features of the metabolic syndrome associated with insulin resistance (221) (Fig. 9.15).

Studies with MIRKO mice demonstrate the utility and value of tissue-specific knockouts for promoting insights into the nature of insulin signaling and testing our concepts of glucose homeostasis and the pathogenesis of type 2 diabetes. They also suggest the presence of some tissue cross-talk between muscle and fat, which, if it also occurs in humans, could contribute to the increase in obesity in people with genetically programmed insulin resistance in muscle, as well as a significant role of muscle insulin resistance in the development of the lipid phenotype of the metabolic syndrome, including elevated plasma triglycerides, FFAs, and central obesity.

MUSCLE-SPECIFIC GLUT4 KNOCKOUT MOUSE

To determine if different types of insulin resistance in a single tissue might produce different alterations in glucose homeostasis, the Cre-*loxP* system also was used to selectively disrupt GLUT4 expression in muscle (216). The muscle-specific GLUT4 knockout (MG4KO) mouse had a greater than 90% reduction of GLUT4 protein in skeletal muscle and no compensatory increase in GLUT1. Basal glucose uptake *in vitro* was reduced 72% to 88% in various muscles of MG4KO mice, and the response to insulin was completely obliterated. In contrast to MIRKO mice, these mice also had increased fasting glucose levels and impaired glucose and insulin tolerance tests. However, they showed no increase in body fat or hyperlipidemia.

LIVER-SPECIFIC INSULIN-RECEPTOR KNOCKOUT MOUSE

The role of the liver in glucose homeostasis has been defined by generating mice with a liver-specific knockout of the insulin receptor using a Cre recombinase under the albumin promoter/enhancer (222). On gross examination, the livers of LIRKO mice were about 50% of normal size, and the insulinreceptor content of the liver was reduced by more than 90%. At 2 months of age, LIRKO mice were hyperglycemic in the fed state as compared with controls and exhibited severely impaired glucose tolerance. Serum insulin levels in LIRKO mice were markedly elevated owing both to an increase in islet size and insulin secretion and to a decrease in insulin clearance. The failure of these mice to respond to insulin in terms of suppression of hepatic glucose output indicates that in mice the direct effect of insulin on this pathway is more important than any indirect effects (157).

FAT-SPECIFIC INSULIN-RECEPTOR KNOCKOUT MOUSE

Mice with a fat-specific knockout of the insulin receptor are perhaps the most interesting of those in the three classical targets of insulin action. Despite the importance of insulin for suppression of lipolysis, FIRKO mice have normal blood glucose levels, normal glucose tolerance tests, and normal levels of FFAs and glycerol (223). In addition, all measures of insulin resistance are within the range of normal controls, including intraperitoneal insulin tolerance tests and fasting and fed serum insulin

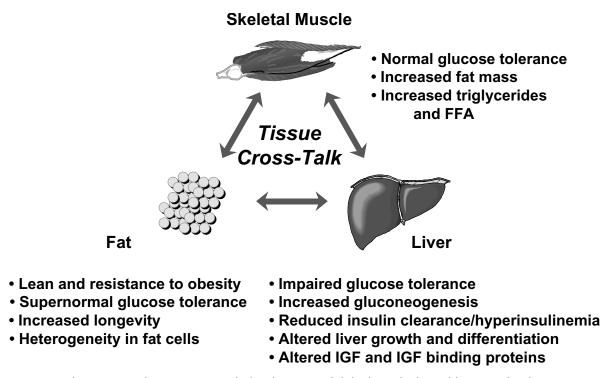

Figure 9.15. Defects in tissue-specific knockout mice of skeletal muscle, fat, and liver. FFA, free fatty acids; IGF, insulin-like growth factor.

concentrations. The FIRKO mice do, however, demonstrate a ~50% decrease in fat mass by 6 months of age that persists throughout life. FIRKO mice are also resistant to becoming obese as they age and even after treatment with gold thioglucose, an agent that produces a hypothalamic lesion and induces hyperphagia. As a result, these mice are also protected from the development of age- and obesity-related glucose intolerance. Perhaps most interesting is the extended life span of FIRKO mice, indicating the importance of body fat, rather than diet, in longevity (224).

USE OF TISSUE-SPECIFIC KNOCKOUT TO DEFINE INSULIN ACTION IN NONTARGET TISSUES

β-Cell Insulin-Receptor Knockout Mouse

One of the characteristic features of type 2 diabetes is a failure of the β -cell to respond to a glucose stimulus while retaining its response to other secretagogues, such as amino acids (225,226). Although data have conflicted regarding the presence of functional insulin receptors on the β -cell, it has been suggested that insulin regulates its own secretion via regulation of expression of some genes and depolarization of the β cell (227-229). The Cre-lox strategy for tissue-specific gene inactivation was applied to assessing the role of the insulin receptor in the pancreatic (β-cell in vivo, taking advantage of mice that carry the Cre transgene on a 668-bp β -cell–specific rat insulin 2 promoter (Rip-Cre) (230-232). This produced a specific recombination and inactivation of the insulin-receptor gene in β -cells but not in non- β -cells. This resulted in a loss of first-phase insulin secretion in response to glucose but not to arginine (19), mimicking the insulin secretory defect in humans with type 2 diabetes (Fig. 9.16). This appeared to be

due to a decrease in insulin-stimulated expression of the enzyme glucokinase, which forms a key component of the glucose-sensing machinery. Islet size, morphology, and insulin content was normal at 2 months of age, but by 4 months of age, islet size and insulin content had fallen below that in control mice.

The findings for the β -cell insulin-receptor knockout (β IRKO) mouse demonstrated that β -cells possess functional insulin receptors and suggest the possibility that some of the defects present in type 2 diabetes may represent alterations in the insulin action in β -cells. This is consistent with the recent studies (229,233) demonstrating that insulin may positively regulate insulin biosynthesis and induce the depolarization required for normal insulin secretion. β -cells have also been shown to contain IGF-1 receptors, and IGF-1 has been shown to negatively regulate insulin secretion (234,235). Deletion of the IGF-1 receptor in β -cells also results in a loss of glucose sensing but in no defect in islet growth (236).

Vascular Endothelial Cell Insulin-Receptor Knockout Mouse

Insulin receptors on vascular endothelial cells have been suggested to participate in insulin-regulated glucose homeostasis by facilitating transcytosis of insulin from the intravascular to extracellular space, by promoting vasodilation and enhancing blood flow, and by generating signaling mediators. The role of insulin action in endothelial function was addressed directly by generating mice with a vascular endothelial cell insulinreceptor knockout (VENIRKO) generated by the *Cre-LoxP* system. Despite the previous studies suggesting a role for these receptors in glucose and blood pressure homeostasis, blood glucose and insulin concentrations, and glucose and insulin

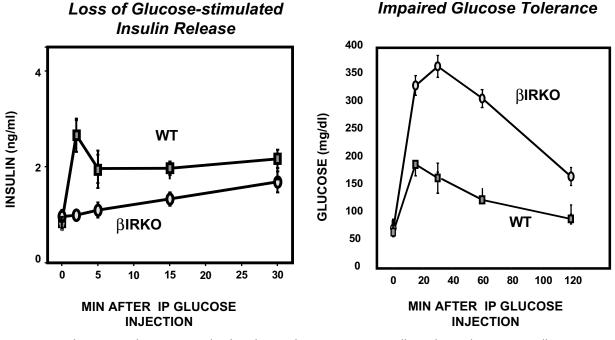

Figure 9.16. The important role of insulin signaling in pancreatic β -cells: studies in the β IRKO (β -cell insulin-receptor knockout) mouse. The left panel illustrates insulin secretion in response to acute intraperitoneal (IP) glucose in β IRKO versus normal mice (WT) and shows the complete loss of first-phase insulin secretion. The right panel shows glucose levels during an intraperitoneal glucose tolerance test in the same mice. Data are for 4-month-old males (19).

tolerance tests, the time course of insulin action on glucose disposal during a euglycemic-hyperinsulinemic clamp and blood pressure were comparable in VENIRKO and control mice (237). However, both endothelial nitric oxide synthase (eNOS) and endothelin-1 mRNA levels were reduced in the endothelial cells of these mice. More important, these mice were protected from the development of neovascularization in a model of retinopathy that mimics diabetes by changing oxygen exposure (238). This is particularly interesting because acute insulin treatment in some patients with poorly controlled diabetes appears to worsen retinopathy over the short term before having its long-term beneficial effects on reducing the progression of retinopathy.

Neural Insulin-Receptor Knockout Mouse: Role of Insulin in the Brain

Insulin receptors have been found to be widely distributed in the brain; however, their function has been highly debated (239). Some studies have suggested a role of insulin in appetite regulation (240,241), and others have suggested a role of insulin in neuron growth (242,243). Again, this problem has been addressed using the tissue-specific knockout technique with the neuron-specific promoter to create the neural insulin-receptor knockout (NIRKO) mouse (18). These mice have normal brain development but exhibit four interesting phenotypes with respect to diabetes and metabolism. First, NIRKO mice are slightly hyperphagic and mildly obese, confirming the role of central nervous system insulin as an appetite suppressant. This also leads to mild insulin resistance and hypertriglyceridemia. Second, NIRKO mice have a defect in the ability of insulin to suppress hepatic glucose output. A role of centrally acting insulin in hepatic metabolism has also been suggested in studies in which insulin has been injected into the third ventricle (244), harkening back to the work 150 years ago of Claude Bernard, who demonstrated that an anatomic lesion to the base of the brain in a rabbit could lead to uncontrolled hepatic release of glucose (245). The third effect of the lack of normal insulin signaling in the brain is a defect in the ability to compensate for hypoglycemia with appropriate rises in catecholamine levels (S. Fisher and C. R. Kahn, unpublished observation, 2003). Finally, the NIRKO mouse also exhibits a form of hypothalamic hypogonadism with reduced fertility (18). Thus, not only does the brain express insulin receptors—these receptors serve a number of important functions.

A UNIFYING HYPOTHESIS OF TYPE 2 DIABETES

Taken together, the studies of these different tissue-specific knockout mice suggest a potential unifying hypothesis for the role of insulin resistance in type 2 diabetes and the metabolic syndrome (Fig. 9.17). In this model, insulin resistance in muscle leads to increased accumulation of fat and secondary insulin resistance, hypertriglyceridemia, and increased levels of FFAs. Insulin resistance in the liver leads to increased hepatic glucose output. Insulin resistance in the brain leads to an increase in appetite, more obesity, and further defects in hepatic glucose output. Finally, insulin resistance in β -cells leads to defects in glucose sensing and thereby to relative insulin deficiency. Thus, insulin resistance in multiple tissues could produce all of the defects associated with type 2 diabetes, and treatments that improve insulin sensitivity would be expected to improve all defects.

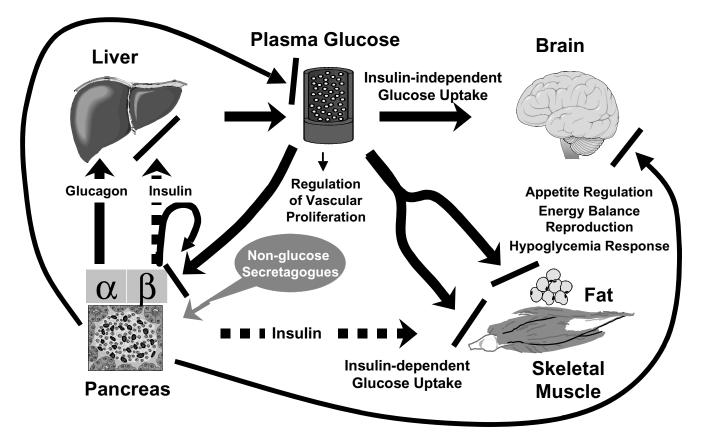

Figure 9.17. A unifying hypothesis for the pathogenesis of type 2 diabetes and insulin resistance based on results from various tissue-specific knockout mice.

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR-I LINKS TO COMPLICATIONS OF DIABETES 175

Retinopathy 175 Nephropathy 176 Neuropathy 176

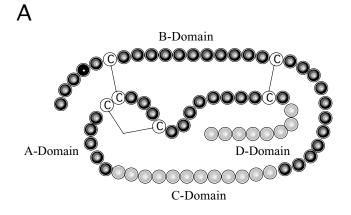

Insulin-like growth factors (IGFs) belong to a family of peptide hormones with structural and functional similarities to insulin. Initially identified on the basis of their insulin-like glucoregulatory effects, IGFs were given the name nonsuppressible insulinlike activity, because hypoglycemia failed to lower their levels in the circulation. Nonsuppressible insulin-like activity was recognized subsequently to consist of various forms of two related proteins, which now are designated insulin-like growth factor-I (IGF-I) and IGF-II. This chapter will focus primarily on IGF-I, a peptide hormone of 7,600 daltons, which is the major mediator of growth-promoting actions of growth hormone. It is present in the circulation at significant levels throughout postnatal life and has glucoregulatory and mitogenic properties that are analogous to those of insulin. IGF-II is related in structure to IGF-I but the product of a separate gene. IGF-II is believed to have important roles in fetal growth and differentiation plus effects on postnatal growth in some tissues. The production of IGF-II by extrapancreatic neoplasms of various types represents an uncommon but well-established cause of tumor-associated hypoglycemia (see Chapter 69 for further discussion).

Unlike insulin, which is derived from a single cell type (pancreatic β -cells) and functions entirely as an endocrine hormone, IGF-I is produced in many different tissues and often acts in a paracrine or autocrine manner. Thus, appreciation of IGF-I function *in vivo* is more difficult than that of a classical endocrine hormone. Insulin and IGFs have common ancestral origins; IGF-I is postulated to have evolved more than 300 million years ago from a single primordial insulin-IGF gene through intron rearrangement followed by gene duplication (1). IGF-I is secreted intact, as it is produced (i.e., not stored

intracellularly), and is composed of four domains designated A through D (Fig. 10.1A). The A- and B-domains are analogous to the A- and B-chains of the insulin molecule. The C-domain is retained in mature IGF-I and IGF-II, whereas the equivalent region is excised during processing of proinsulin to insulin. The D-domain also is present in IGF-I and IGF-II but absent from insulin. The potential for cross-reactivity of IGF-I with insulin receptors, as well as insulin binding to IGF-I receptors, may contribute to complications associated with insulin resistance and diabetes. Despite their substantial homology and capacity for activation of similar cellular signaling pathways, IGF-I and insulin have distinct biologic effects on target tissues. However, IGF-I infusions can occasionally be used to decrease blood glucose in cases of extreme insulin resistance, with IGF-I acting either through its own receptor or through the insulin receptor. The major role of IGF-I in vivo is most likely its involvement in cell division, growth, and proliferation. IGF-I has been implicated in proliferative aspects of certain complications of diabetes, such as retinopathy and nephropathy, although further research is needed to establish the pathologic importance of IGF-I in diabetes complications, and major therapeutic implications have not been realized.

INSULIN-LIKE GROWTH FACTOR-I STRUCTURE AND REGULATION

Circulating IGF-I is substantially derived from liver parenchymal cells, which are stimulated to synthesize and secrete the hormone in response to growth hormone (GH) acting through

hepatic GH receptors. However, IGF-I can also be synthesized locally in a multitude of different tissues under the influence of GH and, to some extent, independently of GH. As shown in Figure 10.1B, IGF-I is homologous to insulin and, even more so, to proinsulin, which includes the C-domain region. Major structural differences are found in the first 16 amino acids of the B-chain, such that IGF-I has considerable affinity for a family of binding proteins that modulate both its circulating half-life and its accessibility to tissues.

Although GH is an important regulator of IGF-I synthesis and secretion, nutritional status and the presence of hyperglycemia also have important influences on concentrations of IGF-I. GH is secreted in a pulsatile and diurnal variable manner from the anterior pituitary under the influence of both positive and negative hypothalamic peptides. GH concentrations peak in the early morning, and because GH acts as a promoter of insulin resistance, rising levels of GH may contribute to earlymorning insulin resistance, the "dawn phenomenon" that occurs commonly in diabetes mellitus. The GH receptor is dimerized upon activation by GH and transmits downstream signals by effecting tyrosine phosphorylation of proteins from both the JAK and STAT families, as well as by activating other

Figure 10.1. A: Domain structure of the insulin-like growth factor-I (IGF-I) protein. The single polypeptide chain extends from the aminoterminal B-domain through the C-domain and A-domain to the carboxyterminal D-domain. The amino acids labeled C represent cysteines, which are linked by disulfide bonds as shown. **B:** Comparative amino acid sequences of human insulin, IGF-I, and IGF-II. Amino acids that are identical in two or more of these hormones are underlined in bold.

signaling intermediates, ultimately leading to changes in expression of genes, including those encoding IGF-I and IGFbinding protein-3 (Fig. 10.2).

Malnutrition, either protein malnutrition or generalized protein-calorie malnutrition (marasmus), also affects IGF-I gene transcription. GH resistance has been reported in malnutrition, with elevated concentrations of GH (2) but low IGF-I mRNA in liver tissue (3,4) and low serum IGF-I (5,6). Fasting has been shown to reduce circulating IGF-I in healthy persons, in association with elevated integrated GH concentrations (7). In rats, GH-binding sites on hepatocytes were reduced following a fast, and GH binding increased in concert with IGF-I plasma concentrations during refeeding (8). In contrast to the effects of overall nutrient restriction, isolated dietary protein depletion results in decreased IGF-I levels in the absence of a change in liver GH-binding capacity, suggesting that postreceptor mechanisms are responsible for the decline in IGF-I in this situation (9-11). Nutritional repletion increases levels of both IGF-I mRNA and protein, and increasing IGF-I concentrations have been shown to predict a return to normal nitrogen balance in ill patients starting nutritional support (12,13). Interestingly, the provision of both energy and protein is required to restore

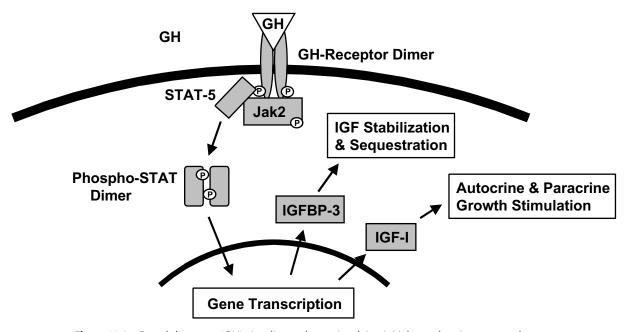

Figure 10.2. Growth hormone (GH) signaling pathways involving initial cytoplasmic events and consequent changes in nuclear gene transcription. IGF, insulin-like growth factor; IGFBP-3, insulin-like growth factor–binding protein-3; P, phosphotyrosine.

IGF-I concentrations. In malnourished laboratory rats, refeeding a eucaloric but low-protein diet was adequate to restore IGF-I, whereas providing protein at 1 g/kg in the face of marked energy restriction was insufficient (14,15). When protein intake is limiting, essential amino acids are more effective at raising IGF-I than is a nonspecific mixture of amino acids (16), although in nutritional support of hospitalized patients, use of essential amino acids has not been associated with improvement in clinical endpoints. As a source of energy, dietary fat appeared to be less effective than carbohydrate in raising IGF-I concentrations and in improving nitrogen balance in a study examining responses to exogenous GH administration in the presence of limited energy intake (15). Hypercaloric nutrition in healthy volunteers has been associated with slight increases in circulating IGF-I, but the effect of overnutrition appears to be much less marked than that of undernutrition (17).

Uncontrolled diabetes is associated with low serum IGF-I concentrations, although whether diabetes has an effect independent of concomitant negative nutritional status has not been determined (18). Insulin-deficient diabetic rats have low IGF-I concentrations, which are restored at least partially with exogenous insulin therapy (19–21). Although nutritional factors confound the relationship between the two hormones, the finding that exposure to insulin *in vitro* increases the number of GH receptors on hepatocytes supports a direct link between insulin status and IGF-I levels (22). Protein restriction in diabetic rats prevents the restoration of IGF-I concentrations following insulin treatment, in contrast to a normalization of IGF-I in insulin-treated diabetic rats given adequate dietary protein (23).

Circulating IGF-I is bound with high affinity to a number of IGF-binding proteins (IGFBPs). Six binding proteins in the range of 20 to 30 kDa have been cloned and sequenced. The bulk (~90%) of measurable IGF-I is bound to IGF-binding protein-3 (IGFBP-3), with only a small fraction (<5%) of total IGF-I being free. IGFBP-3 serves as a reservoir of IGF-I, which retains IGF-I in the circulation, prevents rapid fluctuations in plasma concentrations, and probably functions to prolong the

circulating half-life of IGF-I. IGFBP-3 is generally regulated in parallel with IGF-I, with nutrition and GH being major stimulators of IGFBP-3 concentrations. IGFBP-1, forming a smaller complex with IGF-I, can cross capillary endothelium and may participate in the delivery of IGF-I to the cell surface, where IGF-I receptors are accessible. Food intake, in association with rising plasma concentrations of insulin, lowers IGFBP-1 concentrations abruptly, perhaps by inducing its movement out of the vascular lumen (24). Both IGFBP-1 and IGFBP-2 concentrations increase with fasting (25) and, in the presence of diabetes, show opposite regulation from IGFBP-3 and IGF-I (26,27). Assessment of the kinetics of IGF-I action is difficult, because the functions and importance of the IGFBPs have not been fully defined. Synthetic analogues of IGF-I, altered so that binding to IGFBPs is prevented, are more potent than IGF-I when injected into experimental animals (28,29). This suggests that inhibition of IGF-I action is a major function of the binding proteins, although the binding proteins also may have some actions independent of the IGFs (30).

INSULIN-LIKE GROWTH FACTOR-I RECEPTOR

The IGF-I receptor (also designated type I IGF receptor) is present in multiple body tissues, with the notable exceptions of liver parenchymal cells and adipocytes, in which the levels are very low. IGF-I receptor mRNA is most abundant during embryonic life, with significant but much lower levels during adulthood. The functional receptor is a heterotetrameric transmembrane protein containing two types of subunits joined by disulfide bonds in a B-A-A-B configuration (Fig. 10.3). This is closely analogous to the structure of the insulin receptor. The α -subunits (M_r 135 kDa) are entirely extracellular and contain the hormonebinding site; the β -subunits (95–105 kDa, depending on the tissue) span the plasma membrane, and each contains an intracellular tyrosine kinase domain. IGF-I and insulin receptors are encoded by separate genes, but they exhibit approxi-

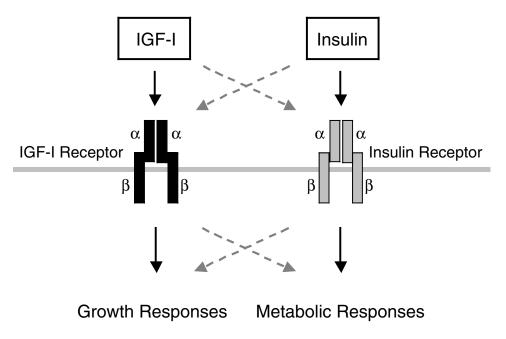

Figure 10.3. Homology in the structures of the insulin-like growth factor-I (IGF-I) and insulin receptors. Each hormone binds with greatest affinity to its own receptor but when present at high concentrations can bind to the other receptor. Both receptors can induce a full complement of cellular signaling responses. However, there is evidence for greater stimulation of cell-growth responses by the IGF-I receptor and greater stimulation of metabolic responses by the insulin receptor.

mately 40% overall amino acid sequence identity, and there is phylogenetic evidence for their emergence from a single precursor receptor. Much higher sequence homology is present in key functional regions, such as the tyrosine kinase domain. In spite of extensive similarities, the critical regions involved in hormone binding establish clear functional differences for insulin and IGF-I receptors. IGF-I and insulin each binds with high affinity to its cognate receptor. There is a potential for binding cross-reactivity related to structural similarities of the ligands and receptors, although such binding generally requires concentrations of the opposing hormone above the normal physiologic range (Fig. 10.3). Thus, the IGF-I receptor binds insulin with much lower affinity than it binds IGF-I.

Hormone-binding specificity depends on key cysteine residues and other structural features in the extracellular receptor α -subunits, whereas the transmembrane β -subunits mediate signal transduction predominantly via their intrinsic tyrosine kinase activity. Binding of IGF-I to its receptors is believed to result in conformational changes that lead to autophosphorylation in a "trans" reaction, in which the tyrosine kinase of one β -chain cross-phosphorylates specific tyrosine residues in the opposite β -chain within the receptor heterotetramer. This positions the active tyrosine kinase domains for the phosphorylation of cellular substrates, such as the insulin receptor substrate (IRS) proteins, which then initiate a cascade of downstream signaling events that result in hormone action (see Chapter 9 for further details on the signaling pathways of the insulin and IGF-I receptors).

INSULIN AND INSULIN-LIKE GROWTH FACTOR-I SPECIFICITY

Although insulin and IGF-I are structurally similar and, at high concentrations, can activate each other's receptors, the receptors provide substantial signaling specificity. IGF-I is approximately 1,000 times less potent than insulin in displacing radiolabeled insulin from its insulin-receptor binding sites. Insulin, in turn, is approximately 500 times less potent than IGF-I in displacing radiolabeled IGF-I from its IGF-I-receptor binding sites. On a molar basis, injected IGF-I is only about 6% as potent as insulin

in causing hypoglycemia in humans (31). IGF-I differs from insulin not only in being produced in a wide variety of tissues but in having markedly different diurnal circulating profiles, with an absence of clear peaks for IGF-I. In skeletal muscle biopsies from obese diabetic humans, binding of insulin to its receptors was markedly diminished, but binding of IGF-I was unchanged. IGF-I-stimulated tyrosine kinase activity examined ex vivo was also not different in tissue extracts from diabetic and control subjects (32). This suggests discrete downstream pathways with differential regulation of insulin and IGF-I receptors. In another study addressing the same issue, skeletal muscle from nondiabetic individuals demonstrated a twofold increase in glucose transport in response to IGF-I, whereas samples from diabetic patients showed no activation of glucose transport. It was observed, however, that binding of IGF-I to skeletal muscle was normal in the diabetic patients (33). This suggests that there may be changes specific to the insulin receptor in type 2 diabetes but that resistance to both insulin and IGF-I is at a common site downstream of the receptor tyrosine kinases.

Insulin signaling through its receptor activates phosphorylation cascades that lead to both metabolic and mitogenic cellular responses (Fig. 10.3), though the most important actions of insulin are thought to affect metabolic endpoints. Although the binding of IGF-I to its receptors can activate many of the same signaling molecules, IGF-I actions are thought to be primarily mitogenic. In cultured fibroblasts expressing similar numbers of insulin and IGF-I receptors, IGF-I activation of pathways leading to DNA synthesis was more marked, suggesting quantitative differences in the stimulation of different postreceptor pathways by IGF-I and insulin receptors (34). Studies on chimeric receptor proteins containing the receptor-binding portion of a neurotrophin receptor fused to the intracellular domains of either IGF-I or insulin receptors indicate that at least part of receptor signaling specificity lies within the intracellular domains (35). When activated by neurotrophin, the insulinreceptor chimera expressed in cultured fat cells was more effective in stimulating glucose transport and translocation of the GLUT4 glucose transporter. By contrast, when expressed in the same fat cell line, the IGF-I-receptor chimera more effectively activated mitogen-activated protein (MAP) kinase pathways,

which are believed to link most strongly to the stimulation of DNA synthesis and cell proliferation.

Investigation of other signaling differences between insulin and IGF-I receptors that confer specificity on each pathway is critically important to our understanding of IGF-I action in vivo. Evidence continues to accumulate that differences between these two signaling pathways exist, although there also appears to be substantial overlap. The use of peptides containing four major phosphorylation sites of IRS-1 in kinase assays with each receptor showed identical specificity of insulin and IGF-I receptors for IRS-1 (36). Although the two hormones activate IRS-1 similarly (at least in vitro), a specific isoform of phosphoinositide 3-kinase (PI 3-K-C2 α), a signaling enzyme activated by IRS-1, was stimulated to a greater extent by insulin receptors than by IGF-I receptors (37). The liver plasma membrane glycoprotein, pp120, also was found to be preferentially phosphorylated by insulin receptors in cultured fibroblasts transfected with insulin as compared with IGF-I receptors (38). By contrast, IGF-I receptors stimulated tyrosine phosphorylation of the signaling adapter Crk II, whereas insulin receptors were substantially less effective (39).

Specificity in IGF-I and insulin action may result from the distinct interactions of these two receptor proteins not only with signal-transducing molecules but also with signaling regulators. For example, Grb10 is a putative adapter protein that has the capacity to bind to IGF-I and insulin receptors through the interaction of motifs in its C-terminal region with phosphotyrosine residues in activated IGF-I and insulin receptors (40–42). Evidence has been presented for both negative and positive effects of Grb10 on IGF-I and insulin signaling. In studies on a specific isoform of Grb10 in mouse tissues (Grb10\delta), much stronger interaction was demonstrated with insulin receptors than with IGF-I receptors (43).

cDNA microarray technology has been used to examine the expression levels of genes in cultured fibroblasts overexpressing either insulin or IGF-I receptors (44). IGF-I activation of its receptors led to increased mRNA levels for 30 genes that were not increased as a consequence of insulin activation of insulin receptors. These were mostly genes known to be important in growth and differentiation. A total of nine genes were much more strongly stimulated by insulin receptors than by IGF-I receptors, none of which had previously been noted to be insulin responsive. The implications of this study are yet unclear because the observations were made only in cultured fibroblast cell lines. However, these data add further support to the concept that IGF-I and insulin receptors mediate distinct signaling responses in their target cells.

Insulin and IGF-I receptors are required for normal embryonic growth and development, but their roles early in development are different from those in postnatal life (45). IGF-I receptors mediate the effects of both IGF-I and IGF-II during embryonic development, whereas insulin receptors mediate effects of IGF-II but not those of insulin (46). Humans with homozygous or compound heterozygous mutations of the insulin receptor who present at birth with the leprechaunism syndrome (a severe form of insulin resistance) have severe intrauterine growth retardation and postprandial hyperglycemia, and die in infancy (47). In fibroblasts derived from a patient with this syndrome, IGF-I binding and IGF-I receptor β-subunit tyrosine phosphorylation were normal, as was IGF-I– stimulated thymidine incorporation into DNA, suggesting the potential therapeutic usefulness of IGF-I (48). Clinical investigations in this patient demonstrated low circulating concentrations of IGF-I and IGFBP-3, which were resistant to GH therapy. Administration of recombinant human IGF-I maintained nearnormal growth and glycohemoglobin for 6 years. Tonsillar

hypertrophy was the only evident complication of IGF-I therapy, as previously has been observed following IGF-I treatment of patients with defects in the GH receptor (Laron dwarfism). Treatment of other patients with insulin-receptor mutations with IGF-I has yielded variable success, with evidence in some patients of combined resistance to both insulin and IGF-I (49). Since IGF-I and insulin receptors exist in part as hybrid constructs composed of one IGF-I and one insulin-receptor $\alpha\beta$ heterodimer, it is possible that some mutated forms of insulin half-receptor could exert a dominant negative effect on the IGF-I half-receptor and thus result in IGF-I resistance.

HYBRID INSULIN-LIKE GROWTH FACTOR-I/INSULIN RECEPTORS

Hybrid IGF-I and insulin receptors (Fig. 10.4) have been described in a number of tissues, and there is some evidence that they have signaling properties more closely related to IGF-I receptors than to insulin receptors. For example, hybrid receptors have a 10-fold lower affinity for insulin than do classical insulin receptors but a preserved sensitivity to IGF-I. It is thought that the fraction of IGF-I or insulin receptors in hybrid constructs in a given tissue reflects the relative abundance of the two receptor types. Thus, in a tissue with much greater abundance of IGF-I receptors than insulin receptors, most insulin receptors would be present in hybrids, whereas there would be a larger fraction of pure IGF-I receptors. The opposite circumstance may characterize skeletal muscle, in which 85% to 90% of IGF-I binding appears to be present in hybrid receptors (50). There is evidence for increased abundance of hybrid receptors in diabetes associated with insulin resistance, although the functional importance of hybrid receptors in vivo will require further study (51,52). As noted above for patients with mutations in the insulin receptor and the leprechaunism syndrome, insulin (and IGF-I) resistance may occur in some instances as a consequence of mutant half-receptors for one of the two hormones exerting a dominant-negative effect on the other halfreceptor. In rodents with dominant-negative mutations in the IGF-I receptor, both insulin and IGF-I signaling pathways are inhibited in association with the development of insulin-resistant diabetes (53). Significant amounts of the insulin receptor were detected in immunoprecipitates of IGF-I receptor from skeletal muscle homogenates in these animals, and vice versa. The data suggest that expression of a dominant-negative IGF-I receptor in muscle induced the formation of nonfunctioning hybrids containing a normal insulin-receptor $\alpha\beta$ pair and a mutant IGF-I receptor $\alpha\beta$. In contrast, knockout of the insulin receptor in muscle was associated with far milder glucoregulatory dysfunction, suggesting that IGF-I receptors can compensate for impaired insulin receptors (54-56).

HUMAN RECEPTOR MUTATIONS

Two individuals with deficient IGF-I function as a consequence of receptor mutations have recently been identified (57). One patient has a distinct substitution mutation in each IGF-I receptor allele (one inherited from each parent). The mutations are located in the receptor α -subunits in the region of the putative IGF-I binding pocket, and the receptors exhibit more than a 10-fold decrease in IGF-I binding affinity. The second individual is heterozygous for a mutation that introduces a stop codon a short distance after the IGF-I–receptor translation start site. The resulting loss of one of two alleles results in a reduction in gene dosage, with a 50% decrease in the abundance of IGF-I

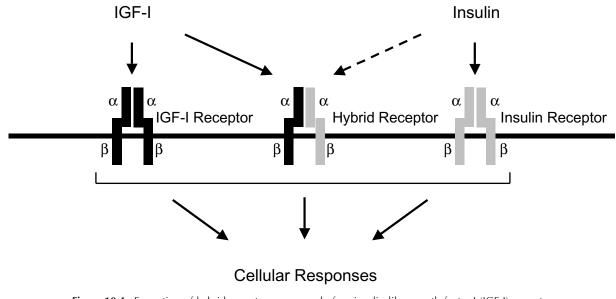

Figure 10.4. Formation of hybrid receptors composed of an insulin-like growth factor-I (IGF-I)–receptor $\alpha\beta$ -dimer linked by disulfide bonds to an $\alpha\beta$ insulin-receptor dimer. Hybrid formation is believed to occur during synthesis of receptor protein and thus reflects, in general, the relative abundance of newly synthesized IGF-I and insulin receptors in an individual cell. Limited experimental evidence suggests that hybrid receptors may bind IGF-I with higher affinity than they bind insulin. The specific actions of hybrid receptors in stimulating cellular responses to IGF-I and insulin are still under investigation.

receptors demonstrated in cultured skin fibroblasts. The phenotype for both of these individuals includes marked intrauterine and postnatal growth restriction but no abnormalities in glucose or insulin levels (at least in childhood). Additional studies have reported intronic and silent polymorphisms in the IGF-I– receptor gene, but the frequency of these variants was not found to be higher in patients with diabetes than in population controls (58). Taken together, these findings suggest that subtotal loss of IGF-I–receptor signaling in humans is not associated with marked abnormalities in carbohydrate metabolism.

Insulin-receptor mutations are associated with insulin resistance, and a variety of resulting clinical syndromes of insulin resistance have been described. When diabetes mellitus occurs under these circumstances, the effect of the mutations on growth is difficult to interpret because hyperglycemia and other metabolic disturbances associated with deficient insulin action itself will limit growth. Hypoinsulinemia from any cause [e.g., pancreatic agenesis (59) or glucokinase mutations (60)] is associated with growth retardation, suggesting that insulin has a major growth-promoting role in human fetuses. Again, however, it is difficult to separate the direct effects of insulin from its indirect actions via disturbed body fuel metabolism.

RECOMBINANT INSULIN-LIKE GROWTH FACTOR-I AND INSULIN ANALOGUES

Human recombinant IGF-I has been available for use in research studies and for rare clinical conditions (e.g., Laron dwarfism as noted above). The administration of large bolus doses of recombinant IGF-I to experimental animals *in vivo* results in hypoglycemia mediated through increases in glucose uptake by muscle, without effects on hepatic glucose output or suppression of free fatty acid output from adipocytes (61). This is quite different from the effects of bolus insulin injection, suggesting that IGF-I is acting through its own receptor and not merely via cross-reactivity with insulin receptors. In BB/w diabetic rats, which are both

insulin deficient and insulin resistant, IGF-I is effective in lowering blood glucose concentrations (62). This occurs in part through decreased hepatic glucose production in response to IGF-I, although the responsible receptor has not been defined. Humans treated with continuous infusions of IGF-I at doses requiring intravenous glucose to maintain normoglycemia show inhibition of circulating free fatty acids and hepatic glucose release, unlike what has been found in the rodent studies of bolus IGF-I administration. Insulin sensitivity as assessed by the insulin/glucose ratio during a glucose tolerance test was increased by an unknown mechanism in humans after IGF-I infusion, possibly through inhibition of release of growth hormone.

The pharmaceutical industry has exploited certain characteristics of the ability of IGF-I to bind the insulin receptor and has investigated the effects of mutation of the insulin molecule to produce insulins with a lower tendency to self-aggregate following subcutaneous injection. One early such compound (B10Asp-referring to substitution with an aspartate on the tenth position on the β -chain of insulin) has mitogenic potential similar to that of IGF-I, and its use in rodents was associated with the development of mammary tumors. Thus, the differential interaction with IGF-I receptors may contribute significantly to the action profile of insulin analogues. In one study, insulin and IGF-I-receptor binding properties and metabolic and mitogenic potencies of insulin aspart (B28Asp insulin), insulin lispro (B28Lys, B29Pro insulin), and insulin glargine (A21Gly, B31Arg, B32Arg insulin) were compared (63). Receptor affinities were measured in purified human receptors, insulin-receptor dissociation rates were determined in Chinese hamster ovary cells overexpressing insulin receptors, metabolic potencies were evaluated using primary mouse adipocytes, and mitogenic potencies were determined in human osteosarcoma cells. Metabolic potencies of the insulin analogues correlated well with insulin-receptor affinities, and mitogenic potencies in general correlated well with IGF-I-receptor affinities. The two rapid-acting insulin analogues, aspart and lispro, resembled human insulin in all parameters except for a slightly elevated

affinity of lispro for the IGF-I receptor. In contrast, the longacting insulin analogue glargine differed significantly from human insulin. The combination of the A21Gly, B31Arg, B32Arg substitutions provided insulin glargine with a six- to eightfold increased affinity for the IGF-I receptor and mitogenic potency as compared with human insulin. The increased growthstimulating potential of insulin glargine initially raised concern about potential IGF-I receptor–mediated side effects. However, these have not been apparent (64), and insulin glargine is currently available for clinical use in the United States.

GROWTH HORMONE/INSULIN-LIKE GROWTH FACTOR-I AXIS AND DIABETES

A relationship between abnormal GH dynamics and glucose intolerance was first recognized many years ago. This included the observation that hypophysectomy improves glycemic control (65). In uncontrolled diabetes, usual findings include reductions in IGF-I levels, elevated IGFBP-1 levels, and somewhat elevated GH levels, highlighting a GH-resistance state. In general, intensive insulin therapy does not completely reverse these abnormalities.

Elevated circulating levels of GH cause insulin resistance. In acromegaly, this progresses to diabetes in approximately 25% of patients. In experimental animals, infusion of GH is associated with reduced whole-body glucose uptake and decreased sensitivity to insulin in liver and skeletal muscle. GH has been shown to cause downregulation of the insulin signaling cascade in liver and skeletal muscle (66). IGF-I has a negative feedback effect on pituitary release of GH and thus may improve insulin sensitivity by reducing circulating GH concentrations. This observation led to interest in the use of IGF-I therapeutically in type 1 diabetes (67–69). In randomized trials in children, IGF-I (40–80 µg/kg per day) added to usual insulin therapy improved glycemic control compared with placebo (70,71). This appeared to correlate with prevention of the typical early morning rise in GH that contributes to the dawn phenomenon. In a study of 12 adults with type 1 diabetes, IGF-I (40 µg/kg per day) administered in conjunction with a reduced bedtime insulin dose for 7 days resulted in a 50% increase in circulating IGF-I concentrations, a 55% reduction in overnight GH concentrations, and improved insulin sensitivity by hyperinsulinemic euglycemic clamp (72,73). Assuming that the glycemic potency of IGF-I is approximately 8% that of insulin, the IGF-I dosage used was equivalent to an insulin dose of about 0.06 U/kg per day. The reduction in usual insulin dose was 0.11 U/kg per day, which suggests that the hypoglycemic action of IGF-I was not solely due to insulin-like activity. Side effects of recombinant IGF-I therapy include edema and headaches. Administration of IGF-I in combination with IGFBP-3 has been shown to permit the metabolic benefits of IGF therapy with fewer adverse effects (74).

It is likely that improved insulin sensitivity as a result of decreased GH secretion accounts for the improvements in metabolic control. Levels of free fatty acids were noted to be decreased during a hyperinsulinemic clamp after IGF-I administration, which may also have contributed to increased glucose utilization through a reduction in competition of fatty acids with glucose via the glucose–fatty acid cycle. Reduced lipolysis, as a result of IGF-I–induced inhibition of GH secretion, may explain the effect, although not all studies have shown such changes in free fatty acids (75). However, in patients with acromegaly, in whom GH concentrations were stabilized with pegvisomant (a GH-receptor antagonist), administration of IGF-I/IGFBP-3 improved insulin sensitivity, suggesting that mechanisms independent of GH levels also may be important (76).

IGF-I has been used therapeutically in patients with rare forms of diabetes associated with severe insulin resistance. Here the utility probably relates to IGF-I stimulation of glucose uptake and other glucoregulatory responses via activation of the IGF-I receptor. In one study of four adult patients, IGF-I given by subcutaneous injection in a high dose (80 μ g/kg) markedly lowered plasma glucose levels (77). In an unusual case of insulin resistance associated with diabetic ketoacidosis in an adolescent patient, IGF-I administration lowered blood glucose levels under circumstances in which insulin was ineffective at extremely high doses. This patient was maintained subsequently on combination therapy with insulin and IGF-I (78). In typical type 2 diabetes, IGF-I therapy by injection can lower plasma glucose levels and improve insulin sensitivity, although it is not clear that this has advantages over the use of insulin alone (79)

Activation of IGF-I receptors by insulin in insulin-resistant states has been associated with untoward effects. For example, in some patients with rare forms of extreme insulin resistance and markedly elevated insulin levels, an acromegalic pattern of body growth has been attributed to insulin cross-reactivity with IGF-I receptors. In polycystic ovary syndrome (PCOS), insulin resistance and secondary hyperinsulinemia are thought to result in activation of ovarian IGF-I receptors, which may contribute to overproduction of androgen and consequent oligomenorrhea and hirsutism. In states of IGF-I excess, IGF-I itself also may lead to IGF-I receptor-mediated production of androgen. For example, in a study of female patients with Laron dwarfism treated with IGF-I, acne and oligomenorrhea developed in parallel with a rise in IGF-I and testosterone levels, and these effects were reversed by interrupting or lowering the dose of IGF-I (80). In cultured theca interstitial cells, both insulin and IGF-I stimulate DNA synthesis in a dose-dependent fashion, with IGF-I having greater potency than insulin (81). An increased number of IGF-I receptors on erythrocytes, irrespective of the patient's body mass index, has been described in patients with PCOS, although serum IGF-I concentrations were similar in the PCOS patients and controls (82). In this study, the degree of hyperinsulinemia, provoked by glucose challenge, correlated as expected with basal insulin but not with the number of IGF-I receptors. However, the number of IGF-I receptors correlated positively with androstenedione levels. This suggests a potential role for altered expression of IGF-I receptors in PCOS and further supports the concept that hyperandrogenism in PCOS may not be a direct result of hyperinsulinemia but a reflection of the ability of either insulin or IGF-I to activate IGF-I receptors. In general, serum IGFBP-1 levels are lower in PCOS, likely because of hyperinsulinemia, and levels of free IGF-I in serum are modestly increased (83). However, many of the findings of links between the IGF system and androgen production from the ovary are confounded by the existence of local production of IGF-I and IGFBPs in both theca cells and stroma of normal as well as cystic ovaries (84,85).

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR-I LINKS TO COMPLICATIONS OF DIABETES

Retinopathy

Activation of the GH/IGF-I axis may contribute to diabetic retinopathy. Early observational studies documented regression of even established retinopathy in patients who developed pituitary failure or underwent hypophysectomy (86). Some studies have reported an association between plasma or intraocular

176 JOSLIN'S DIABETES MELLITUS

levels of IGF-I and the occurrence or progression of diabetic retinopathy (87,88). However, the general consensus of published work is that levels of IGF-I do not correlate with retinopathy. The observed decrease in retinopathy with hypopituitarism may therefore reflect a role of IGF-I not as a primary causal agent but as a contributor at either normal or elevated levels as a permissive factor in diabetic retinopathy.

In a condition somewhat similar to diabetic retinopathy, ischemia-induced retinopathy, the effects of inhibition of GH have been studied in two experimental model systems. Transgenic mice expressing a GH inhibitor gene and normal mice given a GH antagonist both had marked inhibition of ischemiainduced retinal neovascularization compared with control mice (89). Neovascularization was inhibited in inverse proportion to serum levels of IGF-I, and the protective effect was reversed with systemic administration of exogenous IGF-I. In another study, vascular endothelial cell-specific inactivation of the IGF-I receptor by homologous recombination (tissue-specific gene knockout) resulted in a 34% decrease in neovascularization induced by hypoxia (90). This supports a role for IGF-I action specifically in vascular endothelial cells as a contributing factor, at least in experimental hypoxia-induced retinopathy. In the same model system, inactivation of the insulin receptors of vascular endothelial cells resulted in an even more marked decrease of 57% in retinopathy.

The constellation of data overall suggests that systemic inhibition of the GH/IGF-I system may have therapeutic potential in proliferative diabetic retinopathy. However, beneficial effects of lowering IGF-I levels, either directly or via inhibition of GH action, have not yet been clearly demonstrated. Results following treatment with somatostatin have been inconsistent. The GH antagonist pegvisomant, a mutant form of GH that binds but does not activate GH receptors, also has not been effective in inducing regression of diabetic retinal neovascularization (91). The possibility of decreasing diabetic proliferative retinopathy by specifically suppressing IGF-I pathways in the retina remains a question and a challenge for future study.

Nephropathy

Microalbuminuria in diabetes has been associated with increased urinary and plasma IGF-I concentrations. In a study of adolescents with type 1 diabetes, urinary levels of IGFBP-3 initially appeared to be directly correlated with the rate of urinary albumin excretion (92). However, further analysis demonstrated that an N-terminal fragment of IGFBP-3 was being measured, that intact plasma IGFBP-3 actually was lower in diabetic participants with microalbuminuria than in those without microalbuminuria, and that IGFBP-3 proteolytic activity was enhanced in individuals with microalbuminuria. Subsequent studies have demonstrated elevated IGFBP-3 protease activity in both microalbuminuric and macroalbuminuric patients with type 2 diabetes. In another study of children, urinary IGF-I was strongly correlated with kidney size and subsequent diabetic nephropathy (93). Patients with microalbuminuria had significantly higher levels of both urinary IGF-I and GH. Of interest, only 9% of the variance in urinary IGF-I could be attributed to plasma IGF-I. The precise mechanism that leads to increased urinary IGF-I has not been defined, but these observations suggest that alterations in the bioavailability of IGF-I and the effects of IGF-I on mesangial or tubular-cell proliferation might play a role in diabetic nephropathy (94,95). Hyperglycemia increases sensitivity of mesangial cells in culture to IGF-I, representing another mechanism that may lead to an increased glomerular proliferative response (96).

Therapy with somatostatin analogues to inhibit pituitary GH production has been shown to inhibit renal growth in association with reduced renal medullary concentrations of IGF-I (97). Mice with knockout of the GH receptor that subsequently were rendered diabetic with streptozotocin were protected against diabetic nephropathy (98). Control diabetic mice with an intact GH axis developed glomerulosclerosis, increased glomerular volume, and mesangial expansion, and all of these abnormalities were absent in the knockout mice despite equivalent severity of diabetes.

Neuropathy

In contrast to the potential protective effects of IGF-I deficiency on diabetic retinopathy and nephropathy, there is evidence that IGF-I deficiency in neuronal tissue may contribute to the development and progression of diabetic neuropathy as a consequence of loss of antiapoptotic actions of IGF-I (99,100). Insulin and the IGFs have neurotrophic actions on sensory, sympathetic, and motor neurons, all of which can be affected in diabetic neuropathy (99). IGF activity is reduced in nerve tissue in rodent models of diabetes, and some studies have shown that replacement of IGF-I decreases the occurrence of neuropathy despite ongoing hyperglycemia. In rat superior cervical ganglia studied in vitro, hyperglycemia has been shown to induce apoptosis and inhibit neurite growth, similar to what occurs in association with diabetes in vivo (101). Treatment with IGF-I prevented these changes. Schwann cells undergo apoptosis after serum withdrawal, and this can be reversed by IGF-I through antiapoptotic pathways involving PI 3-kinase and protein kinase B (102). Further study will be required to determine whether IGF-I deficiency in neuronal tissue is a significant factor in the development of diabetic neuropathy.

At present, there is considerable interest in new pharmacologic approaches to the inhibition of GH and/or IGF action in the prevention or treatment of diabetes complications. As this work progresses, it will be important to carefully evaluate the potential counterbalancing effects of decreased IGF action in protecting against retinopathy and nephropathy and, at the same time, predisposing to neuropathy.

Investigations during the past 15 years have uncovered a remarkable, unanticipated complexity in the repertoire of biologically active hormones produced by the expression of the proglucagon gene. Because of these new discoveries, an entirely new perspective has arisen regarding the biologic functions and importance of proglucagon-derived peptides in the pathogenesis of diabetes mellitus. The structure of the proglucagon gene, established by DNA cloning approaches, reveals that it encodes a large preproglucagon protein consisting of an N-terminal signal sequence and a prohormone encoding glucagon and several glucagon-like peptides (GLPs). The signal sequence is removed from the prohormone during its synthesis so that the initial completed protein synthesized is the prohormone referred to as proglucagon. The structure of proglucagon is representative of prohormones that encode peptide hormones inasmuch as it contains multiple biologically active hormones that are released from the prohormone by tissue-specific proteolytic cleavages. Proglucagon undergoes alternative posttranslational cleavages whereby the hormone glucagon is produced in the α -cells of the endocrine pancreas (islets of Langerhans) and glucagon-like peptides are produced in the L cells of the intestine. Glucagon and the glucagon-like peptides are all members of a superfamily of peptides structurally related to glucagon, including vasoactive intestinal peptide, secretin, gastric inhibitory polypeptide, and growth hormone-releasing hormone, among others. Each of these glucagon-related peptide hormones is involved to some extent in the regulation of nutrient homeostasis, growth, or development, acting via G-protein-coupled receptors that

increase the formation of cyclic adenosine monophosphate (cAMP). Glucagon is secreted from α -cells and functions predominantly during the fasting state to maintain blood glucose levels by the mobilization of glucose from glycogen stores in peripheral tissues such as muscle and liver. Excessive production of glucagon contributes to hyperglycemia, and thus approaches that antagonize glucagon action in subjects with diabetes mellitus are being actively investigated. The glucagonlike peptides are secreted in response to feeding. Glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP) comprise the intestinal "incretin" hormones released from the intestine in response to feeding and augment glucose-stimulated insulin secretion from the β -cells of the islets of Langerhans. GLP-1 also enhances insulin-stimulated glucose uptake in peripheral tissues (muscle, fat, liver), suppresses glucagon secretion, induces satiety, and promotes the growth and differentiation of new $\beta\text{-cells}$ in the pancreas. These antidiabetic properties of GLP-1 have prompted considerable interest in the therapeutic potential of GLP-1 for the treatment of diabetes mellitus. GLP-2 is a potent growth factor for intestinal epithelium and holds promise for the treatment of inflammatory bowel diseases. This chapter provides an overview of the historical advances in the understanding of the biologic and physiologic roles of these proglucagon-derived peptides and their potential importance in the pathogenesis of diabetes mellitus. A recent review describes the biology of glucagon and the GLPs (1). Additional review articles describe the biology of the GLPs in detail (2-10).

EXPRESSION OF THE PROGLUCAGON GENE

Tissue Distribution

The expression of the proglucagon gene (chromosome 2q36-q37 in humans) is restricted to a limited number of tissues. So far, proglucagon or proglucagon messenger RNA (mRNA) has been found in the α -cells of the endocrine pancreas, L cells in the distal small intestine and colon, and localized regions of the brain (hypothalamus and nucleus of the solitary tract). Current evidence indicates that the regulation of expression of the proglucagon gene takes place at two levels of expression: posttranslational processing of proglucagon and the transcription of the preproglucagon gene.

Regulation

ALTERNATIVE POSTTRANSLATIONAL PROCESSING

Proglucagon, synthesized in the α -cells of the islets, is processed by specific proteolytic cleavages in a pattern that differs markedly from the processing in the L cells in the intestine and the peptidergic neurons in the brain (Fig. 11.1). In the α cells, specific prohormone convertases cleave and liberate glucagon from proglucagon, leaving behind the presumably biologically inert "major proglucagon fragment" and the N-terminal fragment of proglucagon (11). In contrast, in L cells and in peptidergic neurons, cleavages of proglucagon by a different set of prohormone-converting enzymes results predominantly in the formation of GLPs comprising the GLP-1 group of isopeptides and GLP-2.

Much of the new interest and excitement in the field of discovery research on the hormone glucagon produced by the α cells of the islets of Langerhans arises from the findings that the precursor prohormone, proglucagon, also encodes the GLPs and that these peptides have unanticipated novel biologic activities in the regulation of nutrient metabolism, the growth and differentiation of insulin-producing β -cells of the pancreas, the control of appetite, and the promotion of the growth of intestinal epithelium (5,6,12). These recent findings on the actions of GLPs encoded by the preproglucagon gene have prompted great interest in the pursuance of the biochemistry and mechanism of actions of the GLPs.

The proteolytic cleavages-so-called posttranslational processing-of proglucagon that result in the formation of GLPs are somewhat complex. At least six GLP-1 isopeptides are formed: the largest peptides of 37 and 36 amino acids, C-terminal glycine-extended GLP-1(1-37) and C-terminal-amidated GLP-1(1-36)amide; and the N-terminal-truncated GLP-1s, GLP-1(7-37), GLP-1(7-36)amide, GLP-1(9-37), and GLP-1 (9-36)amide. So far, it appears that the biologic activities of the GLP-1s reside in the peptides GLP-1(7-37) and GLP-1 (7–36)amide; the two peptides have indistinguishable activities. The 1-37/36 and 7-37/36 peptides are cleaved from proglucagon by the actions of the prohormone convertases PC1/3 and PC2, whereas the 9-37/36 peptides are derived from the former peptides by cleavage of two N-terminal amino acids by the enzyme dipeptidyl peptidase IV (DPP-IV), also known as CD26 (13,14). DPP-IV is a ubiquitous enzyme expressed in many tissues and carried in the circulation. Cleavages of the GLP-1s by DPP IV occur at the time of their secretion from the intestinal L cells and within the circulation (15). Notably, the 9-37/36 peptides bind to the GLP-1 receptor but are biologically inactive and are weak antagonists. Most of the GLP-1 in the circulation consists of the apparently inert 1-37/36 and 9-37/36 peptides with no known biologic activities heretofore.

TRANSCRIPTION

A second level of the regulation of the expression of the GLPs is that of gene transcription. The preproglucagon gene consists of a transcribed sequence (Fig. 11.2) and a 5'-flanking promoter sequence (Fig. 11.3). The transcribed sequence in turn consists of six exons separated by five introns (16). Notably, each of the glucagon peptides—glucagon, GLP-1, and GLP-2—are encoded in separate exons (exons 3, 4, and 5), suggesting the occurrence of exonic duplication during evolutionary history (7). Although the peptides are encoded in separate exons, unlike many multi-

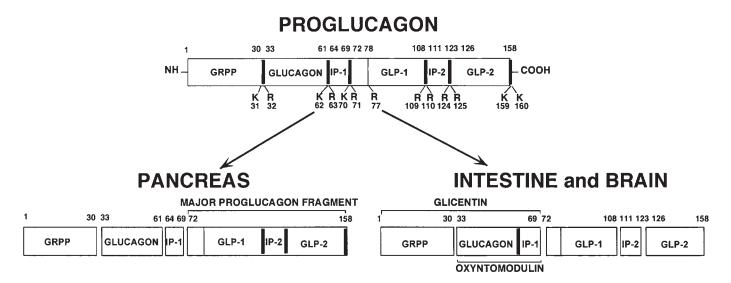

Figure 11.1. Alternative posttranslational processing of proglucagon in pancreas and intestine plus brain. Processing at specific pairs of basic residues produces numerous multifunctional peptide hormones involved in nutrient metabolism. The major bioactive processed hormones are glucagon in the pancreas α -cells and GLP-1 in the intestinal L cells and brain. Numbers on proglucagon denote amino acid positions. K, lysine; R, arginine; GRPP, glicentin-related pancreatic peptide; IP-1 and IP-2, intervening peptides; GLP-1 and GLP-2, glucagon-like peptides. (From Kieffer TJ, Habener JF. exonic genes, the expression of these genes in mammals is not regulated by alternative exon splicing of the RNA; preproglucagons in both pancreas and intestine appear to be translated from identical mRNAs. However, in lower vertebrates (chickens, fish, and frogs), alternative splicing of exons does occur. The promoter of the preproglucagon gene is bipartite with respect to regions responsible for expression in pancreatic α -cells and intestinal L cells. Promoter sequences within 700 base pairs 5' flanking the initiation of transcription are sufficient to direct the faithful expression of the preproglucagon gene in α -cells, whereas sequences required for expression in L cells reside more 5' between nucleotides -3000 to -1000 (5,16, 17). The sequences of these regulatory regions of the promoter contain multiple *cis*-acting control elements that bind proteins termed "transcription factors" that are responsible for activating the transcription of the gene via interactions with the basal

promoter consisting of RNA polymerase in association with basal transcription factors. The cis-acting control elements and DNA-binding transcription factors responsible for the regulation of expression of the preproglucagon gene in α -cells are much better understood than are those in L cells. The α cell-specific expression region of the promoter contains at least six clearly identified regions residing within the proximal 300 base pair of the promoter (Fig. 11.3) (16). These regions or elements are designated G1, G2, G3, G4, C/EBP, and CRE (cAMP response element). Each of these elements binds multiple protein complexes consisting of both relatively α-cell-specific proteins and tissue-ubiquitous proteins. These proteins consist of members of the paired homeodomain (Pax), basic helix-loophelix (bHLH), POU homeodomain, basic leucine zipper (bZip), and hepatocyte nuclear factor (HNF) families of transcription factors. The G1 region of the promoter has been shown to lend

Members of the Super Family of Glucagon-Related Peptides

Figure 11.4. Amino acid sequences of members of the superfamily of glucagon-related peptides. Sequences include human glucagon, human glucagon-like peptides (GLP-1 and GLP-2), human glucose-dependent insulinotropic polypeptide (GIP), exendin-4 (from *Heloderma horridum*), human secretin, human peptide histidine methionine (PHM), human pituitary adenyl cyclase–activating polypeptide (PACAP-38), human growth hormone–releasing factor (GRF), and human vasoactive intestinal polypeptide (VIP). Residues identical to those of glucagon in the same position are outlined. Standard single-letter abbreviations are used for amino acids [International Union of Pure and Applied Chemistry–International Union of Biochemistry (IUPAC-IUB) Commission on Biochemical Nomenclature].  α -cell specificity to the expression of the gene (18). The way nutrient signals and hormones regulate the transcription of the proglucagon gene is not completely understood. However, there is convincing evidence that cAMP and insulin signaling are mediated via the CRE and G3 elements of the proglucagon gene promoter, respectively (19,20).

Superfamily of Glucagon-Related Peptide Hormones

The glucagon superfamily of peptide hormones are so designated because of their close similarities in amino acid sequences (Fig. 11.4). They have a diverse number of functions consisting in part of neurotransmitters, growth factors, and regulators of nutrient metabolism. Of these hormones, GLP-1 has the highest degree of similarity to glucagon (48%). The amino acid sequences of the glucagons and GLP-1s have been highly conserved throughout evolution; the human and anglerfish glucagons and GLP-1s are 75% and 79% identical, respectively (5,7). This strong conservation of sequences over 300 million years of evolutionary time attests to the importance of these hormones in physiologic processes.

GLUCAGON

History

In their early studies (1921), Banting and Best (21) suspected the existence of a hyperglycemia-producing hormone in the pancreas. They observed that dogs administered insulin-enriched pancreatic extracts had a biphasic blood glucose response: There was an initial rise in blood glucose followed by a lowering of blood glucose attributable to the expected actions of insulin. They suspected that the initial increase in glucose level was due to a "contaminant" in the crude pancreas extracts, which was later shown to be glucagon. In 1957, Bromer et al. (22) determined the amino acid composition and partial sequence of glucagon and determined that it was a peptide of 29 amino acids. The availability of pure crystalline glucagon led to the establishment of its hyperglycemic properties via the stimulation of glycogenolysis (23) and gluconeogenesis (24) in liver and skeletal muscle and of lipolysis in fat (25). The semi-

nal studies of Sutherland and DeDuve (26) demonstrated that the glycogenolytic and lipolytic actions of glucagon in liver and fat, respectively, were mediated by the stimulation of the formation of the cellular "second messenger" cAMP. The development by Unger et al. (27) of a radioimmunoassay specific for the detection of glucagon in blood plasma paved the way for numerous cellular and physiologic studies showing that glucagon is a hormone critical for the maintenance of blood glucose levels during fasting (28,29). Furthermore, it was soon established that individuals with diabetes have inappropriately elevated levels of glucagon in the circulation, thereby potentially worsening the physiologic derangements of diabetes by driving the overproduction of glucose by the liver (i.e., increasing hepatic glucose output, and raising blood glucose levels) (28,29). The access to a glucagon-specific antiserum and resultant radioimmunoassay also led to the definitive identification of the α -cells of the pancreatic islets as the source of the production of glucagon; the identification of large, immunoreactive, forms of glucagon in the circulation, known then as glucagon-like immunoactivities (GLIs); and the expression of proglucagons in the L cells of the intestine (1).

Chemistry and Structure of Glucagon

Glucagon was crystallized in 1953 (30), and its amino acid sequence was determined in 1957 (22). X-ray analyses of crystallized glucagon provide a tentative structure of the hormone, in which the N-terminal and C-terminal groups consist of α -helices and are in close proximity by virtue of a "hairpin" bend in the molecule (31). However, it is uncertain whether glucagon in solution or bound to its receptor assumes the same secondary structure as it displays in a crystal. Solution nuclear magnetic resonance (NMR) studies are consistent with a largely unstructured and flexible chain (32). Both in crystals and in solution at high concentrations, glucagon self-aggregates in the form of trimers (32). Structure-function studies of N-terminal- and Cterminal-truncated glucagon peptides provide relatively consistent findings. The N-terminal domain of the hormone is critical for the activation of the cAMP-mediated signal transduction pathway, whereas the C-terminal domain is required for highaffinity binding to the glucagon receptor (33). The N-terminal histidine residue, His1 and Asp9 and Ser16, appears to be particularly important for both receptor binding and the activation of cAMP formation (34,35). Removal of the N-terminal histidine and modification of Asp9 result in the formation of a partial antagonist of glucagon actions.

Ontogeny of Pancreatic α **-Cells**

Although α -cells were identified as being histologically distinct from β -cells in the islets of Langerhans as early as 1907 (36), not until 1962 were α -cells shown to be the source of glucagon (37). The α -cells are one of four recognized hormone-producing cell types in the islets, which also include insulin-producing β -cells, somatostatin-producing δ -cells, and the pancreatic-polypeptide-producing PP cells. In the islets of rodents, the α - and δ cells are located on the surface, or mantle, of the spherical shaped islets, whereas the β -cells comprise the core of the islets. Glucagon is believed to be the earliest endocrine pancreatic hormone expressed during embryonic development of the pancreas-preceding the expression of insulin (38). The pancreas originates by a dual (dorsal and ventral) outbudding of a specialized endodermal epithelium located in the anterior region of the developing gut tube of the embryonic (E) mouse at day 9 to 9.5 in the mouse (39). Proglucagon mRNA and glucagon immunoreactive positive cells are detected in the early pancreatic buds. From days E10 to E12, the buds undergo branching morphogenesis, forming a ductal tree containing clusters of endocrine cells that express glucagon, insulin, neuropeptide Y, and somatostatin. Between days E13 and E14, a major transition occurs in which the exocrine acinar tissue and aggregating endocrine cells separate into distinct compartments. By days E17 to E19, the morphologic development of the pancreas is essentially completed as the islets condense into spherical structures embedded in the exocrine acinar tissue. For 3 to 6 weeks after birth, the endocrine pancreas undergoes considerable remodeling, as the rate of formation of new endocrine cells by proliferation and differentiation from islet progenitor cells located in the ducts remains high and is associated with comparable rates of apoptosis of existing older endocrine cells.

Regulation of Glucagon Secretion

In the absence of ketosis, glucose is the obligate fuel used by the brain (40). Because the brain cannot synthesize glucose and only has enough glycogen stores to last a few minutes, the glucose required by the brain to maintain viability must be provided by the circulation. The importance of the maintenance of adequate blood glucose levels has resulted in the evolution of insulin counterregulatory hormones, among which glucagon is critical. Impaired formation and action of glucagon results in hypoglycemia. Insulin and glucagon are physiologic antagonists; insulin removes glucose from the circulation by stimulating uptake of glucose into liver, muscle, and fat during meals, whereas glucagon stimulates the formation and release of glucose into the circulation, particularly by the liver. Thus, in direct contrast to insulin secretion, glucagon secretion is increased during periods of fasting and is suppressed by elevated plasma levels of glucose. The balanced counteractions of insulin and glucagon maintain blood glucose levels in a relatively narrow range (~120 mg/dL during feeding and 60 mg/dL during fasting).

The most effective regulator of glucagon secretion is glucose, which suppresses glucagon secretion. However, certain amino acids produced by the digestion of proteins, such as arginine, stimulate glucagon secretion. Notably, carnivores, such as canines, have α -cells in their stomachs, suggesting an adaptive mechanism to provide glucagon early during the digestion of a

high-protein meal to defend against insulin-induced hypoglycemia (41). Whether orally ingested fat affects glucagon secretion is unclear, although elevated plasma levels of free fatty acids reduce plasma concentrations of glucagon and inhibit the release of glucagon from the perfused rat pancreas (42). Several hormones regulate α -cell functions and coordinate the secretion of glucagon during changes in nutrient availability. These include the gastrointestinal hormones GLP-1 (5) and GIP (43) and the pancreatic-islet hormones insulin and somatostatin (44). In conditions of metabolic stress, such as hypoglycemia, additional hormones are released (e.g., growth hormone, catecholamines, glucocorticoids, and endorphins) all of which augment the secretion and actions of glucagon on peripheral tissues to ensure the maintenance of adequate blood glucose levels. Glucopenic stress also activates parasympathetic autonomic neural input to the islets that enhances glucagon secretion (45).

The intracellular signaling mechanisms within α -cells that culminate in the secretion of glucagon are complex. In situ hybridization studies of rat α -cells have shown the presence of the mRNAs encoding the KATP channel subunits Kir6.2 and SUR1 (46). Electrophysiologic studies of mouse α -cells in intact islets have determined that, although the expression of ion channels on α -cells is somewhat similar to that of β -cells and δ cells, responses to glucose differ. α -Cells are distinguished from β -cells and δ -cells by the presence of a large tetrodotoxin-sensitive Na⁺ current, a triethylamine-resistant K⁺ current, and two kinetically separable Ca2+ currents: low- (T-type) and highthreshold (L-type) Ca²⁺ channels. In contrast to β -cells, α -cells are electrically silent in the presence of insulin-releasing glucose concentrations. The action potentials generated in the absence of glucose are inhibited by tetrodotoxin, nifedipine, and tolbutamide (47). These findings suggest that the electrical activity in and secretion of glucagon from α -cells is dependent on the generation of Na⁺-dependent action potentials. Furthermore, the KATP channel opener diazoxide inhibits the electrical activity and increases the whole-cell K⁺ conductance leading to glucagon secretion (46). Thus, glucagon secretion depends on a low activity of KATP to maintain sufficient negativity of membrane potential to prevent voltage-dependent inactivation of voltage-gated membrane currents. It was postulated that glucose inhibits glucagon release by depolarizing the α -cell, with resultant inactivation of the ion channels that participate in the generation of action potentials (47).

Metabolism and Degradation of Glucagon

Glucagon is cleared relatively rapidly from the circulation, with a half-life of about 5 minutes [metabolic clearance rate (MCR) ~10 mL \cdot kg⁻¹ \cdot min⁻¹] (48). Both the kidney and the liver remove glucagon from the circulation, accounting for 30% and 20% of disposal, respectively. Notably, the remaining 50% of glucagon is destroyed in the circulation by enzymes, including serine and cysteine proteases, cathepsin B, and primarily DPP-IV, which cleave glucagon into proteolytic fragments. Not all cleavages of glucagon are in the pathway for its disposal. Cleavage after arginines 17 and 18 by an endopeptidase isolated from rat liver membranes results in the formation of glucagon 19-29, so-called miniglucagon (49). Remarkably, miniglucagon was found to be a highly potent activator of Ca2+ channels in heart and liver cells (49). In heart cells it stimulates the accumulation of Ca²⁺ into sarcoplasmic reticular stores, which are targets for Ca2+-induced Ca²⁺ release by glucagon. Unlike glucagon, miniglucagon does not activate adenylyl cyclase. The cAMP-independent actions of miniglucagon in heart cells are mediated by the release of arachidonic acid, which acts synergistically with glucagon-induced

formation of cAMP to trigger inotropic responses (50). There is also evidence that miniglucagon can inhibit glucose-induced insulin secretion from β -cells at picomolar levels (51). The physiologic roles of other potentially biologically relevant truncated glucagon peptides remain to be elucidated.

Physiologic Actions of Glucagon

The most important physiologic action of glucagon occurs during the postabsorptive and fasting states. Through its actions on key enzymes, glucagon induces glycogenolysis, gluconeogenesis, and ketogenesis by the liver, and, to some extent, lipolysis in adipose tissue and glycogenolysis in muscle to mobilize stored energy. In the fasting state, the liver is the essential organ that provides glucose fuel to the brain. In humans the brain requires (utilizes) ~6 g of glucose per hour, whereas all other tissues utilize ~4 g of glucose per hour in the resting state. Collectively, the liver must provide ~10 g of glucose per hour to maintain euglycemia. The actions of glucagon on the liver account for ~75% of the glucose production in the fasting state. Additional fuel is derived from the mobilization of fatty acids from adipose tissue metabolized in the liver to ketone bodies. This process is particularly important during periods of stress or starvation, as these ketones can be used by tissues, particularly the brain, to generate ATP. Other important mediators of this response include catecholamines, growth hormone, and glucocorticoids. The central nervous system senses glucopenia and, in response, triggers neural-sympathoadrenal hormones to counteract hypoglycemia. The ventromedial hypothalamus is proposed to be an important sensor of hypoglycemia and to initiate neural afferent signals to stimulate counterregulatory responses by way of the secretion of catecholamines, growth hormone, and glucocorticoids (52,53).

Glucagon is a major contributor to the immediate responses of the "fight-or-flight" circumstance. During times of sudden and intense physical effort, an instant increase in fuel for skeletal muscle is required without a decrease in fuel delivery to the brain. The skeletal muscles contain a limited supply of glycogen and lipids that can provide energy for the muscles for a short time. Sustained muscular activity requires an increase in circulating glucose and free fatty acids. Catecholamines play a critical role in these fight-or-flight circumstances during which increased fuel in the form of glucose and free fatty acids must be delivered to the circulation. Catecholamines stimulate glucagon secretion and reduce insulin levels during periods of stress and exercise. Notably, the reduction in insulin levels does not limit glucose uptake by exercising skeletal muscle but rather curtails glucose uptake by liver and fat, thereby protecting skeletal muscle from potential deleterious effects of a lowering of blood glucose levels. The increase in glucagon levels, stimulated by increased catecholamines, drives increased glycogenolysis and gluconeogenesis in liver and lipolysis in fat to further augment circulating levels of glucose and free fatty acids.

Mechanisms of Glucagon Action

The glucagon receptor belongs to group IV of the "B" family of seven membrane–spanning G-protein–coupled receptors (54). This family of receptors includes those for the hormones glucagon, GLP-1, GLP-2, GIP, vasoactive intestinal peptide (VIP), pituitary adenylyl activating peptide (PACAP), secretin, calcitonin, parathyroid hormone (PTH), and growth hormone releasing–hormone (GRH). A common feature of the glucagon receptor and these structurally related receptors is their coupling to the G-protein, G_s, that activates adenylyl cyclase and

the resultant production of cellular cAMP. A major component of the cAMP-dependent signaling pathway is the activation of protein kinase A (PKA), an enzyme that phosphorylates and activates the functions of many different proteins in cells (55). PKA can activate proteins in the mitogen-activated protein kinase pathways by phosphorylation of Rap-1 that activates B-Raf and the downstream targets MEKKs (MAPK/ERK kinases), including ERK P-42, and ERK P-44. In addition, cAMP can bind directly to and activate a group of cellular mediators known as GEFs (guanine exchange factors). These additional pathways activate phosphoinositol 3-kinase and release of intracellular stores of Ca²⁺. Thus, the intracellular signaling pathways mediated by the actions of glucagon on its target tissues are highly complex.

The expression of the glucagon receptor has been demonstrated in a large number of different tissues, including not only the generally recognized target tissues of liver, fat, and muscle but also the kidney, heart, lung, brain, intestine, adrenal gland, spleen, ovary, thyroid (56), and the pancreatic islet α -, β -, and δ cells (57). On the basis of these findings, it seems certain that glucagon has wide-ranging metabolic actions on the functions of many organs in the body. Within the pancreatic islets, the glucagon receptor is expressed in most β -cells and on a substantial subpopulation of the α - and δ -cells (57). It has been suggested that the glucagon receptors on β -cells may stimulate small amounts of insulin during periods of fasting to maintain the β -cells in a primed state awaiting a nutrient challenge and also may provide some insulin to peripheral tissues to facilitate glucose uptake during fasting (57).

Notably, the actions of glucagon may be regulated at the level of the expression of the glucagon receptor. In rats, expression of glucagon receptor in brown adipose tissue is downregulated following exposure to cold under the control of the sympathetic nervous system (58). The hepatic expression of glucagon receptor increases progressively from the first day of life to the adult stage in rodents. However, the expression can be increased under conditions in which intrahepatic glucose metabolism is activated, such as during fasting or in diabetes (59). Glucagon, acting through increased cellular levels of cAMP, is capable of downregulating the expression of hepatocyte glucagon receptors (60). Therefore, regulation at the level of the expression of receptors appears to be another means by which glucagon actions are modulated.

Relevance of Glucagon in Human Diseases

It is generally believed that diabetes mellitus is a bihormonal disease consisting of an absolute or relative deficiency of insulin and a relative excess of glucagon (61). Insulin deficiency results in an impairment in the utilization of glucose, and glucagon excess causes an overproduction of glucose. Both circumstances contribute to the hyperglycemia in diabetic individuals. Therefore, inhibition of the actions of glucagon in diabetes is a rational approach to lowering blood glucose levels in individuals with diabetes. Theoretically, inhibition of glucagon actions could be achieved either by lowering blood glucagon levels or by antagonizing the actions of glucagon on the liver to reduce hepatic output of glucose. The former might be achieved by inhibiting the production/secretion of glucagon by α -cells or by neutralizing circulating glucagon. The latter could be accomplished by administering an effective glucagon-receptor antagonist. Such an antagonist should lower both fasting and postprandial glucagon levels and could theoretically be used in combination with insulin or with agents that increase insulin secretion (e.g., sulfonylureas), inhibit glucose absorption (aglucosidase inhibitors), or enhance insulin action (thiazolidinediones). Glucagon antagonists consisting of peptide analogues of glucagon have been shown to lower blood glucose levels in diabetic rodents (62). More recently, nonpeptidyl glucagonreceptor antagonists have been developed that may be more amenable to oral delivery (63,64). However, there are yet no proof-of-concept efficacy studies of glucagon antagonists in humans.

Excessive blood levels of glucagon are seen in rare instances of the development of neoplasms of the α -cells of the pancreas (glucagonomas). Glucagonomas are believed to originate from the islet progenitor cells in the pancreatic ducts (65). The clinical manifestations of glucagonoma, known as the "glucagonoma syndrome," are quite distinct, consisting of glucose intolerance, weight loss, anemia, and migratory erythrodermatitis (66); 60% to 80% of glucagonomas are malignant and often metastasize to the liver. The best success for treatment is surgical removal of the tumor from the pancreas before it has metastasized. Thereafter, chemotherapy is required.

Glucagon deficiency is occasionally a consequence of extensive damage of the pancreas, including the islets, caused by inflammatory or neoplastic disease. A panhormonal deficiency may occur in these circumstances. Deficiencies of both insulin and glucagon result in a type 1 insulin-dependent diabetes with a markedly enhanced sensitivity to administered insulin. Clear examples of hereditary α -cell (glucagon) deficiencies are quite rare. Two published cases of isolated glucagon deficiency describe individuals who manifested severe, intractable hypoglycemia incompatible with life (67,68). Other reports describe recurrent hypoglycemia and no detectable plasma glucagon by radioimmunoassay (69). Treatment with glucagon alleviated the hypoglycemia. Glucagon continues to be used therapeutically for acute treatment of hypoglycemia due to insulin overdose, so-called insulin shock. Glucagon also is given to individuals during gastrointestinal radiologic procedures because its actions of reducing gastrointestinal motility and relaxing and

dilating the proximal and distal regions of the gut enhance double-contrast imaging (70).

GLUCAGON-LIKE PEPTIDES

History

In 1902, Bayliss and Starling (71) postulated that a gut factor(s) might act on the endocrine pancreas in response to oral nutrients, and in 1906, Moore and colleagues (72) attempted to treat diabetes by injecting extracts prepared from duodenal mucosa. La Barre and Still (73) coined the term incretin to describe the hormonal activity released from the intestine that stimulates insulin secretion. The concept that an intestinal incretin factor augments glucose-dependent insulin secretion was set forth by McIntyre et al. (74) in 1964 (Fig. 11.5) and further elaborated on by Unger and Eisentraut (75) to also include nutrients and neuronal pathways originating from the intestine-the so-called enteroinsular axis (Fig. 11.6). For a hormone to be considered an incretin, it must be released from the gut following oral carbohydrate ingestion and stimulate insulin secretion only in the presence of elevated blood glucose levels. The first such incretin hormone to be discovered was gastric inhibitory polypeptide (GIP) (76-78), subsequently renamed glucose-dependent insulinotropic polypeptide (79). Dupré et al. (80) demonstrated that administration of an infusion of a combination of a semipurified preparation of GIP and glucose into human volunteers stimulated the release of more insulin than did the infusion of glucose alone. Thus, GIP was definitively identified as an intestinal incretin hormone that stimulates insulin release in a glucose-dependent manner. However, subsequent studies using immunoneutralization of GIP with anti-GIP sera indicated that meal-stimulated intestinally derived hormone(s) other than GIP contributed substantially to the incretin effect (81). These findings led to the identification of GLP-1 as the "missing" incretin. GLP-1 was

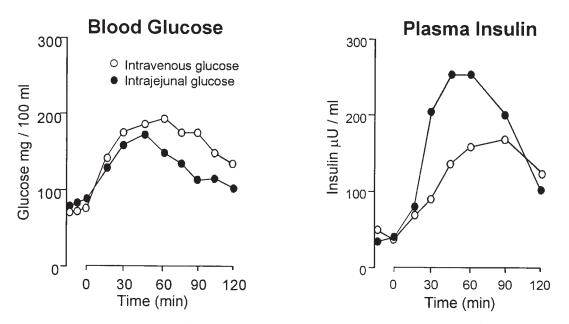

Figure 11.5. Demonstration of the incretin concept. Blood glucose and insulin responses after either intravenous or intrajejunal glucose infusion in healthy subjects. Although plasma glucose levels after intravenous glucose infusion were higher than those after intrajejunal glucose infusion, the latter generated a larger insulin response. On the basis of these results, McIntyre et al. suggested that a humoral substance was released from the jejunum during glucose absorption, acting in concert with glucose to stimulate insulin release from pancreatic β -cells. (Reprinted with permission from Elsevier. From McIntyre N, Holsworth DC, Turner DS. New interpretation of oral glucose tolerance. *Lancet* 1964;2:20–21.)

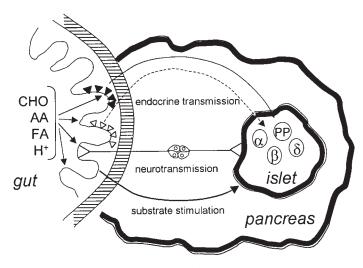

Figure 11.6. The enteroinsular axis. After nutrients are ingested, secretion of hormone from different cell types of the pancreatic islets may be modified by one or more modalities: endocrine transmission; neurotransmission; and direct substrate stimulation. (From Creutzfeldt W. The incretin concept today. *Diabetologia* 1979;16:75–85, with permission. Copyright 1979 by Springer-Verlag.)

first discovered by the cloning of anglerfish preproglucagon complementary DNAs (cDNAs) expressed in the pancreas and the intestine (82). The decoding of the protein-coding sequence of the anglerfish preproglucagon-I cDNA revealed a sequence resembling GIP. This finding led to the postulation that the anglerfish glucagon-related peptide (GRP), resembling GIP, would be a glucagon-like insulinotropic peptide and thus would fulfill the criteria required for an intestinal incretin (82). Mammalian GLP-1s were subsequently cloned (83,84) and found to be insulinotropic in a glucose-dependent manner (85) and released upon ingestion of nutrients (86), thereby fulfilling the criteria of an incretin.

Chemistry and Structure of Glucagon-like Peptide-1

GLP-1 appears to have a structure similar to that of glucagon. When bound to a dodecylphosphocholine micelle, GLP-1 consists of an N-terminal random coil segment (residues 1–7), two helical segments (7–14 and 18–29), and a linker region (15–17) (87). Most of the peptide appears to be necessary for full biologic activity. Thus GLP-1, like glucagon, appears to be folded like a hairpin such that the N- and C-termini must be adjacent to each other to exert optimal biologic actions. Truncation at either the N- or C-terminus drastically reduces biologic activity. Amino acid substitutions throughout the molecule have also identified residues 1 (His), 4 (Gly), 6 (Phe), 7 (Thr), 9 (Asp), 22 (Phe), and 23 (Ile) as important for the binding affinity and biologic activity of GLP-1. These observations explain the difficulty in identifying smaller fragments of GLP-1 that retain potent insulinotropic activity.

Ontogeny of L Cells

The L cells of the intestine that produce proglucagon are reportedly the second most abundant population of endocrine cells in the intestine, outnumbered only by the enterochromaffin cells. They are distributed throughout the distal jejunum, ileum, and colon and have a high density in the rectum. This distribution of L cells is largely distinct from that of the K cells that produce and secrete GIP, which are located predominantly in the stomach, duodenum, and proximal jejunum. The L cells reside throughout the intestinal villi and in the crypts of Lieberkühn. The intestinal L cells are morphologically distinct from the α cells of the endocrine pancreas (88). The L cells are flask-shaped and open-type. The microvilli of the L cells reach the intestinal lumen, and a domain rich in endocrine granules exists near the basal lamina. The shape of L cells suggests that they can respond to luminal stimuli, resulting in their basal discharge of endocrine granules. L cells first appear in human fetuses at 8 weeks of gestation in the ileum, at the 10th week in the oxyntic mucosa, and at the 12th week in the colon (89). The L cells are believed to arise from pluripotential stem cells located in the crypts that also give rise to enterocytes, goblet cells, and Paneth cells (90).

Regulation of Secretion of Glucagon-like Peptides

GLP-1 and GLP-2 are produced in and secreted from the intestinal L cells located in the distal small intestine, colon, and rectum. Before the processes of formation of hormones and peptides by cleavages from proglucagon were understood, the intestinal products derived from the expression of the proglucagon gene in the intestine were known as GLIs (glucagon-like immunoreactivities), as they were measured in blood plasma by various radioimmunoassays (91). The major intestinal GLI measured at that time was glicentin, a peptide consisting of the N-terminal sequence of proglucagon known as glicentin-related pancreatic peptide, glucagon, and the intervening peptide-1 (Fig. 11.1). Glicentin has no clearly defined biologic activities, and with the discovery of the structure of proglucagon, is generally believed to be a leftover, discarded product of proglucagon after cleavages of GLP-1s and GLP-2s have taken place. The development of radioimmunoassays specific for the detection of the GLPs (GLP-1 and GLP-2) has allowed physiologic assessment of the dynamics and factors controlling GLP secretion (11,92-94).

The regulation of the secretion of GLPs from the L cells is complex and appears to involve a combination of nutrient, hormonal, and neural stimuli. Numerous in situ luminal perfusion studies of isolated gut in experimental animals have shown that luminal nutrients, carbohydrate, fat, and to some extent amino acids stimulate the release of GLP-1 into the circulation [reviewed in reference (5)]. However, a paradox arose early in studies of the physiology of GLP-1 secretion (i.e., GLP-1 levels rise in the circulation as early as 15 minutes after a meal or an oral glucose tolerance test, a time much too short for nutrients to reach the distal intestine and colon and mediate luminal stimulation of GLP-1 secretion). The existence of signals arising from the proximal gut to the L cells of the distal gut was proposed to account for the rapid release of GLP-1 in response to ingestion of nutrients (5,95). Indeed, the presence of nutrients in the duodenum of rats can stimulate GLP-1 release, a process that seems to involve the enteric vagal nervous system as well as the duodenal hormone GIP. Thus, L cells that release GIP sense fat and/or glucose in the duodenum, which in turn activates a vagal pathway that ultimately leads to GLP-1 release. Enteric nerves originating in the duodenum may also carry the nutrient signal to the distal L cells.

Given the important actions of GLP-1 in regulating glucose homeostasis, studies have been done to determine whether subjects with type 2 diabetes have impaired GLP-1 secretion. In patients with type 2 diabetes, insulin release is not stimulated more by an oral than by an isoglycemic intravenous glucose load, indicating a loss of incretin-mediated stimulation of insulin secretion (96). However, this issue remains unclear, as there are reports of both decreased (97,98) and increased (99–101) blood levels of GLP-1 in individuals with type 2 diabetes relative to levels in controls. Additional studies are required to clarify these apparent discrepancies. Perhaps approaches that increase the endogenous production of GLP-1 have the therapeutic benefit of improving glucose tolerance. Thus, further investigation into the mechanisms controlling the release of GLP-1 in humans also is required.

Metabolism and Degradation of Glucagon-like Peptides

The rate of removal of GLPs from the circulation is an important determinant of their biologic actions. GLPs are eliminated by at least three processes: renal extraction, hepatic extraction, and proteolytic inactivation within the circulation. The kidney removes GLP-1 from the circulation by a mechanism that involves glomerular filtration and tubular catabolism (102). Thus, circulating levels of GLP-1 are elevated in patients with renal failure and in nephrectomized rats (103,104). Hepatic extraction of GLP-1 also contributes to the clearance of GLP-1 (102). The MCR (the least amount of plasma totally cleared of GLP-1 per unit time) in humans is ~10 mL \cdot kg⁻¹ \cdot min⁻¹, providing a half-life of about 5 minutes (105). However, the half-life of biologically active GLP-1 is 1 to 2 minutes because of its inactivation by proteolytic cleavage in the circulation (106). The biologically active forms of GLP-1 (7–36) amide and GLP-1

(7–37) are rapidly cleaved by DPP-IV (CD26) that removes the N-terminal dipeptide, His-Ala, resulting in the formation of the believed-to-be inactive GLP-1 (9–36) amide and GLP-1 (9–37) isopeptides, respectively (107,108). Likewise, GLP-2 is rapidly inactivated by DPP-IV through the conversion of GLP-2 (1–33) to GLP-2 (3–33) (109). Therefore, DPP-IV–mediated inactivation of both GLP-1 and GLP-2 is a critical determinant of the biologic activities of these hormones.

Physiologic Actions of Glucagon-like Peptide-1

GLP-1 exerts several distinct physiologic actions, reflecting the different organ systems in which the GLP-1 receptor is expressed (Fig. 11.7). Receptors have been identified on the pancreatic islet cells (α , β , and δ), stomach, brain, lung, intestine, heart, kidney, and anterior pituitary [reviewed in reference (5)]. There are some findings, predominantly from *in vitro* studies, of GLP-1 actions on liver, fat, and muscle in which GLP-1 stimulates glycogenolysis and lipogenesis. Although GLP-1 binding sites on these tissues appear to exist, attempts to identify expression of the GLP-1 receptor mRNA in these tissues have been unsuccessful (110). This circumstance suggests that an additional GLP-1 receptor(s) may exist. Considerable understanding has accrued about the physiologic relevance of the actions of GLP-1 on pancreatic islets, stomach, and brain. Understandings

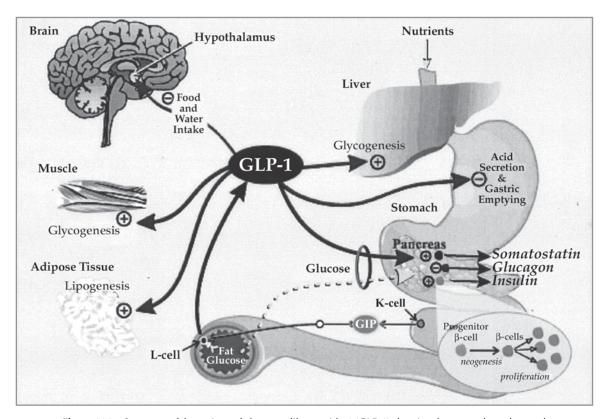

Figure 11.7. Summary of the actions of glucagon-like peptide-1 (GLP-1) showing the currently understood targets of GLP-1 actions. In the endocrine pancreas, GLP-1 stimulates both insulin and somatostatin secretion in a glucose-dependent manner and inhibits glucagon secretion. However, it is uncertain whether GLP-1 inhibits glucagon secretion by direct actions on α -cells or indirectly by the known paracrine-inhibitory effects of insulin and somatostatin on α -cells. The β -cell mass is increased by GLP-1, by the induction of both β -cell neogenesis and proliferation. GLP-1 is an effective inhibitor of gastric motility and emptying and curtails food intake by inducing satiety. Direct "insulinomimetic" actions of GLP-1 on fat, liver, and muscle to induce lipogenesis and glycogenesis have been implied but remain to be definitively established. GLP-1 increases β -cell neogenesis (*lower right*) by stimulating the differentiation of progenitor β -cells (stem cells) and the proliferation of β -cells. (Copyright 1999. The Endocrine Society. From Kieffer TJ, Habener JF. The glucagon-like peptides. *Endocr Rev* 1999;20:876–913, with permission.)

of the physiologic responses of GLP-1 actions on lung, intestine, heart, kidney, and anterior pituitary are incomplete.

The first physiologic action of GLP-1 to be elucidated, after the initial discovery that GLP-1 is a split product of proglucagon derived in the intestinal L cells, was that it is a glucose-dependent stimulator of insulin secretion. GLP-1 is a potent intestinal incretin hormone that acts in concert with GIP to augment glucose-dependent insulin secretion in response to oral nutrients. Although both GLP-1 and GIP augment glucosemediated insulin secretion, only GLP-1, and not GIP, appears to retain insulinotropic activity in hyperglycemic individuals with type 2 diabetes (111,112). The mechanistic basis for this difference between the dual incretin hormones GLP-1 and GIP remains unknown. Not only is the stimulation of insulin secretion by GLP-1 dependent on a threshold level of plasma glucose (~ >60 mg/dL) but the actions of glucose to stimulate insulin secretion require GLP-1 or other factors that stimulate cAMP formation in β -cells (113). The interdependence of the dual signaling by glucose metabolism and cAMP generation, such as provided by GLP-1, is described as the "glucose competence concept" (114) (Fig. 11.8). The successful achievement of nutrient-stimulated insulin secretion by β -cells depends on the concomitant activations of cAMP and glucose metabolism–driven signaling pathways.

In addition to stimulating insulin secretion, GLP-1 stimulates the biosynthesis of proinsulin and the transcription of the proinsulin gene (115,116). In this manner, GLP-1 contributes to repleting stores of insulin lost from β -cells by secretion. The GLP-1 property of stimulating the formation of insulin distinguishes it from the sulfonylurea drugs, which stimulate the secretion but not the biosynthesis of insulin (117).

Recent studies indicate that GLP-1 and its long-acting agonist exendin-4 stimulate the proliferation and differentiation of progenitor/stem cells in the pancreas into β -cells (118–121). In

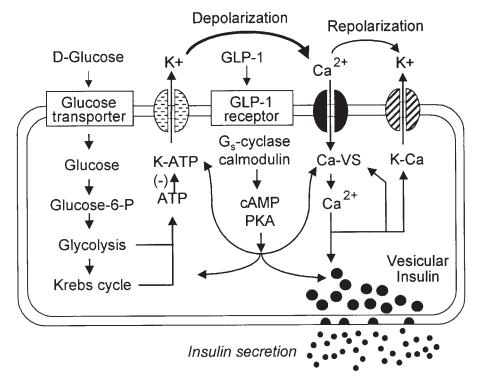

Figure 11.8. Hormonal regulation of glucose-induced insulin secretion from pancreatic β -cells. Essential features of the glucose-regulated adenosine triphosphate (ATP)-dependent signaling system are illustrated on the left. The initial uptake of glucose is facilitated by the type 2 glucose transporter, whereas the conversion of intracellular glucose to glucose-6-phosphate is catalyzed by glucokinase. Stimulation of aerobic glycolysis generates multiple signals, one of which is an increased ratio of intracellular ATP relative to ADP. Binding of ATP to ATP-sensitive K⁺ channels (K-ATP) induces closure of the channels, resulting in membrane depolarization, which is necessary for the opening of voltage-sensitive Ca²⁺-channels (Ca-VS). The opening of Ca²⁺ channels may also be favored by glucose-derived signaling molecules of undetermined origin. Entry of Ca²⁺ across the plasma membrane triggers vesicular insulin secretion by Ca²⁺dependent exocytosis. Repolarization of the membrane results from the action of intracellular Ca^{2+} to activate Ca2+-dependent K+ channels (K-Ca) and to inhibit voltage-sensitive Ca2+ channels. Each of these steps in the glucose-regulated ATP-dependent signaling system is viewed as a potential target for modulation by the hormonally regulated cAMP-dependent signaling system. In this example, GLP-1 binds to cell-surface receptors and activates Gs, a heterotrimeric G protein that stimulates adenylate cyclase. Stimulation of adenylate cyclase by GLP-1 is proposed to require the activated form of calmodulin. Since calmodulin is activated by the glucose-induced rise in intracellular Ca²⁺, the stimulation of adenylate cyclase by GLP-1 is glucose-dependent. The production of cAMP by adenylate cyclase results in the activation of protein kinase A (PKA), which catalyzes the phosphorylation of multiple targets within the glucose-signaling cascade. These targets may include elements of the glucose-sensing mechanism, ion channels, gap junctions, and components of the secretory apparatus that are responsible for mobilization and exocytosis of insulincontaining vesicles. (From Holz GG, Habener JF. Signal transduction crosstalk in the endocrine system: pancreatic beta-cells and the glucose competence concept. Trends Biochem Sci 1992;17:388–393, with permission.)

rats and mice, the β -cell mass turns over every 30 to 40 days by processes of apoptosis and the formation of new β -cells, socalled neogenesis of β -cells (122). Progenitors of β -cells reside in the pancreatic ducts, in the centrolobular acini, and within the islets themselves. Receptors for GLP-1 are expressed in β -cells and in localized regions of the ducts, suggesting that these specialized regions of the ducts are a source of the formation of new β -cells by neogenesis. In the clonal β -cell line, INS-1, GLP-1 stimulates the expression of several immediate-early genes encoding transcription factors, such as *c-fos, c-jun, zif 268*, and *nur-77*, implicated in cell proliferation and differentiation (123). The administration of GLP-1 to glucose-intolerant aged rats improves their glycemic control (124). Therefore, it appears that GLP-1 exerts trophic effects on β -cells and stimulates their growth and differentiation.

The fat-derived satiety hormone, leptin, and GLP-1 exert counterregulatory actions on insulin secretion [reviewed in reference (125)]. Leptin suppresses insulin secretion and gene expression, whereas GLP-1 stimulates insulin secretion and expression. Thus, the enteroinsular axis (GLP-1 secreted from the intestine) and the adipoinsular axis (leptin secreted from adipose tissue) oppose each other (125). Notably, leptin is much more efficient in suppressing insulin secretion in GLP-1 receptor null mice (126). Conversely, GLP-1 is more effective in stimulating insulin release in leptin receptor null mice (db/db) and rats (fa/fa) (127). GLP-1 overrides the suppressive effect of leptin on insulin secretion, thereby ensuring that β -cells will secrete insulin in response to GLP-1 and glucose during a meal even in the presence of markedly elevated, insulin-suppressive blood levels of leptin. It has been postulated that hypersecretion of insulin in obese individuals may be a consequence of a desensitization of leptin reception by β -cells and a resulting loss of the suppressive affects of leptin on insulin secretion (125).

Receptors for GLP-1 are expressed not only in β -cells of the pancreatic islets but also in α -cells and δ -cells (128,129). GLP-1 stimulates the secretion of somatostatin from δ -cells in a glucose-dependent manner. It is believed that nutrient-dependent stimulation of somatostatin by GLP-1 during meals provides a short-loop feedback suppression of insulin secretion to dampen oversecretion of insulin. A possible role for GLP-I receptors on α -cells is to provide positive autocrine feedback control on glucagon secretion during fasting and/or to dampen the potent paracrine suppression of glucagon secretion by insulin during feeding.

It has long been appreciated that the arrival of the contents of a meal (chyme) in the distal small intestine (ileum) exerts an inhibitory effect on gastric motility, the so-called ileal brake phenomenon (130). This feedback, meal-induced inhibition on the stomach is believed to be due to a combination of neural and hormonal influences. The hormones responsible for the gastric inhibition are now known to be GLP-1 and GIP. The administration of either GLP-1 or GIP to volunteers in amounts that achieve normal meal-induced physiologic blood levels of the hormones inhibits gastric acid secretion, gastric motility, and gastric emptying (131-133). The physiologic purpose of feedback inhibition of gastric motility by hormones (GLP-1 and GIP) produced in the intestine is believed to be one of modulation of the rate of delivery of food from the stomach to the small bowel. In consideration of the use of GLP-1 in the treatment of individuals with diabetes, a delay in gastric emptying is beneficial inasmuch as it helps to dampen the magnitude of the postprandial glucose excursion.

A rather unexpected physiologic action of GLP-1 is promotion of satiety and curtailment of food intake (134). GLP-1 is an anorexigenic hormone, similar in actions to the satiety hormone, leptin, produced by adipose tissue. Receptors for GLP-1

exist at high density in the paraventricular and arcuate nuclei of the ventral medial hypothalamus, the region of the brain responsible for the control of appetite (135,136). The intracerebral administration of GLP-1 to rats and mice markedly inhibits feeding (137,138). GLP-1 rapidly activates the expression of the transcription of *c-fos* in the hypothalamus and inhibits the expression of the hypothalamic orexigenic hormones corticotropin-releasing factor and neuropeptide Y (139). These actions of GLP-1 in the hypothalamus are readily inhibited by the peptide exendin 9-39, a potent, specific antagonist of GLP-1 actions. The administration of GLP-1 to volunteers promotes satiety and suppresses energy intake. Although it was initially controversial whether reduced food intake in response to GLP-1 was due to food aversion secondary to delayed gastric emptying (140) or to a central satiety effect, it now seems clear that GLP-1 administered systemically to volunteers reduces food intake and induces weight loss and does so by suppressing appetite (satiety) (141-144).

The production of GLP-1 is known to occur in localized regions of the brain. The proglucagon gene is expressed in the hindbrain (rhombencephalon) in the nucleus tractus solitarius (NTS), which is the nucleus of the vagal nerve (nerve X) of the autonomic nervous system. The vagus mediates autonomic neural reflexes from the pancreas and intestine, among other organs. Remarkably, the proglucagon produced in the NTS is processed to GLPs (145). Further, injection of the retrograde tracer FluoroGold (Fluorochrome, Inc., Englewood, CO) into the NTS showed that the caudal axons of the neurons project to the paraventricular nucleus of the ventral medial hypothalamus, the site of the satiety center (146). The injection of ¹²⁵I-labeled GLP-1 peripherally into rats localized to the subfornical organ and the area postrema in sections of the brain (136). These findings provide an attractive mechanism by which vagal efferent signals arising from the ingestion of a meal and resulting in gastric distention and intestinal stimulation can signal the central nervous system that an influx of nutrients is occurring. These findings of combined hormonal and neural mediation of GLP-1 actions on the satiety center of the hypothalamus strongly suggest that GLP-1 plays an important role in signaling the brain to terminate a meal by providing a feeling of satiation.

Mechanism of Action of Glucagon-like Peptide-1

The GLP-1 receptor is a seven membrane-spanning G-protein-coupled receptor and, by similarities in amino acid sequences, belongs to the glucagon family of such receptors [reviewed in (5)]. The binding of GLP-1 to its receptor activates both cAMP and mitogen-activated protein kinase (MAPK) pathways, depending on the particular developmental and environmental status of the cells that express the receptor. In mature β -cells of the islets of Langerhans, the GLP-1 receptor is coupled to G_s and activates adenylyl cyclase and the formation of cAMP. The cAMP signaling acts synergistically with glucose signaling to stimulate the secretion and production of insulin. In immature β-cell progenitor cells, GLP-1 activates proproliferative and anti-apoptotic MAPK pathways, leading to the differentiation of the progenitor cells into insulin-producing β -cells. Interestingly, in extrapancreatic tissues, such as liver, skeletal muscle, and fat, GLP-1 may suppress cAMP levels and stimulate insulin-dependent glucose uptake (147). Because exendin 9-39, a potent antagonist of GLP-1 actions on the recognized GLP-1 receptor, does not antagonize the actions of GLP-1 on these extrapancreatic tissues, it is suggested that a second, as yet unidentified, receptor for GLP-1 must exist.

The importance of GLP-1 in the maintenance of glucose homeostasis further derives from the phenotype of mice in which the GLP-1 receptor (*GLP-1R*) gene is inactivated by targeted disruption (gene knockout). GLP-1 receptor null mice develop glucose intolerance and display an altered morphogenesis of islet development (148). There is no clear effect of the loss of GLP-1 actions in the GLP-1R^{-/-} mice on feeding behavior, perhaps as a result of compensatory mechanisms arising during development that take the place of the inactivated GLP-1R. Nonetheless, the finding that GLP-1 null mice have perturbations in glucose homeostasis lends strong support to the notion that GLP-1 signaling is important for the maintenance of nutrient homeostasis in mammals. However, genetic analyses indicate that the GLP-1R locus (6p21) is not included in chromosomal loci carrying susceptibility for diabetes (149,150).

Relevance of Glucagon-like Peptide-1 to Human Disease

The prevalence of diabetes is increasing at an alarming rate throughout the world. Most remarkable is the occurrence of an epidemic of obesity-related type 2 diabetes, especially in children. Type 2 diabetes now accounts for 95% of cases of diabetes, although the incidence of type 1 autoimmunity-related diabetes (5%) is also rising. The currently available drugs for treatment of diabetes include injected insulin and oral hypoglycemic agents. The oral hypoglycemic agents consist of the sulfonylureas, which inhibit K^{+}_{ATP} channel activity in β -cells and thereby stimulate insulin secretion; biguanides, which reduce hepatic glucose output; and thiazolidinediones, which increase glucose uptake by peripheral tissues (insulin sensitizers). Without question, the currently available drugs for the treatment of diabetes are useful, but they have several drawbacks. Insulin is administered systemically rather than into the hepatic portal vein where insulin secreted from the pancreas is delivered. Moreover, it is difficult to control for the proper amount of insulin, such that weight gain is often a side effect, as well as hypoglycemia. Insulin also is believed to enhance the development of cardiovascular disease. The sulfonylurea drugs are effective in many individuals with type 2 diabetes, but their actions are not glucose-dependent, causing hypoglycemic episodes. Further, many individuals experience tachyphylaxis at various times after beginning treatment. The biguanides suppress hepatic glucose output but result in lactic acidosis in some.

Metformin is well tolerated with few adverse effects. Mild gastrointestinal symptoms may develop in some individuals but are usually transient and dose-related. Lactic acidosis occurs only rarely and when it occurs is usually associated with significant renal or hepatic insufficiency.

GLP-1 holds substantial promise for the effective treatment of type 2 diabetes, particularly obesity-related diabetes, socalled adipogenic diabetes or diabesity, and may prove effective in the treatment of type 1 diabetes. The desirable and potentially beneficial actions of GLP-1 for the treatment of diabetes are listed in Table 11.1. Like the sulfonylureas, GLP-1 stimulates the secretion of insulin from the β -cells of the pancreas but,

TABLE 11.1. Actions of Glucagon-like Peptide-1

Stimulates glucose-dependent insulin secretion and synthesis Promotes β -cell neogenesis and proliferation Improves glucose disposal Suppresses glucagon secretion Delays gastric emptying Reduces food intake unlike sulfonylureas, also stimulates the biosynthesis of insulin. Moreover, the actions of GLP-1 are glucose-dependent. When the blood sugar levels fall below 50 mg/dL, the insulinotropic actions of GLP-1 are lost, thereby avoiding the development of hypoglycemia. GLP-1 also suppresses the secretion of glucagon by the α -cells of the pancreas, thereby inhibiting hepatic glucose output and leading to an enhancement of glycemic control. Other desirable actions of GLP-1 are to delay gastric emptying, thereby dampening postprandial hyperglycemic excursions, and to promote satiety and inhibit energy intake, perhaps preventing weight gain and encouraging weight loss. GLP-1 also augments insulin-stimulated glucose uptake by peripheral tissues (i.e., increases insulin sensitivity) and promotes the growth and differentiation of pancreatic β -cells to increase β -cell mass.

In practice, both subjects with type 2 and type 1 diabetes have been treated successfully with GLP-1 in clinical experimental studies. GLP-1 administered intravenously, subcutaneously, and as oral buccal tablets for periods of several days to 4 weeks lowered blood glucose levels in individuals with type 2 diabetes. An example of the efficacy of GLP-1 in lowering plasma glucose levels in subjects with type 2 diabetes is shown in Fig. 11.9. A 19-hour continuous infusion of GLP-1 beginning at 22:00 effectively lowered elevated plasma glucose to normal within 2 hours after initiation of the infusion and maintained normal levels, both basal and prandial, throughout the next day (151). The blood glucose-lowering effects of GLP-1 administered to individuals with type 1 diabetes who have no functional β -cells, as determined by the absence of circulating Cpeptide, is attributable to the GLP-1-mediated inhibition of glucagon secretion and pursuant reduction in hepatic glucose

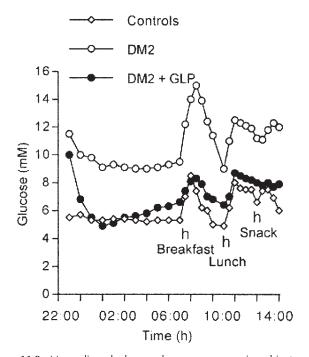

Figure 11.9. Mean diurnal plasma glucose responses in subjects with type 2 diabetes (DM2) in response to continuous 19-hour infusions of saline (*open circle*) or GLP-1 (*closed circle*) compared with subjects without diabetes (*open diamond*). Note that the administration of GLP-1 "normalizes" both the fasting and prandial (meals) plasma glucose levels. (From Rachmen J, Barrow RB, Levy JC, et al. Near-normalisation of diurnal glucose concentrations by continuous administration of glucagonlike peptide-1 (GLP-1) in subjects with NIDDM. *Diabetologia* 1997;40: 205–211, with permission. Copyright 1997 by Springer-Verlag.)

output, delay of gastric emptying, and consequent dampening of postprandial hyperglycemic excursions and augmentation of glucose uptake by peripheral tissues. Long-term clinical trials of the efficacy of GLP-1 as a treatment of type 2 and type 1 diabetes are under way. Several treatment strategies are under consideration, including the administration of GLP-1 analogues that are resistant to cleavage and inactivation by DPP-IV (CD26), coadministration of inhibitors of DPP-IV activity, delivery of GLP-1 by subcutaneous pumps, development of more effective oral delivery systems for GLP-1, and creation of smallmolecule peptide mimetics of GLP-1.

CHAPTER 12

Magnetic Resonance Spectroscopy Studies of Liver and Muscle Glycogen Metabolism in Humans

Roy Taylor and Gerald I. Shulman

PRINCIPLES OF MAGNETIC RESONANCE SPECTROSCOPY 195

Localization of Signal 197

ADVANTAGES OF MAGNETIC RESONANCE SPECTROSCOPY IN METABOLIC RESEARCH 197

FACTORS LIMITING THE USE OF MAGNETIC RESONANCE SPECTROSCOPY IN METABOLIC RESEARCH 197

VALIDATION OF MAGNETIC RESONANCE SPECTROSCOPY 198

METABOLISM IN THE FASTING STATE 198

Liver 198 Muscle 200

PRINCIPLES OF MAGNETIC RESONANCE SPECTROSCOPY

Although the vast majority of atoms have no magnetic properties, several atoms have nuclei with spin properties that impart a magnetic component that causes them to behave as miniature bar magnets. Each of these nuclei spins along an axis, which is normally randomly orientated in the weak magnetic field of the earth (50 μ T). In a strong magnetic field (1.5 to 7.0 T for human studies), the axes of spin of the atomic nuclei move into alignment and precess around the axis of spin. It is from this orderly steady state that the magnetic resonance information is gathered. The atomic nuclei relevant to *in vivo* nuclear magnetic resonance spectroscopy (MRS) are listed in Table 12.1, and the sequence of events is illustrated in a two-dimensional fashion in Figure 12.1.

Application of a radio signal at the appropriate frequency for the relevant atom imparts energy to the nucleus, which causes the angle of precession to increase, effectively moving it out of alignment, usually 90 degrees to the direction of magnetic flux. The radio signal is transient, and when it has passed, the atoms

METABOLISM IN THE POSTPRANDIAL STATE 201

Mechanism of Fatty Acid–Induced Insulin Resistance 204

move back to their original alignment and release the energy absorbed. This energy is released in the form of radio waves emanating from the atoms themselves, and the radio signal can be detected and analyzed. The two-dimensional display in Figure 12.1 is an oversimplification, because the process actually happens in three dimensions. Each atomic nucleus is not static but rather precesses around its own axis with a frequency that is a characteristic property of each element. It is the angle of precession that changes as the nucleus absorbs the radiofrequency energy.

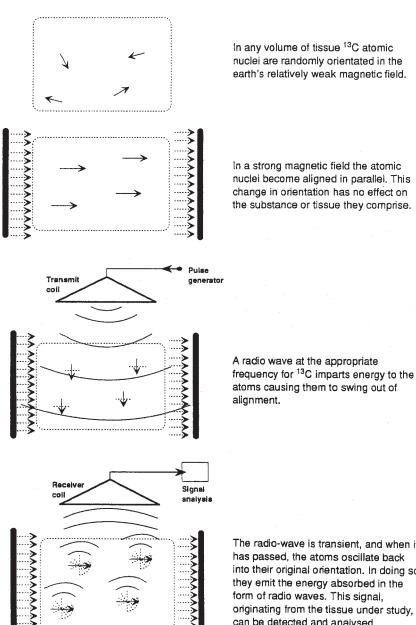

The principle that the greater the radio signal received the greater the concentration of the relevant atoms in the sample is easy to appreciate. It is rather less obvious how it is possible to tell that a given signal is coming from, say, carbon atoms in one compound rather than from any other that may contain carbon. By drawing analogy with the resonance produced by striking a bell, some features can be simply explained (Fig. 12.2). If several bells of the same size (that is, resonance properties) are struck simultaneously, the resulting resonance will have a greater amplitude than that from only one bell, but the resonance will have the same waveform. On the other hand, if two bells of dif-

TABLE 12.1. Properties of Atomic Nuclei Relevant toIn Vivo Studies ^a

MRS, magnetic resonance spectroscopy. ^aBoth natural abundance and magnetic sensitivity determine the ease of detecting signal from each element. The term *relative sensitivity* is the MRS sensitivity of the nucleus relative to that of an equal number of protons multiplied by the natural abundance. It is therefore an index of how readily information may be gathered from each element.

ferent sizes are struck simultaneously, two different waveforms will be superimposed. Thus, the radio waves generated from tissues in a magnetic resonance experiment will consist of many different waveforms, each coming from the ¹³C atoms in the many different compounds. This is so because the electrochemical environment of a carbon atom in, for example, the $-CH_2$ group of triglycerides differs from that of the carbon atom in, say, the –CO(OH) group of glycerol.

These superimposed different waveforms can be unscrambled and converted to an understandable form by Fourier transformation, a mathematical transformation that results in display of the nuclear magnetic resonance (NMR) signal as a spectrum. This changes the display of an oscillating amplitude to one of separation of different frequencies of oscillation (illustrated on the right of Fig. 12.2). The signals from ¹³C in different compounds give rise to spatially separated peaks. These are described in arbitrary units of chemical shift or parts per million.

The radio-wave is transient, and when it has passed, the atoms oscillate back into their original orientation. In doing so they emit the energy absorbed in the form of radio waves. This signal, originating from the tissue under study, can be detected and analysed.

Figure 12.1. Representation in two dimensions of the behavior under different conditions of atomic nuclei that have magnetic properties. In the relatively weak magnetic field of the earth, they are randomly orientated. In a strong, uniform magnetic field they are aligned and can temporarily be moved out of alignment in synchrony by a radiofrequency pulse. In moving back into alignment, the nuclei emit energy, and this is the signal used in magnetic resonance spectroscopy (MRS) studies. (From Taylor R, Shulman GI. New insights into human carbohydrate metabolism using nuclear magnetic resonance spectroscopy. In: Marshall SM, Home PD, eds. The diabetes annual, Vol 8. Amsterdam: Elsevier, 1994:157–175.)

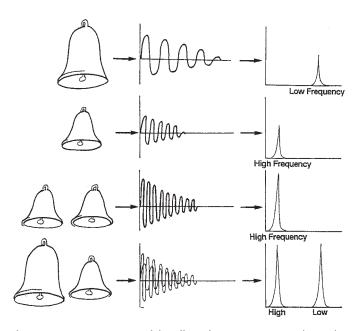

Figure 12.2. Representation of the effect of superimposing similar or dissimilar resonances by analogy with the sound waves produced by bells. A low-frequency note is emitted by the large bell when struck (analogous to the radiofrequency pulse), and a high-frequency note is emitted by the small bell. The oscillating sound wave (radiofrequency wave in the case of magnetic resonance spectroscopy) can be plotted as such or displayed as a frequency display after Fourier transformation (shown on the right). If two small bells are struck (or double the number of nuclei activated), the resulting amplitude of sound is doubled, but this does not change the position of the frequency peak, merely doubling its height). If a large and a small bell are struck simultaneously, a complicated waveform display results, but the frequency display shows two distinct peaks, the position of each being characteristic for each bell. Hence, ¹³C atoms in different compounds, or in different positions in the same compound, will exhibit a characteristic chemical shift of frequency. (From Taylor R, Shulman GI. New insights into human carbohydrate metabolism using nuclear magnetic resonance spectroscopy. In: Marshall SM, Home PD, eds. The diabetes annual, Vol. 8. Amsterdam: Elsevier, 1994:157-175.)

The area under each peak is a measure of concentration of each chemical grouping. To convert such measures to molar terms, it is necessary to place a phantom containing a solution of known concentration into the spectroscope. If the 100 mmol/L solution of glycogen results in a peak of a certain area, then a peak hav-

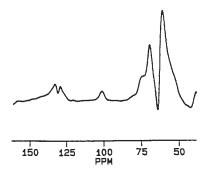

Figure 12.3. ¹³C-MRS spectrum from the liver of a healthy volunteer. The peak resulting from resonance of the C1 atom of the glycogen molecule is seen at its characteristic position of 100.5 ppm (arbitrary units). Peaks corresponding to lipid and glycerol are seen around 130 and 60 ppm, respectively. The spectrum was kindly provided by Drs. J.-H. Hwang and D. L. Rothman, Yale University, New Haven, CT. (From Taylor R, Shulman GI. New insights into human carbohydrate metabolism using nuclear magnetic resonance spectroscopy. In: Marshall SM, Home PD, eds. *The diabetes annual*, Vol. 8. Amsterdam: Elsevier, 1994:157–175.)

ing half that area from an *in vivo* experiment would indicate the presence of 50 mmol/L glycogen in the tissues.

The final spectrum resulting from an NMR acquisition represents the average of many individual radio pulses. Each pulse and resultant signal from the excited atoms lasts only milliseconds and is repeated as rapidly as feasible. For example, routine acquisition of a liver glycogen measurement takes 15 minutes during which time 6,400 signals are accumulated. This allows synthesis of a reliable, reproducible spectrum (Fig. 12.3).

The above explanation is intended to convey a qualitative understanding of NMR spectroscopy. A more quantitative explanation of the technique is found in Gadian (1).

Localization of Signal

If the NMR signals were gathered from the whole body, only limited information could be obtained, as the result would be an average of the signals from liver, muscle, and all other tissues. By having the whole body in a strong magnetic field, but by delivering the radio signal only to a defined volume of tissue, it is possible to be certain how much of which tissue is being studied. In practice, this is achieved by placing a "surface coil" that acts as a radio antenna over the tissue of interest. By altering the power and other parameters of the radio signal, it is possible to know how deeply the signal penetrates. For the study of liver, it is usual to obtain a magnetic resonance image before carrying out spectroscopy to ensure that the organ is entirely within the sensitive volume of the surface coil.

ADVANTAGES OF MAGNETIC RESONANCE SPECTROSCOPY IN METABOLIC RESEARCH

Magnetic resonance spectroscopy allows acquisition of metabolic information in an entirely noninvasive manner. Because multiple measurements may be made, the time course of metabolic reactions and processes can be followed in vivo. Use of surface coils and volume-limited techniques permits accurate sampling of the tissues or organs of interest. In contrast, biopsies are limited to, at most, a few time points, so that time-course studies in a particular metabolite concentration are not feasible. In addition, release of stress hormones during biopsies might alter the concentration of the measured metabolites. The time lag between excision and freeze clamping of tissues, but also freeze clamping per se, may result in misestimation of different metabolic effects. Artifactually high concentrations of intracellular free adenosine diphosphate (ADP) can be explained by rapid hydrolysis of high-energy phosphate or by the tight binding of most of the ADP in intact tissue to proteins of myofilaments. In addition, a delay of several seconds during tissue handling already leads to raised intramuscular glucose-6-phosphate concentrations due to increased glycogenolysis (2). Finally, enzyme activities do not necessarily reflect the actual flux through metabolic pathways.

FACTORS LIMITING THE USE OF MAGNETIC RESONANCE SPECTROSCOPY IN METABOLIC RESEARCH

Subjects with magnetic or paramagnetic metal implants of any kind, including plates on bone, surgical clips, and pacemakers, cannot enter the magnet. Also subjects with claustrophobia of any degree may find the examination unbearable. This is typically not problematic if only a limb is to be inserted into the spectrometer.

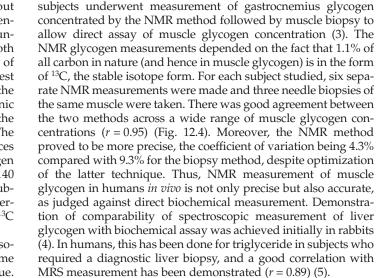

198 JOSLIN'S DIABETES MELLITUS

The ability to detect any compound by NMR spectroscopy depends upon its concentration in the tissue of interest and the properties of the relevant atom (Table 12.1). The hydrogen nucleus has the strongest magnetic atoms, ³¹P having about 6.6%, and ¹³C having about 0.02% of the relative magnetic intensity of the hydrogen nucleus. In addition, the natural abundance of the isotope must be considered. ¹H and ³¹P are both effectively 100% abundant, whereas ¹³C makes up only 1.1% of all carbon, the remainder being ¹²C. Because ³¹P has a modest magnetic sensitivity but the ³¹P isotope accounts for all the phosphorus, a clear signal can be obtained from ATP, inorganic phosphate, and phosphocreatine within cells, even though the concentration of these substances is relatively small. The weaker signal from ¹³C is suitable for studies of substances present in millimolar concentrations or greater. Hence, glycogen is measurable, as fasting concentrations range from 60 to 140 mmol/L in muscle and from 100 to 500 mmol/L in liver. Substances present in lesser concentrations, such as glycolytic intermediaries, could be measured, but only by enriching the ¹³C content by infusion of labeled precursor.

A spectrum is acquired by averaging many sequential resonances; hence, the subject must remain in precisely the same position to allow measurement on the same volume of tissue. This is not usually a limitation with studies on adults and is assisted by use of splints to maintain the position of the part of interest relative to the surface coil. Even for natural-abundance studies of ¹³C requiring total acquisition times of 15 or 20 minutes, comfort and compliance of the subject is not a problem.

VALIDATION OF MAGNETIC RESONANCE SPECTROSCOPY

Validation of the NMR spectroscopy method for determining the concentration of substances *in vitro* was achieved long ago by straightforward chemical analyses on the sample after NMR measurements. For the first studies of the living human body, the assumption was made that the method would be equally precise

in vivo. However, before embarking on clinical studies of glyco-

gen in vivo, it was necessary to define the accuracy and precision

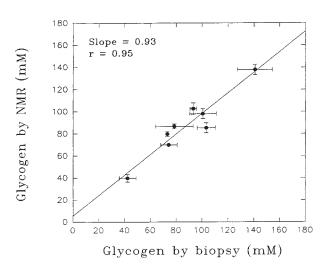

of NMR measurements in vivo. To accomplish this, a group of

METABOLISM IN THE FASTING STATE

Liver

OVERVIEW

The liver contains the only store of glycogen that is readily available for release into the circulation as glucose. For this reason, estimation of the hepatic concentration of glycogen in healthy and diabetic persons is of considerable importance. By combining ¹³C-MRS measurements of net hepatic glycogen content with magnetic resonance imaging (MRI) measurements of liver volume, rates of net hepatic glycogenolysis can be determined. The first accurate measurement on healthy young

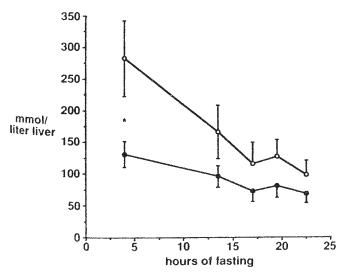

Figure 12.4. Correlation between measurement of muscle glycogen by magnetic resonance spectroscopy (MRS) and by biopsy in a group of healthy volunteers. The vertical and horizontal standard deviation bars for measurement on each subject indicate the greater precision of the MRS measurement. (From Taylor R, Price TB, Rothman DR, et al. Validation of ¹³C-MRI measurement of human muscle glycogen by comparison with biopsy and direct biochemical measurement. *Magn Reson Med* 1992;27: 13–20, with permission.)

Figure 12.5. Decrease in liver glycogen concentration in healthy subjects (*open symbols*) and subjects with type 2 diabetes during a prolonged fast. The first measurement was made 5 hours after an evening meal, and the overnight-fasted values are shown at 12 hours of fasting. (From Magnussen I, Rothman DL, Katz LD, et al. Increased rate of gluconeogenesis in type II diabetes mellitus. *J Clin Invest* 1992;1323–1327, with permission from the American Society for Clinical Investigation.)

Change in hepatic glycogen concentration in healthy subjects (*solid symbols*) and subjects with type 2 diabetes (*open symbols*) during a day in which three isocaloric meals were ingested. (From Hwang J-H, Perseghin G, Rothman DL, et al. Impaired net hepatic glycogen synthesis in insulin-dependent diabetic subjects during mixed meal ingestion. *J Clin Invest* 1995;95:783–787, with permission from the American Society for Clinical Investigation.)

humans demonstrated a glycogen concentration of 251 ± 30 mmol/L of liver after an overnight 15-hour fast (6), and other studies with similar nutritional preparation have observed similar values (7). Subjects with poorly controlled type 2 diabetes (mean fasting blood glucose 14.6 mmol/L) studied after a longer overnight fast were observed to have a significantly lower hepatic glycogen concentration than age- and weight-matched nondiabetic controls (97 ± 18 vs. 169 ± 43 mmol/L) (Fig. 12.5) (8). In subjects with type 1 diabetes, under fairly poor control, fasting concentration of liver glycogen was only slightly lower than in matched nondiabetic subjects (Fig. 12.6) (9).

HEPATIC GLYCOGENOLYSIS

During the overnight period, the hepatic glycogen stores of healthy subjects decrease to around 60% of the level achieved 4 hours after the evening meal (7,9). Direct measurement in two separate groups of healthy subjects has demonstrated that hepatic glycogen concentration decreases in a linear fashion during the night at an average rate of about 6 μ mol/kg body weight per minute (10,11). Higher rates of glycogenolysis were associated with higher initial hepatic concentrations of glycogen. In the overnight-fasted state, about 45% of the isotopically measured rate of whole body glucose production can be accounted for by net hepatic glycogenolysis (Fig. 12.7).

GLUCONEOGENESIS

Assessment of this process whereby the three-carbon substrates lactate, pyruvate, and glycerol are converted into glucose is beset with problems. Using hepatic venous catheterization to measure the uptake of gluconeogenic amino acids, pyruvate, and lactate across the splanchnic bed, Wahren et al. (12) estimated that the contribution of gluconeogenesis to total glucose production was only ~20% during the first 12 to 14 hours of a fast. Consoli et al. (13,14) used [2-¹⁴C] acetate to calculate the ¹⁴C-specific activity of the precursor of glucose produced by gluconeogenesis (phosphoenolpyruvate) to estimate rates of hepatic gluconeogenesis and concluded that hepatic glycogenolysis accounted for 29% ± 2% of overall glucose production after an overnight fast. However, acetate is metabolized in extrahepatic tissues, invalidating this approach (12,15–17). Using [¹⁴C]lactate,

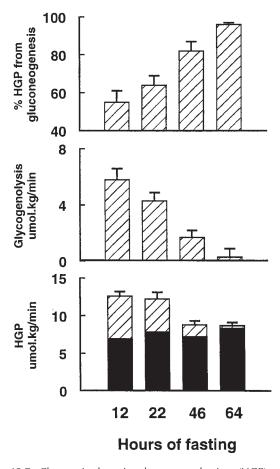

Figure 12.7. Change in hepatic glucose production (HGP), rate of glycogenolysis measured by sequential magnetic resonance spectroscopy, and calculated percentage of HGP due to gluconeogenesis during 64 hours of fasting in healthy subjects. (Data are from Rothman DL, Magnusson I, Katz LD, et al. Quantitation of hepatic glycogenolysis and gluconeogenesis in fasting humans with ¹³C NMR. *Science* 1991; 254:573–576; and Petersen KF, Price T, Cline GW, et al. Contribution of net hepatic glycogenolysis to glucose production during the early postprandial period. *Am J Physiol* 1996;270(pt 1):E186–E191, with permission. Copyright © 1996 by the American Physiological Society.)

Pimenta et al. (18) estimated that glycogenolysis (from glycogen synthesized by the direct pathway) accounted for ~45.7% \pm 4.7% and gluconeogenesis from lactate for a minimum of 18.6% \pm 2.4% of overall hepatic glucose production. However, measurements of gluconeogenesis by the incorporation of label from [¹⁴C]lactate are complicated by the fact that the specific activity of intracellular lactate cannot be estimated from the specific activity of [¹⁴C]lactate in plasma (19).

Rates of gluconeogenesis can be calculated by combining ¹³C-NMR measurement of liver glycogen concentration with magnetic resonance imaging of liver volume and isotopic measurement of hepatic glucose production (HGP). Net hepatic glycogenolysis was determined by sequential measurement of hepatic glycogen concentrations by ¹³C-NMR, and rates of net hepatic glycogenolysis were calculated by multiplying this decrease in liver concentration over time by liver volume. Subtraction of these rates from rates of whole-glucose production determined by tracer turnover techniques yields rates of gluconeogenesis (6). Since the labeled carbon in position C6 of glucose is lost during carboxylation of pyruvate into oxaloacetate and during equilibration with dicarboxylic acids, contributions of glucose cycling between glucose and glucose-6-phosphate or

200 JOSLIN'S DIABETES MELLITUS

between fructose-6-phosphate and fructose-1,6-bisphosphate would not be included in the calculated rate of whole-body glucose production derived from this isotope (20). This approach, therefore, yields a minimum estimate for the rate of whole-body glucose production compared with [2-²H]glucose and [3-³H]glucose and a maximal estimate for the contribution of net hepatic glycogenolysis to the rate of whole body glucose production. Seven healthy volunteers were studied over a 68-hour period, starting with a 1,000-kcal liquid test meal at 5 p.m. Liver glycogen concentration fell from $396 \pm 29 \text{ mmol/L}$ at 4 hours following the meal to $251 \pm 30 \text{ mmol/L}$ at 15 hours and to $42 \pm 9 \text{ mmol/L}$ at 64 hours. Over the first 22 hours of fasting, the rate of decrease of liver glycogen concentration was linear at around 4 mmol/L per minute. After 22 hours of fasting, gluconeogenesis accounted for a mean of 64% of hepatic glucose output (Fig. 12.7).

To estimate the maximum contribution of net hepatic glycogenolysis to whole-body glucose production earlier in the postabsorptive period, studies were performed 5 to 12 hours after the ingestion of a large evening meal. At this time, hepatic glycogen stores were found to be at their maximum daily level (9). $[6,6^{2}H]$ Glucose was used for measuring rates of whole-body glucose production. Under these experimental conditions, net hepatic glycogenolysis contributed $43\% \pm 5\%$ to whole-body glucose production during the first 12 hours after a meal. This is consistent with earlier NMR data and implies that gluconeogenesis typically contributes ~50% to glucose production even under circumstances when hepatic glycogen stores are at their daily maximal concentration (21,22). This is significantly greater than previous estimates (12,13,18). This result has been confirmed by the more recently developed ²H₂O method (23).

Because of the methodologic difficulties in measuring hepatic glycogen content in vivo, few other studies have directly examined the relative contributions of hepatic glycogenolysis to glucose production in humans. Nilsson and Hultman (24) measured hepatic glycogen concentrations by biopsy in nine subjects 12 hours into a fast and once again 4 hours later and found that the rate of net hepatic glycogenolysis was 288 ± 30 μ mol/kg wet liver tissue per minute. This rate is ~30% higher than the MRS-determined rate of 225 µmol/L liver per minute and might be explained by the stress response associated with needle biopsy. These workers, assuming that liver volume was 1.8 L, calculated that net hepatic glycogenolysis contributed ~57% to 67% to the rate of whole-body glucose production (24). If the data of Nilsson and Hultman (24) are recalculated with a liver volume of 1.5 L, as found by NMR imaging, the contribution of net hepatic glycogenolysis would be 47% to 56% of the rate of whole-body glucose production, a figure similar to the findings by NMR spectroscopy.

ADAPTATION TO STARVATION

Since the glycogen stores in the liver are typically limited to approximately 70 g after an overnight fast, and glucose is utilized at a rate of approximately 7 to 10 g per hour, hepatic glycogen stores are largely dissipated early in the course of a prolonged fast (6). Thus, the initial phase of starvation is characterized by an increase in the relative contribution of gluconeogenesis to meet the ongoing demands for glucose by tissues (mainly from the central nervous system). The importance of glucose production from protein is reflected by an increase in urinary excretion of nitrogen in the early phase of starvation (25). During the first 24 hours of a fast, urinary excretion of nitrogen averages 4 to 7 g/m^2 in the absence of nitrogen intake (26). This amounts to approximately 50 to 75 g of protein (~1 g N/6.25 g protein) for the average 70-kg person. Similar results are obtained with isotopic tracer methods for estimating totalbody rates of protein oxidation (27). Therefore, regardless of

whether simple urinary nitrogen balance is measured or a tracer method is used, the results suggest that about 50 g of protein is oxidized in the 24 hours following a meal. Since the protein content of tissues does not exceed 20% by weight for any tissue, 50 to 75 g of protein translates into 250 to 375 g of tissue or the equivalent of 1% to 1.5% of lean body mass lost on the first day of a fast. In muscle, the release of alanine and other glycogenic amino acids increases in conjunction with an acceleration of proteolysis (27). At the same time, the rate of hepatic conversion of gluconeogenic amino acids into glucose is augmented (6). The increase in glucose synthesis from amino acids is not, however, due solely to increased availability of precursor, since plasma levels of alanine and other glycogenic amino acids decline (28). Taken together, these observations suggest that intrahepatic gluconeogenic mechanisms are stimulated as well, enhancing the efficiency of this process.

The major metabolic changes that occur during the first 60 hours of starvation have been quantified by a combination of MRS and isotopic methods (6,10). Figure 12.7 draws on data from two different studies. The whole-body utilization of glucose falls by 25% from the overnight-fasted state, and the proportion of HGP contributed by gluconeogenesis rises from 55% at 12 hours to 96% at 60 hours.

The metabolic adaptations in the early stages of starvation (namely increased gluconeogenesis, proteolysis, and lipolysis) coincide with and are orchestrated primarily by a decline in insulin secretion to below levels in the overnight fasted condition and by a modest increase in circulating levels of glucagon (6,29). Insulin deficiency promotes all aspects of the metabolic response, whereas the effect of glucagon is confined to the liver. Specifically, the decline in insulin promotes the breakdown of protein and fat and thus the delivery of gluconeogenic amino acids from muscle and glycerol from fat stores to the liver, whereas the activation of intrahepatic gluconeogenic processes is promoted by both the increase in glucagon and the decrease in insulin in the portal circulation. Hypoinsulinemia further contributes to glucose homeostasis by reducing glucose metabolism by extracerebral tissues (e.g., muscle) and by increasing the availability of free fatty acids for oxidative metabolism by muscle and liver and ketones for muscle and the central nervous system.

Liver stores of triglyceride are known to be elevated in type 2 diabetes (30,31), and it is also possible to measure the extent of this accurately with MRS (5). The physiologic relevance of this for management of substrate utilization during fasting in type 2 diabetes remains to be elucidated.

Muscle

In healthy humans, after an overnight fast ~1,600 mmol of glycogen is stored in muscle [calculated from reference (32)] compared with ~420 mmol in the liver. The manner in which glycogen stores are regulated was not easily amenable to study until the development of ¹³C-NMR spectroscopy made possible accurate measurements in vivo (3). By emulation of the energy expenditure of the gastrocnemius muscle during walking, ¹³C-NMR spectroscopy was able to show that a steady depletion of muscle glycogen occurred during the initial 90 minutes. Thereafter, the glycogen concentration in muscle remained constant at about 70% of the basal level, even though the exercise was continued for many hours (33). This raised the question of whether the steady state during exercise reflected the cessation of utilization of stored glycogen or simultaneous synthesis and degradation. This question was answered by infusing [¹³C]glucose at a very slowly increasing rate during prolonged lowintensity exercise of the gastrocnemius muscle alone (34). The gradual increase in infusion rate avoided a change in plasma insulin or C-peptide. The accumulation of [¹³C]glucose in muscle under these conditions demonstrated that simultaneous synthesis and degradation allowed a constant muscle glycogen concentration to be maintained during this intensity of exercise. No such turnover of glycogen was seen in the contralateral, nonexercising muscle, although a very low rate of synthesis and breakdown cannot be excluded. During these studies of singlemuscle exercise, plasma levels of insulin, glucagon, and catecholamines remained constant, indicating that autoregulation at the level of the muscle determined this particular aspect of control of glycogen stores and substrate utilization.

In healthy subjects with a normal range of insulin sensitivity a correlation between muscle triglyceride concentration and insulin sensitivity has been observed both by biopsy (35) and by MRS (36). In muscle, triglyceride is stored both as intracellular droplets within the muscle fibers and in adipocytes between the muscle fibers. Measurement of total muscle triglyceride relates less closely to physiologic parameters than does intramyocellular triglyceride, as demonstrated by a biopsy study of normal glucose tolerant women. Intramyocellular triglyceride correlated both with waist: hip ratio and fasting non-esterified fatty acid (r = 0.47 and 0.44, p < 0.01 and 0.04, respectively), whereas total muscle triglyceride correlated with neither (35). Nonetheless, fat stored within muscle is an indicator of insulin sensitivity, as postprandial muscle glycogen synthase activity correlated both with intramyocellular and total muscle triglyceride (r = -0.43 and -0.47, p < 0.03 and 0.02, respectively). It has previously been reported that the concentration of triglyceride in muscle of subjects with type 2 diabetes is elevated considerably (37,38). The abnormality also is present in relatives of people with type 2 diabetes (39). The effect of the elevated concentration of triglyceride in muscle in patients with type 2 diabetes on day-to-day muscle metabolism has yet to be precisely assessed.

METABOLISM IN THE POSTPRANDIAL STATE

Liver

OVERVIEW

The liver is central to maintenance of normoglycemia following food ingestion because of suppression of hepatic glucose production and stimulation of hepatic glucose uptake. Insulin is the primary signal that orchestrates the storage and metabolism of glucose (40). Although glucose is the dominant mediator of insulin secretion, stimulation of insulin secretion with meals involves the secretion of multiple incretins from the pancreas and gastrointestinal tract, as well as signals from the central nervous system (parasympathetic innervation of the β -cells of the pancreas) in response to local gastrointestinal stimulation (41). This becomes apparent when comparing the insulin response to identical amounts of glucose given intravenously versus orally (42). Oral glucose raises insulin levels several-fold higher than comparable glycemia achieved by intravenous administration of glucose (43-46). The differences in physiologic response to pure glucose compared with a mixed meal should be noted. The former brings about a decrease in glucagon secretion, whereas the latter stimulates glucagon secretion together with a much brisker insulin secretory response (47-49).

HEPATIC GLYCOGEN STORAGE AFTER EATING

Before the development of ¹³C-MRS techniques for measuring hepatic glycogen content, data regarding the regulation of hepatic glycogen metabolism in humans were sparse. This technique allows repeated, direct, and noninvasive measurement as

a consequence of the natural abundance of ¹³C (3,50–52). Previous studies of the disposition of glucose following eating have relied upon isotopic methods (53,54), hepatic vein catheterization (55), or both (56), and estimation of change in glycogen stores has not been distinguishable from the rest of splanchnic glucose metabolism. In a group of eight healthy subjects (23.6 \pm 1.5 years old; body mass index 23.1 \pm 0.7), change in hepatic glycogen concentration was followed with MRS over 7 hours after a liquid mixed meal (7). The meal was representative of an average main meal of a day, containing 824 kcal (67.3% glucose, 18.5% fat, 14.2% protein).

After the test meal, the mean hepatic glycogen concentration increased from $207 \pm 22 \text{ mmol/L}$ at an average rate of 0.34 mol/L per minute (Fig. 12.8). The mean of the individual peak concentrations was $316 \pm 19 \text{ mmol/L}$, and the mean time to peak was just over 5 hours. After reaching a peak value in individual subjects, mean liver glycogen concentration decreased in approximately a linearly fashion (p < 0.01) at a rate of 0.26 mmol/L per minute. Over the 260 minutes after the test meal, the average individual increment in glycogen concentration was $79.2 \pm 16.2 \text{ mmol/L}$. Multiplying the individual increase in liver glycogen synthesis of 28.3 ± 3.7 g, equivalent to approximately 20% of the carbohydrate content of the meal.

Previous estimates of splanchnic glucose uptake after oral loads of pure glucose have ranged from less than 25% to 60% of the administered load (55,56). However, such studies were unable to distinguish between liver glycogen storage and splanchnic glucose metabolism. Most previous studies have

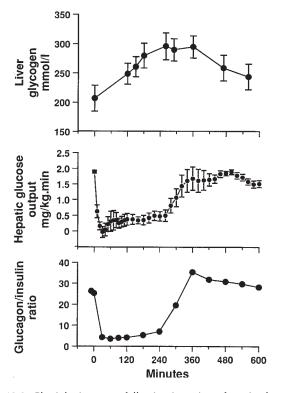

Figure 12.8. Physiologic events following ingestion of a mixed meal in healthy subjects. Change in liver glycogen was tracked by magnetic resonance spectroscopy and hepatic glucose production by the variable rate isotopic method. The plasma molar ratio of glucagon to insulin is shown as a potential controlling influence. (From Taylor R, Magnussen I, Rothman DL, et al. Direct assessment of liver glycogen storage by ¹³C-nuclear magnetic resonance spectroscopy and regulation of glucose homeostasis after a mixed meal in normal subjects. *J Clin Invest* 1996;97:126–132, with permission from the American Society for Clinical Investigation.)

202 JOSLIN'S DIABETES MELLITUS

been terminated at or before 240 minutes (48,55,56), a time when absorption of either glucose or a mixed meal may be incomplete (53,55,57,58) and when liver glycogen storage is submaximal, according to the MRS data. The directly measured 20% of meal carbohydrate present in liver glycogen at peak concentration represents net glycogen synthesis and does not take account of glycogen turnover (59). Hence, to the degree that hepatic glycogen turnover occurs during absorption of meals, the proportion of the meal-derived glucose that becomes at least temporarily incorporated into liver glycogen will be greater than the above net estimates. Liver size would not be expected to exert a major influence on the above estimations, as a 67-hour fast is necessary to decrease liver size by 23% (60).

SOURCE OF GLUCOSE CARBON FOR GLYCOGEN SYNTHESIS

Early work in animals suggested that most liver glycogen is synthesized not from glucose but from three-carbon atom precursors (61,62). More recently, the direct pathway (glu $cose \rightarrow glucose \text{-}6\text{-}phosphate \rightarrow glucose \text{-}1\text{-}phosphate \rightarrow UDP\text{-}glu$ $\cos \rightarrow$ glycogen) has been shown to account for 49% of hepatic glycogen synthesis in the fasting state and for 69% following breakfast (63,64). After a [14C]glucose-labeled test meal identical to that used in the MRS study described above, plasma [14C]glucose specific activity rapidly increased over the 30 minutes after the test meal to 87 ± 7 disintegrations per minute (dpm)/µmol then gradually increased to peak at 134 ± 8 dpm/µmol at 160 minutes. In each subject, the highest [14C]glucose specific activity in plasma was very similar to the specific activity in that individual's test meal. By use of acetaminophen labeling of the hepatic glucuronide pool (63), the calculated contribution of the direct pathway to overall glycogen synthesis was $46\% \pm 5\%$ and $68\% \pm 8\%$ for each time period, respectively. The measurements between 2 and 4 hours postprandially were made during net hepatic glycogen synthesis and during the second period between 4 and 6 hours were made during little net synthesis but continued turnover. The observed increase in the direct-pathway contribution to hepatic glycogen synthesis from 46% between 2 and 4 hours to 68% between 4 and 6 hours postprandially is consistent with the previous observations that directpathway activity is greater after the second meal of the day (63,65). This also is consistent with the observation that glycogen synthesis directly from glucose occurs at a higher rate in primary cultures of hepatocytes isolated from fed rather than from fasted animals (66–68). However, 4 to 6 hours after a meal, rates of net liver glycogen synthesis are low. Hence, less than 10% of the carbohydrate component of a meal is likely to be stored as liver glycogen via the direct pathway between 4 and 6 hours postprandially even though almost 70% of synthesis is via the direct pathway at this time.

LIVER GLYCOGEN CYCLING

The possible occurrence of simultaneous synthesis and breakdown of liver glycogen has been controversial for several decades. That such glycogen cycling occurs in humans has been demonstrated by ¹³C-MRS pulse-chase studies. In a study of healthy subjects, MRS measurements of the glycogen C1 peak were made continuously during a hyperglycemic hyperinsulinemic clamp (69). [¹³C]glucose was infused for 90 minutes, and the clamp was continued using [¹²C]glucose subsequently. In the fasting state, the relative rate of glycogen cycling was 31%, and this increased to 57% in the fed state. The implied autoregulation of hepatic glycogen stores is supported by compilation of data from other studies, which suggests that the higher the glycogen concentration the higher the rate of hepatic glycogenolysis (Fig. 12.6) (6,70).

NORMAL DIURNAL FLUCTUATION IN HEPATIC GLYCOGEN CONTENT

Study of the change of the liver glycogen concentration after a single meal has provided considerable new insight into normal human metabolism. The relatively rapid decline in concentration after attainment of peak levels was particularly striking. However, few people in the Western world eat a single meal per day, and extrapolation from single-meal studies to everyday physiology is unsound. To define the normal diurnal fluctuations in hepatic glycogen concentration, nine healthy subjects $(22 \pm 1 \text{ years; body mass index } 23.4 \pm 1)$ and six subjects with type 1 diabetes (34 ± 2 years; body mass index 23.5 ± 2.4) were studied during a day in which three isocaloric meals were eaten at 5-hour intervals (9). Each meal consisted of normal foodstuffs (12 kcal/kg as 60% carbohydrate, 20% fat, 20% protein). The early-morning insulin resistance was reflected in the healthy subjects by considerably higher peak plasma insulin levels after breakfast (107 μ U/mL) than after the other two meals (52 and 44 µU/mL, respectively). Thus, in this protocol, insulin stimulation and substrate availability were provided at the time the liver glycogen concentration would be expected, from the results of the single-meal studies, to fall.

The changes in liver glycogen concentration are shown in Figure 12.6. It can be seen that liver glycogen concentration increased sequentially during the day, with no decrease between meals, such that there was a total increase of 144 mmol/L between the fasting level and the postdinner peak in healthy subjects but an increase of only 44 mmol/L in subjects with type 1 diabetes. Overnight, hepatic glycogenolysis both maintains fasting blood glucose concentration and returns the hepatic glycogen concentration to normal fasting levels, where-upon the cycle will recommence. In diabetes, the role of glycogenolysis must be of lesser importance in this process.

Muscle

Postprandial storage of glycogen in muscle has been quantitated by using ¹³C-MRS to measure the glycogen concentration of the gastrocnemius muscle in young healthy subjects over a 7hour period following a mixed meal of ordinary foodstuffs (32). Muscle glycogen concentration rose from a mean of 83.3 mM to a peak of 100 mM at 4.9 hours and fell thereafter to a mean of 90.6 mM 7 hours postprandially (Fig. 12.9). It was calculated

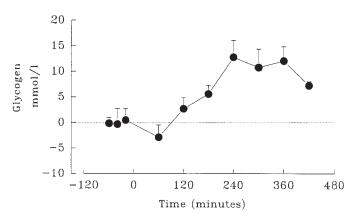

Figure 12.9. Incremental change in gastrocnemius muscle glycogen concentration after breakfast in a group of healthy subjects. Fasting muscle glycogen was 83.3 mmol/L of muscle. (From Taylor R, Price TB, Katz LD, et al. Direct measurement of change in muscle glycogen concentration after a mixed meal in normal subjects. *Am J Physiol* 1993;265: E224-E228, with permission. Copyright © 1993 by the American Physiol logical Society.)

from measurements of total muscle mass and estimation of rates of carbohydrate absorption that, at peak muscle glycogen concentrations, 26% to 35% of the absorbed carbohydrate was stored as muscle glycogen. The fate of oral glucose has previously been examined by limb balance studies (44,53,71) and indirect calculations based on tracer methodology and hepatic vein catheterization (55,56,72,73). These studies have suggested that up to 70% of ingested carbohydrate is taken up by muscle. Such estimates do not concur with the direct MRS measurements, possibly as a consequence of modeling problems. It should be noted that the MRS measurements were made on a single muscle, rather than on a group of muscles with associated other tissues.

Muscle glycogen concentration did not start to rise until 1 to 2 hours after eating. This slow rise was surprising when viewed in the context of the more rapid time course of arteriovenous difference in plasma glucose measured across forearm or leg after oral glucose (43,54,74,75). Hence, it may be inferred that the predominant fate of glucose taken up by muscle in the immediate postprandial period is oxidation; thereafter, a gradual change to net glycogen synthesis takes place. The observed fall in muscle glycogen concentrations after the fourth postprandial hour when glucose oxidation is likely to be minimal suggests that flux of three-carbon compounds out of muscle may be important in allowing redistribution of excess substrate for storage. The unexpectedly early fall in muscle glycogen concentration suggests that skeletal muscle acts as a dynamic buffer to maintain glucose homeostasis during acute food ingestion, preventing an undue rise in plasma glucose and subsequently permitting substrate redistribution for medium-term storage.

EXERCISE

A study of glycogen depletion following heavy exercise of one gastrocnemius muscle in healthy fasting subjects showed that the process of glycogen reaccumulation exhibited a rapid phase

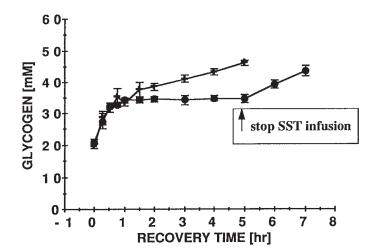

Figure 12.10. Change in muscle glycogen concentration after singlemuscle exercise to deplete glycogen stores. The normal two-phase recovery is shown, together with the pattern of recovery during infusion of somatostatin to suppress plasma insulin levels (*round symbols*). The rapid first phase was unaffected whereas the subsequent slower phase was abolished until the somatostatin infusion was stopped. (From Price TB, Rothman DL, Taylor R, et al. Human muscle glycogen resynthesis afer exercise: insulin-dependent and -independent phases. *J Appl Physiol* 1994;76:104–111, with permission.)

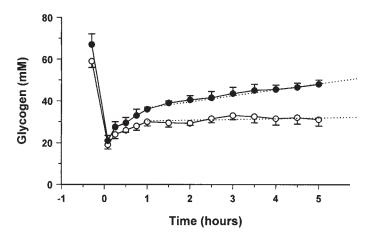

Figure 12.11. Effect of glycogen-depleting exercise and the subsequent rate of recovery of muscle glycogen in control subjects with no family history of diabetes (*solid symbols*) and insulin-resistant relative of subject with type 2 diabetes (*open symbols*). (From Price TB, Perseghin G, Duleba A, et al. NMR studies of muscle glycogen synthesis in insulin-resistant off-spring of parents with non-insulin-dependent diabetes mellitus immediately after glycogen-depleting exercise. *Proc Natl Acad Sci U S A* 1996;93:5329–5334, with permission. Copyright 1996 National Academy of Sciences, U.S.A.)

and a subsequent slower phase. A follow-up study using paired somatostatin or control infusions documented the involvement of insulin in the latter but not the former phase (57). The glycogen recovery during the second, slower phase (2.4 mM per hour) was totally abolished during somatostatin infusion, which brought about a decrease in fasting plasma insulin from 12.4 to $5.3 \mu U/mL$ (Fig. 12.10). This is of particular metabolic interest as it demonstrates a clear effect of insulin upon muscle at fasting concentrations. Previously, it was thought that such levels of plasma insulin did not exert significant effects on muscle glucose metabolism.

The question of whether the insulin resistance characteristic of type 2 diabetes may affect this process of insulin-dependent glycogen repletion has been addressed by study of normoglycemic relatives of people with type 2 diabetes (76). As illustrated in Figure 12.11, the insulin-resistant subjects exhibited subnormal rates of glycogen synthesis, thus demonstrating the practical consequence of low insulin sensitivity even under the condition of basal insulin concentrations. In established type 2 diabetes, it is possible that hyperglycemia provides partial compensation by a mass-action effect of increased muscle glucose uptake (77).

During prolonged exercise in athletes, the depletion of both glycogen and intramuscular triglyceride has been quantified by MRS (78). Heavy exercise (running at 70% of peak oxygen uptake until exhaustion) brought about a 64% decrease in calfmuscle glycogen and a 34% decrease in calfmuscle intramyocellular triglyceride. The exercise capacity of people with type 2 diabetes is not impaired, and further application of MRS studies can be expected to elucidate the dynamics of fuel supply in muscles that are likely to start exercise with lower glycogen and higher triglyceride stores.

MECHANISM OF INSULIN RESISTANCE IN TYPE 2 DIABETES

Insulin resistance is defined as a subnormal change in glucose metabolism in the presence of a given insulin stimulation. Hence, it may be anticipated that specific faulty steps in the cas-

cade of insulin signal transduction may be identified. Defects in glycogen synthase (79-82), hexokinase (83, 84), and glucose transport (85-87) have all been implicated in the subnormal muscle glycogen synthesis in type 2 diabetes. The relative importance of these steps to insulin-stimulated muscle glucose metabolism has been assessed by performing ¹³C/³¹P-MRS studies to measure intracellular concentrations of glucose, glucose-6-phosphate, and glycogen in muscle of patients with type 2 diabetes and age- and weight-matched control subjects (85). Intracellular glucose-6-phosphate is an intermediary metabolite between glucose transport and glycogen synthesis, and hence the relative activities of these two steps will be reflected by its intracellular concentration. In the event of decreased activity of glycogen synthase in diabetes, glucose-6-phosphate in the patients with diabetes would be expected to be increased relative to that in the healthy individuals. When ³¹P-NMR was used to assess intracellular glucose-6-phosphate under conditions of hyperglycemic-hyperinsulinemia, an increase of approximately 0.1 mM intracellular glucose-6-phosphate was observed in healthy individuals but no change was observed in patients with type 2 diabetes. The blunted incremental change of glucose-6-phosphate concentration in the patients with type 2 diabetes in response to insulin stimulation can therefore be ascribed to either decreased glucose transport activity or decreased hexokinase II activity.

Insulin-resistant offspring of patients with type 2 diabetes were studied in an effort to determine whether this defect in glucose transport or hexokinase II activity was a primary or acquired defect secondary to other factors, such as chronic hyperglycemia. The rate of muscle glycogen synthesis and the muscle concentration of glucose-6-phosphate were measured under the same clamp conditions (88). Although these individuals were lean and normoglycemic, they are known to be at an ~40% increased risk for developing diabetes. The children of parents with diabetes exhibited a 50% decrease in the rate of insulin-stimulated whole-body glucose metabolism compared with age- and weight-matched control subjects, and this was mainly a consequence of decreased rates of muscle glycogen synthesis. The severe blunting of their insulin-stimulated increment of intramuscular glucose-6-phosphate indicated impaired muscle glucose transport or reduced hexokinase activity similar to that seen in patients with fully developed type 2 diabetes. When control subjects were studied at similar insulin levels but at euglycemia, both the rate of glycogen synthesis and the glucose-6-phosphate concentration decreased to values similar to those of offspring of patients with type 2 diabetes. Thus, even before the onset of diabetes, insulin-resistant offspring of patients with type 2 diabetes have decreased rates of muscle glycogen synthesis that are secondary to a defect in muscle glucose transport or hexokinase activity. It can be concluded that defects in one or both of these activities occur early in the pathogenesis of type 2 diabetes.

To determine whether glucose transport or hexokinase II activity is rate controlling for insulin-stimulated muscle glycogen synthesis in patients with type 2 diabetes, a novel ¹³C-NMR method has been applied to assess intracellular glucose concentrations in muscle under similar hyperglycemic–hyperinsulinemic conditions (89). Intracellular glucose is a transient intermediate between glucose transport and glucose phosphorylation, and its concentration reflects the relative activities of glucose transporters and of hexokinase II. Unlike the standard biopsy method, this approach is noninvasive and is not subject to the errors caused by contamination of biopsy tissue with plasma glucose or by incomplete removal from the biopsy of nonmuscle constituents. If hexokinase II activity was decreased relative to glucose transport activity in patients with diabetes, a sub-

stantial increase in intracellular glucose would be predicted, whereas if glucose transport was primarily responsible for maintaining intracellular glucose metabolism, intracellular glucose and glucose-6-phosphate should change proportionately. It was observed that intracellular glucose concentration was far lower in the subjects with type 2 diabetes than the value expected if hexokinase II was the primary rate-controlling enzyme for glycogen synthesis (89). When the rates of muscle glycogen synthesis in the subjects with diabetes were increased by infusing greater amounts of insulin, the changes in the concentrations of intracellular glucose and glucose-6-phosphate indicated that the rates of glucose transport were matched by increases in the rates of glucose phosphorylation and glycogen synthesis. These data indicate the major role of glucose transport in determining muscle glycogen synthesis in diabetes, but they do not rule out the possibility that other abnormal features of glycogen synthesis may be found that do not exert rate-controlling effects under these conditions.

Decreased delivery of substrate or insulin to the tissue bed has been hypothesized to be at least partially responsible for the insulin resistance in type 2 diabetes (90). No difference has been observed in the ¹³C-NMR-measured ratio of extra- to intracellular water space in the healthy subjects and subjects with diabetes, implying that insulin-mediated vasodilatation could not be responsible. There was no difference in the interstitial insulin concentrations in the two groups during the hyperinsulinemic clamps, and hence the delivery of insulin is not responsible for the insulin resistance in patients with type 2 diabetes. Overall, these data are consistent with the hypothesis that glucose transport is the rate-controlling step for insulin-stimulated muscle glycogen synthesis in patients with type 2 diabetes. These results also suggest that agents that enhance hexokinase II or glycogen synthase activity will not be as effective as any agent that primarily improves glucose transport activity.

Mechanism of Fatty Acid–Induced Insulin Resistance

Increased concentrations of free fatty acids in plasma are typically associated with many insulin-resistant states, including obesity and type 2 diabetes (91–94). An inverse relationship between fasting plasma fatty acid concentrations and insulin sensitivity was found in a cross-sectional study of young, normal-weight offspring of patients with type 2 diabetes, consistent with the hypothesis that altered fatty acid metabolism contributes to insulin resistance in patients with type 2 diabetes (95). Furthermore, recent studies measuring intramuscular triglyceride content by muscle biopsy (35,96) or intramyocellular triglyceride content by ¹H-NMR (36,97) have shown an even stronger relationship between accumulation of intramyocellular triglyceride and insulin resistance.

The mechanism originally proposed by Randle et al. (98,99) to explain the insulin resistance was that an increase in fatty acids caused an increase in the intramitochondrial acetyl-CoA/CoA and NADH/NAD⁺ ratios, with subsequent inactivation of pyruvate dehydrogenase. This in turn would cause intracellular citrate concentrations to increase, leading to inhibition of phosphofructokinase, a key rate-controlling enzyme in glycolysis. Subsequent accumulation of glucose-6-phosphate would inhibit hexokinase II activity, resulting in an increase in intracellular glucose concentrations and a decrease in glucose uptake.

A recent series of studies have challenged this conventional hypothesis (100–102). In the first study, ¹³C- and ³¹P-MRS were used to measure skeletal muscle glycogen and glucose-6-phos-

phate concentrations in healthy subjects. The subjects were maintained in euglycemic hyperinsulinemic conditions with either low or high levels of plasma fatty acids (100). Increasing the plasma fatty acid concentration for 5 hours caused a reduction of ~50% in rates of insulin-stimulated muscle glycogen synthesis and whole-body glucose oxidation compared with the control studies. In contrast to the predictions of the Randle model, where fat-induced insulin resistance should result in an increase in intramuscular glucose-6-phosphate, the fall in muscle glycogen synthesis was preceded by a decrease in the intramuscular glucose-6-phosphate content. These data suggest that increases in plasma fatty acid concentrations initially induce insulin resistance by inhibiting glucose transport or phosphorylation activity and that the reductions in muscle glycogen synthesis and glucose oxidation follow. The reduction in insulinactivated glucose transport/phosphorylation activity in healthy subjects maintained at high plasma fatty acid levels is similar to that seen in obese individuals (103), patients with type 2 diabetes (85), and lean-normoglycemic insulin-resistant offspring of individuals with type 2 diabetes (88). Hence, accumulation of intramuscular fatty acids (or fatty acid metabolites) appears to play an important role in the pathogenesis of insulin resistance in obese patients and patients with type 2 diabetes. Moreover, fatty acids would seem to interfere with a very early step in insulin-stimulation of GLUT4 transporter activity or hexokinase II activity.

Intracellular concentrations of glucose itself were measured by ¹³C-NMR to distinguish between possible effects of fatty acids on glucose transport activity and hexokinase II activity (101). Since intracellular glucose is an intermediate between glucose transport and hexokinase II, its concentration reflects the relative activities of these two steps. If a decrease in hexokinase activity is responsible for the lower rate of insulin-stimulated muscle glycogen synthesis, intracellular glucose concentrations should increase. However, if the impairment is at the level of glucose transport, there should be no difference or a decrease in the intracellular glucose concentration. Elevated plasma fatty acid concentrations caused a significant reduction in intracellular glucose concentration in the lipid infusion studies compared with control studies in which glycerol (the other metabolite released by lipolysis) was infused in the absence of any exogenous fatty acid. These data imply that the ratecontrolling step for fatty acid-induced insulin resistance in humans is glucose transport.

SUMMARY 222

EVOLVING CONCEPTS ABOUT ADIPOSE TISSUE PHYSIOLOGY

From an evolutionary perspective, the biology of adipocytes begins with the strategies developed by organisms over time to cope with irregular and unpredictable supplies of nutrients. The need for such a mechanism became especially acute in omnivorous mammals and was probably a key survival factor. As Homo sapiens developed complex societal rituals that revolved around shared meals and as social status was assessed by the acquisition of resources, to be well endowed with a layer of fat was a clear sign of success, wealth, and social dominance. However, in more recent times, particularly in industrialized societies over the last 40 years, it has been more popular to possess the least amount of body fat. This modern idealism of slimness represents the new prototype of the species, glamorized by fashion and art. Simultaneously, in the medical community, there is also a greater emphasis on a leaner physique because of the growing alarm over the epidemic of overweight and obesity in adults and even children (see Chapter 31 for a detailed definition and discussion of obesity). The most recent statements from the Surgeon General of the United States and the World Health Organization emphasize the need for the general public to lose weight (specifically to reduce percentage of body fat) because of the established associations between excess body fat and increased risk for a host of serious medical complications (1) (http://

www.cdc.gov/nccdphp/dnpa/obesity/trend/index.htm), including type 2 diabetes and cardiovascular disease, to name just two. It is also recognized that extreme deficiencies in body fat, such as lipodystrophy, can be as detrimental as excess fat in terms of diabetes risk (2). It is therefore important to understand the development and metabolic functions of adipose tissue and how these processes are regulated.

Until the 1990s, adipose tissue had largely been considered an inert storage depot for excess metabolic fuel. Accumulation of excess calories as triglycerides in adipose tissue is driven largely by insulin, and subsequent access to this stored fuel is gated by the β -adrenergic catecholamine receptors and their ability to stimulate lipolysis. The discovery of leptin as an adipose-derived hormone that can "report" on the status of these energy reserves to other organs of the body, including the central nervous system, gave us a new perspective on the biology of adipose tissue (3). The ensuing years have brought a deeper appreciation of the secretion by adipose tissue of a fairly large number of cytokines and growth factors that may play significant roles in insulin resistance, cell differentiation, and growth (Fig. 13.1). We will review aspects of the biology of adipocytes ranging from general anatomy and cellular and molecular biology to exciting new developments that support the concept that adipose tissue is an endocrine organ and that the adipocyte is a critical player in the regulation of insulin sensitivity as a result of its ability to secrete fatty acids, leptin, various cytokines, and other novel peptides.

ADIPOSE TISSUE: STRUCTURAL FEATURES AND ANATOMIC DISTRIBUTION

Adipose tissue is present in every mammal and is critical to the maintenance of energy balance. Until the past few years, adipose tissue had been considered a type of loose connective tissue composed of lipid-filled cells (adipocytes) surrounded by a matrix of collagen fibers and a supporting blood supply. However, the current view of adipose tissue is that of a bona fide organ system with distinct tissue types mediating specific functions [e.g., homeostasis of energy reserves, hormone secretion, and immune regulation (4)]. Adipose tissue has been classified into two major forms on the basis of gross appearance, cell type–specific gene expression, and predominant type of adipocytes (5): white adipose tissue and brown adipose tissue.

White Adipose Tissue

White adipose tissue (WAT) is named for its white/yellowish color. It contains adipocytes with a single large lipid inclusion

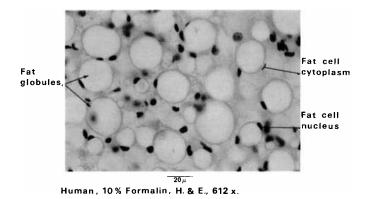

Figure 13.2. White fat cells. The cytoplasm appears as a thin rim at the periphery of the cell. Stored fat is the predominant component of the cell. The nucleus is flattened in the cytoplasm, permitting maximum storage of fat globules. The fat cell lipid is in the form of a single droplet, and these cells are described as unilocular. (From Bergman RA, Afif AK, Heidger PM. *Atlas of microscopic anatomy*, 2nd ed. Philadelphia: WB Saunders, 1974:53 [see color plate], with permission.)

Figure 13.1. Evolving view of the biologic function of the adipocyte. Previously, adipocytes were considered to be inert storage depots releasing fuel as fatty acids and glycerol in times of fasting or starvation. More recently, it has become clear that adipocytes are endocrine glands that secrete important hormones, cytokines, vasoactive substances, and other peptides, with far-reaching effects on other organs and tissues, including the brain. TNF, tumor necrosis factor; ANS, autonomic nervous system; ACRP30, adipocyte complement-related protein-30 kDa (adiponectin). (From Kahn BB, Flier JS. Obesity and insulin resistance. J Clin Invest 2000;106:473-481, with permission from the American Society for Clinical Investigation.)

(termed unilocular), resulting in displacement of the cytoplasm, flattening of the nucleus to the plasmalemma, and appearance of signet ring-shaped adipocytes. After histologic processing with xylene or other fat solvents, WAT sections lose lipid, such that tissue resembles a meshwork of polygonal or ovoid profiles of variable sizes (20 to 200 µm diameter) when seen under the light microscope (Fig. 13.2). WAT is considered to be less well vascularized than brown adipose tissue (BAT). However, capillaries often are observed at the junctions where adipocytes meet. Heavier connective tissue septa separate WAT depots into lobules of various sizes. Special stains have revealed that the connective tissue surrounding white adipocytes contains precursor cells, fibroblasts, immune cells, reticular fibers, and unmyelinated nerves (6). The nerve fibers have been found to be immunoreactive for tyrosine hydroxylase, calcitonin gene-regulated peptide (CGRP), neuropeptide Y, and substance P (7). The postganglionic tyrosine hydroxylase-positive sympathetic nerves terminate primarily on arterioles and, when stimulated, cause vasoconstriction. In support of earlier anatomic and histologic observations, there is good evidence of a direct sympathetic innervation of white adipocytes originating from the central nervous system (8,9). Electron microscopic examination of white adipocytes shows that they are surrounded by a basal lamina. The cytoplasm is compressed into a thin rim containing a small Golgi complex, endoplasmic reticulum, free ribosomes, and filaments (9-11). Pleomorphic mitochondria are located close to the nucleus. The large lipid inclusion is not surrounded by a membrane but is heavily decorated with a protein called *perilipin* (12). The lipid droplet is also devoid of organelles.

WAT is the predominant type of adipose tissue in adult mammals. In healthy humans it accounts for 15% to 20% of body weight in men and 20% to 25% in women. The majority of WAT is organized into a continuous layer in the subcutaneous tissue called the *panniculus adiposus*. Subcutaneous WAT is especially abundant in the lower abdomen and buttocks, particularly in females. Other WAT depots are located in the omentum, breast, mesentery, and retroperitoneal/perirenal regions in humans, some of which can become pathologically large. WAT also accumulates in the axilla, pericardium, bone marrow, orbits, hands, and soles of the feet and functions as a cushion in these latter regions. In rodents, subcutaneous WAT accumulates around the scapular, axillary, and inguinal regions. Intraabdominal depots are located in the retroperitoneal area and in the mesenteric and perigonadal regions. The sexual dimorphism of body contour in humans is accounted for in large measure by differences in subcutaneous WAT (13). In addition to its abundance in the breasts, WAT is more abundant in the hypodermis of the lower abdomen, buttocks, and thighs in women than in men. These differences are influenced in part by sex hormones, as the female (gynoid) pattern of fat distribution tends to be altered to a central (android) location at menopause. Excessive central adiposity (especially intraabdominal) has been linked to the "metabolic syndrome," which includes insulin resistance, dyslipidemia, and increased risk of cardiovascular disease (14).

In general, the proportion of WAT in healthy adults remains fairly constant over prolonged periods. However, WAT can increase markedly with obesity and decrease with anorexia nervosa, cancer, and other wasting diseases. By weight, WAT comprises between 70% and 90% lipid, 5% to 30% water, and 2% to 3% protein. Most of the lipid content is triglyceride (>90%), although small amounts of diglyceride, cholesterol, and phospholipid are present. As noted above, in all species the ability to store calories efficiently within WAT can confer enormous survival advantage against the threat of starvation. As will be discussed later, fat metabolism is dependent on energy requirements and is regulated by nutrient, neural, and hormonal signals. The postprandial increase in glucose and lipids stimulates insulin release and increases fatty acid transport and lipogenesis in adipocytes. Conversely, reductions in glucose and insulin during fasting and stimulation of the sympathetic nervous system lead to lipolysis and the release of fatty acid for use by other tissues.

The morphology of WAT is affected by nutritional status. Obesity is an increased volume of WAT due to hypertrophy and hyperplasia of adipocytes (15-17). Lipid accumulation is associated with the formation of numerous micropinocytotic invaginations and vesicles, which coalesce into multilocular and finally unilocular lipid inclusions (10,11). By contrast, fasting causes a reduction in the size of the lipid droplet, an irregularity of the plasmalemma associated with numerous micropinocytotic invaginations and vesicles, and a prominent smooth endoplasmic reticulum (18). Prolonged fasting causes white adipocytes to take on the appearance of spindle-shaped fibroblastlike cells containing very few lipid inclusions (19). Moreover, the amount of capillaries is increased during fasting, consistent with the reported rise in blood flow in WAT, to facilitate delivery of oxygen and transport of the hydrolyzed free fatty acids (FFAs) to other tissues (20).

In addition to providing nourishment, proteins secreted by vascular endothelium control adipocyte differentiation and maturation (21). Antiangiogenic factors, e.g., angiopoeitin and TNP-40, inhibit angiogenesis as well as adipogenesis, and deplete adipocyte lipid stores in rodents (22,23). Vascular endothelial growth factor (VEGF) is increased with visceral fat accumulation, stimulated by insulin, and decreased by weight reduction (24,25). Importantly, blockade of VEGF inhibits adipogenesis, suggesting a causal role in adipose tissue development (25). In a recent study, targeting of a novel peptide to prohibitin, a vascular marker of adipose tissue, resulted in destruction of adipose vasculature and rapid reversal of obesity in rodents (26). These findings have generated considerable interest in the use of antiangiogenic agents as treatment for obesity.

The idea that obesity is associated with chronic inflammatory response, e.g., abnormal production of acute-phase reactants, and induction of inflammatory signaling pathways, is an old one (27). Chronic low-grade inflammation had been linked to insulin resistance, diabetes, and cardiovascular disease in obese individuals, although the underlying mechanisms

remained unclear until recently. There are remarkable similarities in the patterns of gene expression, activation of complement, and induction of cytokines, among T-cells, macrophages, and adipocytes. Importantly, adipocyte precursors have the capacity to be transformed into phagocytic cells. Futhermore, there is significant overlap between metabolic pathways that mediate lipid metabolism in macrophages and adipocytes. Obesity in rodents and humans triggers a progressive infiltration of the stromovascular compartment of adipose tissue by macrophages (28,29). This process appears to be mediated through production of TNF- α and other cytokines by obese adipocytes, which in turn stimulate preadipocytes and endothelial cells to produce matrix proteins, e.g., monocyte chemoattractant protein (MCP)-1. Macrophage infiltration may be further enhanced by adipocyte hormones, e.g., leptin and adiponectin, as well as oxidative injury to endothelium. A key question is how these local changes eventually lead to diabetes and cardiovascular complications of obesity. Perhaps, cytokines and other chronic inflammatory signals from obese adipose tissue directly regulate glucose metabolism in muscle, liver as well as pancreatic β -cell responses, as shown by the improvement in glucose levels in parallel with inhibition of NF-KB by salicylate (30).

Brown Adipose Tissue

The rich and varied history of BAT as an anatomically discrete type of fat includes early speculations in the 17th century that it was part of the thymus and, a century later, that it was an endocrine organ involved in blood formation or a special form of fat acting as a reservoir for certain nutrients (31). BAT is named for its "brown" color, which is derived from a rich blood supply and an enormous number of mitochondria per cell (5). In overall appearance the adipocytes in BAT are generally smaller than white adipocytes and characterized by numerous small lipid inclusions (termed *multilocular*) (Fig. 13.3). Unlike white adipocytes, the nucleus is eccentric but not flattened.

Only in 1961 was the true function of BAT realized, when it was proposed to be thermogenic (32,33). Since then, an immense body of work has shown that BAT is uniquely capable of responding to various environmental stimuli to generate heat from stored metabolic energy. In response to activation by the sympathetic nervous system, BAT undergoes an orchestrated hyperplastic and hypertrophic expansion, increased blood flow, and recruitment of lipid and carbohydrate fuels for oxidative metabolism (34,35). A unique and critical element of this thermogenic mechanism for dissipation of the proton gradient in brown fat mitochondria was recognized to be due to a brown fat-specific mitochondrial uncoupling protein (UCP) (36), also called thermogenin (37). As illustrated in Figure 13.4 and discussed in greater detail by Ricquier and Bouillaud (38), this mitochondrial protein, now known as UCP1, allows controlled proton leakage across the mitochondrial inner membrane for the purpose of generating heat at the expense of respirationcoupled ATP production. This uncoupling activity in brown fat mitochondria is "activated" by FFAs that are released as a result of catecholamine-stimulated lipolysis.

Developmentally, BAT is most abundant in newborn mammals and is principally involved in heat production (5,39). In the human fetus, BAT is located in the dorsal cervical, axillary, suprailiac, and perirenal regions. Smaller amounts are present in the anterior mediastinum, interscapular, intercostal, and retropubic regions. By contrast, BAT is very prominent in the interscapular and axillary areas in mice and rats, with lesser deposits in the dorsal midline of the thorax and abdomen. Light microscopy examination shows that these BAT depots that

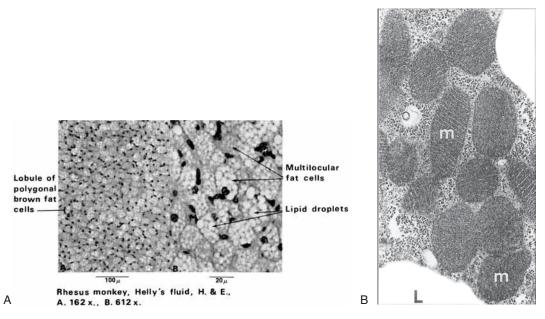

Figure 13.3. A: Brown fat is an uncommon variety of fat found in specific locations in the body. Unlike the more common white fat, brown fat cells contain a number of small lipid droplets; hence the name multilocular fat. **Panel B** illustrates the dense mitochondrial content of brown adipocytes. (From Bergman RA, Afifi AK, Heidger PM. *Atlas of Microscopic Anatomy*, 2nd ed. Philadelphia: WB Saunders, 1989: 54 [see color plate], with permission.)

reside along the midline are partitioned into lobules by dense connective tissue containing numerous blood vessels and nerves. For example, the prominent interscapular BAT in the rat receives two arteries and veins and has abundant capillaries (9). The nerve supply consists of large myelinated fibers, as well as small unmyelinated fibers that stain intensely for neuropeptide Y and tyrosine hydroxylase (9). The latter, which are postganglionic sympathetic fibers, form a periarterial plexus and also innervate brown adipocytes directly. In large mammals such as dogs and primates (including humans), homogenous depots of BAT decline with age beyond infancy but, as in rodents, brown adipocytes can be detected interspersed within typical "white" adipose depots throughout adulthood [reviewed in reference (40)]. Moreover, cold challenge or treatment with a β_3 -adrenergic receptor (β_3 AR) agonist further provokes the elaboration of such brown adipocytes in all of these animals. Humans with pheochromocytoma exhibit large amounts of BAT as a result of chronic catecholamine stimulation (41).

Development of Adipose Tissue

The origin of adipose tissue was a matter of controversy for a number of years (42,43). Early histologists debated whether adipose tissue was a distinct organ or merely a specialized loose connective tissue with lipid-filled fibroblasts. The current view of adipose tissue as a distinct organ was based on studies showing that adipocyte precursors were derived from mesenchyme and that the blood supply of the so-called primitive fat organ was distinct from the surrounding connective tissue. In humans and most mammals, adipose tissue development begins at midgestation. In rats and mice, WAT does not develop until the perinatal period, but established BAT depots are present in the late stages of gestation. Adipose depots arise from "undifferentiated" cells clustered along blood vessels. Adipocyte precursor cells lack lipid droplets and are associated with a rich supply of proliferating capillaries. The transformation of preadipocytes into white adipocytes is characterized morphologically by the

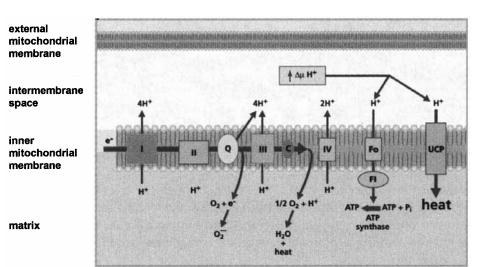

Figure 13.4. Transport of electrons through the respiratory chain complexes (I–IV) is associated with pumping of protons from the mitochondrial matrix into the intermembrane space, creating an electrochemical gradient ($\Delta\mu$ H⁺) for adenosine triphosphate (ATP) synthesis by the ATP synthase (FO–F1). An uncoupling protein (UCP) provides an alternative route for protons to reenter the matrix, thereby uncoupling the oxidation of fuel from ATP production. (Drawing courtesy of Dr. Antonio Vidal-Puig.) accumulation of small lipid droplets that eventually coalesce into a single large droplet.

The concept that preadipocytes exist within adipose tissue, even into adulthood, and that they can differentiate into adipocytes under appropriate hormonal stimulation is supported by studies showing that cells isolated by collagenase digestion from the stromal-vascular compartment of fat pads from many sources, including humans, can differentiate into adipocytes when cultured in vitro in media enriched with insulin and other serum factors [reviewed in reference (44)]. In addition, studies of obesity in various strains of mice indicate that adipocyte hyperplasia can exist into adulthood (45). The ability of adipocytes to replenish a depot following ablation by gene targeting also supports this idea (46). Our understanding of the biochemistry and genetic program controlling adipocyte differentiation has also benefited enormously from studies of immortalized mouse preadipocyte cell lines such as 3T3-L1 and 3T3-F442A (47). These cells are propagated as fibroblastlike preadipocytes that are capable of differentiating into mature adipocytes under appropriate hormonal stimulation and that for the most part express the same genes as white adipocytes in vivo. As a result of extensive studies in these and similar adipogenic cell lines, we know that the adipocyte differentiation program proceeds through a series of well-characterized stages: (a) preconfluent, (b) growth arrest/confluence, (c) clonal expansion, and (d) terminal differentiation. Each stage involves a coordinated expression of transcription factors to culminate in the expression of specific genes for lipid metabolism, hormones, cytokines, and other adipocyte products (44,48).

MOLECULAR EVENTS IN PREADIPOCYTE COMMITMENT AND DIFFERENTIATION

The quest to define the critical required factors and/or temporally specific events in the commitment and differentiation of a given cell type has long fascinated biologists and has driven the field of molecular biology. This line of investigation in general has benefited from the efforts to understand the molecular basis of adipogenesis. The adipogenic cell lines of Green and colleagues (36) provided the technical basis from which to isolate adipocyte-specific genes and identify their regulatory factors. As a result of such approaches, a number of key transcription factors are now known to promote adipogenesis. They include

the family of CCAAT/enhancer binding proteins (C/EBP), peroxisome proliferator-activated receptor- γ (PPAR- γ), and the sterol regulatory element binding protein (SREBP) family (SREBP1c, also known as ADD1). As shown in Figure 13.5, during adipocyte commitment and differentiation, the expression of the C/EBPs and PPAR-y2 occurs in cascade fashion. A large number of studies in cell culture models and in genetically modified animals clearly show that agents or manipulations that interfere with the expression of these factors can inhibit differentiation or result in an incomplete state of differentiation. The genes and signaling pathways that commit cells to the preadipocyte lineage have been less well studied but are now an active area of investigation. In addition, although some of these cell culture models can appear morphologically to differentiate into adipocytes (49), it is now appreciated that in some cases the failure to appropriately express certain transcription factors results in the absence of gene products responsible for critical metabolic activities (50-52).

The PPAR- γ isoform PPAR- γ 2 is expressed at high levels in adipose tissue (53,54). Its identification was based on a search for transcription factor(s) implicated in the expression of adipocyte-specific genes (55–57). Fibroblasts such as NIH-3T3 that are genetically engineered to express PPAR- γ 2 can be coaxed to differentiate into "adipocytes" by the definition of visual proof of lipid accumulation and the expression of genes related to triglyceride synthesis and storage (53). In agreement with a key role for PPAR- γ 2, its failure to be expressed during development prevents adipogenesis (58,59), and deletion of the PPAR γ gene from mature adipocytes *in vivo* results in depletion of cells from the depot and decreased adipose mass (46). Provision of PPAR- γ 2 by retroviral infection to PPAR- γ -deficient cells fully restores the capacity for differentiation (60,61).

While these results support the primacy of PPAR- γ for adipogenesis, several issues remain unresolved. An "endogenous ligand" for PPAR- γ remains undefined. At present there are two views of this situation. One is that a single, specific, high-affinity ligand is produced in target tissues. A second, based on crystallographic data (62) and comparisons of fatty acid binding and activation, is that the ligand-binding pocket of PPAR- γ can accommodate a variety of ligands, leading to the proposition that the receptor may serve as a general sensor of fatty acid milieu: the so-called PUFA receptor (for *polyunsaturated fatty acids*), with no unique fatty acid ligand. In some sense this latter idea is akin to the ability of the cytochrome P450 family to

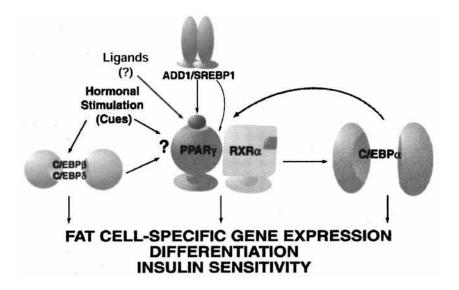

Figure 13.5. The transcriptional control of adipogenesis involves the activation of a variety of transcription factors. These proteins are expressed in cascade fashion, in which C/EBPβ and C/EBPδ are among the earliest seen. These two proteins promote the expression of peroxisome proliferator-activator receptor-y (PPAR- γ), which in turn activates C/EBP α . C/EBP α feeds back on PPAR- γ to maintain a differentiated state. ADD1/ SREBP1 can activate PPAR-y by inducing its expression, as well as by contributing to the production of an endogenous PPAR-y ligand. All these factors contribute to the expression of genes that characterize the terminally differentiated phenotype. (From Rosen ED, Spiegelman BM. Molecular regulation of adipogenesis. Annu Rev Cell Dev Biol 2000;16:145-171, with permission from the Annual Review of Cellular and Developmental Biology, © 2000 by Annual Review.)

accommodate a variety of hydrophobic substrates in the active site of the enzyme, hydroxylating them with turnover numbers that are relatively slow for highly specific enzymes, but nevertheless successfully accomplish the goal of identifying and eliminating xenobiotics (63).

In addition to the endogenous ligand issue, it is clear not only that PPAR- γ is required but also that C/EBP α is critical to the expression of the full complement of genes that define the mature adipocyte phenotype. For example, in NIH-3T3 fibroblasts engineered to express PPAR- γ 2 and differentiated into adipocytes (53), even in this so-called differentiated state, these cells lack C/EBP α . As a result, they also lack certain defining features of the adipocyte, such as insulin-stimulated glucose uptake (50,51) and expression of the adipocyte-specific β_3 AR (52). These metabolic anomalies are corrected following reintroduction of C/EBP α , confirming the need for C/EBP α in the mature adipocyte, at least for specific adipocyte genes and functions. Interestingly, absence of C/EBP α from adipose tissue in mice prevents the appearance of white, but not brown, fat (64).

Although these models have provided a wealth of information about adipocyte differentiation, it is true that most of these conclusions result from immortalized cell lines grown in isolation from other constituents of the adipose organ. Global targeted disruption of PPAR-y2 in mice results in embryonic lethality (58,65,66). Consequently, studies of adipogenesis in PPAR-γ-deficient cells were performed in cultured cells derived from these animals. [However, as already noted, mice with adipose-specific "knockout" of PPARy are viable, lack adipose tissue, and are insulin-resistant (59,67).] In addition, as discussed later in this chapter, the majority of these cell models in culture differentiate into white adipocytes. There have been very few available cell-culture models that differentiate into brown adipocytes, and most do not fully recapitulate the complete characteristics of brown adipocytes in vivo. Over the last decade, several immortalized brown adipocyte cell lines have been generated (68-71), providing the opportunity to advance molecular understanding of brown adipocyte differentiation and gene regulation. Several immortalized brown adipocyte cell lines were developed by a strategy called targeted transgenic tumorigenesis. Tissue-specific promoters were used to engineer SV40 T-antigen or oncogenic mutants of p53 to produce brown adipose tumors, from which cell lines were developed. Initially, the characteristics of these cell lines were, in large measure, quite representative of the brown adipocyte in vivo, but it is interesting that many of these cells have evolved with continuous passage in culture to express fewer and fewer features of the brown adipocyte: loss of expression of UCP1, depressed expression of other markers of mitochondria, and loss of $\beta_3 AR$ expression [(69,71) and S. Collins and K. W. Daniel, unpublished observations, 1996-1999].

In other cases these brown adipocyte models also lack expression of certain brown adipocyte genes (68,72), or simply have not yet been fully characterized. One theory concerning the loss of phenotypic validity with culture passage is that the more differentiated cells in the culture, expressing UCP1, tend to be at a proliferative disadvantage and over time are lost from the population. In addition, murine preadipocyte cultures do not address the contribution of the connective tissue matrix to the maturation of adipose tissue. Finally, among the various adipose depots *in vivo*, there are significant differences in metabolic characteristics and expression of certain genes that presently cannot be replicated in cell culture. The reader is referred to recent reviews that provide additional details (44,73).

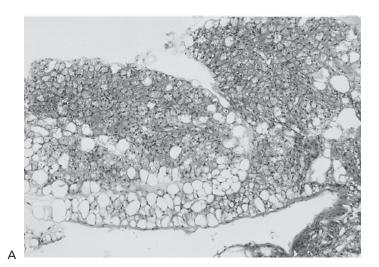

MOLECULAR FEATURES OF WHITE VERSUS BROWN ADIPOCYTES

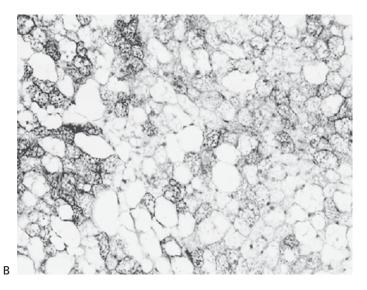

Despite the wealth of knowledge that has accrued over the past 25 years about the molecular events that set in motion and maintain the phenotype of the differentiated adipocyte, our understanding of the genetic programs that distinguish white from brown adipocytes is still far from complete. Historically, the agreement about the existence of BAT in humans and the importance of brown adipocyte thermogenesis has had a very checkered past. As discussed above, it is clear that a discrete adipose depot of homogeneous brown adipocytes exists at birth but does not remain in adult humans. Nevertheless, one can also readily find "brown adipocytes" in adults, as defined by morphologic and UCP1 histochemical criteria, scattered among white adipocytes in various "white adipose" depots, including perigonadal, perirenal, and pericardial, albeit they appear to be a small percentage of total adipocytes (Fig. 13.6). These BAT depots can undergo significant hypertrophy in adult humans under conditions of chronic catecholamine stimulation, as in pheochromocytoma (41). Similarly, in small rodents that retain bona fide BAT depots in adulthood, one finds scattered brown adipocytes in intraabdominal and intrathoracic white adipose depots, but rarely in subcutaneous fat. Part of the difficulty in establishing the extent to which adult humans possess brown adipocytes is that most biopsies are collected from subcutaneous sites. Since this is not the location of brown adipocytes at birth, estimates of residual brown adipocytes in humans, are, indeed, unknown. Thus, several important unanswered questions pertaining to the issue of brown adipocytes in adult humans remain.

First, we need accurate information about the number of brown adipocytes in adult humans. Second, even after we gain an accurate assessment of the number and locations of these scattered brown adipocytes in adult humans, we still must assess whether they are thermogenically active. Finally, we must determine whether these cells can be recruited in greater numbers in response to pharmacologic agents that behave as "thermogenic" drugs in rodent models (discussed in next section).

The unique morphologic differences between brown and white adipocytes (as discussed in an earlier section) are the result of differential gene expression during development and reflect the opposing metabolic functions of these cells: storage of caloric energy versus oxidation of caloric energy as heat. One of the most interesting questions in the field of adipocyte development is how and what molecular "decisions" are made in the mesenchymal precursor cells that give rise to white versus brown adipocytes. As discussed above, our understanding of the molecular events that drive the differentiation of white adipocytes has benefited enormously from the availability of clonal, immortalized cell lines that developmentally and phenotypically recapitulate white adipocytes.

The tissue-specific molecular markers of white and brown adipocytes have traditionally been the fatty acid–binding protein aP2 (also called 442) (55,74) and UCP1 (27), respectively. While aP2 is expressed in both white and brown adipocytes, UCP1 has been the unequivocal defining feature of brown adipocytes. However, for UCP1 to be expressed in such a highly cell type–specific manner, one would expect that other factors in brown adipocytes are required to initiate transcription of the *UCP1* gene. Thus, we still do not know whether there are factors *specifically* expressed in brown adipocytes that are themselves tissue-specific or whether they comprise a set of gene products that are uniquely and coordinately expressed as a result of hormonal cues. Some candidate molecules that are dif-

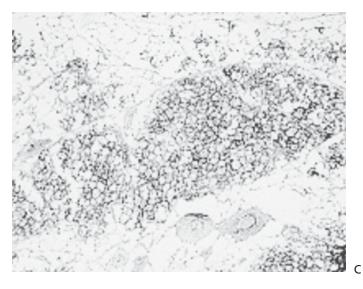

ferentially expressed in brown versus white adipocytes are PPAR- γ -coactivator-1 (PGC1 α) and retinoid orphan receptor- γ (ROR γ). In particular, PGC1 α appears to be an important coordinator and regulator of genes involved in oxidative metabolism (75). For example, when PGC1 α is expressed ectopically in white adipocytes, they appear to be "converted" to brown adipocytes where the cells now express UCP1 as well as a panoply of genes required for the genesis of a mitochondrion (75,76). At least in rodent brown adipocytes, the participation of PGC1 α also appears to be critical for catecholamine-stimulated expression of UCP1 (77).

IMPORTANT ADIPOCYTE METABOLIC ACTIVITIES AND THEIR REGULATION

As befitting the role of adipose tissue as a "bank" for the deposition and retrieval of stored metabolic energy, it is of paramount importance to understand the hormone systems that control its metabolic processes for whole-body energy homeostasis and for interpreting the malfunctioning of these systems in diseases such as in type 2 diabetes. In this section we review results from several fronts that establish the adipocyte as an endocrine organ that secretes factors that report to other organ **Figure 13.6. A:** Brown adipocytes within a strip of human adipose tissue from the mediastinum. Hematoxylin and eosin stain. Courtesy of Dr. Laura Hale, Duke University Medical Center. **B:** Section of retroperitoneal adipose tissue from an A/J mouse following treatment with the β_3 -adipocyte receptor agonist CL316,243. Brown adipocytes visualized by immunostaining with antisera to uncoupling protein 1 (UCP1). From S. Collins and L. P. Kozak, unpublished observations. **C:** Section of inguinal adipose tissue from an AXB8 mouse after being housed at 5°C for 7 days, showing patches of brown adipocytes as visualized by immunostaining with antisera to UCP1. systems about the energy reserve status of the organism. One of the pivotal discoveries in this regard that revolutionized our thinking about the overall function of adipose tissue was the identification of the adipocyte-derived hormone leptin. In addition, since the association of obesity with type 2 diabetes is a well-known clinical phenomenon and since obesity has been documented in many instances to be a major contributing factor to insulin resistance, we also discuss obesity and insulin resistance in terms of adipocyte biology. We integrate this new information into current views of the mechanisms by which insulin, catecholamines, and certain cytokines control storage and release of lipid in the adipocyte.

Leptin: An Adipocyte Hormone Regulating Food Intake and Metabolism

Humans and other mammals have an extraordinary ability to match food intake to energy expenditure over long periods so that body weight and adiposity are maintained at near-constant levels. This homeostatic balance is remarkable given the infinite variety of day-to-day physical activity and the great variation in dietary selections and timing of their intake. On the basis of this observation, Kennedy (78) proposed that a signal emanating from adipose tissue informed the brain about the status of energy reserves, leading to alterations in feeding behavior and energy expenditure in an attempt to maintain energy balance. The concept of an "adipostat" was further supported by results of animal experiments in which food deprivation or surgical lipectomy resulted in compensatory hyperphagia and, conversely, acute forced overfeeding led to a reduction in voluntary ingestion until body weight was restored to the previous level.

Despite considerable effort, the identity of a circulating factor linking adiposity to energy homeostasis remained elusive until technical advances in genetics and computational power were made. These developments, combined with the extensive biochemical, physiologic, and genetic studies of the *ob/ob* (*obese*) and *db/db* (*diabetes*) mutant strains of mice, led to the isolation in the mid-1990s of the genes for these loci. Friedman and colleagues (79) determined that the obese gene encodes a protein with a relative molecular mass of 16 kDa that is expressed mainly in adipose tissue and circulates in plasma. It has a helical structure similar to that of cytokines and is highly conserved among species. They named this adipocyte-secreted hormone "leptin" (from the Greek leptos meaning thin) because it decreased body weight when injected in mice [reviewed in reference (79)]. Moreover, Friedman and others also showed that, as originally postulated by Coleman and colleagues (80,81), the diabetes locus encodes the receptor for leptin (82,83). Together these two discoveries were a major step forward in establishing the existence of an "adipostat," and the work led to a deeper appreciation of the endocrine role of adipose tissue (Fig. 13.1). As will be discussed later, this endocrine status of adipose tissue has expanded beyond what was initially implicated from the isolation of leptin.

REGULATION OF LEPTIN PRODUCTION AND KINETICS

There is a strong positive correlation between percent body fat, plasma concentrations of leptin, and expression of the leptin gene in adipose tissue. Moreover, leptin levels are dependent on nutritional status. They are higher in obese individuals and increase with overfeeding. By contrast, leptin levels are lower in lean individuals and decrease during fasting. The reduction in leptin expression and its circulating levels during fasting is rapid and precedes weight loss, suggesting that leptin might serve as a signal for impending energy depletion. Plasma leptin levels are related to the feeding cycle. In humans, concentrations of leptin appear to peak at night and reach a nadir in the morning. By contrast, in rodents concentrations of leptin reach a nadir during the light cycle and peak after the onset of feeding during the dark cycle, consistent with their nocturnal lifestyle. Various studies have suggested that the nutritional regulation of leptin is mediated at least in part by insulin (84), since the postprandial increase in insulin is temporally associated with increased expression of leptin messenger RNA (mRNA). Conversely, leptin decreases in response to insulin deficiency in humans and rodents. Although insulin stimulates the synthesis of leptin in adipocyte culture, and circulating levels of leptin in *vivo*, this effect appears to be due to insulin-stimulated glucose uptake and its metabolism (85,86) rather than to an effect of insulin signal transduction mechanisms per se on gene expression. This concept of insulin regulation is further complicated by the recent observation that mice lacking insulin receptors in fat have reduced fat mass but inappropriately high levels of leptin (87).

Several other hormonal or environmental factors have been noted to modulate leptin levels (84). For example, increases in circulating levels of leptin have been reported in response to acute infection, inflammatory cytokines, and chronic glucocorticoid and estrogen exposure. Although still largely empiric observations, the latter is postulated to be responsible, at least in part, for the higher concentration of leptin in females than in males. Higher expression of leptin in subcutaneous adipose tissue also is thought to play a role. Factors that have been associated with decreases in leptin levels include testosterone, cold exposure, adrenergic stimulation, growth hormone, thyroid hormone, melatonin, smoking, and thiazolidinediones.

ROLE OF LEPTIN IN FEEDING BEHAVIOR AND METABOLISM

At the time of its discovery, there was wide speculation that leptin was the long sought "satiety" and "antiobesity" factor described several decades ago [reviewed in references (35,36, 38)]. This view was based on the following observations. First, *ob/ob* mice with a genetic deficiency in leptin due to a truncated gene product develop early-onset obesity, impaired thermogenesis, and hyperphagia. Similar abnormalities were observed in *db/db* mice and *fa/fa* rats with mutations in the leptin receptor, suggesting that leptin was involved in the negative feedback regulation of feeding and adiposity. Second, administration of leptin peripherally (and, more potently, by the intracerebroventricular route) prevented weight gain in ob/ob mice (and to a lesser extent in wild-type mice) through inhibition of food intake and increased energy expenditure, in agreement with the notion that leptin was the missing antiobesity factor in these mice (88-90).

Leptin-mediated weight loss also may involve effects on lipid metabolism and adipocyte survival, as peripheral or intracerebroventricular injection of leptin has been shown to increase fat oxidation and to promote adipocyte apoptosis [discussed in reference (79)]. The increase in energy expenditure following the administration of leptin is mediated by activation of the central sympathetic pathway (91,92) and the predicted downstream stimulation of brown fat-specific uncoupling proteins. Since the receptors and neuroendocrine cells controlling food intake and energy expenditure are situated in the hypothalamus and certain other brain regions (93-95), it must be understood how leptin, produced by adipocytes and released into the general circulation, arrives at these privileged sites within the central nervous system. There is general agreement from the current literature that leptin is delivered from the circulation into the central nervous system by a saturable, facilitated transport mechanism. The so-called long form of the leptin receptor (Ob-Rb), which mediates activation of the JAK-STAT (Janus Kinase-Signal transducer and activator of transcription) signal transduction pathway, has been colocalized with key neuropeptides and neurotransmitters in these brain regions involved in feeding behavior and energy balance [reviewed in reference (96-98)]. Recent data suggest that in addition to the Jak Stat pathway, leptin also activates the PI3 Kinase pathway and this may play a role in some of its metabolic effects (99,100). In addition, in skeletal muscle leptin activates the AMP-activated protein kinase (AMPK), and this is necessary for its effect on acetyl CoA carboxylase and stimulation of fatty acid oxidation (100a). In the hypothalamus, leptin and other anorexigenic signals inhibit AMPK activity (100b,100c), and this inhibition is necessary for leptin's effect on food intake and body weight (100c).

LEPTIN AS AN ANTIOBESITY HORMONE

The critical role of leptin in regulation of appetite and body weight has been demonstrated in rodents and humans with genetic leptin deficiency or leptin-receptor mutations; however, such mutations are extremely rare [see reference (101)]. The notion of leptin as an antiobesity hormone could be considered to be inconsistent with the empiric observations in both humans and rodent models that high endogenous levels of leptin do not prevent the accumulation of excess adipose tissue (102). However, a counterpoint argument is that the manner in which hyperleptinemia is indicative of "leptin resistance" is markedly similar to hyperinsulinemia in type 2 diabetes. In the latter circumstance it cannot be argued that the phenomenon of "insulin resistance" thus negates the role of insulin in controlling glucose homeostasis. Mechanisms underlying leptin resistance might include impairment of leptin synthesis or secretion, a decrease in transport of leptin across the blood–brain barrier, and abnormal leptin-receptor or postreceptor signaling. Data support both of these latter two possibilities. As expected, leptin treatment reverses hyperphagia, obesity, and hormonal and metabolic abnormalities when administered in *ob/ob* mice (88–90). Similarly, leptin drastically inhibits appetite, reverses obesity and neuroendocrine and immune abnormalities in the few humans with congenital leptin deficiency (103).

Although leptin receptors are present in several tissues, studies indicate that the antiobesity action occurs primarily in the brain. Ob-Rb and downstream leptin signaling molecules, incuding neuropeptide mediators such as neuropeptide Y, agouti-related peptide, proopiomelanocortin (POMC), and cocaine and amphetamine-regulated transcript, are enriched in hypothalamic neurons that mediate feeding, thermogenesis, and hormonal regulation (98). Importantly, targeted ablation of Ob-Rb in neurons recapitulates hyperphagia, abnormal thermoregulation, morbid obesity, hyperinsulinemia, and other metabolic abnormalites in mice (104). In contrast, loss of Ob-Rb in liver has no substantial effects on body weight or hormone levels (104). Reduced leptin-stimulated phosphorylation of STAT3 in the arcuate nucleus of the hypothalamus has been associated with high-fat feeding in mice (104a,104b). To more fully investigate the contribution of STAT3-mediated leptin signaling, Myers and colleagues (105) replaced Tyr 1138 in Ob-Rb with a serine residue, lepr(S1138), which specifically disrupts the Ob-Rb-STAT3 signal. As is the case in *db/db* mice, lepr(S1138) homozygotes were hyperphagic and morbidly obese. However, infertility, impaired linear growth, and diabetes characteristic of *db/db* mice were absent in lepr(S1138) mutants. Whereas hypothalamic expression of neuropeptide Y was increased in *db/db* mice but not lepr(S1138) mutants, POMC, precursor of the anorectic leptin target α -MSH, was suppressed in both db/dband lepr(S1138) mice. Thus, it appears that the leptin-Ob-Rb-STAT3 signal is functionally coupled to distinct hypothalamic neuropeptides to control energy homeostasis, growth, reproduction, and glucose levels (105).

Neural-specific disruption of STAT3 in mice resulted in hyperphagia and obesity, consistent with failure of negative feedback regulation by leptin (106). Importantly, STAT3 null mice had reduced energy expenditure and elevated glucocorticoids, and were diabetic and infertile, confirming the importance of STAT3-mediated signaling in the neuroendocrine action of leptin (106). Furthermore, as predicted, loss of STAT3 in neurons resulted in hyperleptinemia associated with marked reduction in POMC and increased levels of neuropeptide Y and agouti-related protein in the hypothalamus (106). The latter features were consistent with lack of leptin feedback in the brain, similar to leptin resistance in db/db mice.

Leptin induces suppressors of cytokine signaling (SOCS)-3 levels via JAK-STAT (107,108). Because SOCS-3 inhibits leptin response, it was suggested that this mechanism could explain the failure of elevated endogenous leptin to prevent dietinduced obesity. Recent studies have investigated this possibility in mice (108). Compared to wild-type mice, neuron-specific ablation of SOCS-3 increased leptin response in the hypothalamus, in parallel with induction of STAT3 phosphorylation, increased POMC expression, reduction in feeding, and weight loss (107). Ablation of SOCS3 in neurons also prevented dietinduced obesity and insulin resistance (107). A similar effect of SOC3 was observed in mice with heterozygous SOCS3 deficiency (108). Haploinsufficiency of SOCS3 (+/–) decreased body weight and increased hypothalamic leptin response. Furthermore, SOC3(+/–) mice were protected against diet-induced obesity, insulin resistance, and diabetes (108). Taken together, these data demonstrate important roles for STAT3 and SOCS3 in mediating leptin sensitivity in rodent obesity. However, whether these mechanisms play significant roles in human obesity remains to be determined.

LEPTIN AS A SIGNAL FOR STARVATION

As discussed earlier, the ability to store energy in adipose tissue represents a major adaptation against the threat of starvation. Starvation triggers a complex array of neural, metabolic, and hormonal responses that maintain energy supply to the brain and vital organs. As glucose levels fall during prolonged fasting, there is a corresponding decrease in insulin and an increase in counterregulatory hormones (e.g., glucagon, epinephrine, and glucocorticoids), leading to a switch from carbohydrate- to fat-based metabolism. Triglyceride breakdown generates fatty acids to be used by muscles, kidneys, and various organs. Partial oxidation of fatty acids also generates ketones that can be utilized by the brain. Other responses to starvation include suppression of thyroid and gonadal hormones, inhibition of immune function, activation of the hypothalamic-pituitaryadrenal axis, decreased thermogenesis, and increased appetite. These changes are remarkably similar to the phenotype of leptin-deficient ob/ob mice, suggesting that the reduction in leptin mediates the metabolic and neuroendocrine response to starvation. We substantiated this hypothesis by showing that leptin administration blunted the expected rise in corticosterone and corticotropin and prevented the inhibition of thyroid hormone, growth hormone, and reproductive and immune function during fasting (102). An association between low plasma levels of leptin and obesity was reported in Pima Indians (109) and in mouse strains prone to diet-induced obesity (110). However, this finding has not been confirmed in other studies (111,112).

The role of leptin in mediating the response to fasting has been investigated in humans (113,114). In patients maintained at 10% weight reduction, chronic leptin treatment designed to prevent the fall in leptin blunted the typical reduction in energy expenditure and thyroid hormone associated with caloric deprivation (113). Another study showed that replacement of leptin within the physiologic range in fasted humans normalized the levels of thyrotropin, T3, gonadotropins, and testosterone (114). However, in contrast to rodents, leptin did not affect the pituitary–adrenal axis during fasting (114). The diurnal leptin rhythm as well as leptin pulses are attenuated in patients with hypothalamic amenorrhea; however, whether there is a causal relationship between weight reduction, low leptin level, and disruption of menstrual cycles remains to be determined (115).

Insulin and the Control of Glucose Uptake and Lipogenesis in the Adipocyte

Insulin is a regulator of virtually all aspects of adipocyte biology, and adipocytes are one of the most highly insulin-responsive cell types (116). Insulin promotes triglyceride stores in adipocytes by several mechanisms, including the fostering of the differentiation of preadipocytes to adipocytes and, in mature adipocytes, the stimulation of glucose transport and triglyceride synthesis (lipogenesis), and the inhibition of lipolysis. Insulin also increases the uptake of fatty acids derived from circulating lipoproteins by stimulating the activity of lipoprotein lipase in adipose tissue (117). The metabolic effects of insulin are mediated by a broad array of tissue-specific actions that involve both rapid changes in protein phosphorylation and function, as well as changes in gene expression. The fundamental biologic importance of these actions of insulin is evidenced by the fact that the insulin signaling cascade that initiates these events is largely conserved in evolution from *Caenorhabditis elegans* to humans (118).

The initial molecular signal for insulin action involves activation of the insulin receptor tyrosine kinase, which results in phosphorylation of insulin-responsive substrates (IRSs) on multiple tyrosine residues. These phosphotyrosine residues act as docking sites for many SH2 domain-containing proteins, including the p85 regulatory subunit of phosphoinositide 3kinase (PI 3-kinase). Binding of the p110 catalytic subunit of PI 3-kinase to p85 activates the lipid kinase and this promotes glucose transport (119). Whereas activation of PI 3-kinase is necessary for full stimulation of glucose transport by insulin, emerging evidence suggests that it is not sufficient and another pathway may also be necessary (120-122). The signals downstream of PI 3-kinase are not known, and there is evidence of a role for the serine/threonine kinase, Akt (protein kinase B [PKB]) (123,124), and possibly protein kinase C (PKC) such as λ or ζ (125). Most likely, the pathways that mediate the metabolic effects of insulin diverge downstream of PI 3-kinase (122,124) and show differential sensitivity to varying levels of insulin. For example, the antilipolytic effect of insulin requires much lower insulin concentrations than does stimulation of glucose transport. Hence, even in insulin-resistant states when glucose transport is impaired, sensitivity to the antilipolytic effect of insulin is preserved, resulting in maintenance or expansion of adipose stores. Insulin also activates the ras-mitogen-activated protein kinase (MAPK) signaling cascade. This pathway appears to be important for the mitogenic effects of insulin, but most data do not implicate the MAPK pathway in the wellstudied metabolic actions of insulin.

Insulin also regulates gene transcription in adipocytes. The transcription factor ADD-1/SREBP-1c may play a critical role in the actions of insulin to regulate adipocyte gene expression [(126–128) and references therein] by inducing genes involved in lipogenesis and repressing those involved in fatty acid oxidation. Transcription factors of the forkhead family also play a major role in transducing insulin signals to the nucleus (129). Foxol, for example, plays an important role in gluconeogenesis by interacting with PGC1 α (130). The relative functions of the ADD-1/SREBP and forkhead pathways deserve further investigation.

For a more detailed review of the molecular mechanism of insulin action, the reader is referred to Chapter 9.

INSULIN RESISTANCE IN OBESITY AND TYPE 2 DIABETES

The term *insulin resistance* usually connotes resistance to the effects of insulin on glucose uptake, metabolism, or storage. Insulin resistance is one of the major pathogenic factors in type 2 diabetes and is often associated with other pathologic states, including hypertension, hyperlipidemia, atherosclerosis, and polycystic ovary disease (this combined set of complications has been termed the *metabolic syndrome*, or *syndrome* X) [discussed in references (131) and (132)]. However, whereas it is still not known precisely how obesity promotes insulin resistance, recent new discoveries have expanded our knowledge in this area. In addition, another new concept is that insulin resistance and hyperinsulinemia, in addition to being *caused by* obesity, may actually *contribute to* the development of obesity (116,133).

Insulin resistance in obesity and type 2 diabetes is manifest by decreased insulin-stimulated glucose transport and metabo-

lism in adipocytes and skeletal muscle and by impaired suppression of hepatic glucose output (131). These functional defects may result, in part, from impaired insulin signaling in all three target tissues and, in adipocytes, also from downregulation of the major insulin-responsive glucose transporter, GLUT4. In both adipocytes and muscle, the cascade of insulin binding to its receptor, receptor phosphorylation and activation of tyrosine kinase activity, and phosphorylation of insulinresponsive substrate proteins are all reduced. There are also tissue-specific alterations. For example, in adipocytes from obese humans with type 2 diabetes, IRS-1 expression is reduced, resulting in decreased IRS-1-associated PI 3-kinase activity, and IRS-2 becomes the main docking protein for PI 3-kinase (134). In contrast, in the skeletal muscle of obese subjects with type 2 diabetes, levels of IRS-1 and IRS-2 protein are normal but PI 3-kinase activity associated with both IRS-1 and IRS-2 is impaired.

One mechanism for the signaling defects in adipocytes in the obese state may be the increased expression and activity of several protein tyrosine phosphatases (PTPs) that dephosphorylate and thus terminate signaling propagated through tyrosyl phosphorylation events. Some data indicate that the expression and/or activity of at least three PTPs, including PTP1B, leukocyte antigen-related phosphatase (LAR) and Src-homologyphosphatase 2 (SHP2), are increased in muscle and adipose tissue of obese humans, and PTP1B and LAR have been shown to dephosphorylate the insulin receptor and IRS1 in vitro in rodents (135,136). Overexpression of either PTB-1B or LAR in skeletal muscle impairs its insulin-signaling capability and causes systemic insulin resistance (136,137). Mice with a targeted deletion of the PTP1B gene display increased insulin sensitivity and resistance to diet-induced obesity (138) that is due, at least in part, to increased energy expenditure. By contrast, targeted disruption of LAR in mice has been reported to significantly disrupt glucose homeostasis (139). The increased insulin sensitivity in the PTP1B-/- mice is seen in muscle and liver but not in adipocytes. PTP1B also regulates leptic signaling directly at the step of JAK2 phosphorylation (140,141). Thus, PTP1B appears to regulate leptin and insulin signaling independently.

REDUCTION OF GLUCOSE DISPOSAL INTO ADIPOSE TISSUE IN OBESITY

The action of insulin to lower blood glucose levels results from suppression of hepatic production of glucose and an increase in the uptake of glucose into muscle and fat. Muscle has long been considered to be the major site of insulin-stimulated glucose uptake *in vivo*, with adipose tissue contributing relatively little to total body glucose disposal. Support for this conclusion comes from the finding that measurements of 2-deoxyglucose uptake in vivo show at least ten times more glucose per milligram of tissue going into muscle than into WAT (142). Because muscle mass is considerably greater than WAT mass, at least in lean rodents and humans, this observation has been taken to indicate the prominent contribution of muscle to glucose disposal. Glucose transport into BAT is higher than into many muscle groups, but the mass of BAT is small even in rodents, making this an unlikely site to account for large amounts of total body glucose uptake. Thus, it has been viewed as unlikely that diminished glucose uptake into fat could account for diminished whole-body glucose uptake. Transgenic studies, however, indicate a greater role for glucose uptake into fat in systemic glucose homeostasis than was previously believed. For example, genetic overexpression of GLUT4 selectively in fat was shown to enhance whole body insulin sensitivity and glucose tolerance (143) even in overtly diabetic mice (144). Furthermore, targeted gene disruption to "knockout" GLUT4 selectively from fat results in a degree of insulin resistance similar to that seen with muscle-specific knockout of *GLUT4* (145). This insulin resistance is associated with acquired impairments in insulin signaling and metabolic activity in muscle and liver. Whether this insulin resistance results directly from the absence of glucose transport in adipose tissue or indirectly from possible effects of altered glucose uptake on the release of other molecules from adipocytes remains a key question. Likely candidates for indirect effects are FFA, leptin, tumor necrosis factor α (TNF- α), ACRP30 (also called adiponectin), and resistin (discussed below). However, at least in these rodent models with adipose-specific knockout of *GLUT4*, serum FFAs, leptin levels, adiponectin levels, and adipocyte expression of TNF- α are normal. Undoubtedly, there are other, as yet undiscovered, molecules secreted from fat that influence systemic metabolism.

IMPACT OF THE LOCATION OF BODY FAT ON INSULIN RESISTANCE

Large epidemiologic studies reveal that the risk for diabetes, and presumably insulin resistance, rises as body fat content (measured by body mass index [BMI]) increases from the very lean to the very obese, implying that the "dose" of body fat has an effect on insulin sensitivity across a broad range (146,147), with some ethnic differences noted (148). Although this relationship is seen with measures of general adiposity such as BMI, it is interesting that all sites of adiposity do not contribute equally to diabetes risk. Central (i.e., intraabdominal) fat depots are much more strongly linked than peripheral (gluteal/subcutaneous) fat depots to insulin resistance, type 2 diabetes, and cardiovascular disease (149). The reason for this is not known. It is possible that a common, unknown factor, either genetic or environmental, produces both insulin resistance and central adiposity. Alternatively, perhaps some biochemical feature of intraabdominal adipocytes directly influences systemic insulin sensitivity.

A leading hypothesis is that intraabdominal adipocytes are more lipolytically active. This is postulated to be due either to their complement of ARs or to postreceptor signaling that promotes increased basal lipolysis. The increased intraportal FFA levels and flux might inhibit insulin clearance and promote insulin resistance by mechanisms that are still uncertain and have been reviewed elsewhere (150). Hyperinsulinemia per se also can cause insulin resistance by downregulating insulin receptors and desensitizing postreceptor pathways. This concept is supported by experimental overexpression of insulin in the livers of otherwise normal transgenic mice. This insulin transgene resulted in an age-related reduction in the expression of insulin receptor, glucose intolerance, and hyperlipidemia without any primary genetic defect in insulin action or secretion (151). Another hypothesis is that intraabdominal adipocytes secrete a different mixture of factors (qualitatively or quantitatively) compared with adipocytes in other depots and that these factors are more likely to impair insulin action systemically. These issues deserve further investigation.

BOTH LIPOTOXICITY AND LIPOATROPHY AS CAUSES OF INSULIN RESISTANCE

The term *lipotoxicity* has been coined to describe some of the negative consequences of excess adipose stores in obesity. These include insulin resistance, lipid accumulation in nonadipose tissues, and other adverse effects (152). Paradoxically, the *absence* of adipose tissue, or lipoatrophy, may result in similar pathology. The expanded adipose depot in obesity results in elevated plasma FFA levels due to increased release from the expanded adipose mass and probably also to impaired hepatic metabolism. Elevated FFA levels impair the ability of insulin to sup-

press hepatic glucose output and to stimulate glucose uptake into skeletal muscle and inhibit insulin secretion from pancreatic β-cells. The defect in muscle may involve impaired activation of PI 3-kinase, possibly due to elevations in PKCθ (153). An acquired loss of PI 3-kinase activation in muscle also is seen as a result of a high-fat diet (154). In humans, the triglyceride content of muscle correlates directly with insulin resistance and the fatty acid composition of muscle phospholipids influences insulin sensitivity (155). The signaling pathways mediating the lipid accumulation in nonadipose tissues and the mechanisms by which such lipotoxic impairment of function occurs are not known. However, recent studies of β-cells suggest that longchain fatty acids may exert adverse effects via their induction of the overproduction of ceramide (156). It will be important to determine if fatty acids alter gene expression through binding as ligands to transcription factors of the PPAR family.

Severe deficiency or absence of fat, known as lipodystrophy, also is associated with severe insulin resistance in humans and rodents. In mouse models of lipodystrophy, leptin treatment (157) or fat transplantation (158) reverses the insulin resistance and diabetes. Thus, deficiency of leptin, and quite possibly other secreted products from adipocytes, impairs insulin sensitivity in the mouse. This is further supported by the increased insulin sensitivity and the absence of triglyceride deposits in muscle and liver in mice with markedly reduced adipose tissue due to transgenic overexpression of leptin (159). Consistent with these preclinical studies in animal models, studies in patients with lipodystrophy treated with leptin (160-162) support the concept that leptin might serve a therapeutic role in normalizing triglyceride levels and improving glycemic control, perhaps through direct effects on lipid oxidation that have been reported in animal models (163).

Control of Mobilization of Triglyceride Stores in Adipocytes by Sympathetic Nervous System Activity

In times of caloric excess, energy is stored in adipocytes in the form of triglycerides. These can be formed from preexisting fatty acids in the circulation that become esterified to glycerol, or the acyl moieties can be generated de novo from the oxidation of glucose to acetyl-CoAs and their subsequent condensation [Charts 10.1 and 11.1 of reference (164)]. However, in times of net caloric deprivation, whether it occurs in response to extended food scarcity or fasting, sustained intense physical activity, or even during the later hours of sleep (overnight fasting), the drop in blood glucose triggers the sympathetic nervous system (SNS) to release the catecholamines epinephrine and norepinephrine. This occurs either as the release of norepinephrine from nerve terminals innervating adipose tissue or as the secretion of epinephrine into the circulation from the adrenals. Sympathetic innervation is more profuse in BAT than in WAT, indicating that neural-derived norepinephrine plays a greater role in the former, while catecholamines derived from the circulation play a greater role in WAT. Nevertheless, substantial noradrenergic stimulation can exist in the immediate vicinity of the nerve terminals present in WAT.

The ARs are the recipients of these catecholamine signals. They are members of the large family of G protein–coupled receptors that are integral membrane proteins of the plasma membrane. Of the two main families, α -AR and β -AR, the β -ARs mediate catecholamine-driven mobilization of stored triglycerides in adipose tissue. This is achieved by β -AR–initiated triggering of a classic signaling cascade: activation of adenylyl cyclase, synthesis of increased intracellular levels of

218 JOSLIN'S DIABETES MELLITUS

cyclic adenosine monophosphate (cAMP), and activation of the cAMP-dependent PKA, all of which culminate in the phosphorylation of hormone-sensitive lipase (HSL), the rate-limiting enzyme that initiates cleavage of triglycerides into FFAs and glycerol. This activated state of HSL can also be reversibly dephosphorylated by the actions of insulin. Thus, a balance is maintained between the recruitment and storage of metabolic fuel through the catecholamine and insulin hormone systems, respectively. There are three subtypes of β -ARs (β_1 -AR, β_2 -AR, and β_3 -AR), all expressed in adipocytes, and the relative proportions of these subtypes can vary by species and metabolic status [reviewed in reference (40)]. Extensive pharmacologic and physiologic studies have established (165-167), as reviewed in references (40,168), and molecular genetic manipulations confirm (169,170) that all three β -AR subtypes together control the response to the SNS.

The basic biochemical scheme for the stimulation of lipolysis is presented in Figure 13.7. Also included in this figure (see details in legend) is an expanded view of this process that reflects new developments in our understanding of the downstream signaling cascades triggered by β -AR activation in adipocytes [reviewed in reference (40)]. These include the activation of various MAP kinase cascades in addition to the wellestablished cAMP/PKA pathway. These include ERK1/2 MAPK and p38 MAPK. They are independent of each other and activated by different mechanisms in adipocytes in response to catecholamines. Activation of the ERK1/2 MAP kinases by β adrenergic agonists occurs as a result of receptor coupling to G_i (171) and does not involve PKA (172), while p38 MAPK activation is downstream of β -agonist increases in cAMP levels and PKA activity (172,173). The ERK pathway appears to account

for between 15% and 20% of total lipolysis (174,175). Pharmacologic analyses suggest that at low concentrations of catecholamine essentially all lipolysis is activated by PKA, while the ERK1/2 pathway may be most significant at higher concentrations of epinephrine and norepinephrine (175). By contrast, there is no apparent involvement of the p38 MAPK pathway in β -agonist-stimulated lipolysis (175). While we have yet to establish the functional consequences of p38 MAPK activation in white adipocytes, there is a very clear indication that in brown adipocytes the classic cAMP-dependent stimulation of the UCP1 gene requires this pathway (77,174). These new findings require additional studies to establish the metabolic consequences of these simultaneous signaling cascades emanating from β -ARs, and there must be follow-up studies using samples of primary adipose tissue from humans to assess the importance of this ERK pathway in humans.

In addition to the β -adrenergic stimulation of lipolysis, catecholamines can also be antilipolytic themselves through their interaction with the α_2 -ARs resulting in inhibition of cAMP production. The balance between the relative amounts of the β -AR and α_2 -AR can thus also determine the relative efficacy of catecholamines for triglyceride hydrolysis. There is some evidence from experimental studies in animals and humans that a shift to a higher α_2/β ratio can contribute to obesity and a net lipid storage (176).

A variety of other metabolic enzymes and processes are also activated by β -adrenergic–stimulated phosphorylation, including glycogen synthase and phosphorylase kinase. Other evidence indicates that the adipocyte-derived hormone leptin is also regulated by the catecholamines. In animal models, as well as in humans, the secretion of leptin is decreased by β -agonists

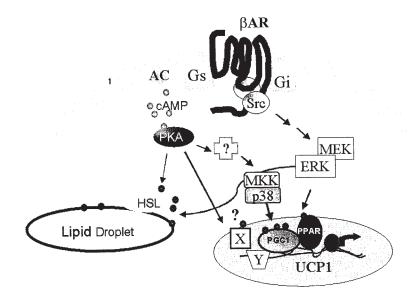

Figure 13.7. The β-adrenergic receptors (β-ARs) mediate the response of the catecholamines norepinephrine and epinephrine to stimulate lipolysis and thermogenesis in white and brown fat. Not shown is the fact that three β-AR subtypes are expressed together in adipocytes. Their signaling mechanism is classically defined as coupling to the stimulatory heterotrimeric G protein G_s , leading to activation of adenylyl cyclase (AC), increased in cyclic adenosine monophosphate (cAMP) production, and activation of the cAMP-dependent protein kinase (PKA). Downstream targets of PKA phosphorylation include hormone-sensitive lipase (HSL), perilipin, and various nuclear transcription factors for the modulation of gene expression. In brown adipocytes, expression of the uncoupling protein 1 (UCP1) is increased by this pathway. As illustrated in the figure, $β_3$ AR couples interchangeably to both G_s and G_i to generate two distinct signaling events: the activation of PKA and ERK1/2. β-ARs also activate p38 MAP kinase (p38) downstream of PKA. The biochemical events linking PKA to MKK3/6 and p38 MAPK is currently unknown (*open cross*), but this pathway is required for transactivation of the *UCP1* gene. Some candidate factors that may be targets of these phosphorylation pathways are indicated, including PPAR- γ and its co-activator, PGC1. Other as-yet-undefined molecules could exist that are targets of these kinases (X and Y).

not yet understood. Curiously, although it has been generally accepted that the increase in lipolysis during fasting is a direct consequence of catecholamine/ β -adrenergic receptor-stimulated events, recent results from studies of mice that lack all three β -adrenergic receptor subtypes reveal that the lipolytic response to fasting is unimpaired (180). Additional work will be needed to establish whether this observation is peculiar to the animal model or also is relevant to humans.

When treated in the laboratory with β_3 -AR-selective agonists, a variety of mammals exhibit a vigorous thermogenic response akin to cold exposure, supporting the notion that the β_3 -AR plays a significant role in this thermogenic response (181–187). However, one of the most puzzling and immensely intriguing features observed is the de novo appearance of brown adipocytes within typical white adipose depots, suggesting a close interplay between these two adipocyte "species." The source of these brown adipocytes is unknown. They may arise from proliferation, but no supporting evidence has been found. There is currently discussion in the field that small pockets of "dedifferentiated" brown adipocytes from the neonatal period may be present in white adipose depots that express very low amounts of β_3 -AR but that might be triggered to redifferentiate (9). However, as discussed below, while this response to catecholamines clearly has a predominant cAMP component, other evidence indicates that MAP kinase pathways may also modulate sympathetically driven brown adipocyte growth/survival.

Further support for a direct role of adipocytes in regulating systemic glucose homeostasis also comes from studies in which rodents or humans were treated with a β_3 -adrenergic agonist (183,188,189). Since β_3 -ARs are expressed almost exclusively in fat, effects of these agents would be expected to be initiated by alterations in fat. Treatment with the β_3 -agonist results in enhanced sensitivity both of whole body glucose uptake and of suppression of hepatic glucose production (188). These effects are accompanied by increased glucose uptake in adipose tissue with no effect on muscle. Thus, increasing glucose uptake selectively in fat with β_3 -AR agonists may improve whole body glucose uptake, with the effects in fat indirectly resulting in increased insulin sensitivity in liver. β_3 -AR agonists may also work by changing the release of some adipocyte product that influences systemic insulin sensitivity. Quite apart from their effects in brown adipocytes, there is also newer evidence for white adipocytes to contribute to UCP1-independent thermogenesis in response to β_3 -adrenergic agonists, and that white adipocyte mitochondria can, under certain conditions, exhibit high oxidative metabolic capacity (190,191).

Other Hormones and Cytokines Secreted by Adipose Tissue: Contribution to Insulin Resistance and Cardiovascular Dysfunction

Adipose tissue produces and secretes factors in addition to leptin that act in an autocrine, paracrine, or endocrine fashion to regulate adipogenesis and various systemic functions. In this section, we will discuss the potential involvement of adiposederived steroids, proinflammatory cytokines, complement factors, and peptide hormones in adipogenesis, glucose homeostasis, and cardiovascular function.

SEX STEROIDS AND GLUCOCORTICOIDS

Adipose tissue does not synthesize steroid hormones de novo. However, adipose stromal cells are involved in steroid interconversion [reviewed in reference (192)]. 17- β -Hydroxysteroid oxidoreductase converts androstenedione to testosterone, and cytochrome P450–dependent aromatase mediates the conversion of estrone to estradiol. The levels of male and female sex steroids in various fat depots are thought to determine fat distribution (193,194). There is a strong association of androgens, central obesity, insulin resistance, and dyslipidemia with increased cardiovascular risk [reviewed in reference (195)]. It is possible that the rise in cardiovascular morbidity at menopause is determined in part by a relative increase in androgens and central adiposity.

The ratio of active to inactive glucocorticoids (cortisol vs. cortisone) in various fat depots is regulated by 11-β-hydroxysteroid dehydrogenase (type 1) (11-βHSD-1) [reviewed in reference (196)]. 11- β -HSD is regulated by insulin and in turn influences the local metabolism of glucocorticoids in adipose tissue. A link between local glucocorticoid metabolism, especially the expression or activity of $11-\beta$ -HSD, fat distribution, and glucose and lipid metabolism has been proposed by some investigators and supported by data from studies in transgenic mice (197, 198). Based on these observations and the well-known association between chronic hypercortisolism in Cushing syndrome and central obesity, insulin resistance, diabetes, hypertension, and cardiovascular morbidity, it has been tempting to speculate that excess local production of cortisol in adipose tissue could be a predisposing factor (199). Cortisol may also alter sexsteroid metabolism in adipose tissue by increasing aromatase activity. However, the pathophysiologic significance of this pathway is less clear.

Recent genetic studies in mice have provided important insights into the role of adipose-derived glucorticoids in metabolism and cardiovascular regulation (200,201). Mice with transgenic overexpression of 11 β HSD-1 in adipocytes have normal circulating levels of corticosterone (the predominant glucocorticoid in rodents; however, local glucocorticoid concentration is increased in adipose tissue (201). As predicted, these mice develop visceral obesity and features of the metabolic syndrome, including insulin resistance, impairment of glucose tolerance, dyslipidemia, hypertension, and hepatic steatosis (200,201). Conversely, deletion of 11 β HSD-1 in mice prevents diet-induced obesity and improves glucose tolerance, insulin sensitivy, and lipid levels (202).

TUMOR NECROSIS FACTOR- α and other proinflammatory cytokines

The role of TNF- α in the pathogenesis of septic shock, autoimmune disease, and cachexia associated with infection and cancer is well known. TNF-α is expressed as a 26-kDa transmembrane cell-surface protein and cleaved into the circulating biologically active 17-kDa form. TNF- α interacts with 55-kDa (p55) and 75-kDa (p75) membrane receptors. In addition to serving as the signal transmission mediator of TNF- α , alternatively processed forms of these receptors exist that are capable of being secreted into the circulation and consequently can alter TNF- α plasma concentrations and bioactivity. TNF- α reduces body weight by decreasing appetite, increasing lipolysis, and promoting adipocyte apoptosis (203). Systemic TNF-α infusion has been reported to blunt insulin-mediated glucose disposal and the ability of insulin to suppress hepatic glucose production (204). However, immunoneutralization of TNF- α improved insulin sensitivity in some rodents and humans, but not in others (205). Since these observations indicated that obesity and insulin resistance in rodents are associated with elevated adipose tissue-derived TNF- α (206), many studies have explored this connection in greater detail in an effort to determine the role of TNF- α in disturbing the process or maintenance of adipogenesis and lipid and glucose metabolism.

220 JOSLIN'S DIABETES MELLITUS

Potential mechanisms mediating TNF- α effects on insulin resistance include increased lipolysis and FFAs; inhibition of GLUT4, insulin receptor, and IRS-1 synthesis; inhibition of PPAR-γ function; and increased IRS-1 Ser/Thr phosphorylation or protein tyrosine phosphatase (PTPase) activity [reviewed in reference (207)]. TNF- α may act in a classical endocrine manner at distant target tissues (e.g., muscle, liver, and brain) to regulate glucose balance. On the other hand, TNF- α may stimulate lipolysis by a paracrine or autocrine mechanism and secondarily alter insulin sensitivity. Other proinflammatory cytokines produced by adipose tissue include interleukin (IL)-1 and IL-6 [see reference (208) and references therein]. The acute-phase C-reactive protein is stimulated by IL-6 and is positively correlated with insulin resistance, obesity, and endothelial dysfunction (209), but further study is required to determine whether IL-6 is a causative link between adipose tissue and the predilection to thromboembolism in obesity.

COAGULATION AND COMPLEMENT FACTORS

Proteins involved in the coagulation and fibrinolytic pathways [e.g., fibrinogen and plasminogen activator inhibitor-1 (PAI-1)] are increased in obesity. PAI-1 is produced mainly by the liver, but significant amounts are synthesized by adipose tissue (210). As with IL-6, there is a significant positive correlation between plasma PAI-1 levels, visceral adiposity, and cardiovascular risk, suggesting that PAI-1 might play a role in thromboembolic complications associated with obesity (211–213).

The link between nutritional deprivation and impaired immunity is well known (214,215). However, there is increasing evidence in support of an independent role of adipose tissue-derived factors in immune regulation. For example, an association between adipose tissue and the complement system was initially suggested by the occurrence of C3 deficiency in a patient with partial lipodystrophy (216). The complement system consists of ~20 proteins that mediate the response to infection and tissue injury. Complement activation via the classical pathway is triggered by antigen-antibody complexes, leading to activation of C1, C4, and C2 to form C4b2b. In the alternate pathway, C3 is hydrolyzed to a C3b-like factor, binds factor B, and is cleaved by factor D to form priming convertase C3bBb. The latter cleaves C3 into C3a and C3b, which interact with factors B and D to form amplification convertase C3bBb. Together the classical and alternate pathways activate the terminal complement factors C5–C9 to produce a membrane attack complex.

Differentiated 3T3-F442A adipocytes synthesize and secrete complement D (adipsin) (217), C3, and B and have been shown to activate the proximal alternate complement pathway in the absence of infection (218). Studies in animal models of obesity demonstrated severe reduction in the expression of adipsin from adipose tissue in genetic obesity (e.g., *ob/ob*, *db/db*), as well as acquired obesity (e.g., monosodium glutamate-treated mice and cafeteria-fed mice) in rodents (219). These findings, and the fact that human adipocytes also express and secrete adipsin (220), led to the notion that adipsin might be involved in obesity and related metabolic abnormalities. However, in humans, unlike rodents, blood concentrations of adipsin are increased in obese individuals and decreased with fasting or in conditions of lipoatrophy (221,222). This difference in the regulation of adipsin may be due in part to hypercortisolism, which is a prominent feature in the leptin-deficient, genetically obese rodents (223). Studies in nonmutant, diet-induced obese animals would be more instructive about whether there is a true species difference in these studies.

A role for the complement system in adipocyte biology was further suggested when a small protein (molecular weight 14,000 kDa) termed acylation-stimulating protein (ASP) was identified in human serum and shown to stimulate triglyceride synthesis in fibroblasts (224). The protein was subsequently found to be identical to C3a-des-Arg and derived from the cleavage of C3a by carboxypeptidase. The synthesis of C3a from C3 requires complement factors B and D (the latter being adipsin). Plasma concentrations of ASP are higher in obese than in lean individuals. Moreover, there is a sexual dimorphism of ASP such that the levels are higher in obese women than obese men, which may be the result of higher ASP production in subcutaneous adipose tissue; a depot that tends to be larger in women than in men. Consistent with a role of ASP as a mediator of lipogenesis, ASP deficiency in mice has been associated with increased postprandial levels of fatty acids and reduced triglyceride synthesis (225). As a result, it has been proposed that dysregulation of the ASP pathway may increase postprandial lipemia and alter lipoprotein profiles, thereby predisposing to the metabolic syndrome X and increased cardiovascular risk. However, since the genetic disruption of ASP expression also results in loss of complement factor C3 itself, additional definitive studies with nonpeptide analogues of ASP would provide important confirmation of the role of ASP.

ADIPONECTIN/ACRP30

Adiponectin, also known by other names, including adipocyte complement-related protein–30 kDa (ACRP30) (226), AdipoQ (227), gelatin-binding-protein-28 (228,229), and adipocyte-most-abundant protein (230), is synthesized and secreted exclusively by differentiated adipocytes. The protein has 247 amino acids and four main domains (231). The globular C-terminal domain shares sequence homology with the family of complement C1q-like proteins, including human type VII and X collagen, hibernation-regulated proteins, and precerebellin. The other domains consist of an NH₂-terminal signal sequence, non-homologous sequence, and a collagenlike region. Although expression and plasma levels of ACRP30/adiponectin/AdipoQ originally were shown to be stimulated by insulin and decreased in obese mice, its functional role was unclear until recently [discussed in reference (232)].

Injection of purified adiponectin was reported to prevent the postprandial elevation of plasma fatty acid levels, in part by stimulating fatty acid oxidation in muscle (233). Moreover, adiponectin reduced body weight without affecting food intake, suggesting an effect on peripheral metabolism. Supporting this idea was the finding that adiponectin inhibited hepatic glucose production in rodents under clamp conditions (234). More recently, studies in rodents show that adiponectin activates AMP kinase in both muscle and liver (235). Furthermore, this report shows that dominant-negative adenovirus-delivered AMP kinase blocks the effects of adiponectin on phospho-enolpyruvate carboxykinase (PEPCK) expression in liver and blunts the glucose-lowering effects of adiponectin in normal mice. Hence, AMP kinase is necessary for at least some of the metabolic effects of adiponectin, at least in the liver. Other work from this group also shows that targeted disruption of the adiponectin gene results in severe insulin resistance on a highfat diet and increased susceptibility to atherosclerosis (236,237). In humans, plasma adiponectin levels are decreased in obesity, type 2 diabetes, and coronary artery disease (229,238-240). The ability of adiponectin to modulate coronary risk may occur by altering the expression of adhesion molecules (241-243). It is interesting that, as the search for the mechanisms underlying the insulin-sensitizing effects of thiazolidinediones continues, several reports have identified adiponectin as a target gene that is upregulated by thiazolidinediones. Insight into the type of receptor for adiponectin to search for has been unclear, since the primary sequence of the molecule did not suggest a structure.

However, an imaginative approach to this problem was the crystallization of adiponectin, wherein it was discovered that the structure of the globular head domain bore striking resemblance to that of another cytokine, TNF- α (Fig. 13.8), thus suggesting that a receptor of similar structural organization and signaling properties might exist for adiponectin (231). However, amidst debate about whether the functionally relevant moiety is the full-length protein or the globular head domain, or whether features of the molecule involved in signaling are distinct from other domains with separate functions, it was reported that adiponectin is modified post-translationally by hydroxylation and glycosylation and exists as low molecular weight (trimers) and higher molecular weight structures (244). These multiple forms are present in plasma in both rodents and humans and, importantly, the ratio of high molecular weight (HMW) to low molecular weight (LMW) adiponectin in circulation is a better predictor of glucose homeostasis than the absolute concentration (244). To understand adiponectin's ability to confer insulin-sensitizing properties requires understanding the receptor(s), their signaling cascade, and their regulation. Two reports of distinct receptor types for adiponectin have been described, the first being a pair of unusual molecules with a predicted architecture like an inverted G protein-coupled receptor (245) and the other as a member of the cadherin family (246). The tissue distributions and activation pathways of these receptors, and perhaps others yet to be described, will likely prove an exciting new direction for understanding how adipose tissue communicates with other metabolic tissues, and might someday yield new therapeutic strategies for metabolic disease.

ANGIOTENSINOGEN

Although angiotensinogen, the precursor of angiotensin II (Ang II), is produced mainly by the liver, adipose tissue also is considered an important source (247). In support of this view, proteins of the renin–angiotensin system (RAS) [e.g., renin, non-

13: BIOLOGY OF ADIPOSE TISSUE 221

renin-angiotensin enzymes (chymase, cathepsins D and G, and tonin), angiotensin-converting enzyme, and Ang II receptors] are expressed by adipose tissue (248,249). The physiologic role of the RAS in adipose tissue is yet to be fully understood. Angiotensinogen mRNA and protein levels are regulated by nutritional status in rats, leading to a rapid decline with fasting and an increase when feeding is resumed (250). Expression of angiotensinogen mRNA is markedly increased during adipocyte differentiation (251,252). Ang II stimulates prostacyclin synthesis, adipocyte differentiation, and lipogenesis (253), suggesting that adipose-derived angiotensin may regulate adipocyte differentiation and growth, as is the case in other tissues. Targeted deletion of angiotensinogen in mice decreased adipose tissue mass and blood pressure, whereas transgenic overexpression of angiotensinogen in adipose tissue increased blood pressure and resulted in obesity (254,255). Furthermore, mice with transgenic overexpression of 11βHSD-1, leading to increased glucocorticoids in adipose tissue, develop hypertension in association with activation of the RAS, confirming a crucial involvement of adipose-derived RAS in the pathogenesis of cardiovascular complications of obesity (256).

RESISTIN

Thiazolidinediones (TZDs) are used as "insulin-sensitizing" agents for the treatment of type 2 diabetes. Although there is a strong correlation between the binding of TZD to the transcription factor PPAR- γ and the antidiabetic action of TZDs, the gene targets of PPAR- γ that mediate insulin sensitivity are not known. A screen for novel TZD-regulated genes resulted in the discovery of a protein that is induced during adipocyte differentiation and suppressed by TZDs (257). The protein, named resistin (257) or FIZZ3 (258), is encoded by a single mRNA transcript (750 residues) and is highly expressed in WAT and to a lesser degree in BAT. A low level of expression, potentially due to WAT, was detected in murine mammary tissue (257,259).

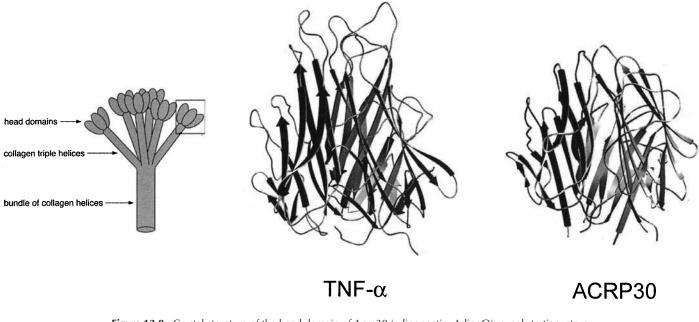

Figure 13.8. Crystal structure of the head domain of Acrp30 (adiponectin, AdipoQ) reveals tertiary structure homology with the cytokine TNF-α. (From Shapiro L, Scherer PE. The crystal structure of a complement-1q family protein suggests an evolutionary link to tumor necrosis factor. *Curr Biol* 1998;8:335–338, with permission. Copyright © 1998 Cell Press.)

Resistin protein was localized by immunostaining in the cytoplasm of white adipocytes. The deduced amino acid sequence includes an NH₂-terminal signal sequence and a unique pattern of cysteine residues. The latter is conserved among a family of resistinlike molecules (RELMs; also named FIZZ1) (258).

Resistin was shown to be secreted into the medium by transfected 293T cells and readily detected in mouse serum (257). More significantly, resistin mRNA and protein were regulated by nutrition and decreased with fasting and increased following refeeding (257). Resistin was found to be markedly elevated in genetically obese mice (ob/ob and db/db) and mice with dietinduced obesity. Neutralization of resistin with IgG-purified antiresistin serum decreased glucose levels in mice with dietinduced obesity. Moreover, antiresistin IgG improved insulin sensitivity. The function of recombinant resistin was analyzed in vivo and in differentiated adipocytes. Intraperitoneal administration of FLAG-tagged resistin improved glucose tolerance in mice and increased insulin-stimulated uptake of glucose in 3T3-L1 adipocytes.

The gene encoding rat resistin has recently been cloned (260). Unlike murine resistin, rat resistin encodes two mRNA transcripts and is highly induced by insulin (261). Human resistin-like molecules have been identified (262,263). As is the case with adiponectin, the crystal structures of resistin (Fig. 13.9) and RELM- β reveal complex trimeric and multimeric forms (264). Infusion of resistin or RELM-β into rodents, or transgenic overexpression of resistin, increases hepatic glucose production (264,265). Conversely, deletion of the resistin gene or attenuation of circulating resistin levels via specific antisense oligodeoxynucleotide to resistin mRNA decreases endogenous hepatic glucose production in mice, the latter effect being associated with suppression of AMP kinase (266,267). Both rat and mouse resistin are decreased by fasting, and stimulated by refeeding and specifically by insulin and glucose (261,268). In contrast to rodents, human resistin is expressed mainly by mononuclear cells in the stromavascular compartments of adipose tissue, instead of adipocytes (269). Moreover, the biology of resistin in humans is uncertain, in regard to its association with body fat, glucose, and insulin (270).

SUMMARY

The biology of adipocytes has advanced from their being considered an inert storage depot for excess caloric energy and body cushioning and relegated to the "connective tissue" section of histology textbooks to having the status of a full-fledged member of the endocrine system that deserves a chapter of its own! The discovery of leptin and a host of other molecules that are secreted from adipose tissue, with important effects on glucose homeostasis and insulin sensitivity, marks a new era in which we are beginning to understand how organ systems communicate their energy demands and reserves. Many questions remain concerning the regulation of adipocyte development, the molecular mechanisms of leptin secretion and action, and the physiology of adiponectin and its target tissues. Similarly, even seemingly well-established mechanisms of biochemical events in adipocytes, such as catecholamine stimulation of lipolysis and thermogenesis, are undergoing revisions as moreelaborate signal transduction pathways are revealed and as new molecules are discovered that are critical to gene regulation and metabolic homeostasis. This inaugural chapter on the biology of adipocytes is an acknowledgment of how far this cell type has come as a player in our understanding of the pathogenesis of type 2 diabetes and the links between obesity, diabetes, and cardiovascular disease.

Figure 13.9. Ribbon diagram of resistin structure. A single resistin protomer, composed of a carboxy-terminal disulfide-rich globular domain and an amino-terminal α -helical region, assemble to form trimer-dimer hexamers. In both resistin and RELMB (not shown) structures, each protomer from one trimer is disulfide linked to a protomer from the associated trimer. SUMMARY 238

ANATOMY

The human body contains more than 600 different skeletal muscles, collectively comprising the largest single organ of the body. The morphology of skeletal muscle at both the microscopic and macroscopic levels is intimately tied to its primary function, which is contractile activity. Each skeletal muscle in the body is covered by a dense connective tissue layer called the epimysium (Fig. 14.1). Extending inward from the epimysium is the perimysium, which surrounds small bundles of individual muscle fibers. Each individual muscle fiber within these bundles is surrounded by the endomysium, a thin layer of connective tissue. Within the endomysium is the cell membrane, which in muscle is called the sarcolemma. A dense capillary network extends throughout skeletal muscle, with several capillaries surrounding each muscle fiber. Individual cylindrical fibers do not always extend from one end of the muscle to the other; therefore, the connective tissue surrounding the muscle fiber bundles may be important for translating the mechanical forces of contraction throughout the length of the entire muscle group (1).

Muscle fibers contain dense networks of contractile proteins that are arranged precisely to achieve muscle contraction and body movement. Each muscle fiber is a single muscle cell. Fibers are roughly cylindrical, with the diameter of the fiber ranging between 10 and 100 μ m (1). The length of fibers is variable, with some fibers extending the entire length of the muscle and to a length of 35 cm. The strength of a muscle fiber is directly proportional to its cross-sectional area, which can change dynamically commensurate with neuromuscular activity and muscle use.

Skeletal Muscle Organelles

Some of the organelles in the muscle fiber are similar to those in other eukaryotic cells but are named differently, such as the sarcolemma, the sarcoplasm, and the sarcoplasmic reticulum, which correspond to the plasma membrane, the cytoplasm, and the endoplasmic reticulum, respectively, of other eukaryotic cells. The sarcoplasm of the muscle fiber differs from the cytoplasm of most eukaryotic cells in that it contains a large quantity of stored glycogen. The sarcoplasmic reticulum is a longitudinal network of tubules within the muscle fiber that runs parallel to and surrounds the myofibrils (Fig. 14.2). The sarcoplasmic reticulum stores calcium, which is released during excitation of the muscle fiber. The transverse tubule system (T tubule) is a tubular network of membranous sacs that intertwines the myofibrils and facilitates the transmission of nerve impulses, as well as the transport of extracellular glucose, oxygen, and other electrolytes, to the individual myofibrils. The T tubules are formed by invaginations of the sarcolemma into and around the muscle fibers (1).

Although many of the organelles inside muscle fibers are common to most eukaryotic cells, muscle fibers are unique in many ways. For example, unlike most eukaryotic cells, which contain single, centrally located nuclei, muscle fibers are multinucleated, and these nuclei are located peripherally along the cell (Fig. 14.2). The nuclei likely act as local governing centers of cellular functions and adaptation to various stimuli and also function as integrated centers that communicate stimuli along the length of the muscle fiber to enable cohesive adaptation (2). The ratio of nuclei to cytoplasmic domain in a muscle fiber seems to be tightly regulated and dependent on the neuromuscular

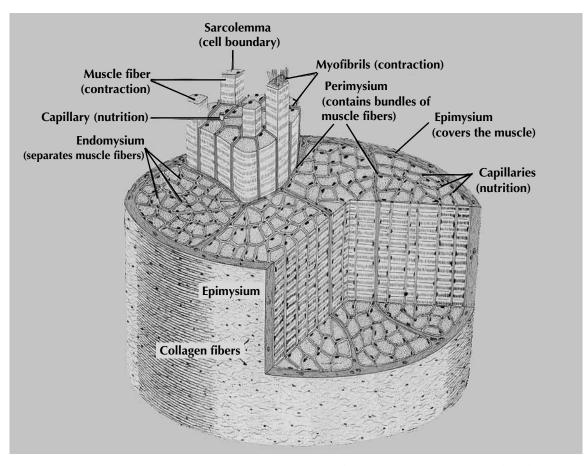

Figure 14.1. Skeletal muscle morphology. Each muscle cell (fiber) is composed of thousands of myofibrils. The membrane surrounding an entire skeletal muscle is called the epimysium. The epimysium invaginates into the muscle and surrounds clusters of individual muscle fibers. The sarcolemma surrounds individual muscle fibers. Each muscle fiber is surrounded by numerous capillaries, which provide oxygen and nutrients. (From Junqueira LC, Carneiro J, Kelley RO. *Basic histology*, 8th ed. Stamford, CT: Appleton & Lange, 1995, with permission.)

activity of the muscle fiber (2). Although mature muscle cells are postmitotic, skeletal muscle tissue has unique regenerative capacity afforded by quiescent myogenic cells called satellite cells that lie between the sarcolemma and the basal lamina of muscle fibers. The precise chemical and physical signals that activate satellite cells from their quiescent state to proliferate and differentiate into mature muscle fibers are still unclear.

Neuromuscular Junction

Muscle contraction occurs following the initiation and propagation of an action potential along a motor nerve to its endings on muscle fibers. The motor nerve enters the muscle and branches out between the muscle fascicles; these branches may then innervate a single muscle fiber or hundreds of muscle fibers. A motor unit is composed of a single nerve fiber and the cluster of muscle fibers that the nerve innervates. The site of neural innervation at the muscle cell surface is called the neuromuscular junction or the motor end plate (Fig. 14.3). The nerve axon terminus contains many mitochondria and synaptic vesicles containing the neurotransmitter acetylcholine. The space between the nerve axon terminus and the muscle fiber is called the synaptic cleft. To increase the surface area for acetylcholine receptors in the synaptic cleft, the sarcolemma is extensively folded in the region of the neuromuscular junction. There is a marked density of nuclei, mitochondria, ribosomes, and glycogen molecules in the sarcoplasm below the synaptic cleft (3).

Sarcomeric Structure

Each muscle fiber is composed of thousands of myofibrils, each of which is a cylindrical filament that runs parallel to the longitudinal axis of the muscle fiber (Fig. 14.4A). The myofibrils consist of a specialized arrangement of myosin and actin filaments, also called thick and thin filaments, respectively. These filaments interact to produce muscle contraction. Each actin filament is connected at one end to a protein structure called the Z line (or Z disc). The area containing actin and myosin filaments between two Z lines is called the sarcomere. Sarcomeres exist as repeating units along the full length of the myofibril and represent the functional (contraction-producing) unit of the muscle (4). The Z line is composed of two major proteins, α -actinin and desmin, which hold adjacent sarcomeres together. Titin is another very important myofibrillar protein that provides a lattice-like support structure that enables the side-by-side arrangement of myosin and actin. The actin filaments extend outward from the Z line into the sarcomere, and myosin filaments surround the actin filaments. The area on either side of the Z line

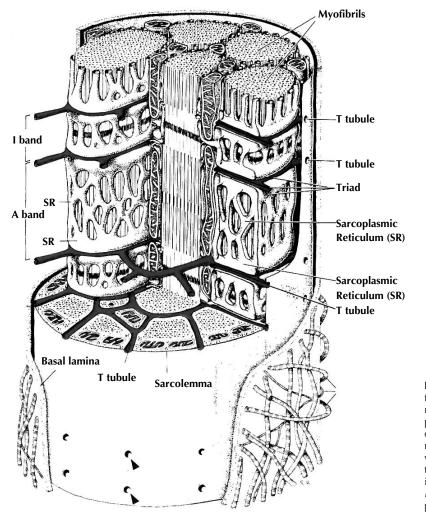

Figure 14.2. Intracellular architecture of the skeletal muscle fiber. The sarcolemma, the sarcoplasm, and the sarcoplasmic reticulum correspond to the plasma membrane, the cytoplasm, and the smooth endoplasmic reticulum, respectively, of other eukaryotic cells. The sarcolemma invaginates into the muscle fibers, creating the transverse tubule (T tubule) system, which facilitates the delivery of glucose, oxygen, and electrolytes to the myofibrils and the transmission of nerve impulses. (From Junqueira LC, Carneiro J, Kelley RO. *Basic histology*, 8th ed. Stamford, CT: Appleton & Lange, 1995, with permission.)

that is occupied only by actin filaments, with no overlap by myosin filaments, is the I band ("I" for isotropic; does not alter polarized light). The A band is the dark area in the middle of a sarcomere where the actin filaments are overlapped by myosin filaments ("A" for anisotropic; birefringent in polarized light) (1). When the muscle is not contracting, there is an area in the middle of the sarcomere occupied only by myosin filaments (H zone). When the muscle sarcomeres shorten, the actin filaments are pulled inward to completely overlap myosin filaments, and the H band disappears (4). The spatial arrangement of the thick myosin and thin actin filaments relative to one another, along with the other myofibrillar proteins that facilitate their interaction, yields a striated pattern observable under the light microscope (Fig. 14.4B).

A myosin filament consists of approximately 200 myosin molecules lined up end to end and side by side. Myosin has been studied extensively, and it is the diverse features of this protein that lead to the tremendous variation in contractile velocity and force production with different fiber types. Each myosin molecule is composed of two identical heavy chains and four light chains (Fig. 14.5A). The heavy chains are cylindrical proteins twisted around each other in a double-helical formation, each with a globular head at one end. The globular head portion of the myosin protein is able to bind both actin and adenosine triphosphate (ATP), as well as to hydrolyze ATP via intrinsic adenosine triphosphatase (ATPase) activity (5). Two myosin light chains are associated with each globular head region of the heavy chains and are thought to regulate the ATPase activity of the myosin head, thereby influencing the speed of muscle contractions. The three-dimensional structure of the myosin molecule is such that a portion of the cylindrical chain and the globular polypeptide head of the myosin molecule extend sideways from the helical body of the filament and form a cross-bridge to the actin filaments. Each cross-bridge is flexible at the place where the cylindrical arm begins to extend outward from the straight chain, as well as where the globular head meets this arm. These hinged regions enable both the extension of the globular myosin head away from the helical portion and movement of the myosin head when it is associated with the actin molecule, as is the case during contraction. The bundles of myosin filaments are twisted around each other so that each pair of myosin heads are separated by precisely 120 degrees, thereby ensuring that cross-bridges extend in all directions from the myosin filaments to interact with actin molecules (5).

The actin filament is composed of a double-helical arrangement of spherical actin monomers, each approximately 40 kilodaltons (kDa) (Fig. 14.5B). The actin monomers are called Gactin, and polymerized G-actin forms filamentous F-actin. Each G-actin monomer has one adenosine diphosphate (ADP) molecule bound to it; it is thought that this ADP molecule provides the binding site for the myosin cross-bridge. These active sites

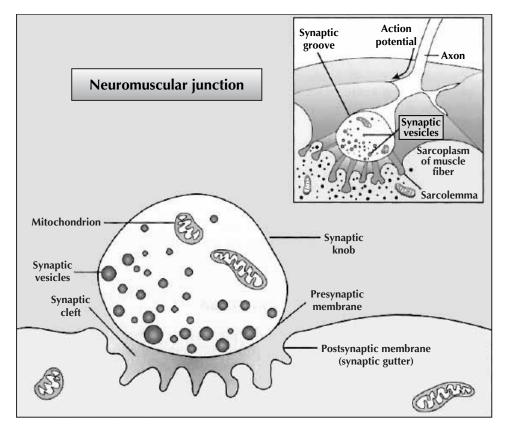

Figure 14.3. The motor end plate or neuromuscular junction. The inset shows the axon of a single motor neuron invaginating into the sarcolemma of a single muscle fiber. In the enlarged view, note that the nerve axon terminus contains many mitochondria and synaptic vesicles with the neurotransmitter acetylcholine. The space between the nerve axon terminus and the muscle fiber is called the synaptic cleft. Upon transmission of the nerve impulse to the axon terminus, acetylcholine is released from synaptic vessels into the cleft, thereby increasing the permeability of sarcolemmal and, subsequently, T tubule and sarcoplasmic reticulum (SR) membranes, resulting in calcium efflux from the SR for interaction with myofilaments and muscle contraction. (From Akert K. Structures and functions of synapses. New York: Raven Press, 1972, with permission.)

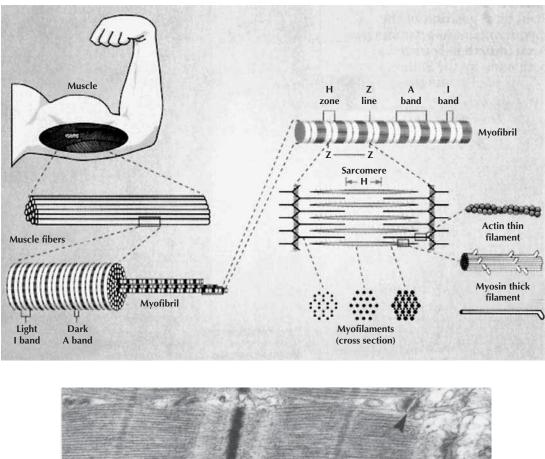

are also staggered for optimal interaction with the axially separated myosin cross-bridges. Two other proteins, tropomyosin and troponin, are associated with the actin filament. Troponin molecules bind approximately every seventh actin monomer along the filament. Troponin is composed of three subunits, Tn-I, Tn-C, and Tn-T (1). The Tn-T subunit binds troponin to tropomyosin and thereby attaches tropomyosin to the actin polymer. The troponin-tropomyosin complex blocks the active sites on actin for myosin cross-bridge formation when calcium is not present. The Tn-C subunit of troponin binds calcium during excitation of the muscle, which results in a conformational change that frees the active site and allows contraction to occur. The Tn-I subunit can inhibit tropomyosin when calcium is not present.

CONTRACTION OF SKELETAL MUSCLE

Skeletal muscle fibers shorten or contract when calcium is released into the sarcoplasm. Calcium release is coupled to depolarization of sarcolemmal and transverse tubule membranes. Taken together, this series of events has been defined as "excitation-contraction coupling." Membrane excitation occurs when the action potential reaches the nerve terminus, causing the synaptic vesicles in the nerve terminus to release acetylcholine into the synaptic cleft. The acetylcholine binds to acetylcholine-gated channels on the sarcolemma and increases the sarcolemmal permeability to sodium, resulting in membrane depolarization and the development of another action potential. The action potential and membrane depolarization is propagated across the entire sarcolemma and into the muscle fiber via the transverse tubule system and the sarcoplasmic reticulum (3). Translation of the action potential and subsequent depolarization of the sarcoplasmic reticulum culminates in the release of calcium into the sarcoplasm and the initiation of contraction.

Following release from the sarcoplasmic reticulum, the calcium ions bind the actin regulatory troponin-tropomyosin complex, thereby releasing the actin active sites so that actinmyosin cross-bridges may form. A basic description of muscle shortening or contraction can be provided by breaking the process into several steps (Fig. 14.6). The myosin ATPase enzyme in the globular myosin head cleaves a molecule of ATP to ADP + Pi (inorganic phosphate), the latter of which remains bound to the myosin head. The energy yielded from ATP hydrolysis causes a conformational change in the myosin head, during which the head extends perpendicular toward and attaches to the actin filament. When the myosin head attaches to the actin filament, the head moves inward toward the cylindrical arm of the myosin filament and pulls the actin filament in the same direction. The inward motion of the myosin head causes a conformational change that releases the bound ADP molecule, and a new ATP molecule binds. The binding of the new ATP molecule causes another structural change in the globular myosin head that releases the head from the actin active site. This cycle of ATP cleavage, myosin-actin attachment, and pulling actin forward repeats until the Z lines (to which the end of the actin filaments are attached) within each sarcomere have been pulled all the way in to the ends of the myosin filaments. This repeating process results in muscle contraction (5). With the cessation of the action potential, calcium is actively transported back into the sarcoplasmic reticulum, troponin can once again inhibit the actin-myosin binding site, and muscle relaxation begins.

Figure 14.4. A: Diagram of the components of the skeletal muscle sarcomere. Each skeletal muscle is composed of numerous skeletal muscle fibers (*left*), which themselves are composed of thousands of myofilaments, consisting of two major proteins, actin and myosin. Actin filaments extend outward from a structure called the Z line (composed of two major proteins, α -actinin and desmin), and myosin filaments surround the actin filaments. This myofilament arrangement is repeated along the length of the fiber and produces a striated pattern, called the sarcomere, that is visible by light microscopy. The area on either side of the Z line that is occupied only by actin filaments, with no overlap by myosin filaments, is called the I band ("I" for isotropic; does not alter polarized light). The A band is the dark area in the middle of a sarcomere where the actin filaments are overlapped by myosin filaments ("A" for anisotropic; birefringent in polarized light). **B:** An electron micrograph of a longitudinal section of skeletal muscle. The Z lines (*Z*), I bands (*I*), and A band (*A*) of one sarcomere are clearly marked, and *M* indicates the presence of mitochondria between adjacent myofibrils. Arrows indicate triads. (**A** from Vander A. *Human physiology*, New York: McGraw-Hill, 1985, with permission; **B** from Junqueira LC, Carneiro J, Kelley RO. *Basic histology*, 8th ed. Stamford, CT: Appleton & Lange, 1995, with permission.)

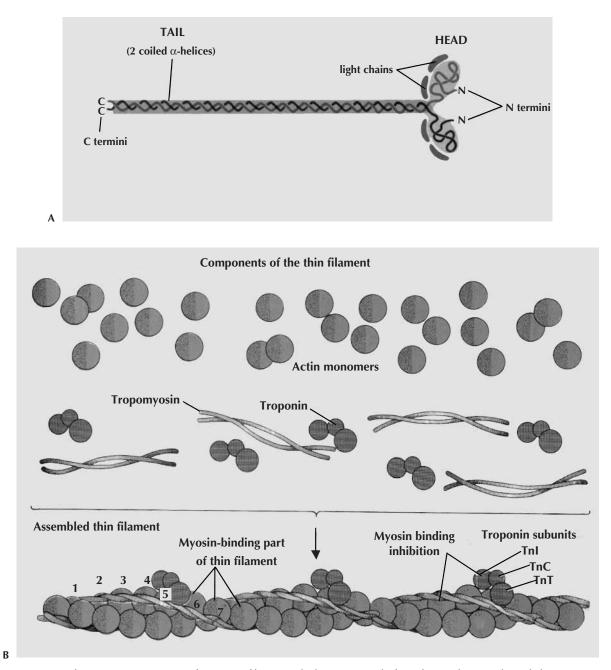

Figure 14.5. A: Diagram of a myosin filament, which is composed of two heavy chains and two light chains. On the C-termini, the heavy chains form a tail of two coiled α -helices, and at the N-termini, two opposing globular heads. The N-terminus or globular head region of the myosin molecule binds actin and has adenosine triphosphatase (ATPase) activity. Four light chains are associated with the globular head portion of the heavy chains, and these are thought to regulate the ATPase activity of the myosin head. **B:** Diagram of the actin filament, which is composed of three proteins: G-actin monomers polymerized to form the F-actin filament and two regulatory proteins, tropomyosin and troponin. Troponin is composed of three subunits, troponin-T, -I, and -C, which bind tropomyosin, inhibit tropomyosin, and bind calcium, respectively, during the cycle of muscle contraction and relaxation. (A from Alberts B, Bray D, Lewis J, et al. *Molecular biology of the cell.* New York: Garland Publishing, 1983, with permission; **B** from Junqueira LC, Carneiro J, Kelley RO. *Basic histology*, 8th ed. Stamford, CT: Appleton & Lange, 1995, with permission.)

When an action potential is propagated to all the nerve endings in a motor unit, all of the muscle fibers in the motor unit contract together. Therefore, motor units are modeled according to the intensity of the contraction required and the degree of motor control needed for various movements. In regions of the body where fine motor control is necessary, each nerve axon may innervate only one muscle fiber. Where coarser control is satisfactory but the development of great tension is desirable, as in moving a limb, larger motor units predominate, in which one motor nerve innervates clusters of muscle fibers (3).

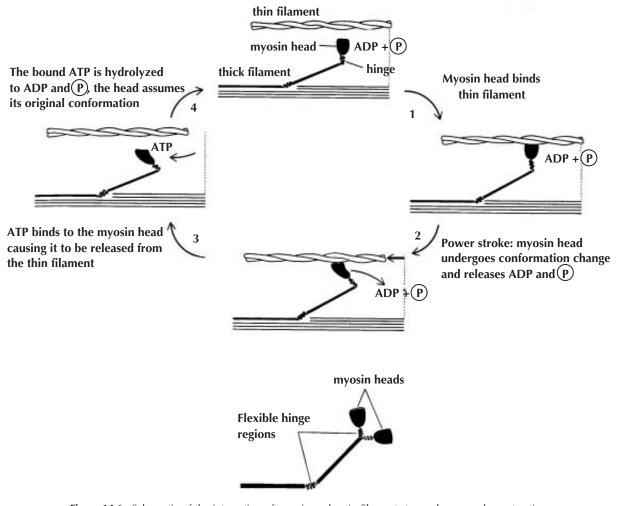

Figure 14.6. Schematic of the interaction of myosin and actin filaments to produce muscle contraction. After cleaving a bound adenosine triphosphate (ATP) molecule, the myosin head undergoes a conformation change and extends upward toward and attaches to the actin filament. The head then moves inward toward the arm of the myosin filament and pulls the actin filament in the same direction. The inward motion of the myosin head releases the bound ADP molecule, and a new ATP molecule binds. The binding of the new ATP molecule causes another structural change in the globular myosin head that releases the head from the actin active site. This cycle results in muscle contraction. (From Alberts B, Bray D, Lewis J, et al. *Molecular biology of the cell*. New York: Garland Publishing, 1983, with permission.)

TYPES OF SKELETAL MUSCLE FIBERS

The muscle fibers differ tremendously morphologically, biochemically, and physiologically. Different muscle fiber types can be characterized by histologic methods according to myofibrillar ATPase activity or aerobic or anaerobic enzyme activity. For example, a reciprocal staining pattern occurs with acid or alkaline preincubation of muscle cross-sections, followed by myosin ATPase staining that reflects the spectrum of fiber types in the muscle. By this method, skeletal muscle was first divided into two major fiber types, type I and type II. Type I fibers are usually red, and type II fibers are white, proportional to the myoglobin content in the muscle. These fiber types are, as stated above, reciprocal in their metabolic enzymatic activities; slow-twitch type I fibers have low myosin ATPase activity and high aerobic oxidative enzyme activity, whereas fast-twitch type II fibers have high ATPase activity, low oxidative enzyme activity, and high anaerobic glycolytic enzyme activity. Investigations over the past 40 years have demonstrated that classifying fiber types by myosin ATPase is an oversimplification, and, in fact, muscle fibers commonly express several myosin isoforms at one time. Muscle fibers display a continuum of myosin isoforms, and a given fiber can alter its myosin ATPase, metabolic, and physiologic characteristics along either direction of this continuum, related to the stimuli received. For example, the human soleus muscle is a postural muscle and as such, contains primarily slow-twitch, oxidative type I fibers. However, under non–weight-bearing conditions, the soleus begins to express type IIa fibers, an intermediate fiber type that tends to be high in oxidative and glycolytic enzymes and in ATPase activity. With time, the soleus will progress further to a type IIb fiber phenotype, acquiring even more glycolytic and fast-contractile characteristics.

Skeletal muscle fibers display tremendous morphologic and biochemical plasticity in response to different stimuli, including altered energy status, gravity/mechanical load, neural stimulation, and intracellular calcium. It is clear that motor nerve activity influences muscle growth and fiber type by regulating

234 JOSLIN'S DIABETES MELLITUS

muscle gene expression (6). The regulation of fiber type-specific gene expression likely occurs through both the pattern of electrical activity (and the resultant calcium release) and the trophic factors released at nerve termini. For example, it has been shown that reinnervation of muscles by motor neurons with a different firing pattern results in muscle fiber transformation. Similarly, remodeling of muscle fiber type distribution, myofibrillar proteins, mitochondria number, and metabolic enzymes has been observed following long-term electrical stimulation; a slow-to-fast fiber transformation is achieved with phasic high-frequency stimulation, and a fast-to-slow transition is achieved through chronic low-frequency stimulation. Chronic low-frequency stimulation decreases the surface area of the neuromuscular junctions and the postsynaptic folds. Many studies have documented an increase in type I slow-twitch fibers with endurance training, and the opposite fiber type transformation (an increase in type IIa fibers) has been shown following high-intensity, short-duration sprint training.

Calcineurin is a calcium/calmodulin-dependent phosphatase and is activated by sustained calcium elevation. Calcineurin is known to dephosphorylate the transcription factor nuclear activated T cells (NFAT), which enables NFAT to translocate into the nucleus and activate gene transcription in T cells. It has been proposed that calcineurin could regulate muscle-specific gene expression by transducing the different calcium signals transmitted through either tonic neural activity or intermittent bursts of neural activity. Calcium concentrations are relatively high in slow muscles and low in fast muscles. Activated calcineurin can upregulate slow fiber–specific gene promoters, and inhibiting calcineurin results in slow-to-fast fiber transformation (7). Further, the transcriptional activation of slowfiber genes is mediated by the NFAT and MEF2 transcription factors.

CHANGES IN MUSCLE MORPHOLOGY AND FUNCTION IN DIABETES

In addition to the well-established metabolic changes in skeletal muscle associated with the progression of diabetes (see below and other chapters), there can be deleterious changes in muscle morphology associated with the advancement of this disease. It is often difficult to determine the evolution of such morphologic change because these types of alterations may precipitate from other end-organ complications, decreased activity, and/or increasing age. Some changes are observed only with long-term, uncontrolled type 1 diabetes.

A rare but severe complication of poorly controlled, longduration type 1 diabetes is acute-onset diabetic muscle infarction (DMI). DMI is characterized by edema, tenderness, and muscle weakness and commonly presents in the vastus lateralis, thigh adductors, biceps femoris, and infrequently the triceps surae. Histologic assessments demonstrate edema; large areas of necrosis, fibrosis, regenerating fibers, and lymphocyte infiltration; and vascular thickening and thrombosis (8,9).

Characterizing the etiology and pathophysiology of type 1 diabetes through patient examination is limiting, as the physiology, genetics, and environment cannot be controlled. Several animal models of type 1 diabetes have been used to enable more comprehensive characterization and therapeutic and preventive strategies. One of the most commonly utilized models is administration of low-dose streptozotocin, which is toxic to β -cells, with diabetes ensuing after a few days (10). Animal models of diabetes have been used to study the time course of

morphologic, neurologic, and vascular changes in skeletal muscle with diabetes. Diabetes progression can be associated with atrophy of skeletal muscle fibers, muscle weakness, diminished nerve activity, and decreased skeletal muscle blood flow (11-13). Diabetic neuropathies affect both sensory and motor nerves, as well as the autonomic nervous system. The physiologic derangements leading to neuropathies are not well defined, but it is hypothesized that hypoxia (precipitating from diabetic vasculitis) and hyperglycemia are primarily involved, as normalizing blood glucose is the most effective therapy (10). Hypoxia results in part from decreased capillary bed density and luminal diameter, resulting in diminished blood flow and oxygen delivery to the skeletal muscle (11). Alterations in the neuromuscular junction, muscle architecture, excitationcontraction coupling, and contractile properties have also been observed in streptozotocin-induced models of diabetes (12,14,15). A decrease in the number of synaptic vesicles and lower resting and end-plate potentials have been observed following induction of diabetes in mice. Further, streptozotocininduced diabetes causes ultrastructural changes in the nerves and muscle fibers, including disrupted neurofilament and microfilament architecture and swollen and disrupted organelles (15). Similarly, a decrease in twitch tension and calcium mobilization in the sarcoplasmic reticulum has been observed in streptozotocin-treated mice (12,14). Together, these alterations may significantly decrease skeletal muscle contractile function.

SKELETAL MUSCLE METABOLISM

The metabolic rate in skeletal muscle is finely regulated by the acute energy requirements of the tissue and by hormonal mechanisms. In the resting condition, the major source of fuel for skeletal muscle is circulating nonesterified free fatty acids, providing approximately 85% to 90% of the required fuel (16). In the postprandial condition, when insulin is released from the pancreas, glucose uptake into muscle increases and the free glucose is rapidly phosphorylated by hexokinase to glucose-6phosphate. If the muscle is not actively contracting, the majority of glucose-6-phosphate is shunted toward nonoxidative glucose disposal, resulting in increased muscle glycogen. The presence of high levels of glycogen in skeletal muscle is a unique feature of the sarcoplasm compared with the cytosol of other cell types.

Skeletal muscle is also unique among tissues because of its need to respond rapidly to large changes in cellular metabolism. There is only enough ATP stored within muscle fibers to sustain contractile activity for less than 1 or 2 seconds. The first source of energy used to restore ATP is phosphocreatine, which is stored within the muscle at levels that are approximately five times higher than those of ATP. When the chemical bond between creatine and phosphate is broken, the phosphate ion is transferred to ADP to form ATP by a reversible reaction catalyzed by creatine kinase. However, phosphocreatine as an energy source for ATP regeneration is also limited, capable of supporting only a few seconds of maximal muscle contractions. Energy is then provided for the resynthesis of ATP both by the anaerobic breakdown of glucose and glycogen to pyruvate and lactate and by the aerobic oxidation of carbohydrates, lipids, and proteins. The details of these metabolic pathways, along with a thorough discussion of their interactions, are described in other chapters in this text (Chapters 8, 16, 17, and 24).

Fatty Acid Metabolism

Of the various lipids in the body, fatty acids are the most important metabolic fuel for skeletal muscle. Sources of fatty acids can include triglycerides stored in the muscle or triglycerides stored in adipose cells within the muscle tissue (17). However, the majority of fatty acids are derived from the uptake of circulating fatty acids bound to albumin and circulating triglycerides present in the lipid core of very-low-density lipoproteins and chylomicrons. The enzyme lipoprotein lipase (LPL) is required to hydrolyze the fatty acids from circulating lipoprotein triglyceride before fatty acid transport across the vascular endothelium can occur (17). LPL activity is much higher in slow-twitch type I fibers than in more glycolytic type II fibers. Insulin downregulates LPL activity by decreasing LPL transcription and, therefore, its abundance.

The circulating fatty acids have to be transported into the mitochondria for oxidation, passing through the vascular endothelium, the interstitial space, the sarcolemma, and finally the outer and inner mitochondrial membranes. The transport of fatty acids across the vascular endothelium has not been clearly elucidated, but it is accepted that the fatty acids diffuse through the endothelium following release from albumin and are likely to rebind to interstitial albumin and to be brought to the sarcolemmal membrane. Transport across the sarcolemmal membrane is mediated by a transmembrane fatty acid transporter (FAT) found in a variety of tissues, including fat and muscle (17), although the mechanism and kinetics of this transporter are not fully understood. Once inside the sarcoplasm, fatty acids bind to fatty acid binding protein (FABP) and diffuse across the sarcoplasmic space to the mitochondrial membrane. The fate of fatty acids within skeletal muscle is either storage, in the form of triglyceride, or oxidation. After esterification to coenzyme A (CoA) by fatty acyl CoA synthetase, activated fatty acids can be transported into the mitochondria by carnitine to be oxidized (17). Carnitine acyl transferase I in the outer mitochondrial membrane converts fatty acyl CoA to acyl carnitine, which crosses the inner membrane via the carnitine-acyl carnitine translocase, in exchange for free carnitine. In the inner mitochondrial membrane, carnitine acyl transferase II catalyzes the exchange of the carnitine in the acyl carnitine for CoA, yielding intramitochondrial fatty acyl CoA, to be oxidized through the Krebs cycle.

Obesity and type 2 diabetes are associated with increased circulating levels of fatty acids and triglycerides and decreased muscle oxidation of fatty acids, leading to the accumulation of triglycerides in muscle (18). Lipid accumulation in muscle and liver is known to impair insulin signaling and metabolic enzyme activity and is strongly linked to the development of skeletal muscle insulin resistance and the multitude of diabetic metabolic complications (19). Indeed, it has been shown that interventions such as weight loss induced by dietary restriction and physical activity or treatment with peroxisome proliferatoractivator receptor-y agonists, the thiazolidinediones, can decrease muscle triglyceride content and improve insulin sensitivity (18,19). The precise mechanisms for the decrease in oxidation of fatty acids in skeletal muscle and the increase in lipid esterification in diabetes and obese states are unclear. However, proportional decreases in carnitine palmityl transferase 1 activity, the long-chain fatty acyl CoA mitochondrial translocase, and oxidative enzymes are consistent with a reduction in mitochondrial content or function or both (20).

Another mechanism by which altered intramuscular fatty acids have been proposed to induce insulin resistance in muscle is through the Randle glucose–fatty acid cycle. The Randle cycle

suggests that glucose and fatty acids are oxidized reciprocally by skeletal muscle on the basis of their availability. An increase in fatty acid oxidation would lead to an increase in mitochondrial acetyl CoA, an inhibition of pyruvate dehydrogenase, and an increase in cellular citrate. The increase in citrate would lead to a downregulation of phosphofructokinase and, therefore, a decreased glycolytic rate. Decreased glycolytic flux would lead to an accumulation of glucose-6-phosphate and inhibition of hexokinase II, resulting in an increase in intracellular glucose and a decrease in glucose uptake (20). However, a series of investigations in which nuclear magnetic resonance (NMR) spectroscopy was employed to assess muscle glycogen and glucose-6-phosphate concentrations clearly demonstrated that fat-induced insulin resistance decreased glucose-6-phosphate concentrations and glycogen synthesis in muscle, likely due to a decrease in insulin-receptor signaling and glucose transport. As an alternative mechanism, it was proposed that the increase in by-products of fatty acid metabolism (fatty acyl CoA, diacylglycerol, and ceramides) activates serine/threonine kinases that phosphorylate insulin receptor substrate (IRS) proteins 1 and 2, thereby decreasing insulin signaling to phosphatidyl inositol 3-kinase (PI 3-kinase) and glucose transport (21).

Carbohydrate Metabolism

The maintenance of levels of skeletal muscle ATP through the oxidation of carbohydrate involves multiple steps. Of the three principal monosaccharides digested in the body, glucose is the major fuel source for oxidation, and under normal conditions, fructose and galactose are of minor importance. Once glucose is transported into skeletal muscle fibers, it is committed to cellular metabolism via phosphorylation by hexokinase to form glucose-6-phosphate. Glucose-6-phosphate then has one of three fates: (a) oxidation to pyruvate in the glycolytic pathway; (b) oxidation in the pentose phosphate pathway; or (c) synthesis to glycogen by glycogenolysis. The transport and metabolism of glucose are critical for cellular homeostasis in skeletal muscle, and under normal physiologic conditions, it is the transport process that is rate limiting for glucose utilization (22).

GLUCOSE TRANSPORT

The ability of skeletal muscle to remove glucose from the circulation in response both to food consumption and to physical exercise is a critical factor for the maintenance of euglycemia in humans. Glucose is transported into the muscle by a process of facilitated diffusion, utilizing glucose-transporter carrier proteins. Transport in muscle occurs through an increase in the maximal velocity of transport, without an appreciable change in the substrate concentration at which glucose transport is half maximal (23). Glucose transporters are a family of structurally related proteins that are expressed in a tissue-specific manner (24). In mouse, rat, and human skeletal muscle, GLUT4 is the major isoform present, whereas expression of the GLUT1 and GLUT5 isoforms is much lower (25,26). Studies of GLUT4 knockout mice reveal that this transporter is necessary for normal rates of basal, insulin-stimulated, and exercise-stimulated glucose transport (27,28).

Insulin and exercise increase glucose transport in skeletal muscle through the translocation of GLUT4 from an intracellular compartment to the sarcolemma and transverse tubules (29,30). The combination of exercise and insulin can have additive or partially additive effects on glucose transport, as well as an additive effect on GLUT4 recruitment to the cell surface, suggesting that there are different mechanisms leading to the

stimulation of muscle glucose transport by exercise and insulin (29). GLUT4 translocation in skeletal muscle occurs by the exocytosis, trafficking, docking, and fusion of GLUT4-containing storage compartment or "vesicles" into the cell-surface membranes. Understanding of the composition, specificity, and trafficking of GLUT4 vesicles is still limited. Several of the so-called SNARE (soluble N-ethylmaleimide attachment protein receptor) proteins have been proposed to be involved in the regulation of the docking and fusion of GLUT4-containing vesicles. Following stimulation, the vesicle-associated SNARE proteins (v-SNARE), including vesicle-associated membrane protein-2 (VAMP-2), bind to the target-membrane SNARE proteins (t-SNARE), which include syntaxin 4 and SNAP23. This complex is thought to facilitate the fusion of GLUT4-containing vesicles into the cell-surface membrane. In studies with syntaxin 4 heterozygous knockout mice, syntaxin 4 has been shown to be a major molecule responsible for the regulation of insulinstimulated GLUT4 redistribution and glucose transport in skeletal muscle (31). The roles of the SNARE proteins in exercisestimulated GLUT4 translocation are less well understood, although VAMP2 has been shown to translocate to the cell surface in response to exercise (32).

There can be profound decreases in insulin action in people with type 2 diabetes, and impaired insulin-stimulated glucose transport at the level of skeletal muscle is a critical factor in the pathogenesis of this disease. The mechanism of the decreased insulin-stimulated glucose transport has not been fully elucidated, although, somewhat surprisingly, it is now well established that people with type 2 diabetes have normal levels of GLUT4 protein in their skeletal muscles (30). However, individuals with type 2 diabetes do have defective insulin-stimulated glucose uptake and GLUT4 translocation (33,34). Defects could include impaired ability of the GLUT4-containing vesicles to dock and fuse to the plasma membrane and/or T tubules or changes in specific activity of the glucose transporters on the membrane. Similar to the findings in humans, defects in GLUT4 translocation have been observed in animal models of type 2 diabetes and obesity (35,36). In contrast, exercise-stimulated glucose uptake and GLUT4 translocation in the Zucker rat (36-38) and in diabetic subjects (39) are normal. These studies reveal that the translocation machinery is intact in patients with type 2 diabetes but that there are likely to be defects in the insulin signal transduction system leading to GLUT4 translocation. The fact that the exercise stimulus functions via an independent mechanism that is able to bypass defects in insulin action, leading to normal glucose uptake into skeletal muscle, makes this mechanism a potential target for drug development.

GLYCOGEN METABOLISM

Glycogen is synthesized and stored within muscle fibers in response to feeding and in the period following exercise. The first step in glycogen synthesis is isomerization of glucose-6phosphate to glucose-1-phosphate, which then is followed by conversion to uridine diphosphate (UDP)-glucose. UDP-glucose donates glucosyl residues to the priming protein glycogenin, which then passes linked glucosyl units to glycogen synthase and branching enzyme to assemble glycogen. The formation of $\alpha(1\rightarrow 4)$ oligosaccharides by glycogen synthase is considered to be the rate-limiting step in glycogen biosynthesis in skeletal muscle (40,41). Glycogen synthase is a multimeric protein consisting of four 85- to 90-kDa polypeptides. Catalytic activity of the enzyme is regulated by phosphorylation and dephosphorylation of up to nine serine residues. Net phosphorylation of glycogen synthase by various kinases leads to a reduction in catalytic activity, whereas dephosphorylation by phosphatases increases activity. Even when glycogen synthase is in the most

highly phosphorylated form, maximal activity can be achieved by the allosteric effector glucose-6-phosphate. Therefore, net activity of glycogen synthase *in vivo* is controlled by a combination of allosteric regulation by glucose-6-phosphate and hierarchical phosphorylation and dephosphorylation of specific serine residues.

Glycogenolysis, the breakdown of glycogen, occurs in skeletal muscle in response to exercise and starvation. Muscle does not express glucose-6-phosphatase; therefore, glycogen breakdown in this tissue does not result in the release of glucose into the circulation. The rate-limiting enzyme for glycogenolysis is glycogen phosphorylase. Insulin inhibits the phosphorylation of the inactive form phosphorylase (b) to the active form (a). In contrast, the release of epinephrine results in glycogenolysis by a phosphorylation cascade that includes increasing levels of cytic adenosine monophosphate (cAMP) levels and cAMPdependent protein kinase, leading to the phosphorylation and activation of phosphorylase b kinase.

Skeletal muscle of patients with type 2 diabetes is characterized by deficiencies in glycogen storage. NMR studies have indicated that persons with type 2 diabetes have a 60% reduction in muscle glycogen synthetic rate and that this reduction is not related to alterations in the glycogen synthase enzyme. Instead, this decrement in glycogen storage is due to alterations in glucose transport and hexokinase II activity that reduce the availability of glucose-6-phosphate (21,42). Patients with poorly controlled type 1 diabetes also have muscle insulin resistance, as evidenced by a decrease in the rate of glycogen synthesis (43). In this condition there is decreased glycogen turnover and glycogen phosphorylase (44), but these alterations are not due to primary defects in glycogen synthase activity (43).

Amino Acid Metabolism

There is a common misconception that the contribution of protein and amino acid metabolism to overall skeletal muscle metabolism is insignificant. However, as evidenced by dramatic changes in muscle size when the muscle is subjected to an increase (e.g., resistance exercise) or decrease (e.g., bed rest) in load, it is clear that the skeletal muscle has a tremendous capacity to alter rates of protein synthesis and degradation to adjust to changes in its fuel requirements. Understanding the regulation of protein synthesis and degradation in skeletal muscle has become an important research focus for the development of therapeutics to offset muscle wasting that occurs with trauma or in disease states such as diabetes, AIDS, cancer, or sepsis.

Because muscle is the largest source of protein in the body, the breakdown and synthesis of muscle proteins play a significant role in the maintenance of circulating levels of amino acids, acid-base balance, and, importantly, the generation of threecarbon intermediates for the Krebs cycle and gluconeogenesis. The interplay of muscle, hepatic, and renal protein turnover largely influences the pool of free amino acids, in addition to the rate of transport between the blood and tissues through transmembrane amino acid transporters. There is a dearth of knowledge about the specificity and kinetics of amino acid transporters, as compared with that about the glucose transporter. The transporters have generally been classified as system-A, for short-chain neutral amino acids, or system-L, for large neutral amino acids, for example (45). The translocation of amino acid transporters from endosomal sites, like glucose transporters, was not demonstrated until recently, when it was shown that insulin stimulates the exocytosis (although not the translocation or activity) of system-A transporters (SAT2) from a chloroquine-sensitive endosomal compartment in skeletal muscle (46). In general, alanine is a major muscle metabolite

transported by system-A transporters, which are sodium dependent and insulin sensitive. System-L (insulin insensitive) transports branched chain amino acids (BCAA) and aromatic amino acids and is sodium independent and insulin insensitive. System-N (sodium dependent) transports glutamine, asparagine, histidine, and 3-methylhistidine across the sarcolemmal membrane. The activity of system-N is elevated following trauma or sepsis, for example, because glutamine is a major substrate for immune cells. The upregulation of both system-A and system-N appears to occur in response to changes in concentrations of the amino acid pool, resulting in transcriptional activation of genes encoding these transporters, whereas system-L appears to be regulated primarily by blood flow and the magnitude of the BCAA gradient across the muscle. BCAA cannot be degraded by the liver and therefore is taken up and degraded primarily by the muscle. Muscle breakdown of BCAA provides an abundant nitrogen source, which is used to synthesize alanine and glutamine and released by the muscle into the circulation (45).

Diabetes can be associated with skeletal muscle atrophy. Muscle atrophy results primarily from an increase in myofibrillar protein breakdown, which occurs through the activation of the ubiquitin proteasomal system (13,47). Streptozotocininduced diabetes is associated with an increase in the mRNA levels of several proteasomal subunits and ubiquitin, the abundance of ubiquitin-protein conjugates/rate of conjugation, and the rate of ATP-dependent protein degradation, which is suppressed by proteasome inhibitors (48,49). These data suggest a role for the ubiquitin proteasomal system in mediating diabetic muscle atrophy.

SKELETAL MUSCLE SIGNALING

Biologic functions in mammalian cells involve the integration of highly regulated signaling cascades. A deviation from physiologic homeostasis is communicated to the inside of the cell by physical and biochemical interactions with the cell surface. In the case of skeletal muscle, signaling cascades can be grouped by the similarity of the events surrounding the initiation of the signal or the intracellular molecules and patterns of activation following signal initiation. This section will focus on insulin and exercise signaling mechanisms that have been implicated in the regulation of metabolic and transcriptional processes in skeletal muscle, because these have particular relevance for diabetes.

Insulin Signaling

In skeletal muscle, numerous biologic events require communication between the extracellular and intracellular compartments of the muscle fibers in response to insulin. Insulin signaling is initiated by the binding of insulin to the α -subunits of its cell-surface receptor, followed by phosphorylation of the insulin receptor on multiple tyrosine residues. Phosphotyrosine residues on the insulin receptor then interact with phosphotyrosine binding domains on several proteins, including the IRS proteins, of which IRS-1 and IRS-2 are expressed in skeletal muscle. Tyrosine-phosphorylated IRS can then act as docking proteins and interact with SH2 domains of other intracellular proteins, including the regulatory subunit of class IA PI 3-kinases, resulting in the activation of the associated enzyme catalytic subunit (50,51). Activation of class IA PI 3-kinases leads to the formation of specific phospholipids, including phosphatidyl inositol (3,4,5)P₃, which are critical for the recruitment of downstream molecules such as Akt to the membrane for phosphorylation by phosphoinositide-dependent protein kinase-1

(PDK-1). The activation of class $I_A PI$ 3-kinases is critical for the actions of insulin, as nearly all physiologic responses of mammalian cells to insulin are prevented by pharmacologic inhibition or by overexpression of dominant-negative mutants of class $I_A PI$ 3-kinase (52).

GLUCOSE TRANSPORT

The complete signaling mechanism leading to insulin-stimulated glucose transport remains elusive. It is now well established that PI 3-kinase is necessary, but not sufficient, for insulin-stimulated glucose uptake in skeletal muscle and other insulin-sensitive tissues. Some data support a role for the serine/threonine kinase Akt (also known as protein kinase B, PKB) downstream of PI 3-kinase in insulin-stimulated glucose transport. Overexpression of constitutively active forms of Akt in muscle cells mimics the actions of insulin on glucose transport (53,54), and mice deficient in the Akt2 isoform exhibit reduced insulin-stimulated glucose transport in isolated adult skeletal muscles (55).

GLYCOGEN SYNTHESIS

The dephosphorylation of serine residues on glycogen synthase that increases the catalytic activity of the enzyme could be due to the inhibition of a protein kinase that phosphorylates these regulatory sites or to the stimulation of a phosphatase that dephosphorylates them, or both. Several enzymes have been shown to exhibit specificity toward these sites in vitro. Signaling proteins that have been proposed to regulate glycogen synthase activity in muscle include protein phosphatase-1 (PP1_G) and glycogen synthase kinase-3 (GSK-3) (40,41). $PP1_G$ is a musclespecific, type 1 serine/threonine phosphatase that is capable of dephosphorylating all nine regulatory sites of glycogen synthase (40,41). $PP1_G$ is a heterodimer consisting of a catalytic subunit and a regulatory subunit (R_{GL}) that targets the protein to glycogen and sarcoplasmic reticulum membranes (40,41). PP1_G has been proposed to mediate insulin-stimulated glycogen synthesis in skeletal muscle (56). It has been hypothesized that insulin binding to its receptor would lead to 90-kDa ribosomal S6 kinase (RSK2)-induced phosphorylation of $R_{GL\prime}$ which would then enable PP1_G to dephosphorylate and activate glycogen synthase (56). However, it has since been demonstrated that mice deficient in R_{GL} display a normal activation of glycogen synthase in response to insulin treatment (57), strongly suggesting that PP1_G is not necessary for insulin-stimulated glycogen metabolism. On the other hand, there is a great deal of evidence suggesting that insulin-stimulated glycogen synthase activation is mediated in part through a PI 3-kinase-dependent mechanism that leads to the inhibition of GSK-3 (40,41).

PROTEIN SYNTHESIS

The effect of insulin to increase muscle protein has been recognized for many years; however, whether the importance of insulin actions on protein metabolism is to increase the synthetic rate or to decrease protein degradation has not been resolved. It is known that the ability of insulin to stimulate protein synthesis is absent when the availability of amino acids is inadequate (58). Combining these two ideas, a recent investigation (59) demonstrated that combined administration of insulin and leucine elevated rates of protein synthesis by more than 50%. The mechanism of insulin action on protein synthesis appears to be through (a) the increased phosphorylation of the translational repressor, eukaryotic initiation factor (eIF) 4E binding protein-1 (4E-BP1), releasing its inhibitory effect on the formation of the eIF4G*eIF4E complex and the initiation of protein translation, and (b) increased phosphorylation and activation of the ribosomal protein S6 kinase (p70S6 kinase) (59).

GENE TRANSCRIPTION

Recent investigations have demonstrated that insulin signaling in skeletal muscle leads to an increase in metabolic gene expression (60–65). In regard to insulin signaling, insulin has been shown to mediate an increase in the gene expression of the p85 α regulatory subunit of PI 3-kinase, whereas inhibition of the PI 3-kinase/Akt/p70S6 kinase pathway blocks this effect (61). Interestingly, insulin has been shown to increase GLUT4 and hexokinase II transcription, and this effect of insulin may also be mediated through the PI 3-kinase/p70S6 kinase pathway (62,63). The increased expression of glycogen phosphorylase in skeletal muscle in diabetic muscle also appears to be mediated by insulin signaling and may contribute to the glycogen storage deficiency observed with diabetes (65).

ALTERATIONS IN INSULIN SIGNALING WITH DIABETES

Skeletal muscle is the largest storage reservoir for glucose in the body, and defects in insulin action to promote glucose uptake by muscle can result in elevations in circulating concentrations of glucose and altered storage of glycogen by muscle. As discussed in a previous section, in insulin-resistant states such as obesity and type 2 diabetes, expression of GLUT4 protein is normal in skeletal muscle but translocation of GLUT4 is defective (66-68). These defects are thought to be a consequence of impaired intracellular signaling. In some conditions this may involve defective activation of PI 3-kinase, which results, at least in part, from decreased expression of the p85 regulatory subunit (69,70). Insulin-stimulated activation of PI 3-kinase is impaired in skeletal muscle in rodent models of genetic obesity and hyperinsulinemic diabetes (71,72), in rats rendered insulin resistant with high-fat feeding (73) or glucocorticoid treatment (74), and in humans with obesity (69) and type 2 diabetes (70).

Downstream of PI 3-kinase, defective insulin-stimulated Akt activation has been shown in nonobese humans with type 2 diabetes (75). In contrast, muscle biopsy samples obtained from obese and from obese diabetic subjects have demonstrated normal insulin-stimulated Akt1, Akt2, and Akt3 activation despite marked reductions in glucose disposal, IRS-1- and IRS-2associated PI 3-kinase activity, and glycogen synthase activity (76). (GSK-3) a downstream target of Akt, has been reported to be altered in human subjects with type 2 diabetes. Muscle biopsy samples obtained from people with type 2 diabetes were shown to have 25% to 50% greater expression of GSK-3 α and β protein and substantially elevated total GSK-3 activity (77). Significant inverse correlations also were observed between expression of GSK-3 protein and insulin-stimulated glycogen synthase activity and whole-body rates of glucose disposal, suggesting that GSK-3 may contribute to peripheral insulin resistance. In addition to Akt and GSK-3 being potential mediators of insulin resistance, there are reports of the atypical protein kinase (PKC) isoforms, λ/ζ , being downstream of PI 3-kinase in insulin signaling. Interestingly, insulin-stimulated PKC λ/ζ activity in skeletal muscle of individuals who are obese or obese with type 2 diabetes is reduced compared with the activity in lean control subjects, and this decrease in activation may be due to the reduced expression of PKC λ/ζ protein in the skeletal muscle of the patients (78). Thus, there is good evidence that insulin resistance in skeletal muscle may stem from impaired expression and/or function of multiple insulin signaling proteins that are likely critical for insulin action on glucose transport and glycogen synthesis. The mechanisms that lead to the downregulation of these skeletal muscle signaling proteins are not fully understood at this time.

Exercise Signaling

Multiple insulin-independent signaling pathways may lead to stimulation of glucose transport in skeletal muscle. Exercise is probably the most physiologically relevant of these stimuli; the intracellular signaling molecules leading to contractionstimulated glucose transport are less well defined than those for insulin. In contrast to the effects of insulin, exercise does not increase tyrosine phosphorylation of the insulin receptor, IRS-1, IRS-2, or PI 3-kinase activity (79). Furthermore, wortmannin, a PI 3-kinase inhibitor, does not inhibit glucose transport in isolated rat muscle incubated and contracted in vitro (80-82). A study of genetically altered knockout mice that do not express insulin receptors in skeletal muscles has shown that exercise can normally increase glucose transport, whereas insulin-stimulated glucose transport in muscle is fully inhibited (83). Likewise, IRS-2 knockout mice have normal rates of exercise-stimulated glucose transport (84). Thus, although exercise and insulin both recruit GLUT4 to the plasma membrane and activate glucose transport, proximal insulin signaling events are not necessary for exercise to increase GLUT4 translocation or glucose transport in skeletal muscle.

Studies implicating the AMP-activated protein kinase (AMPK) as a critical signaling molecule for the regulation of multiple metabolic and growth processes in contracting skeletal muscle have provided exciting advances in the field of skeletal muscle biology. AMP kinase is a member of a metabolitesensing protein kinase family that acts as a fuel gauge monitoring cellular energy levels and is the mammalian homologue of the SNF-1 protein kinase in Saccharomyces cerevisiae, which is critical for the adaptation of yeast to nutrient stress (85). When AMPK "senses" decreased energy storage, it acts to switch off ATP-consuming pathways and to switch on alternative pathways for ATP regeneration. AMPK is rapidly activated in skeletal muscle under numerous conditions, including contraction, hypoxia, uncoupling of oxidative phosphorylation, and osmotic shock (86). AMPK is activated by an increase in the AMP/ATP ratio by a mechanism that involves allosteric modification, phosphorylation by an AMPK kinase, and decreases in phosphatase activities.

Initial evidence in support of a role for AMPK in contractionstimulated glucose transport came from studies using 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR). AICAR is taken up into skeletal muscle and metabolized by adenosine kinase to form ZMP, the monophosphorylated derivative that mimics the effects of AMP on AMPK (87,88). AICAR can stimulate glucose transport in the absence of insulin, similar to the effects of exercise (88,89), and AICAR-stimulated transport is not inhibited by wortmannin, the pharmacologic inhibitor of PI 3-kinase. Furthermore, the increase in glucose transport with the combination of maximal AICAR plus maximal insulin treatments is partially additive, whereas there is no additive effect on glucose transport with the combination of AICAR plus contraction (88). Short-term infusion of rats with AICAR (and glucose to maintain euglycemia) also increases 2-deoxyglucose transport in multiple muscle types. Interestingly, patients with type 2 diabetes have normal activation of AMPK in skeletal muscle (90). The recent generation of a transgenic mouse expressing an inactive (dominant-negative) AMPK protein has suggested that AMPK may only be part of the mechanism leading to contraction-stimulated glucose transport (91). Elucidating additional mechanisms for contraction-stimulated glucose transport will be an important goal for skeletal muscle research in the next several years.

In addition to glucose transport, AMPK has been proposed to mediate the effects of muscle contractile activity on multiple

other metabolic and transcriptional events in skeletal muscle. The initial studies showing AMPK activation in skeletal muscle provided the first evidence that AMPK plays an important role in the regulation of fatty acid oxidation during exercise (92-94). This occurs through AMPK phosphorylation of the β isoform of acetyl-CoA carboxylase (ACC β), resulting in ACC inactivation, a decrease in malonyl-CoA content, and a subsequent increase in fatty acid oxidation after removing the inhibition of carnitine palmitoyl transferase I (92-94). Evidence for regulation of glycogen metabolism by AMPK in skeletal muscle is more controversial. In vitro AMPK can phosphorylate proteins involved in glycogen metabolism, including Ser⁷ on glycogen synthase in vitro (95), which would be expected to inhibit glycogen synthesis (96), and phosphorylase kinase (95), the immediate upstream effector of glycogen phosphorylase. On the other hand, there is also compelling evidence that AMPK functions to increase glycogen synthesis, because chronic AICAR treatment for 5 to 28 days increases glycogen content in both type I and type II fibers (97,98). However, because chronic AICAR treatment causes numerous metabolic responses as well as increased GLUT4 content in skeletal muscle (97), the increased glycogen content may be due to the effects of AICAR on metabolism rather than direct regulation of glycogen synthase or glycogen phosphorylase.

Studies of SNF-1, the AMPK homologue in yeast, have provided evidence that AMPK plays an important role in the regulation of gene transcription (85). Studies of skeletal muscle support the concept that AMPK is involved in gene regulation, because chronic administration of AICAR via daily injections for 5 to 28 days significantly increases the expression of GLUT4 and hexokinase in multiple muscles composed of different fiber types, including epitrochlearis, gastrocnemius (99), and red and white quadriceps muscles (97). Furthermore, AICAR infusion resulted in significantly increased transcription of the genes encoding uncoupling protein 3 (UCP3), heme oxygenase-1 (HO-1), hexokinase II, and GLUT4 in rat gastrocnemius muscles (100). The mechanism by which AMPK modulates gene transcription remains unclear. However, these studies raise the possibility that AMPK is a key intermediary in the effects of a single bout of exercise in altering the induction of multiple genes. The accumulation of these individual effects of each exercise bout may lead to adaptations by muscle to chronic exercise training.

SUMMARY

The past 20 years have brought considerable advances in understanding the biochemistry underlying skeletal muscle contraction and metabolism. Of particular relevance to diabetes is the considerable enhancement of our understanding of the molecular mechanisms of insulin action as well as of the mechanism by which contractile activity enhances carbohydrate metabolism in skeletal muscle. With the continued development of novel methodologies for investigating signal transduction, metabolism, and transcriptional regulation in skeletal muscle, progress in this important area should continue in the near future.

CONCLUSION 261

INTRODUCTION

Background

Glucose provides a major energy supply for mammalian cells; however, some tissues are much more dependent than others on this source. For example, glucose is the primary energy source for the brain and renal medulla and is essentially the sole provider for red blood cells and the retina. The total daily consumption of glucose in a 70-kg person is about 160 g. The brain uses about 120 g of this. Therefore, tissues that make up about 5% of the body weight consume more than 75% of the glucose metabolized each day. Some 10 to 15 g of glucose is available in the extracellular fluid (ECF), and ~300 g can be stored in the glycogen reservoirs. Thus, less than a 24-hour supply of glucose is directly available in circumstances when no exogenous supply is available. A constant supply of glucose must be available, as moderate hypoglycemia (<50 mg/dL) causes disabling symptoms and severe hypoglycemia (<20 mg/dL) can have devastating and irreversible effects on the central nervous system (CNS). By contrast, hyperglycemia must be avoided, as this causes its own set of deleterious consequences, albeit on a considerably longer time scale.

An intricate mechanism has evolved for maintaining ECF glucose within a relatively narrow range. In broad physiologic terms (Fig. 15.1), this involves the regulated production of glucose by the liver from glycogenolysis and gluconeogenesis and, to a lesser extent, from gluconeogenesis in the kidneys and

small intestine. This is counterbalanced by the regulated peripheral clearance of glucose by tissues such as skeletal muscle, adipose tissue, and the splanchnic bed, including the liver. This chapter concerns the homeostatic role the liver plays in these processes by serving as a consumer, producer, and reservoir for glucose. Descriptions of the control processes involved in glucose homeostasis generally center on hormonal regulation (Fig. 15.1). A major thesis of this chapter is that glucose and/or glucose metabolism is a (the) central player in these events. This point will be made by first outlining the general steps in metabolic control, then by illustrating how these processes affect glucose metabolism, and vice versa.

Intracellular Symbols of Energy Charge, Glucose Homeostasis, and Carbon Balance

Multicellular organisms have elaborate mechanisms for sensing changes in the external environment and for generating signals that can then be transduced into an appropriate compensatory response (Table 15.1).

Glucose homeostasis is a case in point. Acute hypoglycemia results in the immediate release of glucagon, which binds to the hepatocyte plasma membrane and thereby promotes the generation of cyclic adenosine monophosphate (cAMP). cAMP is therefore an intracellular symbol of hypoglycemia (1). Hyperglycemia, through insulin release and the subsequent activation of phosphodiesterases that hydrolyze cAMP, reduces the concentration of this nucleotide. A low-molecular-weight activator

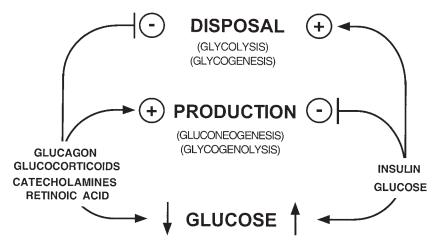

Figure 15.1. Overview of the hormonal regulation of glucose metabolism in the liver.

of phosphofructokinase-1 (PFK1) was found in the livers of rats given a glucose load and was absent in the livers of rats treated with glucagon (2,3). This molecule, fructose-2,6-bisphosphate (F-2,6-P₂), is thus a symbol of hyperglycemia. As discussed below, F-2,6-P2 activates glycolysis and inhibits gluconeogenesis, as would be expected of a symbol of hyperglycemia, for which the maintenance of homeostasis requires that glucose utilization be promoted and its production inhibited. Glucose metabolism is a major source of adenosine triphosphate (ATP), which is synthesized by successive phosphorylation steps from AMP. The intracellular levels of AMP and ATP, or the AMP/ATP ratio, are thus a reflection of energy sufficiency or depletion, as the case may be, within the cell. Citrate, an early intermediate in the citric acid cycle, is a symbol of the carbon supply necessary for a variety of biosynthetic pathways. Alanine, synthesized in a single step from pyruvate, serves a similar purpose. Although probably not a complete list, cAMP, F-2,6-P2, AMP/ATP, citrate, and alanine play key roles, by a variety of mechanisms that will be described below, in regulating hepatic glucose metabolism, which is a major source of energy and carbon for various biosynthetic reactions.

Metabolic Pathways

The elucidation of metabolic pathways, along with the principles that govern the regulation of these pathways, is one of the major achievements of 20th century biological research. The deciphering of how thousands of reactions are coordinated, as well as the purification and characterization of the enzymes involved, was accomplished using techniques that often were very primitive by contemporary standards. This set the stage for more recent developments that allow for the analysis of

Change	Symbol
Hypoglycemia	cAMP
Hyperglycemia	Fructose-2,6-bisphosphate
Low energy charge	AMP; high AMP/ATP ratio
High energy charge	ATP; low AMP/ATP ratio
Carbon supply	Citrate, alanine
cAMP, cyclic adenosine monophosphate	e; ATP, adenosine triphosphate.

components of these pathways by overexpression of an enzyme in a tissue of interest, or the selective removal of an enzyme, by transgenic and gene knockout technologies. These, and other newer techniques, are providing supportive evidence for the fundamental importance of certain enzymatic steps and have led to the discovery of regulatory processes heretofore unappreciated. The regulation of glucose metabolism in the liver, the topic of this chapter, has been of central interest to investigators for more than 100 years. As will be discussed below, many of the principles of metabolic regulation were derived from these studies.

CONTROL MECHANISMS

A living cell is an intricate machine, and it generally has several ways of regulating critical processes, with redundant systems for backup support. Most disturbances of a cell, even quite severe ones, are tolerated because, under normal circumstances, homeostatic mechanisms restore the affected process (or processes) to, or near, the original state.

Simple Control Mechanisms

The simplest type of control is afforded by substrate availability. Flux through an enzyme step is directly related to the concentration of substrate and to the affinity of the enzyme for that substrate. For example, hexokinases catalyze the phosphorylation of glucose to form glucose-6-phosphate (G-6-P). The Michaelis-Menten constant (K_m) for the 100-kDa hexokinases (HK-I–III) is low (20–120 µM), so these enzymes are very efficient at low ECF glucose concentrations (4). Glucokinase, a 50-kDa hexokinase found in liver and pancreatic β -cells, has a $K_{\rm m}$ for glucose of 5 to 10 mM, so it is very active when glucose concentrations in the ECF are high, particularly in the portal circulation, as happens after a meal (5). These high glucose concentrations are well above the K_m of the 100-kDa hexokinases, which are relatively less influential under such circumstances. Glucokinase therefore plays an important role in hepatic glucose clearance during the postprandial period. Substrate availability provides a very rapid and simple control mechanism and is a major control mechanism in unicellular organisms. However, these organisms are relatively defenseless in the face of large changes of substrate availability, particularly when the substrate is not abundant.

Substrates and reaction products afford another type of direct regulation in which they affect their own concentration

by influencing the activity or amount of an enzyme by positive or negative mechanisms. Positive control occurs when a downstream component activates a subsequent enzyme and promotes forward flux, or induces the synthesis of an enzyme that accomplishes the same purpose. Fructose-1,6-bisphosphate (F-1,6-P₂) activates a downstream enzyme, pyruvate kinase (PK), and thus promotes glycolytic flux (6); (Fig. 15.2). This provides a mechanism for ensuring that flux continues in the forward direction, but it generally does not afford finetuning of substrate concentration or flux because it is unidirectional. Negative feedback control, which is much more common than positive control, occurs when the product of a reaction is capable of feedback inhibition of upstream enzyme activity or synthesis. Negative feedback control can be exerted at many upstream reaction steps in a pathway and helps define the points at which metabolic-control strength is exerted. This mechanism, analogous to the function of a thermostat in temperature control, adjusts substrate concentration in a narrow range around a preset value. When the concentration of the reaction product falls, negative feedback inhibition is relieved and the reaction (or reactions) produces more of the regulatory molecule. High concentrations shut down the system,

thus providing up-and-down fine-tuning. For example, physiologic levels of G-6-P, the product of the hexokinase reaction, provide feedback inhibition of the 100-kDa hexokinases but not of glucokinase (7). This provides for appropriately regulated levels of the branch-point substrate G-6-P in most tissues. Tissues or organs wherein glucokinase is the predominant hexokinase, such as liver and pancreatic β -cells, are able to continuously phosphorylate glucose owing to the lack of feedback inhibition by G-6-P, the reaction product. The liver is thus able to clear glucose in the postprandial state, and β -cells are able to employ glucokinase as a glucose sensor for regulated secretion of insulin (8). Substrate availability and feedback/feedforward control are prominent mechanisms in single-cell organisms.

Complex Control Mechanisms

Simple regulatory systems are advantageous in that they provide very rapid and quickly reversible control. The major disadvantages are that the unicellular organism is susceptible to major environmental changes of substrate availability and the regulation is provided by molecules that are themselves reaction

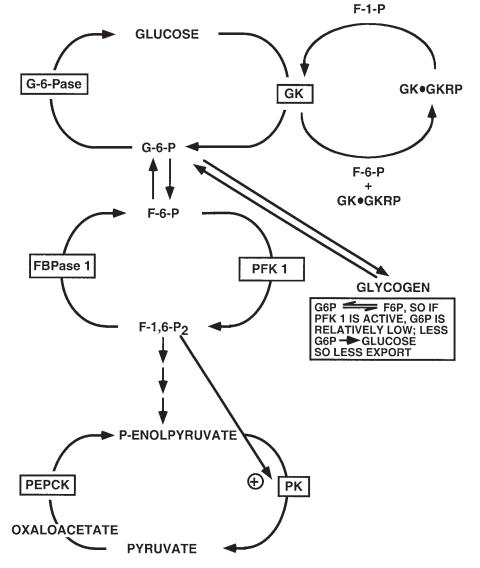

Figure 15.2. A simple control mechanism is provided by substrate availability, which influences the activity or amount of metabolic enzymes. G-6-P, glucose-6-phosphate; F-6-P, fructose-6-phosphate; F-1-P, fructose-1,6-bisphosphate; GK, glucokinase; GKRP, glucokinase regulatory protein; G-6-Pase, glucose-6-phosphatase; FBPase, fructose-1,6-bisphosphatase; FBPase, fructose-1, PFK 1, phosphofructokinase-1; PEPCK, phosphoenolpyruvate carboxykinase; PK, pyruvate kinase.

components. As noted, these mechanisms are frequently employed in glucose metabolism in multicellular organisms. However, the complexity of these organisms is such that certain environmental changes that are threats to survival are often perceived by one tissue or organ and the responses that allow for homeostasis are facilitated by one or more distant organs. Communication between the sensors of the environment and the organs or tissues that provide the appropriate response to recognized challenges is accomplished by the nervous and endocrine systems. For example, hypoglycemia is perceived by the CNS, which triggers the release of glucocorticoids, catecholamines, and glucagon and the inhibition of insulin secretion (Fig. 15.1). These hormones, the so-called first messengers, provide much of the cell-cell communication necessary for the coordinated response that restores the ECF glucose level to the normal range. A variety of intracellular molecules serve as so-called second messengers, including cAMP, cyclic guanosine monophosphate (cGMP), calcium ion, and various phosphatidylinositides. These molecules share several properties. They act as intracellular symbols of particular environmental changes, and more than one of these may be symbols of the same challenge, e.g., hypoglycemia. The concentration of these molecules is labile within the cell, as befits their regulatory potential. In contrast to the simple mechanisms of regulation described above, none of these molecules is a component (substrate or product) of a reaction pathway, nor are they structural analogues of such components. Finally, these regulatory molecules all initiate signal transduction cascades that result in the ultimate biologic response. Again, these cascades are not mutually exclusive, as different signals can activate the same, or complementary, steps in a given pathway. A wide variety of metabolic control mechanisms are affected by these signals, including allostery, posttranslational protein modification, protein translocation, protein-protein interaction, and changes in the amount of key proteins (Table 15.2).

ALLOSTERIC CONTROL

Some of the enzymes and proteins involved in glucose homeostasis are regulated by allosteric control mechanisms. Rather than exhibiting classical Michaelis-Menten kinetics, in which there is a hyperbolic association between substrate binding and enzyme activity, a plot of enzyme activity against substrate concentration shows a sigmoidal relationship. This occurs when substrate binding to one active site influences, in a cooperative fashion, binding to a second site in the same molecule. For example, the reaction velocity of PFK1 increases in a sigmoidal fashion as the concentration of the substrate, fructose-6phosphate (F-6-P), increases (9–11) (Fig. 15.4B, center panel). Some molecules regulate activity of the allosteric enzyme by binding to regulatory sites distinct from substrate binding sites. The allosteric regulator F-2,6-P₂ significantly shifts the velocity of the PFK1 reaction for the substrate F-6-P to the left (12,13) (Fig. 15.4B, center panel).

POSTTRANSLATIONAL MODIFICATION OF PROTEINS

Several dozen different types of posttranslational modifications alter the activity of proteins, including many enzymes involved in glucose homeostasis. Modification of enzyme activity by phosphorylation of serine, threonine, or tyrosine residues is a particularly common mechanism. First described in the control of enzymes of glycogen metabolism, regulation by phosphorylation, and dephosphorylation, is employed in many different signal transduction pathways. For example, the binding of glucagon to its cell-surface receptor on the hepatocyte results in the activation of adenylyl cyclase and the production of cAMP from ATP. cAMP activates a kinase cascade that catalyzes the phosphorylation of phosphorylase b on the serine 14 residue of each monomer of this enzyme (14). This phosphorylation results in the conversion of the inactive phosphorylase b to the active phosphorylase a form and glycogen degradation by phosphorolysis.

PROTEIN TRANSLOCATION

The movement of proteins from one cellular compartment to another, with a subsequent change in activity or function of that protein, is an important control mechanism. One of the first examples of this control mechanism is the insulin-promoted movement of the glucose transporter 4 (GLUT4) from an intracellular reservoir to the plasma membrane in skeletal muscle and adipose cells (15,16). In the absence of insulin, there is a continuous movement of GLUT4 into and out of the plasma membrane. The interaction of insulin with its cell-surface receptor activates one or more signal transduction pathways that promote GLUT4 vesicle exocytosis in excess of transporter internalization. The role of phosphoinositide 3-kinase (PI 3kinase), with possible involvement of downstream kinases such

Process	Example
Substrate utilization	Glucokinase has a higher <i>K</i> _m for glucose than hexokinases I–III
Positive feedforward control	Fructose-1,6-bisphosphate stimulates pyruvate kinase activity
Negative feedback control	Glucose-6-phosphate inhibits hexokinases I–III
Allosteric control	Fructose-2,6-bisphosphate activates phosphofructokinase-1
Protein modification	cAMP promotes the phosphorylation of phosphorylase
Protein translocation	Glucokinase moves from nucleus to cytoplasm
Protein-protein interaction	Glucokinase regulatory protein associates with glucokinase
Regulation of protein amount	Insulin increases general mRNA translation
Regulation of gene transcription	Glucose inhibits phosphoenolpyruvate carboxykinase gene transcription

as protein kinase B (PKB) and protein kinase C (PKC ζ/λ), is quite well established in this process (17,18). However, the activation of PI 3-kinase may not be totally sufficient. The role of various signal transduction pathways in moving the GLUT4 vesicle into and out of the plasma membrane remains to be established. Nonetheless, activation of the insulin signal transduction pathway (or pathways) results in a marked enhancement of glucose entry into skeletal muscle and adipose cells because of a protein translocation process.

PROTEIN–PROTEIN INTERACTION

Interactions with other proteins influence the activity of certain proteins. A complex array of protein-protein interactions is involved in regulating the transcription of genes that encode enzymes involved in glucose homeostasis, as will be described below. The interaction of glucokinase with the glucokinase regulatory protein (GKRP) is a pertinent example of a protein-protein interaction (19) and of how more than one mechanism is employed to facilitate a given process, in this case glucose phosphorylation. When glucokinase is bound to GKRP, a reaction facilitated by the allosteric binding of F-6-P to the GKRP (Fig. 15.3), glucokinase is inactive and located in the nucleus of hepatocytes. The exchange of F-6-P with fructose-1-phosphate (F-1-P) results in the dissociation of GKRP from glucokinase and the translocation of the latter to the cytosol, where it is an active enzyme. The regulation of glucokinase activity thus involves allosteric control, protein-protein interaction, and protein translocation, in addition to substrate control. The amount of the enzyme can also be influenced by the rate of transcription of the glucokinase gene.

REGULATION OF PROTEIN AMOUNT

The examples described above, in one way or another, regulate activity without changing the amount of enzymes or proteins. Several mechanisms also are employed to change the amount of a specific protein in a cell such as a hepatocyte. The concentration of a protein in the cell at any instant represents a balance between the relative rates of its synthesis and degradation. This balance is different for all proteins and is a regulatable process. The rate of synthesis of a protein (mRNA translation) is directly related to the amount of the encoding mRNA and the efficiency of translation of that specific mRNA. Translation is an exceedingly complex, multistep process, and it is extensively regulated. Insulin affects a critical step, the formation of the active translation factor eukaryotic initiation factor-4E (eIF-4E). Stimulation of cells by insulin and other growth factors results in activation of the mammalian target of rapamycin (mTOR) and mitogen-activated protein (MAP) kinase pathways and the phosphorylation of eIF-4E (20). This phosphoprotein associates with several other translation factors to form the eIF-4F complex, which binds to the mRNA cap and allows for translation initiation (20). This mechanism is thought to be responsible for the general anabolic effects of insulin, and it could come to play in enhancing the synthesis of specific proteins.

About 1% to 2% of total body proteins turn over each day in humans, and the liver is actively involved in this process. Hepatic proteins have markedly different turnover rates, measured as the half-life $(t_{1/2})$, the time required for a protein to be reduced to 50% of its initial value. This is an important concept, particularly in view of regulation, as the time required to move from one steady state to another, either up or down, is a function of the turnover time of the protein (or any other substance for that matter, e.g., mRNA, lipid, drug). Thus, one can calculate that about five turnover times are required to effect a change of steady state, e.g., $100 \rightarrow 50 \rightarrow 25 \rightarrow 12.5 \rightarrow 6.25 \rightarrow 3.13$, or vice versa. This has useful predictive value in considering how long it will take for an induced or repressed enzyme (or mRNA) to reach its new steady-state level. For example, the t_{1/2} for phosphoenolpyruvate carboxykinase (PEPCK) mRNA and protein are ~0.6 and 2.0 hours, respectively (21). After the addition of glucocorticoids, a PEPCK gene inducer, the new steady states for the mRNA and protein are reached in ~3 and 10 hours, respectively, assuming there are no effects of the inducer on mRNA or protein turnover (and in this case and others there often are).

The $t_{1/2}$ for liver proteins varies from 30 minutes to more than 150 hours. In general, proteins that play a key role in metabolic regulation, such as PEPCK, tyrosine aminotransferase, and hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase, have short $t_{1/2}$ values in the range of 0.5 to 2 hours, and as

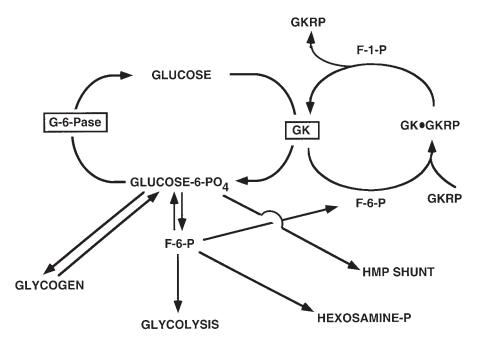

Figure 15.3. Regulation of the glucose/glucose-6-phosphate (G-6-P) cycle. G-6-P is a branch point for several metabolic pathways. G-6-Pase, glucose-6-phosphatase; GK, glucokinase; GKRP, glucokinase regulatory protein; F-6-P, fructose-6-phosphate; F-1-P, fructose-1-phosphate; Hmp-hexose monophosphate.

mentioned above, these rates can be decreased or increased in response to physiologic signals. Metabolic flux can thus be significantly influenced by the turnover of key enzymes. By contrast, other enzymes, such as aldolase or lactate dehydrogenase, have prolonged $t_{1/2}$ values in the range of more than 100 hours. Changes in the amount of such enzymes are not involved in acute adaptive processes.

REGULATION OF GENE TRANSCRIPTION

The rules of turnover are also applicable to a consideration of the concentration of a specific mRNA in the hepatocyte. The amount of a given mRNA represents the balance between its synthesis, from gene transcription, and its degradation. mRNAs, like proteins, have markedly different turnover times. In the liver, these range from a $t_{1/2}$ of 10 to 15 minutes to a $t_{1/2}$ of days for different individual mRNAs. In general, a specific mRNA turns over more rapidly than its cognate protein, and mRNAs that encode enzymes involved in acute metabolic regulation have shorter $t_{1/2}$ values than those that direct the synthesis of the so-called housekeeping proteins (21). In addition, hormones that regulate the rate of transcription of a gene also often affect the rate of turnover of the respective mRNA. Thus, glucocorticoids and cAMP increase the rate of transcription of the PEPCK gene, and they both prolong the $t_{1/2}$ of PEPCK mRNA (22,23). The net result of these two effects is to increase the amount of this mRNA in the hepatocyte and prolong its presence. This provides for more PEPCK synthesis and an extended influence of the enzyme on gluconeogenic flux.

Much more is understood about the regulation of mRNA synthesis than is known about its degradation. As will be described in detail below, complex arrays of protein-DNA and protein-protein interactions are involved in the regulation of the initiation phase of transcription of specific genes. These assemblies are controlled by a series of events that follow in sequence from the interaction of a hormone with the target cell. Regulation of the activity of PEPCK in the hepatocyte provides a case in point. This enzyme is not appreciably affected by feedforward, feedback, or allosteric control mechanisms, nor is its activity subject to change as a result of posttranslational modification of the protein, by protein-protein interactions, or by its location in the hepatocyte. Changes of PEPCK activity are attributable to alterations in the amount of the enzyme in the cell, which is directly related to the amount of PEPCK mRNA available for translation. This amount is principally determined by the rate of PEPCK mRNA synthesis, although degradation of the mRNA can also be important in certain circumstances (22,23). cAMP enhances PEPCK gene transcription by first promoting the phosphorylation of a protein, cAMP response element binding protein (CREB), that binds to the cAMP response element (CRE) in the PEPCK gene promoter (24,25). This phospho-CREB-CRE complex triggers the assembly of a set of protein-protein interactions that result in enhanced initiation of transcription through the PEPCK gene promoter (26). Glucocorticoids bind to the cytosolic glucocorticoid receptor (GR), which then dissociates from a chaperone protein and translocates into the hepatocyte nucleus to bind to the glucocorticoid response element (GRE). Occupation of the GRE by the GR triggers a different series of protein-DNA and protein-protein interactions that also result in an enhanced rate of PEPCK gene transcription and, in sequence, increased mRNA and protein synthesis and enzyme activity (27,28). Insulin, through its signal transduction cascade, inhibits PEPCK gene transcription and also slows the rate of PEPCK mRNA translation (27,29). Thus, the regulation of PEPCK activity, which has significant control strength in gluconeogenesis, is regulated by several mechanisms.

Metabolic Control Analysis

Until recently the guiding principle in metabolic control has been the idea that there is a single rate-controlling step in any metabolic pathway. Flux through such a pathway could thus be increased or decreased by changing the activity of that single rate-determining enzyme. The advent of recombinant DNA technology enabled investigators to rather easily change the expression of a given enzyme in a cell; yet this often does not result in the change of flux predicted by the rate-limiting enzyme hypothesis. These results were not surprising to students of metabolic control analysis, a concept first proposed by Kacser some 30 years ago (30). Metabolic control is assessed by measuring all enzyme activities, their kinetic properties, the substrates and products of each reaction, and the relevant regulatory molecules in a particular pathway. An analysis of the data allows one to assign a quantitative control strength value (C) to each step in this pathway. The sum of the C values for a pathway equals 1.0. High C values indicate high control strength. When appropriately analyzed, it is apparent that control strength can be distributed among the several steps in a pathway, and the C value for a given step can be changed by different metabolic circumstances. An examination of glucose metabolism in the isolated, beating heart provides a good example of these principles. In a heart preparation perfused with a physiologic concentration of glucose, control of the early steps of glucose metabolism is distributed between glucose transport (C value of 0.4) and glucose phosphorylation (C value of 0.6) (31). The addition of insulin results in a remarkable change in the distribution of control strength. Under these conditions the C value for glucose transport is now negligible (0.0002), whereas the C value for glucose phosphorylation increases to 0.97 (31). Phosphoglucoisomerase accounts for the other 0.02. Metabolic control analysis also allows one to assign relative importance to a set of reactions within a complex pathway. For instance, in the case cited, the distribution of control provided by transport/ phosphorylation (0.58), glycolysis (0.25), and glycogen synthesis (0.17) was assessed.

At equilibrium, the supply of an end product by the series of enzymes and substrates equals the demand afforded by product utilization and degradation. Thus, the demand side can also influence metabolic control by providing a pull on the system. Two recent studies illustrate the importance of this concept. In studying tryptophan biosynthesis in yeast, investigators first showed that exogenous provision of excessive amounts of the first enzyme in the biosynthetic pathway did not increase flux to tryptophan. All of the enzymes in the pathway had to be overexpressed to increase flux (32). This illustrates the point made above about so-called rate-limiting steps. Of more interest was the observation that the biosynthetic enzymes ("supply side") accounted for only about 25% of the control strength. The other 75% was presumably provided by the "demand side," e.g., the use of tryptophan for protein synthesis. This is similar to the example cited above, in which, in the heart, glycolysis and glycogen synthesis exert control strength downstream from glucose transport/phosphorylation (31). That demand may also be an important control step as illustrated in another recent report. Glycolysis, as noted above, provides ATP from glucose. Yeasts engineered to have an excess of the ATP-degrading enzyme adenosine triphosphatase (ATPase) have a remarkable increase in glycolytic flux (33). This observation is pertinent to the topic of this chapter. The energy charge in these cells, as reflected in a low AMP/ATP ratio, resulted in increased glycolytic flux. As described in detail below, a low AMP/ATP ratio promotes flux through the critical glycolytic enzymes PFK1 and PK in hepatocytes. It thus is important to recognize that supply and demand are both significant, that control is distributed, and that this distribution is subject to change according to metabolic circumstances.

GLUCOSE AUTOREGULATION IN LIVER

Glucose Transport by Hepatocytes

Glucose enters all cells by facilitated diffusion (from a high to low concentration) through one of the members of the glucose transporter family of proteins (34). This is basically a unidirectional process in cells that cannot produce glucose, as one of the four hexokinase family members (HK-I–IV) rapidly converts glucose to G-6-P, which cannot be exported by the glucose transporter. The activity of these hexokinases keeps the intracellular free-glucose concentration low, so most cells have a net uptake of glucose due to inward, passive diffusion. The only regulation of this process is afforded by the extracellular glucose concentration (substrate control) and by G-6-P, which inhibits (by negative feedback) the 100-kDa hexokinases (isoforms I–III).

Hepatocytes, which can produce glucose from glycogenolysis and gluconeogenesis, can export and import glucose. The direction of glucose flux depends on the concentration gradient. Under certain metabolic conditions (e.g., fasting or hormonal conditions that favor glycogenolysis and/or gluconeogenesis), hepatocytes release glucose into the ECF. The ability of the hepatocyte to effect net glucose release is a function of its high K_m hepatic transporter coupled with a regulatable high K_m hexokinase (HK-IV, or glucokinase). When hormonal conditions favor glucose utilization (high insulin, low glucagon), glucokinase activity is high, intracellular glucose is rapidly phosphorylated, and glucose entry is facilitated along a downhill gradient. When conditions favor glycogenolysis or gluconeogenesis (low insulin, high glucagon), glucokinase activity is reduced, the low rate of glucose phosphorylation results in intracellular accumulation of glucose, and glucose is exported by facilitated diffusion. The hepatic GLUT2 transporter has a K_m for glucose of ~40 mM and generally functions with pseudo first-order kinetics with respect to the intracellular or extracellular glucose concentration (34). Because the portal vein glucose concentration normally does not exceed 10 mM, transport is not limiting for either hepatic glucose import or export. Because of this feature there is no need for regulation of the hepatic glucose transporter.

General Features of Hepatic Substrate Cycles

Hepatic glucose production and utilization involve the movement of substrates through three major cycles (2,35) (Fig. 15.2). Hepatic glucose production, by gluconeogenesis, is a biosynthetic pathway. Glucose utilization, by glycolysis, is a degradative pathway. Degradative and biosynthetic pathways are usually catalyzed by separate sets of enzymes. This affords unique, but flexible, control of each pathway. The latter is particularly important in this instance, as the production of a single molecule of glucose from gluconeogenesis requires the expenditure of six high-energy bonds [four ATP and two guanosine-triphosphate (GTP)], whereas glucose degradation to two pyruvate molecules results in the production of two ATP molecules. Futile cycling between the cycles involved in gluconeogenesis and glycolysis could thus be very wasteful in terms of energy consumption and heat production. In general, a negative free-energy charge (AMP, or a high AMP/ATP ratio) promotes glycolysis, and a high free-energy charge (ATP, or a low AMP/ATP ratio) favors the gluconeogenic pathway.

The direction and magnitude of substrate movement, along either the glycolytic or the gluconeogenic pathway, is controlled by six enzymes that catalyze essentially irreversible reactions and thus have high metabolic control strength (2). The three enzymes that catalyze the glycolytic reactions must be bypassed by three different enzymes that direct the gluconeogenic pathway and vice versa. The activity of these six enzymes is modulated by acute (seconds to minutes) and chronic (minutes to hours) regulatory mechanisms. The acute regulation of hepatic glucose metabolism occurs through hormone-mediated changes in enzymatic activity, principally the phosphorylation or dephosphorylation of two key enzymes, PK and phosphofructokinase-2/fructose-2,6-bisphosphatase (PFK2/FBPase2, the bifunctional enzyme), and the allosteric regulation of GK by GKRP and of PFK1 and FBPase1 by F-2,6-P₂ (2,3). Hormones also exert chronic effects on glucose metabolism by changing the rate of enzyme synthesis. These chronic effects are mediated through alterations of the rate of mRNA synthesis and, in some cases, by changes in the rate of degradation of specific mRNAs.

The net flux through the glucose/G-6-P, F-6-P/F-1,6-P₂, and phosphoenolpyruvate/pyruvate cycles depends on the relative activity of the enzymes illustrated in Figure 15.2. Conditions favoring gluconeogenesis (the combination of high plasma glucagon, catecholamine, and glucocorticoid levels with a low plasma insulin level, as occurs when animals are starved or fed a low-carbohydrate diet) result in increased activity of PEPCK, FBPase1, and glucose-6-phosphatase (G-6-Pase) and a coordinate decrease in the activity of GK, PFK1, and PK. Reciprocal changes in the activities of these enzymes occur when animals are fed a carbohydrate diet, particularly after a prolonged fast (2,3). In this situation, the plasma insulin concentration increases, levels of the counterregulatory hormones decrease, and glycolysis predominates. The F-6-P/F-1,6-P₂ substrate cycle is also regulated by a subcycle in which the amount of the regulatory molecule F-2,6-P2 is controlled by the bifunctional enzyme (2,3). The relative activity of these seven enzymes, established by the interaction of several hormones, determines whether the hepatocyte is a consumer or producer of glucose. The activity of the enzymes involved in the cycles is controlled by all of the control mechanisms described above. Many other enzymes are also involved in these processes; however, they catalyze equilibrium reactions that are not rate determining.

Regulation of the Glucose/ Glucose-6-phosphate Cycle

Upon entering the hepatocyte through the GLUT2 transporter, glucose is converted to G-6-P by the enzyme glucokinase (Fig. 15.3). Glucokinase is an unusual member of the hexokinase family. Its K_m for glucose is greater than 5 mM, whereas the K_m for HK-I–III (glucokinase is HK-IV) varies between 20 and 120 μ M (4,5). This difference in K_m values gives the brain, muscle, and red blood cells, which have isoforms I–III, preference when the glucose supply is limited. Portal vein and liver sinusoidal glucose concentrations are high after a meal. Hepatocytes efficiently convert glucose to G-6-P because glucokinase (HK-IV) works most efficiently at this elevated glucose concentration (7). Also, unlike HK-I–III, glucokinase is not subject to feedback inhibition by physiologic concentrations of the reaction product, G-6-P (7). Because GLUT2 operates by facilitated diffusion,

the activity of glucokinase, which keeps intracellular glucose concentrations very low, determines glucose clearance by hepatocytes.

This cycle is important because G-6-P is a branch-point substrate for, or a product of, the glycolytic, gluconeogenic, glycogen formation/degradation, hexosamine, and hexose monophosphate shunt pathways (Fig. 15.3). The balance of glucose phosphorylation and G-6-P hydrolysis, and thus the production or metabolism of glucose, as well as the avoidance of futile substrate cycling, requires the interplay of a number of control mechanisms.

Glucokinase activity is not altered by covalent modification, but its activity is regulated by an allosteric mechanism and by changes in the amount of the protein (2,19). Glucose phosphorylation, by glucokinase, results in increased intracellular levels of G-6-P. Although physiologic concentrations of G-6-P do not inhibit glucokinase, G-6-P is in near equilibrium with F-6-P through the action of the reversible enzyme phosphoglucoisomerase. F-6-P increases the affinity of binding of the nuclear GKRP to glucokinase (19). When bound to GKRP, glucokinase is found primarily in an inactive form in the nucleus of the hepatocyte (36-38). This complex is subject to allosteric regulation, as the inhibition of glucokinase by F-6-P is reversed by F-1-P, which competes with F-6-P for binding to the GKRP (19). F-1-P binding causes a conformational (allosteric) change of GKRP. This results in the dissociation of glucokinase, which can then translocate to the cytoplasm as an active enzyme (38). Thus fructose, which is converted to F-1-P by fructokinase, promotes hepatic glucose clearance by its indirect activation of glucokinase (38) (Fig. 15.3).

Glucokinase gene transcription, glucokinase mRNA, and glucokinase activity are decreased when plasma glucagon is high and plasma insulin is low (e.g., fasting or diabetes) (7,37,39–41). Refeeding a diet high in carbohydrate results in an increase of these parameters. A 20- to 30-fold increase in transcription occurs within 30 to 60 minutes after the injection of insulin into a diabetic rat or after the addition of insulin to primary cultures of hepatocytes (40-42). Glucokinase mRNA increases accordingly (40,41), and a significant increase of glucokinase activity and attendant flux from glucose to G-6-P ensues (43). The inhibitory effect of glucagon (or cAMP, its intracellular messenger) on glucokinase gene transcription is dominant over the stimulatory effect of insulin, because cAMP blocks the effects of insulin at all concentrations of insulin in cultured cell systems (44). These hormone effects are not dependent on the presence of glucose in the medium (41,44).

G-6-Pase is a multisubunit enzyme located on membranes of the endoplasmic reticulum. It has a K_m for G-6-P of about 2 mM, which generally exceeds the concentration of this substrate in the hepatocyte (34). Therefore, the enzyme is usually quite active, and glucose phosphorylation and G-6-P hydrolysis are controlled by substrate concentrations to a significant extent. G-6-Pase is not known to be regulated by allosteric or post-translational modifications.

It has been known for some time that hepatic G-6-Pase activity is increased by starvation and in diabetic rats (45). These conditions favor glycogenolysis and gluconeogenesis, which, when coupled with elevated G-6-Pase levels and decreased GK activity (and decreased glycolysis), result in net carbon flux toward glucose and its export from the hepatocyte. It therefore is not surprising that insulin reduces, and cAMP increases, G-6-Pase gene transcription (46), just as occurs with the PEPCK gene, which encodes another gluconeogenic enzyme. Insulin inhibits transcription of the G-6-Pase gene in the absence of other hormones and exerts a dominant inhibitory effect over the actions of cAMP and glucocorticoids (46). This effect of insulin requires the PI 3-kinase signal transduction pathway and appears to be exerted, at least in part, through the TGGT-GTTTTG DNA element used in the PEPCK gene promoter (46).

How is glucose flux through this cycle regulated and how is futile cycling avoided? Net glucose output occurs during active glycogenolysis and gluconeogenesis. The G-6-P generated by these processes is readily hydrolyzed because its concentration is still well below the K_m of G-6-Pase (34). Futile cycling by phosphorylation of glucose is prevented by several mechanisms. First, the glucose readily exits the hepatocyte through the GLUT2 transporter and is diluted in the ECF. Second, the interconversion of G-6-P and F-6-P allows GKRP to bind and sequester glucokinase in an inactive form. Finally, the hormonal conditions that promote glucose production through glycogenolysis and gluconeogenesis (high glucagon/low insulin) combine to inhibit subsequent steps in the glycolytic pathway that would divert G-6-P from its hydrolysis to glucose (see below). Net glucose uptake and utilization, as occurs after a glucose load is presented to the liver, requires that the rate of glucose phosphorylation exceeds that of G-6-P hydrolysis. High intracellular levels of glucose increase flux through glucokinase simply because of substrate availability. The hormonal changes consequent to a glucose load (high insulin/low glucagon) activate glycogen synthesis and the downstream glycolytic enzymes (see below). These processes "pull" G-6-P toward utilization. One consequence of reduced G-6-P levels is a reduction of F-6-P and reduced binding of glucokinase to the inhibitory GKRP and thus continued glucose phosphorylation. Therefore, a series of regulatory steps combine to effect net glucose utilization.

Regulation of the Fructose-6-phosphate/ Fructose-1,6-bisphosphate Cycle

G-6-P can be directed along several metabolic pathways; thus the conversion of F-6-P to F-1,6-P₂ is the first committed step in glycolysis, and PFK1 is the most important enzyme in this process. The entire array of intracellular symbols of energy charge and glucose homeostasis operate through a number of mechanisms to provide complex regulation of the F-6-P/ F-1,6-P₂ substrate cycle (2,9) (Fig. 15.4A), which is a major determinant of glycolytic/gluconeogenic flux in liver. One objective of this regulation is to stimulate glycolysis when the energy charge is low and to provide a carbon supply for biosynthetic processes. By contrast, gluconeogenesis is stimulated when signals of glucose deficiency predominate and the energy charge is high.

F-1,6-P₂ affects substrate cycling at the pyruvate/phosphoenolpyruvate substrate cycle by feedforward activation of pyruvate kinase (47). F-1-6-P2 levels are controlled by the activities of the gluconeogenic enzyme FBPase1 and by PFK1, the opposing glycolytic enzyme. The activity of these enzymes, and net flux through the F-6-P/F-1,6-P₂ cycle, are modulated by hormones that reflect the dietary status (48-51). For example, food deprivation results in the release of glucagon, which leads to the production of cAMP, an intracellular symbol of glucose deficiency. cAMP increases FBPase1 activity and gluconeogenesis, while inhibiting PFK1 activity and flux through glycolysis. By contrast, a glucose meal, with attendant insulin secretion and the consequent reduction of cAMP, results in the activation of PFK1 and the inhibition of FBPase1. This favors flux through glycolysis. Intracellular symbols of energy charge, AMP/ATP and citrate, are also involved in the regulation of these enzymes. High levels of ATP reduce the affinity of PFK1 for its substrate, F-6-P, by an allosteric mechanism (52) (see sigmoidal curve in Fig. 15.4B, left panel). Glycolysis also provides a carbon source for a variety of biosynthetic reactions. Citrate, as an early intermediate in the citric acid cycle, is a symbol of carbon sup-

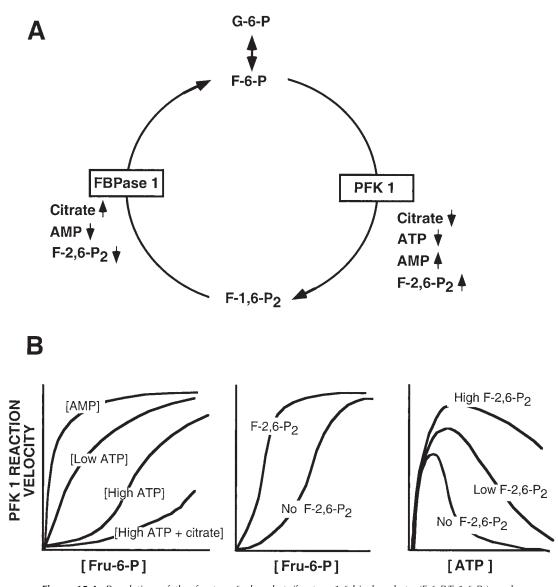

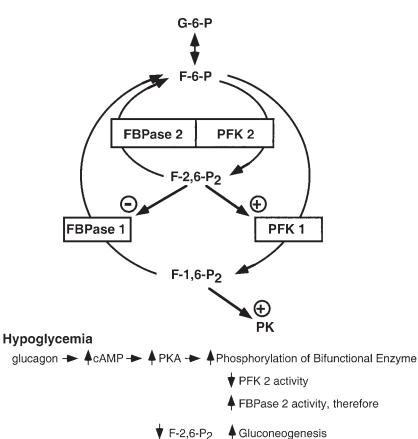

Figure 15.4. Regulation of the fructose-6-phosphate/fructose-1,6-bisphosphate (F-6-P/F-1,6-P₂) cycle. **A:** Glycolysis is stimulated when the energy charge of the cell is low, whereas gluconeogenesis is stimulated when glucose is deficient and the energy charge is high. **B:** Reaction velocities of phospho-fructokinase-1 (PFK 1) are influenced by molecular symbols of carbon supply and energy charge. G-6-P, glucose-6-phosphate; ATP, adenosine triphosphate; AMP, adenosine monophosphate; FBPase, fructose-1,6-bisphosphatase; F-2,6-P₂, fructose-2,6-bisphosphate.

ply. Citrate provides feedback control of the PFK1 reaction by enhancing the inhibitory effect of ATP. This puts an additional brake on glucose degradation when the carbon supply is sufficient. Citrate also causes a reciprocal activation of FBPase1. The net effect of this is decreased glycolytic and increased gluconeogenic flux. AMP, a symbol of a low energy charge, counteracts the effect of ATP on PFK1 and is an inhibitor of FBPase1 (Fig. 15.4B, left panel). Thus, PFK1 activity is high when the energy charge is low and low when the energy charge is high.

For some time it was not clear how these effectors interacted to regulate the enzymes that drive this substrate cycle. Both enzymes are substrates for cAMP-dependent protein kinase, and it was first thought that this was the mechanism whereby these activities were altered [see reference (2) for review]. However, *in vitro* phosphorylation by cAMP-dependent protein kinase (PKA) had little effect on the activity of these enzymes (52,53). Furthermore, the inhibition of PFK1 activity seen in crude extracts of hepatocytes incubated with glucagon disappeared on partial purification of the enzyme (54). It was subsequently shown that a low-molecular-weight effector, F-2,6-P₂, is involved in the regulation of both PFK1 and FBPase1 by cAMP (2,3,55,56).

The synthesis of F-2,6-P₂ involves the PFK2 reaction (F-6-P + ATP \rightarrow F-2,6-P₂ + ADP), whereas its degradation is catalyzed by a specific FBPase2 reaction (F-2,6-P₂ \rightarrow F-6-P + P) (Fig. 15.5). A unique bifunctional enzyme, PFK2/FBPase2, catalyzes both of these reactions (57). Phosphorylation of this enzyme by PKA on serine 32 results in inhibition of the kinase and activation of the bisphosphatase and thus in low levels of F-2,6-P₂. Dephosphorylation results in opposite changes of the enzyme activities and increased levels of F-2,6-P₂ (58). These changes explain the rapid modulation of F-2,6-P₂ that occurs when β-adrenergic agonists and glucagon (high cAMP) or insulin (low cAMP) are added to isolated hepatocytes (59,60).

Hyperglycemia

Glycolysis

Figure 15.5. Regulation of the fructose-6-phosphate/ fructose-2,6-bisphosphate (F-6-P/F-2,6-P₂) subcycle. F-2, 6-P₂ is a powerful allosteric regulator of both phosphofructokinase-1 (PFK 1) and FBPase 1 and so determines whether glycolysis or gluconeogenesis prevails. G-6-P, glucose-6-phosphate; FBPase 2/PFK 2, fructose-2,6bisphosphatase/phosphofructokinase-2 (the bifunctional enzyme); FBPase 1, fructose-1,6-bisphosphatase; PK, pyruvate kinase; cAMP, cyclic adenosine monophosphate; PKA, cAMP-dependent protein kinase.

F-2,6-P₂ increases the affinity of PFK1 for F-6-P (Fig. 15.4B, center panel) and thus is a potent activator of the enzyme. It is a competitive inhibitor of FBPase1 (2,9,12,55,56). Therefore, gluconeogenesis prevails when the glucagon/insulin ratio is elevated, as in starvation or diabetes, because cAMP levels are high and F-2,6-P₂ is low. The opposite situation occurs after refeeding or insulin administration. In this case, glycolysis, and the generation of three-carbon fragments for lipogenesis, prevails.

AMP and F-2,6-P₂, symbols of a low energy charge and hyperglycemia, respectively, interact synergistically to stimulate PFK1. In so doing, these agents override the inhibitory effects that citrate and ATP have on this enzyme. In a reciprocal action, AMP and F-2,6-P₂ inhibit the gluconeogenic enzyme FBPase1. The sensitivity of PFK1 to F-2,6-P₂ exceeds that of FBPase1. This partial inhibition allows for some cycling through the gluconeogenic part of this cycle, even in the fed state. This escape provides some relief from potential problems related to lactate accumulation (and acidosis) from excessive glycolysis (3). Other features of the regulation of this cycle are noteworthy. F-6-P, the substrate of the PFK2 reaction, is a noncompetitive inhibitor of the FBPase2 reaction (61). Conditions that favor the increase of F-6-P, such as a glucose load or glycogenolysis mediated by α -adrenergic agonists, vasopressin and angiotensin, none of which act through cAMP (62), promote the formation of F-2,6-P₂ and stimulate glycolysis. However, the cAMP effect is dominant over that of glucose. PKA-mediated phosphorylation of the bifunctional enzyme results in reduced concentrations of F-2,6-P₂ even in the presence of glucose (3).

This cycle is functionally entwined with the cycles that precede and follow it. As mentioned above, F-6-P is in near equilibrium with G-6-P. F-6-P promotes flux down the glycolytic pathway by serving as a substrate for the formation of the allosteric regulator F-2,6-P₂. It also enhances the net formation of this important molecule by inhibiting FBPase2, the enzyme that degrades it. F-2,6-P₂ stimulates PFK1, which converts F-6-P to F-1,6-P₂. This reduces the level of F-6-P, which results in the release of GK inhibition by GKRP and hence in an increase in glucose flux through phosphorylation. The other product of this cycle, $F-1,6-P_2$ causes feedforward activation of pyruvate kinase, a key component of the downstream substrate cycle.

The primary regulation of this substrate cycle involves alterations of enzyme activity. Long-term regulation, by changes in the rate of synthesis of these proteins, also occurs (35). cAMP inhibits expression of the PFK1 and bifunctional enzyme genes. Glucocorticoids enhance the level of bifunctional enzyme mRNA. Insulin has opposite effects on these genes, but this effect requires glucose and is probably due more to this than to insulin. This is discussed in detail below. Glucocorticoids are potent inducers of bifunctional enzyme gene expression. These hormones increase the rate of transcription of the gene in livers of adrenalectomized rats, in primary hepatocytes, and in FTO-2B hepatoma cells. Like glucocorticoids, insulin causes a 10- to 20-fold increase of bifunctional enzyme mRNA in hepatoma cells. These effects require glucose (see below) and are completely blocked by the concomitant addition of cAMP. FBPase1 gene expression is increased severalfold in diabetic animals, and insulin reduces this to the baseline value. cAMP, by contrast, is reported to increase FBPase1 mRNA in cultured hepatocytes. These effects on the FBPase1 gene have been difficult to replicate and extend. The primary regulation of this component of the cycle appears to be accomplished through regulation of enzyme activity.

Regulation of the Pyruvate/ Phosphoenolpyruvate Cycle

This cycle is regulated by the glycolytic enzyme PK and the gluconeogenic enzyme PEPCK (Fig. 15.6). The PK reaction plays a critical role in the regulation of glycolysis and thus is an important site of nutrient and hormonal regulation. Glucagon (cAMP) strongly inhibits flux through PK, whereas epinephrine, which primarily exerts α -adrenergic, cAMP-independent effects in liver, is not very effective (63,64). Insulin, by decreasing cAMP levels, relieves the inhibition of PK activity caused by glucagon and increases flux through this enzyme (64–66).

The liver isozyme of PK (L-PK) is an allosteric enzyme. It exhibits sigmoidal kinetics for its substrate, phosphoenolpyruvate, and is activated by F-1,6-P₂ by a feedforward mechanism. This promotes glycolytic flux. L-PK is inhibited through allosteric mechanisms by alanine and ATP. The inhibitory effect of glucagon (cAMP) on L-PK is explained by the observation that the enzyme is phosphorylated by PKA (67). Phosphorylation increases the apparent K_m of the enzyme for phosphoenolpyruvate, and the phosphorylated enzyme is more readily inhibited by alanine and ATP than is the nonphosphorylated enzyme (Fig. 15.6). There are many subtle interplays between these regulatory systems, but the important point is that the inhibition of PK allows for the accumulation of PEP and its routing through the gluconeogenic pathway. It also prevents excessive production of lactate. These events are important during starvation, when gluconeogenesis is essential. Thus, in metabolic conditions that favor gluconeogenesis over glycolysis, cAMP as a symbol of glucose deficiency, alanine as a symbol of carbon supply, and ATP as a symbol of energy sufficiency combine to shut down flux through PK.

The activity of PEPCK, in contrast to that of PK, is not significantly affected by allosteric or posttranslation modifications, such as phosphorylation. There is thus no short-term or acute regulation of PEPCK. Rather, all changes of PEPCK activity are due to changes in the amount of the enzyme present in the hepatocyte. This is primarily controlled by the amount of PEPCK mRNA. A variety of effectors, including glucocorticoids, cAMP, thyroid hormones, and retinoic acid stimulate transcription of the PEPCK gene (27,68). These agents enhance gluconeogenic flux by this mechanism. Insulin and glucose act independently to exert dominant inhibition of PEPCK gene transcription and of gluconeogenesis, even in the presence of the inducers (27,69). A great deal has been learned about how these various hormones and metabolic signals converge to regulate the transcription of this gene. This is discussed in more detail below. Several of these agents also have effects on the stability of PEPCK mRNA. Glucocorticoids and cAMP enhance the rate of transcription of the gene, and both stabilize the mRNA against degradation (22,23,27). These combined effects result in a net increase of the mRNA and enhanced rates of translation of the protein.

PK is also subject to transcriptional control by many of these same effectors, but in a direction opposite to that exerted on the PEPCK gene. L-PK mRNA, decreased in starved or diabetic rats, is restored to normal levels by the refeeding of a carbohydrate diet or insulin. Both effects involve an increased rate of L-PK gene transcription; however, the insulin effect is delayed (compared with the rapid effect on the PEPCK gene) and is indirect. Further studies showed that glucose, or more exactly a metabolite of glucose, is the direct effector (70,71). Insulin, by promoting glucose phosphorylation through stimulating GK, supplies this glucose metabolite and is thus acting indirectly (35,70,71). Glucagon, acting through cAMP, inhibits transcription

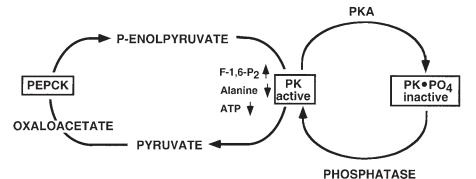

Figure 15.6. Regulation of the phosphoenolpyruvate (PEP)/pyruvate cycle. Pyruvate kinase (PK) is regulated by allostery, phosphorylation, and its biosynthesis, whereas phosphoenolpyruvate carboxykinase (PEPCK) is regulated primarily by control of its biosynthesis. F-1,6-P₂, fructose-1,6-bisphosphate; PKA, cAMP-dependent protein kinase; ATP, adenosine triphosphate.

PEP / PYRUVATE CYCLE

of the L-PK gene. The cAMP effect is dominant over the effects of insulin/glucose (72). As with PEPCK, but in reverse, cAMP increases the rate of degradation of L-PK mRNA, and insulin/glucose stabilizes this mRNA (72).

In summary, cAMP, which causes a potent inhibition of PK by phosphorylation, also reduces the amount of the enzyme in the hepatocyte. Insulin reverses this phosphorylation effect by reducing the cAMP concentration in the cell but also works with glucose to promote an increase in the amount of the enzyme. cAMP, with glucocorticoids and retinoic acid, increases the amount of the gluconeogenic enzyme PEPCK in hepatocytes. Insulin and glucose, which inhibit gluconeogenesis, do so in part by reducing the amount of PEPCK in the cell. Thus, there is a multilevel, reciprocal regulation of the activity and the amount of the enzymes that drive the phosphoenolpyruvate/pyruvate substrate cycle.

Regulation of Glycogen Metabolism

After a meal enriched with carbohydrates, glucose in excess of that needed for immediate consumption is stored as glycogen, which is used as the body's primary reservoir of glucose during fasting. The regulation of the synthesis of glycogen (glycogenesis) or the breakdown of glycogen into glucose (glycogenolysis) is critically important for glucose homeostasis. Glycogenesis and glycogenolysis are controlled by a set of enzymes that are subject to a broad range of regulatory mechanisms, including phosphorylation, substrate availability, protein-protein interactions, allostery, and subcellular localization. In the fed state, glucose and insulin promote glycogenesis, whereas glucagon and its second messenger, cAMP, promote glycogenolysis in the fasted state. A familiar theme is that these agents often have reciprocal effects; i.e., they promote flux through one pathway while inhibiting flux through the other [for reviews see references (14) and (73–75)]. Another recurring theme is that glucose,

or its metabolites, is a direct participant in the reactions that control its disposal into glycogen and its formation from glycogen.

The synthesis of glycogen in the liver begins with the influx of glucose through the GLUT2 transporter, whereupon it is phosphorylated to G-6-P by glucokinase (Fig. 15.7). G-6-P, converted to G-1-P by phosphoglucomutase, is then conjugated with uridine 5'-diphosphate by uridine diphosphate (UDP)– glucose pyrophosphorylase to form UDP-glucose. Two additional enzymes are required for glycogenesis: (a) glycogen synthase, which serially adds UDP-glucose subunits in a linear array through the formation of α -1,4-glycosidic bonds, and (b) branching enzyme, which causes a bifurcation of the growing glycogen chain through the formation of α -1,6-glycosidic bonds (14).

Glycogenolysis is mediated by the active form of the enzyme glycogen phosphorylase (phosphorylase a), which removes G-1-P residues from the glycogen polymer. G-1-P is converted to G-6-P by phosphoglucomutase and to glucose by G-6-ase (Fig. 15.7). Phosphorylase a is converted from the inactive form (phosphorylase b) by phosphorylase kinase, an enzyme that adds a phosphate group to serine 14 of phosphorylase b (14). Phosphorylase kinase, in turn, is activated by PKA (76). PKA is activated by an increase in the second messenger cAMP, which is an intracellular symbol of glucose deficiency, as described above. Thus, hypoglycemia results in the activation of phosphorylase a, which leads to the breakdown of glycogen and the production of glucose. This process is regulated by a phosphorylation cascade that amplifies the initial signal (glucagon) to promote a large biological response (glycogenolysis) (14,75) and by glucose (or G-6-P) itself.

Glycogenesis is regulated by glycogen synthase activity, whereas glycogenolysis is regulated by phosphorylase activity. The metabolic logic of the regulation of glycogen synthesis and degradation is evident in the observation that effectors that increase the activity of one enzyme decrease the activity

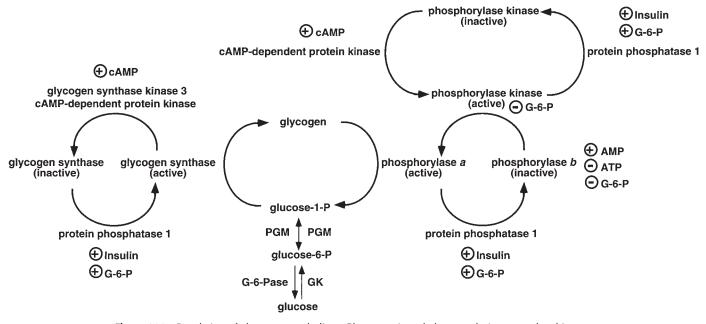

Figure 15.7. Regulation of glycogen metabolism. Glycogenesis and glycogenolysis are regulated in a reciprocal manner. Elevated cyclic adenosine monophosphate (cAMP) concentrations increase cAMPdependent protein kinase and glycogen synthase kinase 3 activity, leading to decreased glycogenesis and increased glycogenolysis, whereas increased insulin and glucose-6-phosphate (G-6-P) levels increase protein phosphatase 1 activity, leading to increased glycogenesis and decreased glycogen degradation. G-1-P, glucose-1-phosphate; G-6-Pase, glucose-6-phosphatase; GK, glucokinase; PGM, phosphoglucomutase.

The activity of glycogen synthase, like that of phosphorylase, is regulated by the phosphorylation of several serine residues. Fasting [high glucagon (cAMP) and low insulin] results in phosphorylation and enzyme inactivation. After a carbohydrate-enriched meal, the concerted actions of insulin and glucose increase glycogen synthase activity by promoting the removal of the inhibitory phosphate residues. Insulin increases the activity of protein phosphatase 1 (PP1), the phosphatase that removes the inhibitory phosphates (77). In addition, insulin decreases the activity of the kinases that promote phosphorylation and enzyme inhibition, specifically PKA and glycogen synthase kinase 3 (78). The first product of glucose metabolism, G-6-P, binds to glycogen synthase and causes a conformational change that makes the enzyme a better substrate for PP1 (73). In addition, G-6-P promotes the proper intracellular localization of glycogen synthase (see below).

Whereas insulin and G-6-P activate glycogen synthase, thereby promoting glycogenesis, these two effectors reciprocally inhibit the activity of phosphorylase a, the active form of the enzyme that is primarily responsible for glycogenolysis (Fig. 15.7). G-6-P binds to the active site of phosphorylase a, and this has two consequences: (i) it is a competitive inhibitor with glycogen for binding to the active site of the enzyme, and (ii) the binding of G-6-P causes a conformational change in phosphorylase a that makes it a better substrate for PP1, thereby facilitating the conversion of the enzyme to its inactive form (phosphorylase b). Owing to the high transport capacity of GLUT2, and the high K_m of glucokinase, the concentration of G-6-P inside hepatocytes is proportional to the plasma glucose level. Therefore, phosphorylase a acts as a sensor of plasma glucose levels; the higher the glucose concentration, the more G-6-P is able to bind to the active site of phosphorylase a and inhibit glycogenolysis (14). Phosphorylase a is also inactivated by dephosphorylation, which is mediated by the insulin-dependent activation of PP1. In addition, PP1 dephosphorylates and inactivates phosphorylase kinase (Fig. 15.7). Furthermore, insulin decreases the intracellular concentration of cAMP by activating phosphodiesterases, the enzymes that degrade this effector molecule (78). Thus, insulin disrupts the entire cAMP-dependent kinase signaling cascade that activates phosphorylase b, while simultaneously acting to dephosphorylate and activate glycogen synthase. G-6-P also acts reciprocally on both ratecontrolling enzymes, inactivating phosphorylase a and activating glycogen synthase, respectively (Fig. 15.7).

SPATIAL ORGANIZATION OF GLYCOGEN METABOLISM

The enzymes of glycogen metabolism exhibit a spatial organization that has profound effects on the regulation of glycogen synthesis and degradation. A family of proteins named glycogen targeting subunits (the liver-specific form is designated G_L) act as a scaffold for most of the enzymes involved in the regulation of glycogen metabolism. $G_{\mbox{\tiny L}}$ is distributed in a gradient within the hepatocyte (75). The highest concentration is found near the plasma membrane, and the lowest concentration is near the center of the cell. Glycogen particles have the same subcellular distribution (73). GL, which was originally studied as a subcellular targeting subunit of PP1, also has binding sites for glycogen, glycogen synthase, phosphorylase a, and phosphorylase kinase (75). Thus, all of the significant players in glycogen metabolism are localized on one scaffolding protein. This arrangement increases the local concentration of these enzymes and increases the efficiency of these sequential reactions. The differential localization of enzymes on G_L has other important regulatory implications. For example, the binding of phosphorylase a to G_L results in the allosteric inhibition of PP1, which results in reduced phosphorylation of glycogen synthase and thus in the activation of this enzyme. In addition, insulin and glucose promote the translocation of glycogen synthase from an intracellular site to the plasma membrane, presumably to G_L , although the mechanism of this translocation is not completely understood (75). Under some circumstances, the abundance of G_L is rate limiting for glycogen storage. Diabetic animals have decreased glycogen storage and decreased amounts of G_L . Glucose-intolerant animals injected with a recombinant adenovirus that expresses a G_L family member in the liver have increased hepatic glycogen content and normalized oral glucose tolerance (79).

In summary, glycogen metabolism is spatially restricted within hepatocytes and is controlled by a relatively small set of regulatory proteins. Glycogenesis is controlled by glycogen synthase, whose activity is increased by signals related to hyperglycemia and decreased by signals related to hypoglycemia. Glycogenolysis is controlled by glycogen phosphorylase, whose activity is increased by a phosphorylation cascade initiated by the fasting state and decreased by insulin during the fed state, which interferes with the former signaling cascade. G-6-P regulates its own abundance using a feedback control mechanism, inhibiting glycogenolysis by the repression of phosphorylase a activity and promoting glycogenesis by increasing glycogen synthase activity.

Regulation of Glucose Metabolism by Gene Transcription

Flux through metabolic pathways depends on the amount of critical enzymes present in the cell. An intricate set of mechanisms controls the rate of synthesis of the mRNAs that encode these enzymes. These control mechanisms are responsive to changes in the concentration of the hormones and effectors that provide overall metabolic control. As described above, hormones such as glucagon (acting through cAMP), glucocorticoids, retinoic acid, thyroid hormone, and insulin regulate the rate of transcription of genes that direct the synthesis of metabolic enzymes (Fig. 15.8). Glucose or, more likely, certain of its metabolic products are also directly involved in this process (see further on).

The paradigm that developed as a result of studies conducted about 25 years ago held that a ligand-receptor complex bound to a specific region of DNA in the promoter of target genes and that this interaction somehow resulted in a change in the frequency of transcription initiation. This valuable concept quickly led to the definition of specific, short DNA sequences that indeed could bind the ligand-receptor complex. This in turn led to the definition of discrete DNA sequences that could mediate the function of each hormone. These DNA sequences were called hormone response elements, or HREs. Often, but not always, this simple HRE could function in the context of a heterologous promoter/reporter system (Fig. 15.9A). It soon became apparent, however, that none of these hormone effectors employs an exclusive, or single, HRE that simply binds a ligand-hormone receptor complex to regulate transcription. It now appears that most, if not all, HREs function in necessary concert with accessory factors in the context of natural promoters. These multicomponent complexes include the receptor and accessory factor binding sites and are termed hormone response units (HRUs) or composite elements (80). Interestingly, some of the components of one HRU are components of another HRU and participate in the response to more than one

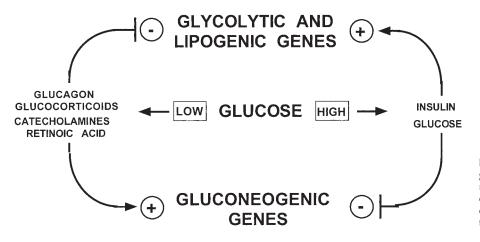

Figure 15.8. Regulation of glucose metabolism by gene transcription. An array of hormonal and nutritional signals regulate genes whose products catalyze reactions of glucose metabolism. The coordinated and reciprocal actions of these effectors contribute to glucose homeostasis.

hormone (81). In addition to this collection of protein-DNA interactions, a number of protein-protein interactions between the DNA-bound ligand-receptor and accessory factor complexes and one or more coregulatory proteins are required for the assembly of a functional transcription complex. This is illustrated schematically in Figure 15.9B.

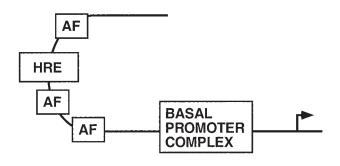

This concept is well illustrated by the arrangement of the PEPCK gene promoter. The PEPCK gene promoter is divided into several HRUs, including the following: a cAMP response unit (CRU) that is assembled in response to glucagon, which acts by the cAMP signaling pathway; a glucocorticoid response unit (GRU) that is assembled in response to glucocorticoids; a retinoic acid response unit (RARU); and an insulin response unit (IRU) (24,81–84) (Fig. 15.10). Whereas the CRU, GRU, and RARU mediate increased expression of the PEPCK gene, the IRU is necessary for dominant repression by insulin.

Whereas a simple HRE may provide an "off-or-on" control, an HRU provides a more flexible and versatile regulation of gene transcription and may allow for a more precise control of gene expression. The assembly of multiple HRUs has been called a metabolic control domain (MCD) (26,80,85,86). As discussed

A. CONTROL BY A SIMPLE HORMONE RESPONSE ELEMENT

B. CONTROL BY A HORMONE RESPONSE UNIT

above, different hormones recruit different sets of transcription factors and coactivators to the PEPCK gene promoter. Our current thinking is that this arrangement may explain the phenomena of additivity, synergism, and dominant repression observed in the presence of different combinations of hormones. The MCD may thus be an organizational structure that integrates the action of a variety of hormonal signals to provide a transcriptional response that is appropriate for a particular physiologic situation.

Although not as extensively characterized as the PEPCK MCD, several other genes that encode enzymes and proteins involved in metabolism appear to be regulated by a similar mechanism. Examples include the tyrosine aminotransferase, insulin-like growth factor binding protein-1 (IGFBP-1), G-6-Pase, PK, glucokinase, aldolase, and bifunctional enzyme genes (80).

Regulation of Hepatic Gene Expression by Glucose

An animal that ends a prolonged fast with a meal enriched in carbohydrates exhibits a characteristic pattern of gene expression

Figure 15.9. Hormonal regulation of gene transcription. The transcription of genes is regulated by either simple hormone response elements (**A**, HRE) or more commonly by hormone response units (**B**, HRU), which require the presence of additional DNA-binding proteins called accessory factors (AF).

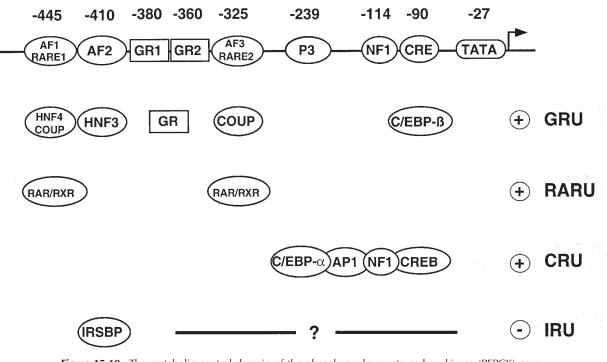

Figure 15.10. The metabolic control domain of the phosphoenolpyruvate carboxykinase (PEPCK) gene promoter. The metabolic control domain is composed of overlapping hormone response units. This arrangement allows for the integration of a variety of hormonal and environmental signals to provide an appropriate physiologic response. The numbers at the top of the figure represent the distance in base pairs from the transcription start site of individual elements characterized in the PEPCK promoter. The shaded portion contains the names of proteins that bind these elements and that are involved in the individual response units, shown on the right. GRU, glucocorticoid response unit; RARU, retinoic acid response unit; CRU, cAMP response unit; IRU, insulin response unit.

that contributes to the regulation of the plasma glucose level. These changes include an increase in the transcription of the genes that encode glycolytic and lipogenic enzymes and a decrease in the transcription of genes that encode gluconeogenic and ketogenic enzyme genes (87,88). Thus, hepatic glucose utilization is increased and glucose production is diminished, providing an impetus toward normal glucose levels. This programmatic change in gene expression, as discussed further on, requires the concerted actions of both insulin and glucose (Fig. 15.11).

Glucose exerts, through its metabolism, very strong effects on the transcription of genes that encode the enzymes that regulate its utilization and production. Because the glucose transporter, GLUT2, is not rate limiting in the liver, glucose clearance by hepatocytes is regulated primarily by the presence, abundance, and activity of glucokinase, as described above (5). Glucose flux through glucokinase acts as a sensor of the intrahepatic glucose concentration (5). Because glucokinase gene expression requires the presence of insulin and insulin decreases plasma glucose, it is very difficult to separate the effects of insulin and glucose in vivo. Cultures of isolated hepatocytes and hepatoma cells provide a system in which various environmental conditions can be carefully controlled. For example, in such systems insulin induces transcription of the glucokinase gene in the absence of glucose, but it has no effect on the PK gene (which appeared to be regulated by insulin in vivo). Reasoning that insulin induced glucokinase synthesis, and glucokinase initiated glucose metabolism, Kahn and coworkers tested whether glucokinase expression, in the absence of insulin, would stimulate PK gene transcription (89). Indeed, in

hepatocytes treated with either retrovirus or adenovirus constructs that express glucokinase, glucose can stimulate transcription of the PK gene and repress the PEPCK gene in the absence of insulin (69,89).

How does glucose metabolism alter gene transcription? G-6-P, the product of the glucokinase reaction, can be directed through a number of metabolic pathways, including glycolytic, glycogenic, the hexose monophosphate shunt, or the glucosamine pathways (Fig. 15.12). In principle, any of these pathways could generate a metabolite that could act as a second messenger of glucose flux and therefore influence the transcription of genes encoding the enzymes of glucose utilization and production. Two candidate signaling metabolites, G-6-P and xylulose-5-P (xyl-5-P), have been identified. G-6-P is considered a candidate because its concentration rises and falls in a time course that precedes the comparable changes of mRNA levels of genes that are regulated by glucose (90). Xyl-5-P, a metabolite of the hexose monophosphate shunt, is also a candidate. Hepatocytes treated with xylitol, which is rapidly converted to xyl-5-P, show the same pattern of gene expression as cells treated with glucose (91). Furthermore, the xylitol effect occurs at very low concentrations, as would be expected for a signaling metabolite. What is particularly intriguing about the possibility of xyl-5-P as a signaling metabolite is that this molecule is known to stimulate the activity of protein phosphatase 2A (PP2A), which dephosphorylates PFK2, thereby increasing F-2,6-P2 levels and increasing the activity of PFK1 and flux through glycolysis (92). In addition, as described below, the activation of PP2A increases the nuclear localization of a transcription factor that is involved in the stimulation of glucose-responsive genes (93).

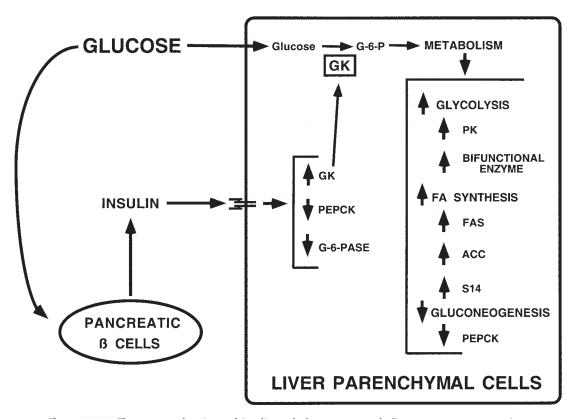

Figure 15.11. The concerted actions of insulin and glucose on metabolic enzyme gene expression. Insulin increases the expression of glucokinase (GK), allowing glucose signaling metabolites to alter the expression of metabolic genes in a coordinated fashion. G-6-P, glucose-6-phosphate; PEPCK, phosphoenolpyruvate carboxykinase; G-6-Pase, glucose-6-phosphatase; PK, pyruvate kinase; FA, fatty acid; FAS, fatty acid synthase; ACC, acetyl-CoA carboxylase; S14, spot 14 protein.

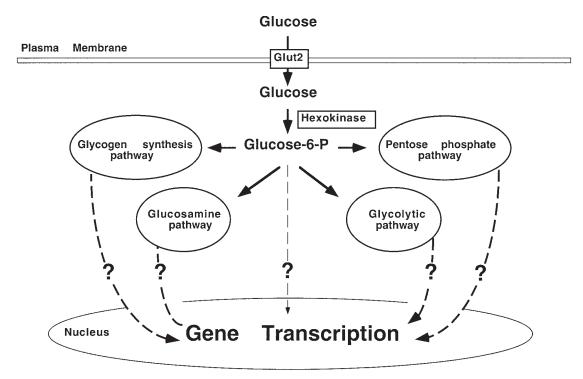

Figure 15.12. The metabolism of glucose provides a metabolic signal that alters gene transcription. The glucose signaling metabolite may be glucose-6-phoshate (G-6-P) or may originate from any metabolic pathway through which G-6-P is directed.

The glucose or carbohydrate response elements (ChoREs) of two genes, spot 14 (S14) and PK, have been studied in great detail. The function of the protein encoded by the S14 gene is incompletely understood, but it probably regulates lipid biosynthesis, a pathway that depends on the three-carbon molecules derived from glycolysis. The ChoREs of the PK and S14 genes are very similar; they each consist of two E-boxes separated by five base pairs (94). An E-box is a DNA element that binds to transcription factors having a basic helix-loop-helix (bHLH) DNA binding motif. Indeed, many bHLH transcription factors bind to the ChoREs, but it has been difficult to assign particular factors to the regulation of the glucose response. For example, upstream stimulating factor (USF) binds quite well to both the S14 and PK ChoREs in vitro (95,96). However, these elements can be mutated so that USF no longer binds but the element still conveys a glucose response (95). This observation made it clear that other factors are involved in the glucose response.

A transcription factor, termed the carbohydrate response element binding protein (ChREBP), has many of the characteristics expected of a protein that mediates the glucose response. ChREBP, isolated from the livers of fed animals, binds to the PK gene ChoRE more abundantly than when it is isolated from the livers of fasted animals. Furthermore, its binding activity is regulated by phosphorylation. ChREBP, when phosphorylated, is localized in the cytoplasm and is unable to bind DNA. Moreover, it is phosphorylated by PKA. Thus, when cAMP levels are high, as during a fast, ChREBP is prevented from activating the PK gene; the phosphorylation of one amino acid prevents nuclear localization, and the other restricts DNA binding (93). The termination of a fast with a meal enriched in carbohydrates results in increased glucose flux through glycolysis and the hexose monophosphate shunt, which activates PP2A, perhaps by increasing xyl-5-P. This results in the dephosphorylation and nuclear translocation of ChREBP, allowing this transcription factor to bind to the ChoREs of target genes. ChREBP is also regulated by fatty acids. Polyunsaturated fatty acids (PUFA) inhibit the effect glucose has on gene transcription. ChREBP is also phosphorylated by AMP kinase, an enzyme whose activity increases as the AMP/ATP ratio rises. Ingestion of PUFA increases AMP levels about 30-fold without changing ATP levels, and this increases AMP kinase activity about twofold. AMP levels rise as a consequence of fatty acid activation, a reaction that is required for fatty acid oxidation. The phosphorylation of ChREBP by AMP kinase, on an amino acid residue distinct from the PKA sites, prevents the factor from binding to DNA (97). Thus, ChREBP can be viewed as a nutrient sensor, balancing the requirements for glycolysis and lipogenesis by monitoring whether the available exogenous metabolic fuel is carbohydrate or fat.

However, this is not the complete story of glucose-regulated gene expression. It was noted above that glucose per se stimulates the coordinated expression of many glycolytic and lipogenic genes and represses the PEPCK gene in the absence of insulin, provided that glucokinase is present. However, the magnitude of the response of the PK, fatty acid synthase, and other genes is not as great with glucose alone as it is when both insulin and glucose are present, even with abundant glucokinase. Therefore, glucose and insulin may act together to elicit the carbohydrate response. Thus, for example, insulin is required for glucokinase activity (44). A transcription factor, sterol regulatory element binding protein-1c (SREBP-1c), is stimulated by insulin and can mimic the insulin-mediated induction of glucokinase in some systems (98). SREBP-1c overexpression in transgenic animals results in a pattern of expression of glycolytic and lipogenic enzymes consistent with the fed state-even when the mice are fasted. Furthermore, the

carbohydrate response is reduced, but not completely blocked, in animals lacking SREBP-1c (99,100). A recent series of experiments led to a possible explanation of these observations. The fatty acid synthase gene promoter has two distinct DNA elements that are involved in the glucose/insulin response. One is a ChoRE and one is an SREBP binding site. The ChoRE binds to a ChREBP (or closely related transcription factor), and the SREBP binding site binds to SREBP-1c. If either site is mutated in the fatty acid synthase (FAS) gene promoter, only a very weak response to glucose remains. However, the binding of both factors, in the presence of insulin, allows a strong synergistic response to glucose—one that essentially matches the physiologic response (101). Thus, glucose and insulin act together to coordinately regulate enzymes involved in glucose and lipid homeostasis.

INTEGRATION AND VALIDATION OF THESE CONCEPTS BY CURRENT TECHNIQUES

The analysis of metabolic control has benefited greatly from experimental approaches developed in recent years. One can now perturb a cell by transfection of the corresponding cDNA to increase a specific mRNA or by the use of antisense or interfering RNA to decrease a specific mRNA. The consequent increase or reduction of the cognate protein allows one to test for the role of a specific enzyme in a particular metabolic process.

Another technique available for studies of the regulation of glucose metabolism is the use of nonreplicative recombinant adenoviruses. These viruses are constructed with vectors wherein an essential gene for the lytic cycle (E1A) is replaced with cDNAs that express genes of interest, such as metabolic enzyme genes. When driven by a strong promoter like the cytomegalovirus promoter, very high levels of expression can be achieved. Ade-noviruses have the advantage of being highly infectious, with 70% to 100% of cultured cells positive for gene transfer. In addition, they have a wide host range, so that most cultured cells are transduced by adenoviruses very effectively. Furthermore, recombinant adenoviruses, unlike retroviruses, efficiently transfer genes to terminally differentiated primary cells because they do not require cell division for infection and subsequent gene expression (102).

It is also possible to manipulate the amount of specific gene products in the context of an intact animal. The expression of a particular protein can be enhanced by the pronuclear injection of a construct that consists of a promoter and a selected cDNA that has appropriate initiation and termination signals. If one employs a promoter from a gene that is ubiquitously expressed (e.g., the SV40 promoter), the protein will be expressed in all tissues. Tissue-specific expression can be achieved by using a promoter from a gene that is restricted to the tissue of interest (e.g., albumin for liver, myosin for muscle). Certain limitations to these experiments are imposed by the fact that copy number and insertion site cannot be controlled in these transgenic experiments.

Another powerful technique involves the so-called geneknockout approach. Constructs are made in which a system known as Cre-loxP provides for the deletion of a DNA segment and subsequent genetic recombination. If an essential portion of the coding region of a gene is targeted by the Cre-loxP, the protein will be rendered functionless. Knockout mice are generated by introducing Cre recombinase sites (or loxP sites) on both sides of the gene to be removed, or knocked out, in embryonic stem cells. The embryonic stem cells are then introduced into blastocysts, which are placed into the uterus of pseudopregnant mice. The offspring and subsequent generations become transgenic mice containing loxP sites on either side of the gene to be knocked out. These mice can then be crossed with a transgenic strain that expresses the Cre recombinase, either in all cells or in specific tissues if the expression of Cre is driven by a tissue-specific promoter (103).

These approaches have been used to confirm ideas of how hepatic glucose metabolism is accomplished, to define alternative metabolic pathways, to illustrate new regulatory principles, and to explore how certain pathways might be involved in diabetes mellitus. A few vignettes, which summarize much larger stories, are used to illustrate these points.

1. *The role of PEPCK in gluconeogenesis.* The conversion of oxaloacetate to phosphoenolpyruvate, catalyzed by the enzyme PEPCK, is an important early step in gluconeogenesis. PEPCK is the most highly regulated of the gluconeogenic enzymes, which underscores the importance of this step (68). Unrestrained glucose production from gluconeogenesis is an important pathophysiologic feature in type 2 diabetes (104); hence abnormal regulation of PEPCK, particularly faulty suppression of the transcription of this gene by insulin, has been implicated in this disease. Bosch and colleagues generated transgenic mice in which excessive amounts of PEPCK mRNA were produced in the liver (105). These mice had hyperglycemia, abnormal responses to a glucose load, and a metabolic picture similar to that of type 2 diabetes.

The treatment of fasted animals with 3-mercaptopicolinic acid, an inhibitor of PEPCK, causes hypoglycemia (106). Treatment of neonatal mice with this compound, when emerging gluconeogenesis is critical for glucose homeostasis, is lethal. PEPCK is thus an important gluconeogenic enzyme. However, it does not control the only route to gluconeogenesis. The cytosolic PEPCK gene was knocked out by the Cre-loxP method. Animals in which the gene was knocked out in all tissues died in the neonatal period, as did animals given 3-mercaptopicolinic acid (107). A different result was obtained when the gene was selectively eliminated in liver. These mice are viable and can maintain euglycemia even after a 24-hour fast (107). They thus have managed to maintain gluconeogenesis (perhaps from an alternative hepatic route or from kidney or small intestine) and thereby avoid the disastrous CNS consequences of hypoglycemia. There is a metabolic cost to the use of an alternative route that does not involve hepatic PEPCK, as these mice have steatosis, a fatty liver. Thus, these studies show that there are important alternative routes to gluconeogenesis, that the route through PEPCK is preferred, and that the unrestrained expression of PEPCK can result in the altered glucose homeostasis similar to that seen in type 2 diabetes.

2. The role of glucokinase in hepatic glucose clearance and glycogen synthesis. The effects of overexpression of a particular metabolic enzyme on the regulation of glucose metabolism have been studied using recombinant adenoviruses. An example is provided by the overexpression of glucokinase or HK-I in freshly isolated rat hepatocytes. Hepatocytes express two different hexokinases, glucokinase and HK-I. Glucokinase provides about 75% of the glucose-phosphorylating capacity of the cell, and the remainder is provided by HK-I (108). Recall that the low K_m HK-I is maximally active at fasting levels of glucose and is inhibited by physiologic concentrations of its reaction product, G-6-P. In contrast, glucokinase has a *K*^m for glucose of about 8 mM, well within the physiologic range (~4-12 mM), so that glucokinase activity increases with increasing concentrations of glucose (5), and glucokinase is not inhibited

by physiologic concentrations of G-6-P. Primary hepatocytes were transduced with recombinant adenoviruses that express either glucokinase or HK-I at titers that provided an equivalent glucose-phosphorylating capacity to investigate the role these hexokinases play in the regulation of glycolysis and glycogen synthesis (108). As expected, overexpression of glucokinase dramatically increases both glucose flux through glycolysis and glycogen synthesis when cells are incubated in glucose at concentrations of 5 mM or greater. The increase in glycolytic flux is linear with respect to glucose concentration, whereas the increase in glycogen synthesis is sigmoidal, with the greatest increase occurring between 5 and 10 mM. Thus a threshold of G-6-P abundance must be reached before glycogen synthesis begins (108). In stark contrast, HK-I overexpression increased glucose flux through glycolysis (particularly at low glucose levels; at high glucose levels it is inhibited by G-6-P) but had no effect on glycogen synthesis. These results were observed despite the fact that, at 5-mM glucose, the concentration of intracellular G-6-P was identical when either glucokinase or HK-I was overexpressed (108).

How is it that G-6-P produced from HK-I has different metabolic effects than G-6-P produced from glucokinase? One possible explanation lies in the different cellular compartments in which glucokinase and HK-I reside. HK-I is partitioned into two compartments. It is bound to the mitochondria, where the high local concentrations of ATP increase its activity, and it is diffusely distributed throughout the cytoplasm. The overexpression of HK-I does not alter the relative distribution of HK-I in the cell (108). By contrast, glucokinase is localized in the nucleus, bound to the GKRP, until glucose concentrations rise above 5 mM, at which time it migrates into the cytoplasmic compartment (109). Glycogen is synthesized in the cytoplasm, and the major regulatory enzymes, including glycogen synthase, are bound to the scaffolding protein, GL (75). Glycogen synthase is activated by G-6-P. Thus, by virtue of its strategic cellular translocation, glucokinase produces G-6-P that is more efficiently funneled into glycogen than the relatively distantly located HK-I.

In another experiment, a transgenic mouse strain with the glucokinase gene flanked by loxP sites (GKlox/lox) was crossed with a transgenic strain with the liver-specific albumin promoter driving the expression of cre recombinase (Alb-cre). The result was a liver-specific glucokinase knockout transgenic mouse ($GK^{lox/lox} + Alb$ -cre), providing a model to study the metabolic perturbations caused by a lack of hepatic glucokinase in the whole animal (110). These animals appear to be normal, having only a slightly elevated plasma glucose level. However, when the animals were fasted or fed or infused with an appropriate amount of glucose to reach a predetermined hyperglycemic concentration (an experimentally induced glucose clamp), a number of metabolic effects were noted. Fasting $GK^{lox/lox}$ + Alb-cre mice have a 40% higher plasma glucose concentration than controls, and fed animals have twofold higher plasma insulin levels, suggesting the animals are insulin resistant. Under a hyperglycemic clamp, these animals showed a 90% reduction in the ability to synthesize glycogen, and several glucose-responsive genes were inappropriately regulated. In addition, the GK^{lox/lox} + Alb-cre mice secreted 70% less insulin in response to the hyperglycemic clamp. These studies demonstrated that glucokinase plays an important role in glucose homeostasis by virtue of its requirement for glucose uptake and utilization in the liver and by indirect effects on pancreatic insulin secretion (110)

3. The role of F-2,6- P_2 in the regulation of glucose metabolism. Another study that used recombinant adenoviruses to test specific questions about glucose metabolism in the liver was performed using a double mutant of the bifunctional enzyme that ensures high kinase activity and low phosphatase activity (111). Recall that the bifunctional enzyme produces the allosteric effector, F-2,6-P2, which activates PFK1 and inhibits FBPase1 (58). Lange and colleagues constructed a mutant of the bifunctional enzyme (Bif-DM) that contains an alanine substitution of serine 32, which prevents the phosphorylation and inactivation of the enzyme by cAMP (111). In addition, the Bif-DM has an alanine that replaces histidine 258, which decreases the phosphatase activity of the enzyme. This combination of mutations results in a very high kinase-to-phosphatase activity ratio, and its expression increases the abundance of F-2,6-P2. The Bif-DM was introduced into recombinant adenoviruses, which were infused into the livers of normal mice or mice that had been treated with streptozotocin to destroy pancreatic β -cells, a model of type 1 diabetes. Overexpression of the Bif-DM in streptozotocin-treated diabetic mice resulted in near-normal plasma blood glucose, lactate, free fatty acid, and triglyceride levels and increased hepatic glycogen stores relative to levels in diabetic controls (111). These results are consistent with the idea that $F-2,6-P_2$ increases flux through glycolysis and glycogen synthesis and decreases flux through gluconeogenesis. The above study was essentially repeated in kk mice, animals that are a model of type 2 diabetes (112). In the latter studies, diabetic kk mice treated with the Bif-DM adenovirus had near-normal blood glucose levels along with a gene expression pattern of glycolytic, lipogenic, and gluconeogenic genes that reflects a fed rather than a diabetic state (112). These experiments demonstrate that F-2,6-P₂ is a powerful regulator of glucose metabolism in vivo.

CONCLUSION

The definition of the metabolic pathways and of the intricate mechanisms by which flux through these pathways is regulated represents one of the most important achievements of 20th century biological science. This understanding underpins the explanation of the metabolic consequences of hundreds of monogenic diseases. More complex genetic (and environmental) diseases, such as diabetes mellitus, will ultimately be understood on this basis as well. Although much has been learned, it is apparent that important control mechanisms are still being discovered and that known mechanisms are being refined and expanded upon.

The examples discussed in this chapter point to the fact that glucose is an important regulator of its own production, storage, and metabolism in the liver. A further understanding of this process will no doubt help reveal secrets about the role this organ plays in diabetes mellitus.

TYPE 2 DIABETES AND BODY FAT DISTRIBUTION 269

TYPE 2 DIABETES AND METABOLISM OF VERY-LOW-DENSITY LIPOPROTEIN TRIGLYCERIDES 271

CONCLUDING COMMENTS 271

The pathophysiology of diabetes mellitus involves impairments in insulin secretion and insulin action. Whereas type 1 diabetes results from extreme impairment or absence of insulin secretion, an important causal factor in type 2 diabetes is resistance to insulin action, with impairment in insulin secretion progressing as the disease continues. In both type 1 and type 2 diabetes, major changes in fatty acid metabolism are concomitant with alterations in carbohydrate metabolism. As will be discussed, perturbations in the release of free fatty acids (FFAs) by adipose tissue result in an increase in plasma concentrations of FFAs. Abnormally high concentrations of FFAs can lead to defects in insulin action. In addition, recent evidence suggests high plasma concentrations of FFAs can affect the secretory capacity of pancreatic β -cells.

OVERVIEW OF FATTY ACID METABOLISM

In the postabsorptive state, muscle, heart, liver, and renal cortex use fatty acids as their primary fuel (1). In humans, in contrast to rodents, there is very little *de novo* synthesis of fatty acids (2), either in adipose tissue or in the liver. Hence, the proximate source of fatty acids in humans is dietary, with the fatty acids generally stored in adipose tissue or oxidized (3).

In the postprandial absorptive state, dietary fatty acids are packaged in the intestinal mucosa as chylomicrons and transported by the lymphatic system to the circulation. These triglyceride-rich particles are cleared rapidly under normal circumstances, with the majority of the lipid content stored in adipose tissue (3). The cholesterol-rich chylomicron remnant particles are cleared by the liver by binding to specific receptors (low-density lipoprotein receptor–related protein) on hepatocytes. Plasma FFAs derive almost exclusively from lipolysis of adipose tissue triglycerides by hormone-sensitive lipase (HSL), which is so named because of its responsiveness to insulin and catecholamines. The one apparent exception is following the ingestion of a mixed meal, when some plasma FFAs arise from the rapid hydrolysis of plasma chylomicron triglycerides by lipoprotein lipase (LPL), an enzyme that acts primarily to allow tissue uptake of circulating triglycerides (4). In the postabsorptive state, lipolysis by adipose tissue HSL is likely the overwhelming, if not the only, source of FFAs (5).

The hydrolysis of circulating lipoprotein triglyceride is mediated by LPL at the capillary lumen (6). LPL activity is greatest in adipose tissue, where its regulation is reciprocal to that of HSL. During the postabsorptive state, HSL is activated, whereas LPL is inhibited; in the absorptive state, HSL is inhibited and LPL is activated. The regulation of LPL activity also is tissue specific, with LPL activity in adipose tissue stimulated by insulin, whereas LPL activity in skeletal muscle is unaffected by insulin (7,8).

After their release from adipose tissue, circulating FFAs are bound to albumin, which is a very effective solubilizer. FFAs are rapidly removed from the circulation by various tissues, with a half-life of less than 4 minutes (5), and they supply 25% to 50% of energy requirements postabsorptively in adults. FFAs not utilized for oxidative needs are reesterified, probably to a large extent in the liver, and exported as very-low-density lipoprotein (VLDL) triglyceride. The VLDL triglyceride is then re-stored primarily in adipose tissue. FFAs can thus be released in excess of energy needs without disastrous consequences because the cycle of FFA to VLDL triglyceride back to adipose tissue triglyceride is relatively efficient under most circumstances.

Plasma concentrations of FFAs reflect the balance between their release and uptake, but this relationship is not linear over the physiologic range (9,10). At low flux rates, a disproportionate decrease in plasma concentrations of FFAs occurs, whereas at very high flux rates, plasma levels of FFAs may increase to a greater degree than would be predicted if the relationship between flux and concentrations were linear. Basal FFA flux typically exceeds the fatty acid oxidation rate (measured by indirect calorimetry) by 50% to 100%; the excess FFAs are thought to be reesterified into triglycerides in the liver (11) and muscle (12–15). FFA clearance increases dramatically with exercise, such that at the onset of exercise plasma concentrations of FFAs may decrease even while rates of FFA release are increasing. Thus, although FFA concentrations are a reasonable indicator of FFA release, it is not possible to use concentration values to make quantitative estimates of release rates, and in some circumstances FFA concentrations can be misleading with respect to changes in lipolysis.

Many hormones regulate lipolysis in adipose tissue, thereby influencing the rate of FFA release. Given the profound disturbance of fat metabolism in diabetes mellitus and the fact that insulin administration to a large extent reverses the abnormalities, it is important to understand the role of insulin in the regulation of adipose tissue metabolism. Insulin is the major regulator of adipose tissue lipolysis through its inhibition of the activity of HSL, thereby reducing the release of FFAs and glycerol. Lipolysis is normally exquisitely sensitive to suppression by insulin, with a half-maximal effect occurring at concentrations of approximately 12 pmol/L. To put this in perspective, fasting concentrations of insulin typically may vary from approximately 6 to 60 pmol/L (16). Adipose tissue is much more sensitive than many other tissues to insulin in this regard. Lipolysis is more sensitive than glucose uptake and metabolism to changes in insulin concentrations (11,16). In addition to insulin, other important endogenous inhibitors of lipolysis include ketone bodies (which also stimulate insulin secretion), adenosine, and FFAs themselves (17-20).

Several hormones accelerate the release of FFAs from adipose tissue and therefore raise plasma concentrations of FFAs. Catecholamines (epinephrine and norepinephrine) are the most important stimulators of lipolysis, although growth hormone (GH) and, to a lesser degree, cortisol, also increase the release of FFAs. Catecholamines stimulate the activity of adenyl cyclase through their β -adrenergic effect, hence increasing the tissue availability of cyclic adenosine monophosphate (cAMP), which in turn stimulates the activity of HSL (2). Catecholamines reach adipose tissue through the circulation or via adrenergic nerve terminals, and the relative importance of their local neural versus systemic origin has not been fully established.

In contrast, glucocorticoids promote lipolysis via synthesis of new HSL protein through a cAMP-independent pathway (2). Cortisol may be an important promoter of lipolysis only in conditions of relative insulin deficiency and marked cortisol elevations, as in uncontrolled diabetes or stress states (21-24). This conclusion is based on experimental observations that cortisol does not stimulate lipolysis during cortisol infusion unless compensatory hyperinsulinemia is prevented by a pancreatic somatostatin clamp (21). There is evidence that the effect of GH on lipolysis depends on the synthesis of proteins involved in the formation of cAMP (2,22,25,26). However, the creation of acute GH deficiency results in a lower availability of FFAs within several hours (27), and pulsatile delivery of GH results in enhanced lipolysis within 60 to 90 minutes. These observations suggest that GH may have some direct stimulatory effects on lipolysis in vivo. Other weaker stimulators of lipolysis include thyroxine, tumor necrosis factor- α (TNF- α), and prostaglandin I₂ (28–30). Insulin antagonizes the effects of these lipolytic hormones. The antilipolytic effects of insulin and drugs such as nicotinic acid are accounted for by inhibition of adenyl cyclase activity (2).

ASSESSMENT OF FATTY ACID METABOLISM

Both *in vitro* and *in vivo* approaches have been used to study fatty acid metabolism. The *in vitro* approach permits the investigator to control a maximum number of variables during studies of lipolytic regulation. However, *in vivo* studies allow a more physiologic assessment and an understanding of the metabolic processes in the context of the whole organism.

In vivo methods for studying systemic lipolysis (10,31,32) include isotope-dilution techniques, selective catheterization of adipose tissue venous drainage, and adipose tissue microdialysis. Regional lipolytic rates can be measured with the arteriove-nous catheterization (33–35) or microdialysis techniques (34). The combination of arteriovenous catheterization and isotope-dilution techniques allows investigators to collect information regarding regional fatty acid kinetics (uptake and release). This approach is perhaps one of the most useful techniques for gaining an understanding of regional FFA metabolism *in vivo*.

Systemic appearance and disappearance of FFAs can be accurately measured with isotope-dilution techniques under both steady-state and non-steady-state conditions. An intravenous tracer infusion coupled with arterialized venous or arterial blood sampling provides data that mirror the physiology of the release by adipocytes of FFAs into the venous circulation for delivery to tissues via the arterial circulation. Under conditions of stable FFA concentrations and flux (steady state), the rate of FFA appearance equals its rate of disappearance. FFA flux is calculated using the ratio of tracer infusion rate and the specific activity or enrichment of the tracer in plasma FFAs (32).

The choice of isotopic tracers is important in the assessment of FFA kinetics. Although there are slight regional differences in the metabolism of different fatty acids (36), the kinetics of the long-chain fatty acids are sufficiently similar to consider the rate of appearance of a single fatty acid such as palmitate or oleate representative of FFA turnover in humans. Differences in the kinetics of linoleate and stearate (the other major long-chain fatty acids) compared with the kinetics of FFAs as a whole are such that tracers of these FFAs are not used to measure FFA flux (36,37). Both stable isotopic tracers (¹³C or ²H) and radioactive tracers (¹⁴C or ³H) are used. The main disadvantage of ¹⁴C or ³H tracers relates to radiation exposure. They are unacceptable for use in pregnant women and in children, and some institutions and governments place severe restrictions on the administration of radioisotopes to humans for research purposes. The use of stable isotopic tracers of FFAs provides the advantage of avoiding radiation exposure; however, relatively large amounts of tracer (requiring substantial amounts of albumin) are needed for standard gas chromatography and mass spectroscopy analysis. Recent advances in stable isotope approaches appear to have overcome some of these limitations (38).

Isotopic tracers of glycerol have been used to measure systemic lipolysis. The rate of appearance of glycerol is considered to reflect whole-body adipose tissue lipolysis, because adipose tissue does not contain glycerol kinase, the enzyme needed for reuse of glycerol for esterification of fatty acids (39–44). Recent studies of glycerol metabolism have suggested that this assumption is unlikely to be rigorously correct (45); thus, the rate of glycerol appearance is not a totally reliable measure of total adipose-tissue lipolysis in humans.

Regional FFA kinetics can be estimated with arteriovenous catheterization techniques combined with isotopic-tracer approaches and measurement of plasma flow (46), as well as by microdialysis techniques (47–51). Regional rates of FFA release can be related to regional fat content to assess the lipolytic rates of different adipose tissue beds. Regional fat mass usually is assessed by imaging studies [computed tomography (CT) or

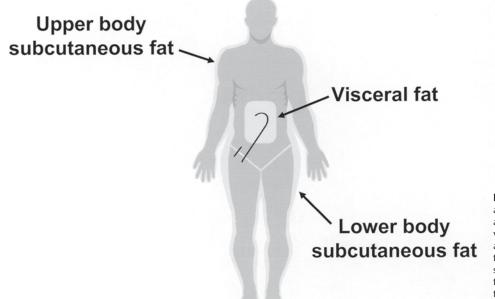

Figure 16.1. Approach to assessing regional adipose tissue release of free fatty acid (FFA) and regional uptake of FFA. A combination of vascular catheterization techniques (femoral artery, femoral vein, and hepatic vein catheters), FFA isotope-dilution studies, and measurement of regional plasma flow is used. Systemic release of FFAs can then be apportioned to leg, splanchnic, and nonsplanchnic upper body [total – (legs + splanchnic)] regions.

magnetic resonance imaging (MRI)] (52) and/or by dual-energy x-ray absorptiometry (53). For the most part, these approaches allow accurate measurement of systemic and regional (leg, splanchnic, and nonsplanchnic upper body) FFA kinetics. It should be noted that FFAs released into the portal circulation by omental and mesenteric adipose tissues are partially taken up by the liver before reaching the systemic circulation (5,15). Therefore, this portion of "hidden" or "unseen" visceral lipolysis cannot be accurately determined despite the use of tracer techniques and arteriovenous catheterization approaches. Nevertheless, it is possible to use the combination of regional catheterization and isotope-dilution techniques to determine the relative contribution of the splanchnic bed, leg, and nonsplanchnic upper-body adipose tissue to systemic lipolysis (Fig. 16.1).

Several agents have been used to manipulate FFA availability to determine the effects of FFA on tissue function. The agents most commonly used to lower plasma FFA concentrations are nicotinic acid (54) and acipimox (55–57). Etomoxir (57,58) (inhibits carnitine acyltransferase) has been used to inhibit FFA oxidation without lowering FFA concentrations. FFA plasma levels have been raised by intravenous infusion of a lipid emulsion to raise serum levels of triglycerides together with heparin to release LPL into the circulation (6,59), thereby generating FFA by the intravascular hydrolysis of triglycerides.

GLUCOSE-FATTY ACID INTERACTIONS

In 1963, Philip Randle and coworkers first described an interaction between glucose and fatty acid metabolism (60), which subsequently has been termed the *glucose-fatty acid cycle* or *Randle cycle*. Studying rat heart muscle and diaphragm, they observed that increasing fatty acid oxidation by these tissues impaired their oxidation of glucose. The mechanism they suggested involved increased mitochondrial ratios of [acetyl-CoA]/[CoA] and [NADH⁺]/[NAD] as a result of increased fatty acid oxidation. They proposed that these changes inhibit pyruvate dehydrogenase and thus limit the entry of pyruvate derived from glycolysis into the mitochondria for participation in the citric acid cycle. In addition, increased acetyl coenzyme (acetyl-CoA) derived from β -oxidation leads to accumulation of citrate that in turn inhibits phosphofructokinase, one of the key regulators of glycolysis. This results in the accumulation of intracellular glucose-6-phosphate, which further inhibits hexokinase II, the glucose-phosphorylating enzyme present in muscle (57,60). Reduced activity of hexokinase II serves to reduce glucose transport into the muscle cells. Subsequently, this metabolic cycle was extended to involve inhibition of nonoxidative glucose metabolism by inhibition of glycogen synthase by elevated FFA levels (61–63).

Recognition of the glucose-fatty acid cycle as observed in studies of laboratory rats brought appropriate attention to the interactions between FFAs and glucose. Much subsequent work has shown that equally important glucose-FFA interactions occur in humans but that these result from quite different regulatory mechanisms (64,65). Human studies failed to show either reduced activity of glycogen synthase and pyruvate dehydrogenase enzymes in skeletal muscle biopsies as a consequence of FFA elevation (induced by lipid emulsionheparin infusion) (66) or an elevation in citrate or carnitine palmitoyltransferase activity reflecting increased fatty acid oxidation (62). Intramuscular concentrations of glucose-6phosphate were not increased in response to FFA concentrations as high as 0.5 mM during hyperinsulinemia (61), suggesting reduced glucose transport/phosphorylation as an alternative primary cause of reduced glucose uptake. Concordant findings have been reported using nuclear MRI to study human skeletal muscle during a euglycemic hyperinsulinemic clamp in the presence of elevated FFA levels (64,65). Reductions in insulin-receptor substrate-1-associated phosphatidylinositol 3-kinase activity were found, which could lead to inhibition of glucose transport into the myocytes. In addition, it was shown that non-insulin-mediated glucose uptake was not reduced as a result of elevated FFA concentrations in nondiabetic humans, suggesting that the effect of fatty acids on glucose transport is mediated through the insulin-responsive glucose transport system (67).

In recent years, a reverse "glucose–fatty acid" cycle has been proposed (68,69), through which hyperglycemia in the presence of elevated FFA concentrations reduces fat oxidation. This could

result from a reduction in the entry of fatty acids into the mitochondria as a consequence of inhibition of carnitine acyltransferase activity (68), although increased reesterification of fatty acids in sensitive tissues represents another potential mechanism that has not been studied. In summary, although the glucose–fatty acid cycle involves a clear reciprocal relationship between glucose and fatty acid oxidation in muscle, the fundamental mechanism by which this occurs is likely different from that originally proposed on the basis of rat studies. Nevertheless, whatever the cellular mechanism of this vital metabolic cycle, elevated levels of FFAs impair the stimulation of glucose uptake by insulin in human skeletal muscle, and this represents a major site of altered glucose metabolism in individuals with type 2 diabetes.

Glucose uptake also occurs in the liver, especially during hyperglycemia. It is unclear whether the glucose–fatty acid cycle exists with respect to hepatic glucose uptake. *In vitro* studies of rat hepatocytes have shown a time- and dose-dependent reduction in activity of hepatic glucokinase with exposure to longchain fatty acids (70). Because glucokinase activity, not glucose transport, is thought to be the rate-limiting step in hepatic glucose uptake (71–73), the elevated level of FFAs in type 2 diabetes could reduce hepatic uptake of glucose. This, in turn, could contribute to reduced rates of hepatic glycogen synthesis and aggravate postprandial hyperglycemia in diabetes.

FREE FATTY ACIDS AND THE LIVER

Early studies demonstrated that FFAs can stimulate gluconeogenesis from lactate and alanine in the perfused rat liver (74,75), and evidence for the stimulation of gluconeogenesis by FFAs in vivo was obtained subsequently (76,77). The proposed mechanisms include generation of acetyl-CoA from FFAs, activation of pyruvate carboxylase, and inhibition of pyruvate dehydrogenase enzymes. FFA oxidation also generates the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and adenosine triphosphate (ATP). The former facilitates conversion of glycerol to glucose, and the latter favors the conversion of 1,3phosphoglycerate to glyceraldehyde 3-phosphate. Further support for this hypothesis came from studies that found increased activity of the Cori cycle (a surrogate marker of gluconeogenesis) without any change in endogenous glucose production in the postabsorptive state subsequent to a lipid emulsion-heparin infusion (78). A more recent study showed that elevation of FFAs increased the relative contribution of gluconeogenesis to endogenous glucose production in the postabsorptive state, as measured by the deuterated water technique, although the absolute rate of endogenous glucose production did not increase (79).

The "single-gateway hypothesis" has recently been proposed as a mechanism that attributes a central role for FFAs in the determination of insulin effects on carbohydrate metabolism (80). According to this model, insulin traverses the endothelial cell boundaries in skeletal muscle and adipose tissue to stimulate glucose uptake and inhibit lipolysis, respectively. The declining FFA level in turn reduces endogenous glucose production primarily by reducing levels of the substrates necessary for gluconeogenesis. Direct support for this hypothesis has been provided by a number of investigators (81), and a positive correlation (82,83) between FFA concentrations and endogenous glucose production has been reported (84). Furthermore, acipimox (an inhibitor of lipolysis) allowed normal insulin-mediated suppression of endogenous glucose production by insulin in type 2 diabetes (85), whereas maintenance of elevated FFA concentrations with lipid emulsion-heparin reversed the effect of acipimox (80).

Whatever the mechanism, it appears clear that elevated FFA concentrations result in higher rates of gluconeogenesis and impairment of insulin suppression of endogenous glucose production.

FREE FATTY ACIDS AND INSULIN KINETICS

Data from a prospective study have shown a predictive value of elevated FFA concentrations for the future development of type 2 diabetes in Pima Indians (86). However, this correlation was not significant after adjusting for acute insulin response, suggesting that the relationship may relate to the inhibitory effects of FFAs on insulin secretion and not solely to their effect on glucose disposal. Both *in vivo* and *in vitro* experiments have implicated elevations in FFA concentrations in altered insulin secretion and insulin kinetics.

In one study, the infusion of a lipid emulsion for 48 hours to elevate FFA levels in healthy subjects was shown to increase glucose-stimulated insulin secretion (determined by C-peptide deconvolution techniques) during a hyperglycemic clamp (87). The increase in insulin secretion was not accompanied by a change in insulin clearance. In contrast, another study demonstrated a reduced acute insulin response to an intravenous glucose tolerance test after increasing FFA concentration with a 24hour lipid-emulsion infusion, whereas a 6-hour lipid-emulsion infusion enhanced the acute insulin response to intravenous glucose (88). A third study showed greater glucose-stimulated insulin secretion during acute (90-minute) FFA elevation but unaltered glucose-stimulated insulin secretion after chronic (48hour) FFA elevation (89). During both acute and chronic FFA elevations, the insulin sensitivity index (SI) obtained by application of the minimal model to the intravenous glucose tolerance test was impaired. Estimation of the "disposition index" (the product of SI and insulin secretion rate) revealed that during acute FFA elevation, higher insulin secretion compensated for reduced SI and normalized the disposition index. In contrast, during chronic FFA elevation, insulin secretion failed to compensate for the reduced SI, thereby resulting in a reduced disposition index. The insulin clearance rate also was reduced during chronic FFA elevation.

The mechanism of FFA effects on insulin secretion has been investigated through both in vivo and in vitro animal experiments. In female Wistar rats exposed to prolonged (48 hours) high FFA concentrations, basal insulin and C-peptide concentrations were shown to increase, whereas glucose-stimulated insulin secretion during a two-step hyperglycemic clamp was substantially reduced (90). A study in prediabetic Zucker fatty rats demonstrated a rise in plasma FFA concentrations coincident with decreases in glucose-stimulated insulin secretion and the GLUT2 glucose transporter content of β -cells (91). Reversal of elevated FFA levels by pair feeding with lean littermates corrected all of the observed $\hat{\boldsymbol{\beta}}\text{-cell}$ abnormalities. In vitro studies of rat islets cultured for a week in medium containing 2 mM FFA demonstrated increased basal insulin secretion at 3 mM glucose, whereas the first-phase insulin response to glucose was reduced by 68%. Similar results were obtained in islets harvested from prediabetic animals (91). Others have reported that long-term (48-hour) exposure of rat islets to FFA (92) increased basal insulin secretion but resulted in a 30% to 50% decrease in proinsulin biosynthesis and insulin secretion induced by hyperglycemia. Results from other studies in rats have indicated that chronically elevated FFA levels reduce β-cell insulin content by increasing basal insulin secretion to an extent that is not compensated for by increased proinsulin biosynthesis (93). Levels of preproinsulin mRNA were elevated, suggesting that FFA may inhibit the

translation of proinsulin mRNA. In the INS-1 clonal pancreatic cell line, long-chain fatty acids were shown to inhibit the expression of the acetyl-CoA carboxylase gene (94). This could increase fatty acid oxidation in the β -cell, thereby potentially causing glucose insensitivity. FFAs induce expression of the carnitine acyl-transferase I gene in the INS-1 cell line, providing an additional mechanism for stimulation of fatty acid oxidation. FFA elevation also has been shown to reduce GLUT2 and glucokinase levels in rat pancreatic islets (95) and to open K⁺-ATP channels, thereby inhibiting insulin secretion (96). In summary, there is substantial evidence for FFA effects on insulin secretory pathways, which may contribute to the altered physiology of type 2 diabetes.

Insulin clearance or degradation is thought to be a receptormediated process (97). Normally, approximately 50% of the insulin secreted by the pancreas is cleared via interactions with insulin receptors in liver parenchymal cells (97,98). Approximately 50% of insulin degradation takes place at the surface of the hepatocyte cell membrane (97). Internalization of the insulinreceptor complex by an endocytic mechanism then follows and is coupled to cleavage of the insulin molecule by various proteases. Of the insulin that is not cleared by hepatocytes, approximately 25% is removed by the kidney and the rest is removed by muscle, adipose tissue, and other tissues. Elevated circulating concentrations of FFAs have been shown to reduce hepatic clearance of insulin, hence contributing to peripheral hyperinsulinemia. Isolated rat hepatocytes show a dose-dependent decline in cell-surface insulin-receptor binding when exposed to palmitate, one of the major FFAs (99). This was attributed to a reduction in the number of insulin receptors as well to a reduction in the amount of internalized insulin within the hepatocytes. Similar effects of oleic acid have been described (100). On the basis of current evidence, it is reasonable to hypothesize that elevated FFA levels in individuals with type 2 diabetes have a significant role in decreasing hepatic clearance of insulin, thereby contributing to peripheral hyperinsulinemia.

INSULIN REGULATION OF LIPOLYSIS IN TYPE 2 DIABETES

Lean, nondiabetic humans are exquisitely sensitive to insulininduced inhibition of lipolysis and, hence, to rates of FFA appearance (7,16). Persons with upper-body obesity and persons with type 2 diabetes have increased plasma concentrations of FFAs in the postabsorptive (101) and postprandial states (84,102), suggesting that dysregulation of FFA metabolism could play a role in the pathogenesis of hyperglycemia. Resistance to the inhibitory effects of insulin on lipolysis occurs in individuals with upper-body obesity and type 2 diabetes (7,101). Euglycemic stepwise insulin-clamp studies have shown reduced suppression of lipolysis by insulin in nonobese subjects with type 2 diabetes (11). Furthermore, rates of lipolysis during the postabsorptive stage have been shown to be higher in obese diabetic than in matched nondiabetic subjects (103). Experiments performed in our laboratory compared subjects with type 2 diabetes with equally obese healthy controls in the presence of comparable hyperglycemia (approximately 9 mM) and insulin levels (104). We found significantly increased rates of wholebody lipolysis in the diabetic individuals, resulting in modest elevations of FFA concentrations.

Because of evidence for regional heterogeneity in rates of FFA release by adipose tissue, it is important to understand the relative contribution of various adipose tissue beds to systemic FFAs. Therefore, in the above-mentioned study (104), regional splanchnic, leg, and nonsplanchnic upper-body release of FFAs was measured. Although FFA release from each adipose tissue

bed was greater in diabetic than nondiabetic subjects, the relative contributions of the different regions to systemic lipolysis did not vary between the two groups. The major component of systemic lipolysis in both the diabetic and the nondiabetic subjects was the upper-body nonsplanchnic region, accounting for approximately 75% of FFA release (105). The importance of upper-body nonsplanchnic adipose tissue in delivering excess FFA to the systemic circulation was further demonstrated by a study of postprandial metabolism of FFA in upper-body obese and lower-body obese women (106). Postprandial release of FFA was 240% greater in the women with upper-body obesity despite higher insulin concentrations, and 73% of the excess FFA originated from the upper-body nonsplanchnic region (Fig. 16.2). It appears that although visceral fat is an excellent marker for abnormal FFA metabolism, it is not the major source of excess FFA.

Thus, type 2 diabetes is associated with higher fasting and postprandial FFA concentrations than occur in equally obese nondiabetic subjects. There still is some uncertainty, however, about how much of the resistance to insulin inhibition of lipolysis in persons with diabetes is a result of the metabolic state itself and how much is due to the associated features of upperbody or visceral obesity that frequently also are present.

TYPE 2 DIABETES AND BODY FAT DISTRIBUTION

Insulin resistance is one of the common links between type 2 diabetes, obesity, hypertension, dyslipidemia, hyperinsulinemia, and increased cardiovascular disease and mortality. This clustering of metabolic abnormalities has been termed the *meta*bolic syndrome, syndrome X, or the insulin resistance syndrome, as proposed by Reaven (107). Vague (108) was the first to report that obesity-related adverse health and metabolic consequences occur predominantly in those with a masculine or upper-body fat distribution as opposed to a lower-body fat distribution. The relationships between the components of the metabolic syndrome inclusive of type 2 diabetes are stronger with upperbody obesity (as measured by waist-hip ratio) than with obesity per se (106,109,110). In particular, abdominal or visceral fat is most strongly associated with the presence of insulin resistance and the components of syndrome X (111-113). Visceral fat can be estimated using CT or MRI scans of the abdomen. Several large heritability studies [the HERITAGE family study (114) and the Quebec Family Study (115)] reported genetic and familial tendencies toward the development of visceral fat. Furthermore, the Nurses' Health Study (116) confirmed that being overweight increases the relative risk of type 2 diabetes and that the waist-hip ratio and waist circumference are powerful independent predictors of type 2 diabetes and coronary artery disease in U.S. women (117). Several investigators have confirmed a similar association of visceral adiposity with glucose intolerance and elevated plasma insulin, C-peptide, and triglyceride levels in men (112,118,119) and premenopausal women (120). Not all studies, however, support the conclusion that visceral fat is the best correlate of insulin resistance. Glucose disposal rates in middle-aged men with various degrees of adiposity were found to best relate to abdominal subcutaneous fat in one study (121). Body fat topography has also been shown to have different effects on glucose disposal rates in premenopausal women. Studies in nonobese women confirmed that total body fat mass appeared to be the primary determinant of insulin sensitivity, with abdominal visceral fat exerting a somewhat more significant effect in obese women (111).

In vitro studies have consistently shown that intraabdominal visceral fat (omental and mesenteric) has a high fractional lipolytic rate when compared with other fat depots in the body.

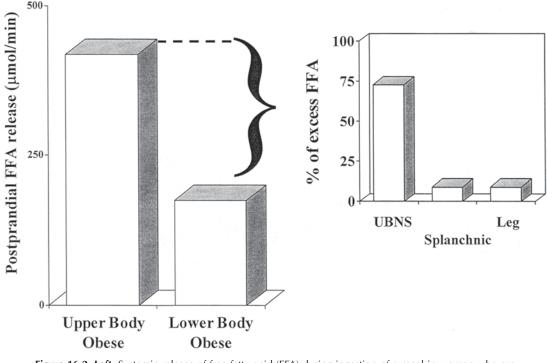

Figure 16.2. Left: Systemic release of free fatty acid (FFA) during ingestion of a meal in women who are upper-body obese and lower-body obese. **Right:** Relative amount of "excess" FFA release from the three different adipose tissue regions in the group with upper-body obesity. UBNS, upper-body nonsplanchnic. (Data are from Guo Z, Hensrud DD, Johnson CM, et al. Regional postprandial fatty acid metabolism in different obesity phenotypes. *Diabetes* 1999;48:1586–1592.)

As such, visceral fat could play a significant quantitative role (approximately 26% of upper-body release of FFA), which is out of proportion to its absolute mass (46). There is therefore a distinct possibility that in addition to the arterial delivery of FFAs to the liver, the delivery of FFAs through the portal route could have significant effects on the liver. This in turn could, by increasing the supply of gluconeogenic substrates, contribute to a reduction in insulin suppression of gluconeogenesis, resulting in an increase in endogenous glucose production. Furthermore, an increase in the availability of FFAs could also reduce insulinstimulated peripheral glucose disposal (mainly in skeletal muscle, which is the most relevant site of insulin resistance). As discussed earlier, increased delivery of FFAs to the liver could potentially reduce hepatic insulin extraction (122,123), thereby contributing to peripheral hyperinsulinemia. This in turn, by suppressing subcutaneous adipose tissue lipolysis, potentially could magnify the ratio of visceral to systemic lipolysis (124).

The authors' laboratory conducted a series of experiments (125) to determine the effects of regional fat distribution on regional lipolysis in obesity (4,9,46). We found that rates of systemic lipolysis were greater in premenopausal women with upper-body obesity than in a matched group with lower-body obesity, especially during hyperinsulinemia. The majority of FFA release originated from the nonsplanchnic (subcutaneous) upper-body region. We found that the antilipolytic effect of a mixed meal was reduced in women with upper-body obesity compared with those with lower-body obesity or in nonobese women. A separate series of experiments also has revealed regional heterogeneity of insulin-regulated lipolysis, with the visceral adipose tissue being more resistant than leg adipose tissues to insulin-induced lipolysis. Further explorations on the regional postprandial FFA metabolism in different obesity phenotypes revealed a major contribution of nonsplanchnic upper-body tissues to total FFA flux in women with upperbody obesity, accounting for the greater postprandial FFA availability in these women. The nonvisceral upper-body source of postprandial release of FFA suggested that visceral fat might be a marker but not the source of excess postprandial FFA in obesity. Of interest, reduction of visceral fat by surgical removal (126) or by caloric restriction (127) in Sprague-Dawley rats has been shown to reverse hepatic insulin resistance. The finding that surgical removal of intraabdominal fat improves some aspects of insulin resistance suggests that there may be direct effects on hepatic metabolism unrelated to release of FFA by visceral adipose tissue. Other possible explanations for this observation include differences between rat and human physiology or indirect effects of intraabdominal fat on FFA release by subcutaneous adipose tissue.

There are a number of other hypotheses regarding the link between visceral adipose tissue and hepatic insulin resistance. These include potential roles of TNF- α , interleukin-6, and leptin (128). The presence of enlarged adipocytes in subcutaneous abdominal adipose tissue is predictive of adverse consequences of upper-body obesity (129), although this could be a result of resistance to insulin-mediated suppression of lipolysis (86,130). A large average fat-cell volume was found to be predictive of type 2 diabetes independent of age, gender, percent body fat, and body fat distribution in Pima Indians (131).

A recent study (132) has suggested a link between visceral adipose tissue and glucocorticoids. In this study, mice overexpressing the enzyme 11- β -hydroxysteroid dehydrogenase-1 (which converts the inactive form of glucocorticoids to the active form in mice and in humans) in adipose tissue developed visceral obesity, insulin-resistant diabetes, and hyperlipidemia that were exaggerated by a high-fat diet. Hence, it is possible that increased adipocyte expression of this enzyme

Physiologic function	Effects of FFAs
Glucose metabolism	
Insulin-mediated glucose uptake	Elevated EEAs inhibit insulin action
Insulin-mediated suppression of endogenous glucose production	Failure to suppress FFAs impairs effects of insulin
Glucose-mediated uptake of glucose	None
Glucose-mediated suppression of endogenous glucose production	Elevated FFAs impair suppression ¹⁴⁰
Insulin secretion	
Short-term	Stimulation of insulin secretion
Long-term	Inhibition of insulin secretion; possible islet toxicity
Insulin clearance	Reduced hepatic clearance of insulin
VLDL metabolism	Increased FFA associated with greater production of VLDL triglycerides

TABLE 16.1. Effect of Free Fatty Acids on Diabetes-related Physiologic Function

could potentially be a molecular etiology for visceral obesity and the metabolic syndrome. Another recent report (133) has shown increased 11-β-hydroxysteroid dehydrogenase-1 activity in adipose tissue of obese humans, lending further support to a link between visceral obesity and glucocorticoid metabolism.

Recent studies also have examined the relationship of subdivisions of subcutaneous abdominal adipose tissue to insulin resistance. Deep subcutaneous abdominal adipose tissue, separated from the superficial abdominal adipose tissue by a fascial plane, has been shown to have a strong negative correlation with insulin-stimulated glucose disposal (134). Misra et al. (135) have also reported that the deep subcutaneous adipose tissue located in the posterior as opposed to the anterior half of the abdomen is more closely correlated with insulin resistance.

TYPE 2 DIABETES AND METABOLISM **OF VERY-LOW-DENSITY LIPOPROTEIN TRIGLYCERIDES**

Type 2 diabetes has a well-known association with hypertriglyceridemia. In addition, fasting hypertriglyceridemia in subjects with type 2 diabetes has been linked to postprandial lipid and lipoprotein abnormalities. In 1976, Kissebah and colleagues (136) noted that FFA levels correlated with increased turnover of VLDL in subjects with type 2 diabetes, suggesting that increased hepatic production of VLDL may be driven by excess FFA. Although the patients with diabetes were hyperinsulinemic at the end of the study, no correlation was found between plasma insulin levels and the rate of VLDL turnover. A subsequent series of investigations clearly established that elevation of plasma FFA levels acutely stimulates VLDL production in nondiabetic individuals (137). These studies further showed that elevating plasma FFA levels in hyperinsulinemic subjects attenuates but does not completely abolish the suppressive effects of insulin on VLDL production. This suggested that in healthy individuals the acute inhibition of VLDL production by insulin is due only in part to suppression of FFA and may also be due to an FFA-independent process.

In considering the mechanism of FFA effects, it is relevant to note that degradation of the important VLDL protein apoB is inhibited by the FFA oleate (138,139). Thus, increased hepatic FFA delivery, as characteristically occurs in type 2 diabetes, may stimulate the assembly and secretion of apoB-containing

VLDL by targeting apoB for secretion rather than intracellular degradation.

CONCLUDING COMMENTS

This chapter has provided a review of the causes and consequences of altered fat metabolism in diabetes mellitus. Although our knowledge of the intricate regulating interrelationships between FFA levels, insulin secretion and action, glucose metabolism, and triglyceride metabolism undoubtedly will undergo further advances, it is clear that FFA levels have a key role in contributing to the metabolic disturbances of diabetes (summarized in Table 16.1). Therapeutic approaches that lower FFA levels and restore FFA metabolism can be expected to have substantial beneficial effects in patients with diabetes. Lowered FFA levels in response to metformin and thiazolidinediones may contribute to the therapeutic efficacy of these agents, and the development of new agents that lower FFA levels in diabetes should be considered an important goal.

CONCLUSION 287

HISTORICAL PERSPECTIVE

Before insulin treatment became readily available, stunted growth, cachexia, and muscle wasting were well recognized in patients with type 1 diabetes mellitus (1,2). Indeed, this association has been known for millennia, as documented in ancient Sanskrit literature describing diabetes mellitus as "honey-urinedisease" (3). The Greek physician Aretaeus described diabetes as a condition with "melting of flesh into urine." Alternatively, the anticatabolic effect of insulin therapy has been well documented during the past 80 years (1,4,5). This anticatabolic effect is associated with normalization of urinary losses of nitrogen (4,6); increases in body cell mass, as indexed by total body potassium (7); and decreases in the concentrations of amino acids, especially of branched-chain amino acids (BCAA) (8,9). Intraarterial infusion of insulin during the postabsorptive state in subjects without diabetes decreases the net amino acid release from the forearm, indicating a net decrease in protein breakdown (10). Collectively, these observations demonstrate the important anabolic effects of insulin in humans. However, the mechanism by which insulin promotes the growth and

maintenance of lean tissue continues to be debated, and the effects of insulin on the synthesis and breakdown of a variety of individual proteins remains an area of intense research.

This chapter reviews current knowledge of protein turnover in type 1 and type 2 diabetes mellitus. It describes the specific effects of insulin and other selected hormones on the components of protein turnover (i.e., protein breakdown and protein synthesis) and gives a general overview of the mechanisms by which insulin affects protein synthesis and breakdown within the cell. Although emphasizing human studies, it discusses important work from animal and *in vitro* studies and notes the discrepancies between different experimental approaches.

BALANCING PROTEIN SYNTHESIS AND BREAKDOWN

The balance between protein synthesis and breakdown determines the protein content of the whole body and individual tissues, as well as the concentrations of specific proteins. Consequently, protein turnover is not only important for increasing

and maintaining cell size but also fundamental to tissue remodeling, adaptation, and repair. Specific proteins are synthesized and catabolized at variable rates in response to particular functional demands upon the cell. In considering the proteins involved in the regulation of processes such as differentiation, growth, energy production, or gene repair, it is important to recognize that small alterations in protein balance may have large effects on cell function. Changes in the content, function, and integrity of specific proteins involved with these types of cellular processes probably contribute to the chronic complications associated with diabetes mellitus. However, an understanding of the underlying mechanisms is complicated by the regulation of protein turnover by a number of hormones other than insulin, including cortisol, glucagon, growth hormone, insulinlike growth factors and other growth factors, thyroid hormones, and testosterone. Substrates such as amino acids, fatty acids, and ketones and different physiologic states such as fasting, exercise, pregnancy, aging, and chronic disease also influence protein turnover. Recent advances in molecular biology and isotopic tracer technology have enhanced the capacity to study human protein metabolism. The human genome project provides information that sets the stage for a new era of investigation that not only will help define the functions of proteins encoded by newly identified genes but also will provide insight into their regulation and turnover dynamics. This undoubtedly will expand our understanding of the influence of diseases such as diabetes mellitus on protein metabolism and the impact of altered protein dynamics on the course of diabetes.

EFFECTS OF INSULIN ON PROTEIN TURNOVER

Insulin has been shown to stimulate protein synthesis both *in vitro* and *in situ* (11–16). Studies in animals with low insulin levels, as occurs with fasting or β -cell destruction, have clearly shown that insulin replacement stimulates protein synthesis (12,17,18–21). Increased protein synthesis has been demonstrated in muscle tissue of nondiabetic animals after insulin administration in some (22,23) but not all (24) studies. The absence of an observed insulin effect in some reports may be related to the ages of animals studied and diminished insulin action in older animals (23–25). Studies on perfused or incubated rat diaphragm (26), skeletal muscle (12), and heart (17,21) have shown that insulin also decreases the breakdown of muscle protein.

The effects of insulin on protein metabolism in healthy human subjects without diabetes are less clear. In general, whole-body protein synthesis is not stimulated when insulin is infused during the postabsorptive state (fasting) (27-29). However, when insulin is infused under these conditions, circulating amino acids, especially BCAA, decrease in a dose-dependent manner (8,9,30). In contrast, when insulin is secreted in response to a meal under physiologic conditions, there is a simultaneous influx of dietary amino acids. Therefore, the lack of increase in protein synthesis observed in postabsorptive studies possibly relates to a decrease in the availability of amino acids. This concept is supported by studies that have examined the effects of infusing amino acids together with insulin in healthy subjects without diabetes (31-36). It generally has been observed that protein synthesis increases when insulin and amino acids are infused at rates sufficient to produce hyperinsulinemia and hyperaminoacidemia (32,36,37) but not with hyperinsulinemia and normal physiologic levels of amino acids (33). One study demonstrated that infusion of supraphysiologic doses of insulin together with amino acid supplementation can stimulate protein synthesis by more than 100% in forearm muscle of healthy subjects without diabetes (38). This protocol

was designed to simulate, at the local muscle level, the high insulin concentrations used in many of the in vitro studies examining protein turnover. Therefore, the findings may help reconcile the observation of increased protein synthesis in vitro with the general absence of changes in protein synthesis in vivo in the presence of physiologic doses of insulin. In contrast to protein synthesis, the inhibitory effect of insulin on protein breakdown is readily demonstrated in subjects without diabetes even in the absence of infused amino acids (27,33,36,39,40). Similarly, several (27,28,39,41), but not all (42) studies measuring protein turnover in human limb muscle vascular beds have demonstrated decreased protein breakdown with insulin infusion. To summarize, findings in humans without diabetes concur with *in* vitro analyses and most animal studies in the demonstration of inhibitory effects of insulin on protein breakdown. By contrast, effects of insulin on protein synthesis in different experimental systems have not been consistent.

MECHANISMS OF INSULIN ACTION

Protein turnover in specific tissues and cell types is known to be affected differently in diabetes mellitus, depending on the degree of insulin deficiency, amino acid availability, and the level of glycemic control (40,43,44). It is likely that proteins in individual cellular subfractions (cytoplasm, mitochondria, nuclei, and contractile structures) respond differently to the effects of insulin and that these responses may be influenced by diabetes mellitus. The pathways by which insulin influences cellular processes such as gene transcription, messenger RNA (mRNA) stability, protein targeting for breakdown, and enzyme regulation undoubtedly are complex and exquisitely regulated. Knowledge of specific signaling pathways mediating insulin effects on protein synthesis and breakdown is advancing, and this new understanding will likely lead to practical new approaches to the management of the complications of diabetes mellitus.

Protein Synthesis

Although the role of insulin in regulating protein synthesis in humans remains uncertain, stimulation of protein synthesis by insulin in various in vitro models has been clearly shown (11-16). These somewhat divergent findings probably are related in part to methodologic issues. For example, it is difficult to show direct effects of insulin on gene expression and subsequent protein synthesis in intact animals because insulin deficiency and/or replacement results in concurrent changes in substrate concentrations and fluxes, changes in concentrations of counterregulatory hormones, and other factors. To circumvent this problem, investigators often attempt to maintain concentrations of glucose, amino acids, and various hormones by using clamp techniques. However, it is probably impossible to control all the known and still unknown factors that affect protein synthesis. For this reason, cell lines, primary cell cultures, tissue cultures, and in situ preparations represent useful systems for examining a more controlled cellular environment. These experimental models have the advantage of making it possible to evaluate insulin effects on gene expression in isolation or as a permissive or augmenting influence with other selected factors, but have the disadvantage of often uncertain physiologic relevance of the observed findings.

Insulin may influence protein synthesis through numerous sites of regulation (14,15), including effects on gene transcription (mRNA production), mRNA stability, ribosome biogenesis, initiation and elongation steps of mRNA translation, and the regulation of preexisting enzymes (Fig. 17.1). The effect of insulin

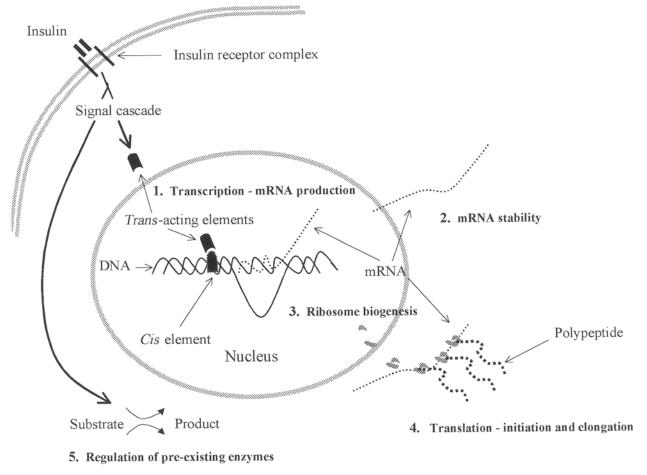

Figure 17.1. Sites of action of insulin in the regulation of protein synthesis. Insulin action depends on binding to the insulin receptor complex and initiation of a cascade of steps leading to its ultimate effect on protein synthesis. Insulin effects have been shown at various levels: (1) transcription of genetic message to mRNA; (2) contribution to mRNA stability; (3) biogenesis of ribosomes; and (4) translation—both at initiation and elongation. (See text for details of effects of each of these steps.)

on gene transcription is usually viewed in terms of the *cis/trans* hypothesis, in which intracellular trans-acting factors bind to cis-acting DNA sites in the nucleus. The specific gene sites affected by insulin are referred to as insulin response sequences or elements (IRSs/IREs), which are usually located in the gene promoter region. Positive or negative effects can be mediated through these cis/trans interactions. Reputed IREs for a variety of genes, including glyceraldehyde 3-phosphate dehydrogenase, pyruvate kinase, glucagon, phosphoenolpyruvate carboxykinase (PEPCK), and insulin-like growth factor binding protein 1, have been identified (15). The transmission of the insulin signal to these genes could presumably upregulate the encoded protein, in isolation or in addition to the effects of insulin on general cellular protein synthesis, by producing more mRNA for translation. Examples of mRNAs that are selectively increased by insulin include eukaryotic elongation factor 2 (eEF-2) (45), phosphorylated heat- and acid-stable protein (PHAS-I) (46), and myosin heavy chain α (47).

Insulin can also exert a selective influence on protein synthesis by stabilizing specific mRNA species. Degradation of mRNA can be measured by a decrease in radiolabel in an mRNA species prelabeled before the experiment, usually in the presence of transcription inhibitors. In these studies, stabilization of mRNA by insulin has been demonstrated for glycerol 3phosphate dehydrogenase, glycogen phosphorylase, and glucose transporter 1 (GLUT1), among others (15,48). Conversely, insulin has been shown to destabilize some mRNAs, such as PEPCK (49,50) and GLUT4 (50). This leads to the interesting observation that insulin can stabilize some mRNA species and destabilize others within the same cell, further demonstrating the intricacy by which insulin regulates cell function. An example is the divergent effect of insulin on the stability of glycogen phosphorylase (48) and phosphoenolpyruvate carboxykinase mRNAs within hepatocytes (49). The specific mechanisms by which insulin influences mRNA stability are poorly understood at present.

Protein translation involves a complex set of reactions that decode the genetic information provided by mRNA into a polypeptide chain. Translation usually is divided into three phases: initiation, elongation, and termination. Protein-chain initiation involves binding of a methionyl-transfer RNA (tRNA) to a start codon in the mRNA, which in turn binds to 40S and 60S ribosomal subunits. The resulting mRNA-ribosome unit then adds tRNA-bound amino acid residues to the elongating peptide chain. Termination is the phase in which the completed polypeptide chain is released from the ribosome. Translational efficiency, particularly with regard to the initiation and elongation phases, has been a major focus of investigations of the effects of insulin on cellular protein synthesis. This is important because increases in translational efficiency have the potential to increase protein synthesis without necessarily changing the total RNA content. The mechanisms by which insulin affects translation have been the topic of a recent comprehensive review (51). In general, this occurs through a series of interactions of the mRNA, ribosomal subunits, and specific binding and initiation factors, often involving the phosphorylation of one or more of these factors (52–56). Initiation starts with the binding of methionyl-tRNA to the 40S ribosomal subunit mediated by eIF-2 (51,57). It is noteworthy that eIF-2 will bind methionyl-tRNA only when the eIF-2 is complexed with guanosine triphosphate (GTP). Another initiation factor, eIF-2B, controls the recycling of eIF-2 between its GTPbound and guanosine diphosphate (GDP)-bound forms. Methionyl-tRNA recruitment to the 40S ribosomal subunit is followed by mRNA binding and subsequent joining to the 60S ribosomal subunit. The resulting 80S initiation complex is then competent to enter the elongation phase. Insulin regulates the initiation of translation in part by enhancing the binding of mRNA to the 40S ribosomal subunit. One important step in this process requires attachment of the eIF-4E (cap-binding protein) and the eIF-4E-binding proteins PHAS-1 (4E-BP1) and eIF-4G to the 7-methyl guanine cap structure at the 5' end of eukaryotic mRNAs (13,58,53,54). Insulin and perhaps other hormones stimulate this process by enhancing the phosphorylation of PHAS-1, dissociating it from eIF-4E so that eIF-4E can complex with eIF-4G, which associates with the 40S ribosomal subunit (58). Insulin has also been shown to increase the activity of eIF-2B, which regenerates eIF-2 as noted above (54,59). Rats made insulin deficient by blocking insulin secretion with diazoxide show a large decrease in the binding of eIF-4E to eIF-4G and an increase in eIF-4E * 4E-BP1 complex formation (56).

Insulin may increase protein synthesis by selectively upregulating the initiation of translation of mRNAs containing a polypyrimidine tract at their 5' transcriptional start site. These mRNAs encode important components of the translational apparatus, including ribosomal proteins and translational elongation factors that would likely increase the overall capacity of the cell for protein synthesis. Translation of such 5'-polypyrimidine mRNAs appears to be regulated in part via multisite phosphorylation of the 40S ribosomal protein S6 by p70 S6 kinase (p70^{S6K}) (60,61). An increase in S6 phosphorylation has been observed in a variety of cells in culture exposed to insulin [reviewed in references (14,62-64)], and S6 phosphorylation generally correlates with increased protein synthesis (63). Investigators have shown that expression of a dominant interfering mutant of p70^{S6K}, which prevents the activation of wild-type p70^{S6K}, blocks serum-activated translation of 5'-polypyrimidine tract mRNA in human kidney 293 cells (61).

The elongation phase of protein synthesis involves the progressive addition of amino acyl-tRNAs to the ribosomal mRNA complex, causing a lengthening of the peptide chain until termination. At least two elongation factors (eEF-1 and eEF-2) are important in facilitating this process. The eEF-1 factor is complexed with GTP in a fashion similar to that described above for eIF-2, and GTP-bound eEF-2 mediates the attachment of amino acyl-tRNA to the ribosome. Subsequently, eEF-2 is required for the movement of the ribosome relative to the mRNA and for migration of the amino acyl-tRNA from the acceptor site to the peptidyl site of the ribosome (65). Like eEF-1, eEF-2 is a phosphoprotein and is regulated by insulin. Phosphorylation of eEF-2 by way of eEF-2 kinase results in its complete inactivation (66). Insulin appears to increase the rate of elongation by the inactivation of eEF-2 kinase through a pathway sensitive to the antifungal agent rapamycin, which is discussed in greater detail below (67). Collectively, these studies indicate that insulin may enhance important steps in translation initiation and elongation. The significance of these steps in

insulin-stimulated protein synthesis and the steps that are rate limiting remain to be determined.

The capacity of the cell to synthesize protein can be determined in part by the abundance of ribosomes. As noted above, ribosomes are essential components of the translational machinery, and their biogenesis involves the synthesis of approximately 80 ribosomal proteins and four rRNA species transcribed by RNA polymerases I (18S, 28S, 5.8S) or III (5S) (68,69). Production of ribosomal precursor molecules is dependent on the stage of cellular development, nutrient levels, growth factors, and hormones (69,70). Nucleoli contain the rRNA genes and are the sites of rRNA synthesis, processing, and assembly into ribosomes. To accommodate the demand for rapid production of large numbers of ribosomes, the rRNA transcription units are repeated in tandem up to 1,000 times in eukaryotic nucleolar sites (71). From the nucleolus, the components must be packaged and moved to the cytoplasm, where translation occurs. Insulin has been shown to increase the synthesis of ribosomal proteins fourfold in chick embryo fibroblasts (72) and to stimulate ribosomal protein synthesis in mouse myoblasts (73).

Although the mechanisms by which insulin increases the cellular content of functional ribosomal complexes are still largely unknown, there is evidence for a significant effect of insulin on posttranscriptional events (72,73). For example, the addition of insulin results in a selective increase in the fraction of ribosomal protein mRNAs associated with polysomes in mouse myoblasts (73), and the association of polysomes with the cellular cytoskeleton is increased in response to insulin when protein synthesis increases (74,75). The synthesis of rRNA species also is stimulated by insulin in a variety of cell types, including fibroblasts (72,76), myoblasts (73), and hepatocytes (77). Changes in rDNA transcription can involve changes in chromatin structure to permit the formation of initiation complex, alterations in RNA polymerase activity, or alterations in associated transcription factors. Insulin-stimulated increases in rRNA transcription in mouse fibroblasts and a rat hepatoma cell line are not associated with a change in the cellular content of RNA polymerase I (76). However, increases in upstream binding factor (UBF) and RNA polymerase I-associated factor 53 have been observed; both appear to aid in recruitment of RNA polymerase I to the rDNA promoter. It is interesting that overexpression of UBF in mouse fibroblasts was able to directly stimulate rDNA transcription (76). Finally, insulin may also diminish the rate of ribosome degradation (14,77,78).

The transmission of the insulin signal from outside the cell through the plasma membrane and cytoplasm and into the nucleus, where it can influence trans-acting factors, is an important component of insulin action. At least two general pathways by which insulin may affect gene transcription have been suggested. The first is the classical signal transduction in which formation of an insulin-receptor complex at the plasma membrane transmits a cascading signal through the cytoplasm into the nucleus via second-messenger molecules and protein phosphorylation/dephosphorylation reactions. The second, and less firmly established, pathway involves the effects of insulin on intracellular receptors (79). This hypothesis is supported by several reports of mediation of changes in transcription by internalized insulin (79-81) through nuclear insulin receptors (82,83). Whether direct insulin interactions with nuclear receptors and DNA IREs have important effects on protein synthesis is unknown.

Although direct nuclear actions may be significant, insulin is thought to exert most of its effects by changing the phosphorylation state of various regulatory proteins important to protein synthetic pathways via classical signal transduction (14). This

pathway involves autophosphorylation of insulin receptors initiated by the binding of insulin, followed by increased tyrosine phosphorylation of intracellular proteins such as insulin-receptor substrates (IRS-1, IRS-2, IRS-3, and IRS-4) and the protein Shc. IRS-1 is the best characterized of the IRS family of proteins. Its phosphorylated tyrosine sites are thought to associate with high-affinity src homology 2 domain (SH2)-containing proteins such as on the 85-kDa regulatory subunit (p85) of phosphoinositide 3-kinase (PI 3-kinase). Of note, both the insulin receptor and IRS-1 appear to be required for the insulin-mediated stimulation of general and growth-related protein synthesis (84). PI 3-kinase is emerging as the only phosphotyrosineactivated effector downstream of IRS-1 that is essential for protein synthesis (84-87). LY 294002, a specific inhibitor of PI 3kinase, completely prevents insulin-mediated stimulation of protein synthesis in rat skeletal muscle (86). A number of other effectors downstream of IRS-1 are also being investigated for their roles in insulin signaling to protein synthesis, including protein kinase C (59,88), ras (89), mitogen-activated protein (MAP) kinases (85), p70^{S6K} (85), and PHAS-1 (13,55,86,90).

There appear to be essentially two mechanisms of insulinstimulated protein synthesis, one controlled by PI 3-kinase and the other by the GTP-binding protein p21^{ras} (87,88). The insulinstimulated PI 3-kinase pathway appears to exert its effect primarily by way of the Ser/Thr protein kinase Akt and subsequent activation of p70^{S6K} (91) and PHAS-1 (92). Akt and p70^{S6K} can be activated directly by the products of PI 3-kinase, phosphatidylinositol 3,4-bisphosphate and phosphatidylinositol 3,4,5-trisphosphate (93). The use of the antifungal agent rapamycin helps in characterizing the pathway downstream of PI 3-kinase and Akt by acting at the level of TOR (target of rapamycin; mTOR in mammalian cells), a novel protein kinase, which appears to be on the pathway between Akt and both p70^{S6K} and PHAS-1. Rapamycin inhibits activation of both of these factors (46,84,86,88,94) and attenuates insulin-stimulated protein synthesis (13,85,86). Alternatively, there appears to be a rapamycinindependent pathway involving an atypical protein kinase C isoform (PKCζ) downstream from PI 3-kinase involved in insulin-stimulated protein synthesis (88). It has been suggested that one pathway, through PKCZ, leads to general or "housekeeping" protein synthesis, whereas the other pathway, through Akt, stimulates growth-regulated protein synthesis (88).

Insulin stimulates Ras activity by two known mechanisms that involve binding the Grb/SOS complex by either Shc or IRS-1 (51,95) and subsequently leading to the formation of the active GTP-bound state of Ras. Ras then stimulates a cascade of protein serine/threonine kinase events that involve Raf, MEK, and the MAP kinases ERK1 and ERK2 (96,97). However, it is uncertain whether the activation of the MAP kinases contributes significantly to insulin-stimulated protein synthesis (13,84,98). Furthermore, it is important to note that the PI 3-kinase and p21ras branches are not completely separate and that there is evidence that PI 3-kinase may be upstream of ras under some conditions (87,99,100). Of interest is the finding that increases in IRS-1 tyrosine phosphorylation (101), PI 3-kinase activity (102), p85-PI 3-kinase mRNA expression (101), and Akt kinase activity (103) in response to insulin are diminished in skeletal muscle of patients with type 2 diabetes.

Protein Breakdown

A normal 70-kg adult synthesizes and degrades approximately 280 g of protein each day under standardized conditions (104). Most of this protein turnover occurs within cells. Intracellular protein turnover is continuous, albeit at vastly different rates (i.e., different protein half-lives), depending on the identity, function,

and location of the protein, as well as on the physiologic state of the organism. Catabolic states such as acute starvation or untreated type 1 diabetes result in increased protein breakdown, particularly from skeletal muscle, which is an important reservoir of amino acids under these conditions. The resulting increase in circulating amino acids provides precursors for protein resynthesis and for gluconeogenesis in the liver, and the BCAA offer an additional energy source for the remaining muscle tissue. The amino acids from protein breakdown also are crucial for maintaining synthesis rates of essential proteins such as clotting factors produced by the liver. Fortunately, the regulation of cellular protein breakdown is highly specific and preciseoften able to select less essential proteins for breakdown, to the overall benefit of the organism. The regulatory mechanisms responsible for this specificity in protein breakdown remain to be defined. Rapid or sustained breakdown of protein, as occurs in starvation, catabolic disease states, and other severe physiologic stresses, may result not only in losses in muscle mass but also in an overall disruption of homeostasis. Understanding the cellular mechanisms involved in protein breakdown is an essential step toward developing pharmacologic or other interventions that might reduce excessive losses of essential proteins during catabolic conditions.

It is important to emphasize that the influence of protein breakdown extends to the regulation of cell function under all physiologic conditions and not just to catabolic states. Generally, this essential regulatory process is observed as enzymes, transcription factors, receptors, and other signaling proteins undergo selective degradation. For example, the levels of gluconeogenic enzymes, such as PEPCK, increase in rat liver with fasting and promptly decrease after refeeding (105,106). Such rapid fluctuations in hepatic cell enzyme content require a significant change in the ratio of protein breakdown to protein synthesis. Another example of the mediation of metabolic change by protein breakdown is evident in the degradation of enzymes such as glutamine synthetase, ornithine decarboxylase, and 3-hydroxy-3methylglutaryl coenzyme A (HMG-CoA) reductase in response to the accumulation of their reaction products (107). Alternatively, a decrease in the breakdown of a family of proteins known as heat-shock proteins (e.g., hsp70) occurs when cells are exposed to heat treatment (108). Heat-shock proteins appear to be cytoprotective during a variety of cellular insults, in part by facilitating the recovery of metabolic pathways that have been perturbed by cellular stress (109). It is interesting that hsp70 and cofactors known as DnaJ homologues are themselves essential in the preparation of certain abnormal proteins for breakdown in eukaryotic cells (110). In summary, protein breakdown is essential for cellular well-being through its roles in eliminating potentially lethal accumulations of abnormal, damaged, or foreign proteins; promoting normal tissue remodeling and repair; facilitating regulation of numerous metabolic pathways; and providing nutritive substrates in catabolic states. Defects in protein breakdown mechanisms clearly have the potential to cause abnormal tissue growth, whereas accelerated protein breakdown can result in tissue or organ wasting.

Our information on the control of protein breakdown is limited compared with that on insulin-mediated protein synthesis. Nevertheless, it is known that cellular protein breakdown can occur via several mechanisms, including (a) lysosomal pathways, (b) the adenosine triphosphate (ATP)–dependent ubiquitinproteosome pathway, (c) Ca²⁺-dependent proteases, and (d) ATPindependent pathways. Protein degradation within lysosomes involves several acid proteases called cathepsins and other hydrolases. Lysosomal pathways are responsible for degrading the long-lived protein pool ($t_{1/2} \sim 40$ hours) in the liver, which includes the vast majority (>99%) of hepatic proteins (111). Amino acid and/or insulin deprivation, glucagon, and β -agonists have been shown to induce lysosomal autophagy of this hepatic protein pool. A short-lived hepatic protein pool (t_{1/2} ~10 minutes) is also present but does not appear to be regulated and probably is subject to nonlysosomal breakdown. In most tissues, lysosomal pathways are primarily those responsible for degrading extracellular, membrane, and organellar proteins. Examples include the downregulation of plasma membrane receptors or the breakdown of proteins identified by the immune system and presented on cell-surface major histocompatibility complex class II molecules. Lysosomal mechanisms can account for up to 10% to 20% of overall protein breakdown in skeletal muscle (112) but are quantitatively unimportant when considering protein breakdown during catabolic states.

The majority of proteins in mammalian cells are degraded by the ubiquitin-proteosome pathway, which is particularly important during catabolic conditions (113). This process involves the selective marking of proteins for breakdown by covalent conjugation to a small protein called ubiquitin (Fig. 17.2). The mechanism involves the formation by an E1 ubiquitin-conjugating enzyme of a high-energy thioester linkage with the COOHterminal end of the peptide ubiquitin, a process that requires ATP. The activated ubiquitin is then transferred to carriers called E2 proteins, and the carboxyl group is coupled to the ε-amino groups of lysines on the target proteins by a ubiquitinprotein ligase known as E3. Multiple ubiquitin molecules are added in a chain, and the targeted protein then is recognized and degraded by an ATP-dependent complex known as the 26S proteosome (104). Ubiquitin conjugation appears to be the rate-limiting step of the pathway (114,115). The 26S proteosome consists of a 20S core proteosome and a 19S complex that recognizes ubiquitin-conjugated proteins (104). Nonspecific protein digestion is prevented in part by limiting proteolysis to unfolded proteins. This specificity is accomplished via the 19S complex, which catalyzes the unfolding of ubiquitin-targeted proteins and facilitates their transport into the central chamber of the 20S core proteosome for proteolytic cleavage (90,116–118). A variety of specific E2 carrier protein and E3 enzyme pairs

impart another important level of selectivity through their capacity to catalyze the ubiquitization of certain targeted proteins or classes of proteins (119,115,120). One particular pair, $E2_{14k}$ and $E3\alpha$, account for most of the ubiquitin conjugation that occurs in soluble extracts from skeletal muscle (121). Conjugation by this pathway has been termed the "N-end rule pathway" (122). This term originates from the fact that $E3\alpha$ recognizes proteins that contain basic and hydrophobic amino acids at the NH₂-terminus.

Studies of muscles removed from acidotic and septic animals have been used to assess the involvement of the ubiquitinproteosome pathway in catabolic states. When these muscles are incubated in the presence of a specific proteosome inhibitor (MG132), protein breakdown decreases to levels similar to those in control muscles (123–125). Studies of atrophying muscles under similar conditions have demonstrated an increase in levels of mRNAs that encode for several components of the ubiquitin-proteosome pathway, including ubiquitin, E2, and certain proteosomal subunits (112,126–128). However, this increase has not necessarily resulted in increases in the corresponding encoded proteins (126).

There is evidence for the involvement of the ubiquitin-proteosome pathway in accelerated protein breakdown in animal models of diabetes mellitus. For example, increases in muscle protein in rats made acutely insulinopenic with injections of streptozotocin can be greatly blunted by inhibition of ATP synthesis (129). This does not occur with selective inhibitors of lysosomal function or calcium-dependent proteases. In another study, the ubiquitin-proteosome and calcium-dependent pathways, but not the lysosomal pathway, were shown to be activated in muscles from streptozotocin-treated rats (130). Further evidence for upregulation of the ubiquitin-proteosome system in muscle during insulinopenia are the increases in mRNAs for proteosome and ubiquitin subunits and in the transcription rate of the ubiquitin gene (129). An interesting finding is an increase in ubiquitin binding to endogenous muscle proteins in acutely diabetic rats (126). This increase in ubiquitization occurs primarily through the Nend rule pathway and appears to be rate limiting for protein

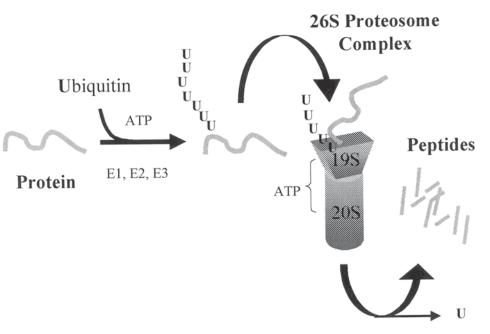

Figure 17.2. The ubiquitin-proteosome pathway for protein breakdown. Proteins are marked for degradation by covalent conjugation to multiple ubiquitin molecules (U) forming a chain. This process is mediated by E1, E2, and E3 proteins and is adenosine triphosphate (ATP) dependent. The targeted protein is degraded by the 26S proteosome complex, which consists of a 20S core proteosome and a 19S complex that recognizes ubiquitin-conjugated proteins. Proteins bind to the 19S subunit and are transferred to 20S proteosome, a process that releases the ubiquitin chain and requires ATP. Multiple proteolytic sites within the 20S proteosome degrade the protein (details are given in text).

breakdown. Treatment of diabetic rats with insulin for at least 24 hours reverses the breakdown of muscle protein and returns the mRNAs for the ubiquitin-proteosome pathway to control levels (131). The potential for interplay of insulin depletion with other hormone systems is illustrated by an apparent glucocorticoid requirement for pathway activation. This can be observed in the prevention of accelerated muscle protein breakdown in diabetic rats by adrenalectomy and the restoration of accelerated protein breakdown with subsequent administration of glucocorticoids (131). Increased cortisol levels are not universally observed in humans during insulin deprivation, and cortisol dependency of ubiquitin-proteosome-mediated protein breakdown under these conditions remains to be established. Collectively, these findings suggest that the ubiquitin-proteosome pathway is important in stimulating the breakdown of muscle protein during severe insulin deprivation and that insulin limits ubiquitin-proteosome activity under normal conditions. The molecular mechanisms that cause the inhibition of protein breakdown in response to physiologic as opposed to pathologic changes in circulating insulin levels remain to be established.

PROTEIN-TURNOVER METHODOLOGY

Whole-Body Study Methods

Most studies examining whole-body protein turnover in humans use a model based on the assumption that the entire protein pool exists as one compartment (Fig. 17.3). With this model, net protein turnover can be calculated as the difference between the degradation and synthesis of body protein. Net urinary nitrogen loss approximates net protein loss. The balance between protein breakdown, protein synthesis, amino acid oxidation, and exogenous amino acid input from dietary proteins determines the pool of free amino acids. A labeled (stable or radioac-

tive isotope) essential amino acid (e.g., L-[1-13C] or [1-14C]leucine) can be used in tracer amounts in a primed continuous infusion to estimate whole-body protein synthesis, breakdown, and amino acid oxidation. The acquisition of a plateau steady state in the plasma, which is essential for the validity of these calculations, can be reached within 90 to 180 minutes of infusion. In the postabsorptive state, dietary protein can be effectively eliminated from the model so that free-leucine enrichment is diluted only by the appearance of leucine from protein breakdown. Consequently, protein breakdown can be estimated directly from leucine flux when leucine is labeled in the carboxyl moiety (1-C), which is not synthesized in the body. Because the only known fates of leucine are protein synthesis and oxidation, whole-body protein synthesis under steady-state conditions often is estimated by subtracting leucine oxidation from leucine flux. Leucine oxidation can be calculated from ¹³CO₂ production using ¹³C enrichment of α -ketoisocaproate (KIC), which is the immediate transamination product of intracellular leucine (132-134). Similar measurements can be obtained using other isotopic amino acid tracers including [2H3]phenylalanine, ¹⁵N]phenylalanine, and L-[1-¹³C,¹⁵N]leucine, albeit using somewhat different assumptions and having unique advantages for specific applications [reviewed in references (133) and (135)]. For example, L-[1-¹³C,¹⁵N]leucine can be used to determine nitrogen flux of leucine or transamination or both (136–138).

Methods for the Study of Regional Protein Metabolism

Measurement of whole-body protein dynamics represents the combined changes occurring in all the tissues of the body. Therefore, this method yields little information about the specific contributions of different tissues, organ beds, or proteins. It can be important to assess more localized protein dynamics,

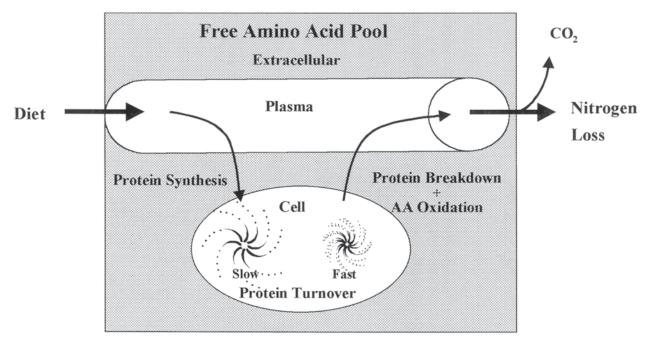

Figure 17.3. A model for *in vivo* protein turnover. The traditional way of determining protein balance is by measuring the net loss of nitrogen (nitrogen intake minus nitrogen output), which is determined by the balance between protein breakdown and protein synthesis. Although organs such as skeletal muscle constitute the major stores of body proteins, the pace of turnover (breakdown and synthesis) of proteins in muscle is much slower than that in other organs, such as gut and liver. As a result, the major contributors to the whole-body protein turnover are those organs with a fast rate of protein turnover. AA, amino acid.

because protein turnover occurs in individual tissues at distinct rates, and in the same tissue, specific proteins can be synthesized and degraded at different rates (139–142). For example, skeletal muscle constitutes greater than 60% of the cell mass in most individuals, while contributing less than 30% to the whole-body protein synthesis (44). This is the consequence of a much slower overall protein synthesis rate in skeletal muscle than in other tissues such as the liver (139). Some proteins in skeletal muscle are synthesized at slower rates [e.g., myosin heavy chain (143)] than others [e.g., mitochondrial proteins (144)]. Similarly, the rates of synthesis of some liver proteins, including apoB-100 and fibrinogen, are faster than the rate of synthesis of albumin (145). Individual proteins also are affected differently by factors regulating protein turnover, as indicated, for example, by the differential effect of insulin on the hepatic synthesis rates of albumin and fibrinogen (145,146). Although it is essential to measure the synthesis rates of individual proteins when considering mechanisms underlying abnormal protein levels, regional studies across tissue and organ beds also have great importance for understanding the interorgan transfer of amino acids that is essential for maintaining optimal wholebody function over a range of physiologic conditions. It is important to recognize that insulin is a key hormone regulating interorgan transfer of amino acids, as well as a regulator of the synthesis of specific proteins.

Many techniques are available for measuring protein turnover from individual tissue beds and synthesis rates of specific proteins. Some methods involve measuring the flux of labeled amino acids in the steady state and blood flow across a limb or tissue bed through arterial and venous sampling. For example, protein turnover in skeletal muscle can be measured by placing a venous catheter in the femoral vein or a deep forearm vein that drains primarily muscle tissue. An arterial catheter is also placed so that blood entering the muscle bed can be sampled. These techniques are helpful for estimating the relative contribution of skeletal muscle to whole-body protein turnover. However, their interpretation is complicated by the fact that in most cases multiple tissues constitute a given vascular bed. Although tissues such as bone, skin, and fat may be minor contributors in a limb, they ultimately cannot be discounted when protein synthesis and breakdown are considered. As an alternative method, the incorporation of labeled amino acids into mixed proteins or individual proteins from tissue biopsy samples (e.g., vastus lateralis muscle) can be measured to determine the effects of hormones, substrates, and altered physiologic states on rates of protein synthesis in specific tissue types (133). In this way the contributions to protein synthesis of minor tissues within a vascular bed can be eliminated. In vivo measurement of protein breakdown from a tissue bed or anatomic region remains limited to arteriovenous studies.

TYPE 1 DIABETES MELLITUS

Whole-Body Protein Turnover

Numerous studies have demonstrated increased protein breakdown and increased protein synthesis, indicated by a high leucine flux and nonoxidative leucine flux, respectively, in type 1 diabetes during insulin deprivation (31,35,36,138,147–151). An increase in amino acid oxidation with insulin deficiency has also been demonstrated in many studies by increases in leucine oxidation and urinary nitrogen excretion. Furthermore, leucine nitrogen flux resulting from leucine transamination is increased. A net catabolic effect occurs during insulin deprivation because the increase in protein breakdown is greater than the increase in protein synthesis. Insulin infusion can reduce both whole-body protein breakdown and synthesis, but the magnitude of the effect on breakdown exceeds that of synthesis, resulting in net protein anabolism (138,147-149,152). These responses have been confirmed in prepubertal children with type 1 diabetes (153). The effect of infusing amino acids with insulin has been studied in patients with type 1 diabetes, as described earlier in this chapter for subjects without diabetes. These investigations consistently demonstrate decreases in endogenous protein breakdown and increases in leucine oxidation (31,34,35). In addition, there is evidence for increased whole-body protein synthesis during insulin and amino acid infusion in two of the published studies (34,35) but not in a third study (31). Therefore, decreased availability of amino acid substrate may contribute to the reduction in protein synthesis observed in the studies that replace insulin without amino acid supplementation. In summary, insulin deprivation associated with type 1 diabetes results in greater increases in whole-body protein breakdown than protein synthesis, resulting in negative net protein balance. Reintroducing insulin appears to improve whole-body protein balance primarily by suppressing protein breakdown.

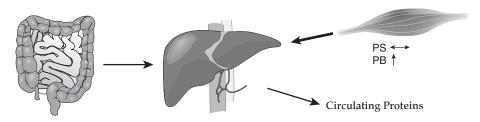

Regional Protein Turnover

Regional studies of protein turnover are important for determining amino acid traffic from one organ bed to another under various conditions (Fig. 17.4). Amino acid isotope labeling techniques combined with measurements of amino acid concentrations can be used to determine whether a change in protein synthesis and/or breakdown causes a net exchange of amino acids across an organ or tissue bed. With this approach, the skeletal muscle bed has been found to be a major donor of amino acids in the postabsorptive state (40). Muscle releases amino acids as a consequence of increased protein breakdown. The amino acids are taken up by the splanchnic bed (presumably by the liver) and used for synthesis of essential proteins such as clotting factors. During the postprandial state, amino acids absorbed from a meal are taken up in part by the liver and then released to the circulation. Skeletal muscle ultimately takes up a major portion of the circulating amino acids, thus resulting in a transition from net release to net uptake of amino acids. Circulating insulin levels decrease progressively in the postabsorptive state, facilitating protein breakdown, whereas increased circulating insulin and amino acids in the postprandial state not only decrease muscle protein breakdown but also increase the incorporation of amino acids into muscle proteins. It has been demonstrated that insulin deprivation in patients with type 1 diabetes leads to protein breakdown in the splanchnic bed and leg skeletal muscle, whereas protein synthesis increases almost exclusively in the splanchnic bed (138) (Fig. 17.5). Again, a net release of amino acids from muscle occurs during insulin deprivation because of an increase in protein breakdown (Fig. 17.6). By contrast, amino acid uptake increases in the splanchnic bed as a consequence of increased protein synthesis to an extent that exceeds a coincident increase in protein breakdown.

Skeletal Muscle

Skeletal muscle is an extremely important contributor to insulin effects on protein metabolism not only because it represents 50% of total body protein but also because it represents the majority of insulin-responsive tissue in the body. Studies of patients with type 1 diabetes during transient insulin deprivation have

A. Postabsorptive or Low Insulin State

B. Postprandial or High Insulin State

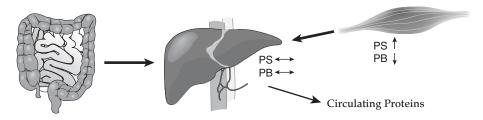

Figure 17.4. Amino acid exchanges across the major organs. The splanchnic bed (presumably reflecting predominantly liver) is a net receiver of amino acids during the postabsorptive state. Liver gets a continuous supply of amino acids so that the synthesis of various essential circulating proteins such as clotting factors can be maintained. There is a net release of amino acids from skeletal muscle [by increasing protein breakdown (PB)] during the postabsorptive state. In contrast, during the postprandial state, muscle is a net receiver of amino acids [by increased protein synthesis (PS) or reduced protein breakdown] and the splanchnic bed (presumably following the absorption of amino acids from the meal) is a net releaser of amino acids. Insulin is the key hormone involved in the regulation of amino acid release from muscle. Insulin inhibits muscle protein breakdown and facilitates the net uptake of amino acids in skeletal muscle in the postprandial state (131).

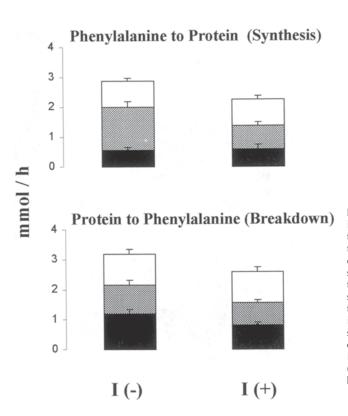

Figure 17.5. Regional protein dynamics in persons with type 1 diabetes during insulin deprivation [I(-)] and insulin treatment [I(+)]. Splanchnic protein turnover is represented by gray, skeletal muscle protein turnover by black, and turnover of other proteins by white. During insulin deprivation, protein breakdown was higher than protein synthesis in skeletal muscle, whereas in the splanchnic bed, protein synthesis was higher than protein breakdown. Insulin treatment decreased both protein breakdown and protein synthesis in the splanchnic bed, resulting in no net change in protein loss. In contrast, insulin treatment decrease only protein breakdown in skeletal muscle, thus resulting in a decrease in net protein loss. Consequently, the entire decrease in protein synthesis observed at the whole-body level during insulin replacement occurred in the splanchnic bed, and the entire protein conservation due to insulin treatment was caused by a decrease in muscle protein breakdown. (Adapted from Nair KS, Ford GC, Ekberg K, et al. Protein dynamics in whole body and in splanchnic and leg tissues in type 1 diabetic patients. *J Clin Invest* 1995;95:2926–2937.)

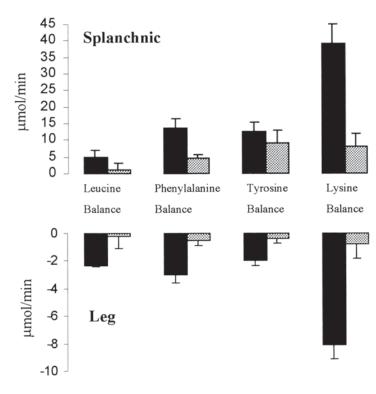

Figure 17.6. Splanchnic bed and leg amino acid balance in patients with type 1 diabetes during insulin deprivation (*black*) and replacement (*gray*). A net release of amino acids from the leg muscle bed and a net uptake of amino acids by the splanchnic bed occur during insulin deprivation. Leucine, phenylalanine, tyrosine, and lysine balance became less negative with insulin replacement in the leg, whereas they became less positive in the splanchnic bed. (Adapted from Nair KS, Ford GC, Ekberg K, et al. Protein dynamics in whole body and in splanchnic and leg tissues in type 1 diabetic patients. *J Clin Invest* 1995;95:2926–2937.)

consistently documented increases in the breakdown of muscle protein without an effect on the synthesis of muscle protein (28,31,132,138,152,154,155,164). These findings are consistent with in vitro and in vivo studies reporting increased protein breakdown in skeletal muscle from diabetic rats (19,78,129, 130,156–158). However, unlike in humans with type 1 diabetes, rates of synthesis of muscle protein in rats with alloxan- and streptozotocin-induced diabetes (20,158-162) and in eviscerated dogs (163) are consistently decreased compared with rates in control animals. In addition, a recent study demonstrated a significant decrease in protein synthesis in rat muscle during diazoxideinduced postprandial insulin deficiency (56). Collectively, these studies indicate that the loss in muscle protein associated with a deficiency in circulating insulin is caused by an increase in the breakdown of muscle protein, resulting in an increased release of amino acids. Despite the evidence that insulin is a promoter of protein synthesis, acute insulin withdrawal does not appear to decrease protein synthesis in human skeletal muscle.

In cross-limb arteriovenous studies of insulin infusion in patients with type 1 diabetes, most (138,154,155), but not all (152), have demonstrated decreases in protein breakdown, suggesting a direct effect on skeletal muscle. By contrast, protein synthesis measured across the limbs of patients with type 1 diabetes remains unchanged with insulin replacement (138,143, 154,155). Other investigations have used incorporation of amino acids with an isotopic label into protein to measure protein synthesis rates in muscle fractions. These studies also have shown that rates of synthesis of mixed muscle protein (132) and skeletal muscle myosin heavy-chain protein (143) remain unchanged in patients with type 1 diabetes when insulin is replaced (31,143, 154). Again, these findings differ from in vitro, in situ, and other animal models of insulin deprivation (11-14,16), which consistently have shown that the addition of insulin stimulates protein synthesis (12,15,17,18,20,21). The discrepancy between human and animal studies may represent species differences, the difference between growing rodents and mature humans, or the acute versus chronic nature of the insulin deficiency. Recent studies in

a pig model (165) and in nondiabetic humans (166) demonstrated that insulin selectively stimulates the synthesis rate of muscle mitochondrial proteins with no significant effect on myosin heavy chain or sarcoplasmic proteins. These human studies, showing the effect of insulin on muscle mitochondrial protein synthesis, were performed while glucose and amino acids were infused to prevent the insulin-induced fall of these substrates.

Splanchnic Bed

Insulin replacement in patients with type 1 diabetes decreases protein turnover (synthesis and breakdown) in the splanchnic bed (138). The decrease in splanchnic protein synthesis appears to account completely for the decrease in whole-body protein synthesis observed under these conditions. Whether changes in splanchnic protein turnover occur in the liver or intestine or both is not clearly established. In one study (167), a decrease in the rate of protein synthesis was demonstrated in duodenal mucosa obtained endoscopically from insulin-deprived patients with type 1 diabetes. The decrement in mucosal protein synthesis was corrected with insulin treatment. This raises the possibility that diminished synthesis of intestinal mucosal protein may contribute to the development of gastrointestinal complications in patients with poorly controlled type 1 diabetes. Protein turnover and protein balance may be particularly important for gut mucosa remodeling because of the rapid turnover rate of this tissue. The observation that hepatic synthesis of plasma proteins such as fibrinogen is increased during insulin deprivation in patients with type 1 diabetes supports the hypothesis that liver also is a contributor to the increased rate of splanchnic protein synthesis under these conditions (146). Insulin and amino acids have been shown to suppress the breakdown of hepatic proteins in perfused rat liver (140, 168,169), and degradation of hepatic protein is more rapid in livers from diabetic rats than in normal rats (170). A recent human study demonstrated that although insulin has only a

Renal Hypertrophy

The kidney is another organ system that significantly contributes to whole-body protein balance (172), and alterations in protein turnover may contribute to renal complications in patients with diabetes (173). Hypertrophy of the kidney is a consistent finding in early type 1 diabetes in humans (174) and in animal models of diabetes (175–177). An early study attributed the net increase in rat kidney protein mass following streptozotocin induction of diabetes entirely to inhibition of protein breakdown (178). Alternatively, streptozotocin treatment of mice was shown to increase kidney protein breakdown, as determined by a double isotope pulse-chase valine labeling technique, despite the finding of renal hypertrophy (175). This increase in protein breakdown involved mitochondrial, nuclear, microsomal, and cytosolic fractions of the kidney. It therefore was hypothesized that both renal protein synthesis and breakdown are increased with insulin deficiency. However, the increase in protein breakdown during the early stages of diabetes is less than the increase in protein synthesis, resulting in renal hypertrophy. In agreement with this hypothesis are in vitro findings of studies of proximal-tubule suspensions from animal kidneys. One study reported higher rates of protein breakdown for incubated opossum proximal tubules in the absence of insulin (179). Another study demonstrated a nearly twofold increase in the incorporation of [3H]valine into proteins obtained from streptozotocin-treated rat proximal tubules compared with that of controls (180). Alternatively, studies of proximal tubules isolated from rats with streptozotocin-induced diabetes have reported decreased protein breakdown rates in vitro (181,182). Thus, there is not complete agreement in the literature about the primary mechanism for renal hypertrophy seen in animal models of diabetes. Further studies on renal protein turnover in human diabetes also are needed.

TYPE 2 DIABETES MELLITUS

Whole-Body Protein Turnover

The effects of type 2 diabetes on protein metabolism are less well understood than the effects of type 1 diabetes. Unlike patients with type 1 diabetes, patients with type 2 diabetes are similar to obese individuals without diabetes in terms of protein stores (183). In addition, nitrogen balance studies have shown that lean body mass is preserved in patients with type 2 diabetes even in the setting of hyperglycemia and reduced dietary intake of protein (184). Most studies using isotopelabeled amino acid tracer techniques support the hypothesis that whole-body protein metabolism is affected modestly, if at all, in type 2 diabetes (185-188). For example, whole-body leucine carbon flux (¹³C), leucine nitrogen flux (¹⁵N), and leucine oxidation were not different in obese women without diabetes and obese women with type 2 diabetes (186). In addition, more rigorous insulin therapy that improved plasma glucose did not alter leucine kinetics. Welle and Nair (188) observed an absence of change in leucine kinetics following improved glucose control in obese women with type 2 diabetes after 2 weeks of treatment with an oral hypoglycemic agent (glyburide) and again after 2 weeks of insulin therapy. Luzi et al. (185) found no significant differences in decreased leucine

flux, leucine oxidation, and nonoxidative leucine flux during euglycemic hyperinsulinemic clamps in the postabsorptive state in patients with type 2 diabetes and control subjects. When these subjects were given a combined insulin and amino acid infusion, plasma leucine concentration, leucine oxidation, and nonoxidative flux increased and leucine flux decreased as compared with basal values. However, the changes were similar for the subjects with and without diabetes. Alternatively, Denne et al. (189) reported findings consistent with increased whole-body protein breakdown in patients with type 2 diabetes. This study documented an increased rate of whole-body phenylalanine flux in obese subjects with type 2 diabetes during poor glycemic control as compared with obese control subjects without diabetes. Although the rate of protein breakdown was reduced during a hyperinsulinemic euglycemic clamp in the subjects with diabetes, the suppression was not different from that observed in the control subjects. Subsequent treatment of hyperglycemia with intensive insulin therapy did not alter the results in the basal or hyperinsulinemic condition.

Gougeon et al. (190-192) studied integrated feeding-fasting protein metabolism in patients with type 2 diabetes as compared with that in obese subjects without diabetes by a 60-hour oral [¹⁵N]glycine method in which urine [¹⁵N]urea enrichment is used to measure nitrogen flux and calculate protein synthesis and breakdown. The data suggested that whole-body nitrogen flux, protein synthesis, and protein breakdown are greater in hyperglycemic patients with type 2 diabetes on an isoenergetic diet than in obese control subjects without diabetes. In addition, patients with type 2 diabetes on a low-energy diet with preserved protein content did not completely equilibrate negative nitrogen balance over a 6-week period, in contrast to obese control subjects, despite restoring glycemia to near-normal levels (190). However, exogenous insulin (191) or oral hypoglycemic agents (192) in doses sufficient to improve hyperglycemia improved the altered protein metabolism in the patients with type 2 diabetes.

Collectively, these results suggest that there is a dissociation between the effects of insulin on protein and carbohydrate metabolism in type 2 diabetes. Most studies indicate that whole-body protein metabolism is essentially normal in the postabsorptive state. This suggests that the maximal effect of insulin on protein turnover may occur at basal levels of insulin and that further increases in circulating insulin necessary to achieve normal glucose levels may not have any additional effects. Alternatively, integrated fed-fasting whole-body protein metabolism in patients with type 2 diabetes may be altered during poor glycemic control. This condition requires further investigation.

Regional Protein Turnover

Reports documenting regional protein dynamics in patients with type 2 diabetes are limited. The effects of type 2 diabetes on 3-methylhistidine excretion, an index of myofibrillar protein breakdown, have been studied to a limited extent. In two studies, increases in urinary excretion of 3-methylhistidine were demonstrated in patients with poorly controlled type 2 diabetes as compared with healthy subjects (193) and obese subjects (192) without diabetes. In both studies, excretion of 3-methylhistidine decreased with improved glycemic control. However, patients with type 2 diabetes appear to be less sensitive than patients with type 1 diabetes to glycemic control (193). By contrast, one study using arteriovenous techniques across the leg showed a decrease in [$^{2}H_{5}$]phenylalanine flux in obese subjects with type 2 diabetes as compared with obese subjects without diabetes, suggesting a decrease in breakdown of skeletal mus-

cle protein (189). Furthermore, euglycemic hyperinsulinemia reduced protein breakdown by 42% across the leg in the subjects without diabetes but did not inhibit breakdown in the subjects with diabetes. Of interest is the increase in BCAA concentrations in obese patients with type 2 diabetes (194,195). However, BCAA concentrations in nonobese subjects with type 2 diabetes and nonobese healthy subjects are comparable (185). Moreover, BCAA levels do not change with improved glycemic control in subjects with type 2 diabetes (186). Limited data are available examining splanchnic protein metabolism in type 2 diabetes. One study reported that postprandial splanchnic uptake of [¹⁴C]phenylalanine from a standardized meal in nonobese subjects with type 2 diabetes is not different from that in normal control subjects (196).

ADDITIONAL FACTORS

Other Hormones

Insulin deprivation results in changes in a number of other hormones and substrates (Table 17.1). In many instances, these changes are dependent on the duration of insulin insufficiency. For example, increases in glucagon and growth hormone can occur in the short term, whereas catecholamines, cortisol, and insulin-like growth factor (IGF-1) remain relatively unchanged. An increase in IGF-binding proteins, however, may reduce the free IGF-1 levels (197). After a longer period of insulin deprivation, levels of cortisol, epinephrine, and norepinephrine may increase and the level of IGF-1 may decrease (198). Whole-body studies in humans have shown that elevated concentrations of glucagon during insulin deficiency cause substantial increases in leucine oxidation and resting metabolic rate and a slight increase in protein breakdown (199,200). When insulin is present at normal concentrations, the protein breakdown associated with hyperglucagonemia is normalized (201,202) but leucine oxidation is not (199,202). Furthermore, a somatostatin-induced decline in glucagon levels decreases leucine oxidation but not protein breakdown as indexed by leucine flux (199). These findings suggest that insulin deficiency increases protein breakdown but that hyperglucagonemia is primarily responsible for the increased leucine oxidation observed during insulin deprivation. Glucagon appears to exert its effects primarily on the liver with no apparent effect on skeletal muscle in humans (44).

The roles of the adrenal hormones cortisol and epinephrine in diabetes-induced protein turnover are largely unknown. High-dose glucocorticoids have been shown to increase protein breakdown (203,204) and oxidation (205). However, even though glucocorticoid-induced muscle wasting in humans is well described in Cushing syndrome and during administration of high doses in treatment of various diseases, the effects of these conditions on skeletal muscle protein dynamics remain uncertain (44). Whole-body measurements suggest that epinephrine infusion decreases protein breakdown in the short term (206,207), with no apparent effect after prolonged exposure (208). In skeletal muscle, epinephrine administration appears to decrease protein breakdown and synthesis initially, with improved net protein balance occurring after prolonged treatment, primarily due to a return to normal synthesis rates (209). The anabolic effect of catecholamines is further supported by the use of the potent β -agonist clenbuterol in livestock (210) and by some athletes (211) to increase muscle mass.

Infusion of growth hormone acutely decreases leucine oxidation and increases whole-body protein synthesis (212). Nonmuscle protein synthesis appears to be the greatest contributor to the increases in whole-body protein synthesis observed after administration of growth hormone. However, in studies that measure both protein synthesis and breakdown, positive net muscle protein balance is consistently demonstrated with systemic growth hormone replacement (44). Growth hormone also appears to blunt the decrease in muscle protein breakdown observed in the presence of insulin (213). The direct effects of growth hormone on protein turnover are difficult to distinguish from the effects mediated by IGF-1. One study found that local infusion of growth hormone increased muscle protein synthesis to a greater extent than systemic delivery of growth hormone (214). This suggests a direct action of growth hormone on muscle protein synthesis; however, actions through locally produced IGF-1 and/or IGF-binding proteins in this study cannot be excluded (215,216). Locally delivered IGF-1 has been shown to stimulate synthesis of muscle protein (44,217-219), whereas systemic infusion does not increase wholebody protein synthesis (220). In summary, during insulin deprivation the effects of the so-called counterregulatory hormones may be as important to the changes observed in protein metabolism as insulinopenia itself.

Substrates

Circulating levels of glucose, ketoacids, fatty acids, and amino acids all increase during insulin deprivation. BCAA, especially leucine, have been shown to inhibit whole-body protein breakdown and specifically decrease muscle protein breakdown, while increasing leucine oxidation (198,221). Therefore, increased levels of BCAA may play a pivotal role in preventing rapid depletion of body protein during insulin deficiency. As discussed above, amino acid supplementation to obtain hyperaminoacidemia during insulin infusion usually results

TABLE 17.1.	Changes in Hormones and Su	bstrates with Insulin	Deprivation

in an increase in protein synthesis. Glucose concentration per se has no apparent effect on protein turnover in humans (222). Increased levels of fatty acids are associated with decreases in protein breakdown and leucine oxidation, suggesting a general anabolic effect (203,223). There appears to be no effect of fatty acids on protein synthesis. Alternatively, infusion of β -hydroxybutyrate decreases urinary nitrogen loss and leucine oxidation, while increasing whole-body and muscle protein synthesis (224).

CONCLUSION

It is well established that protein turnover is greatly increased with a net negative nitrogen balance during short-term insulin deprivation in patients with type 1 diabetes. This increased protein loss is almost exclusively due to increased breakdown of muscle protein. Insulin has been shown to act at different levels of the protein synthetic process, although short-term insulin infusion in individuals without diabetes or short-term insulin deprivation in patients with type 1 diabetes has no apparent effect on mixed muscle protein synthesis. Alternatively, insulin seems to have distinct effects on different tissue protein pools and individual proteins. Changes in whole-body or regional protein turnover are much less apparent in type 2 diabetes than in type 1 diabetes. However, little is known about the effects of insulin-resistant conditions on protein turnover in subcellular compartments or on the synthesis of individual proteins. Changes in the turnover dynamics of proteins affecting key regulatory pathways, cellular structure, and/or energy production may be critical to the pathogenesis of diabetes or its associated complications. The subcellular pathways affecting protein synthesis and breakdown in diabetes mellitus are being defined. An exciting era of investigation has been introduced by the sequencing of the human genome and the subsequent development of genome-wide search strategies. Consequently, identifying the protein products of promising diabetes candidate genes will move forward, and protein characterization and an understanding of regulatory events, including turnover dynamics, will become critical. Challenges awaiting investigators include further definition of the contribution of various cell and tissue types to regional protein turnover (e.g., splanchnic bed). In addition, the effects of counterregulatory and other hormones on protein synthesis and breakdown in patients with diabetes need to be more clearly defined. The development of more sophisticated techniques that will aid in the measurement of protein synthesis and breakdown in individual cell compartments and specific proteins will be essential for understanding and ultimately modulating the underlying mechanisms.

CHAPTER 18 Rodent Models for the Study of Diabetes

Clayton E. Mathews and Edward H. Leiter

ANIMAL MODELS OF SPONTANEOUS TYPE 1 (INSULIN-DEPENDENT) DIABETES MELLITUS 292

Nonobese Diabetic Mice 292 The BioBreeding Rat 303 Komeda Diabetes-prone Rats 305 Single Gene Mutations Producing Insulin-Responsive Diabetes 306

Patients with diabetes share the clinical symptom of hyperglycemia accompanied by either insufficient circulating insulin or inadequate insulin action, but the genetic and environmental interactions leading to the metabolic disorder are complex because of etiopathologic heterogeneity. Because of the multifaceted nature of diabetes, etiologic dissection of diabetes in humans has been difficult. Much of the current understanding of diabetes etiopathogenesis has evolved from analysis of animal models in which either insulin-dependent or insulin-resistant forms of diabetes develop spontaneously. As early as the late 19th century, the importance of animals in the study of human disease was established when Oscar Minkowski (1a,1b) discovered the link between the pancreas and diabetes by pancreatectomizing dogs. The use of dogs and their pancreata by Banting and Best (1c,1d) in the 1920s in their discovery and isolation of insulin as a treatment for humans with insulin-dependent diabetes stands as a landmark in the history of medicine.

While animals have been used for physiologic and pharmacologic studies of diabetes for more than 100 years, animals with genetic syndromes that are models for various forms of diabetes in humans have been developed only during the last 50 years. Since the previous edition of this book, there has been an explosive increase in the number of new mouse models generated by gene-targeting technology wherein specific genes are disrupted (1e). Genetically engineered mutant mice used in diabetes research may or may not serve as good models for the natural course of the development of diabetes in humans but provide valuable tools for evaluating the role of a single gene in the maintenance of either metabolic or immunologic homeostasis (2). The focus of this chapter is rodent models of spontaneously occurring diabetes. We discuss information on targeted mutations of diabetogenic significance only to aid in understanding the spontaneous disease syndrome, especially autoimmune (type 1 or insulin-dependent) diabetes mellitus in the nonobese diabetic (NOD) mouse.

Research involving the available rodent models of both type 1 diabetes and type 2 diabetes (non–insulin-dependent) tends to

be compartmentalized, with immunologists and immunogeneticists focusing on the NOD and BB (BioBreeding) rat models of type 1 diabetes. In turn, investigators interested in mechanisms of metabolic control and in obesity focus on the models of type 2 diabetes. This "division of interest" can obscure an important "lesson" taught by viewing the totality of rodent models available. Such a survey would suggest potential pathologic synergism among genomes selected for susceptibility to type 1 or type 2 diabetes. For instance, it is not difficult to envisage that combinations of genes contributing to impaired immune tolerance (a defect associated with type 1 diabetes) might interact deleteriously with genes contributing to impaired β-cell function or impaired glucose tolerance (IGT; both defects proposed to be central to the etiopathogenesis of certain types of type 2 diabetes). One such deleterious interaction was uncovered by mating type 1 diabetes-prone NOD mice to a wild-derived inbred strain carrying a predisposition to obesity (3,4). The biology of the pancreatic β -cell now provides a common meeting ground for researchers in both type 1 and type 2 diabetes. This chapter will describe a variety of relatively new inbred strains generated by sib matings of outbred Swiss (or CD-1) mice. The progenitor-outbred population is considered a model of an outbred human population segregating genetic susceptibility for type 1 and type 2 diabetes. Extensive inbreeding of pairs of mice from this family produced lean, glucose-tolerant strains (SWR, SJL, FVB), strains moderately obese and exhibiting IGT (NON, NSY), and strains developing overt type 2 diabetes with moderate (ALS) or more pronounced obesity (TallyHo) (Table 18.1). An interesting aspect to this family of mice is that it also contains the NOD strain, the most widely used animal model of type 1 diabetes. This chapter will discuss the available models of type 1 and type 2 diabetes in current use. The first portion of the chapter discusses in detail the mouse and rat models of type 1 diabetes. The remainder of the chapter will briefly cover several models of non-immunemediated insulin-sensitive diabetes and then briefly describe each of the 15 rodent models of type 2 diabetes. The intent of

this chapter is to provide a guide for the interested investigator so that careful selection and use of the appropriate systems can be made.

ANIMAL MODELS OF SPONTANEOUS TYPE 1 (INSULIN-DEPENDENT) DIABETES MELLITUS

Type 1 diabetes mellitus, or insulin-dependent diabetes mellitus (IDDM), is an endocrine disease in humans that, in most cases, results from an autoimmune destruction of the insulin-producing β -cells within the pancreatic islets of Langerhans (5). Clinical presentation of symptoms of type 1 diabetes (fasting hyperglycemia, glycosuria, and ketoacidosis) is usually abrupt in onset and is indicative of destruction of more than 90% of the β cell population of the endocrine pancreas. The underlying autoimmune processes producing this level of extensive β -cell destruction, however, are believed to be chronic in nature. The two most intensively studied rodent models of autoimmune type 1 diabetes, the NOD mouse and the BB rat, clearly establish that T lymphocytes are both initiators and the final effectors of β-cell destruction (6). Certain clinical and immunopathologic differences distinguish these two models, indicating that the pathways leading to autoimmune type 1 diabetes in humans may be diverse. Because of the greater definition of the mouse genome, coupled with the ease of introducing transgenes and genetically targeted mutations ("knockouts") into this genome, the NOD mouse has surpassed the BB rat as the more commonly studied model of type 1 diabetes. Yet, given important genera differences between Mus and Rattus in the pathogenesis of type 1 diabetes, investigators considering a rodent model of type 1 diabetes for therapeutic intervention studies should look for efficacy in both the mouse and the rat models if the ultimate goal is to extrapolate such therapies to humans. The clinical heterogeneity of type 1 diabetes is illustrated by a dominant negative mutation in one of the two mouse insulin genes, creating an insulin-dependent syndrome in the absence of autoimmunity in the C57BL/6J-Ins2Akita mouse, a new model to be described below (7). A final example of this clinical heterogeneity is an insulin-responsive diabetes superimposed upon a monogenic obesity syndrome represented in a C57BLKS/J stock congenic for the *fat* mutation at the carboxypeptidase E locus (*Cpe^{fat}*).

Nonobese Diabetic Mice

ORIGINS AND RELATED STRAINS

NOD is a descriptor string denoting the nonobese diabetic inbred strain developed by inbreeding of ICR (Swiss) mice in Japan (9). The strain is best referred to as NOD, since not all NOD mice will develop diabetes, although most mice of this strain develop insulitis. The discovery of these mice emphasizes the role of serendipity in science. The NOD and certain of the NOD-related inbred strains were developed from Jcl:ICR progenitors at the Shionogi Research Laboratories in Aburahi, Japan, by Dr. S. Makino (8-10). Selection for dominant cataract with microphthalmia was the initial objective of the breeding program in Makino's laboratory. This selective breeding program led to the development of the CTS (cataract Shionogi) strain, in which all mice develop cataracts, and of NCT, a cataract-free control strain. At the sixth generation of inbreeding (F6), Makino noticed that some mice that were free of cataracts exhibited high fasting blood glucose levels. By selective breeding of F6 sibs and their progeny that exhibited this phenotype, Makino hoped to develop a new inbred strain exhibiting spontaneous diabetes. At the same time, he recognized the need for a euglycemic control strain and simultaneously inbred F6 sibs and their progeny that exhibited normal fasting blood glucose levels. In 1974, at the 20th generation of inbreeding (F20), a female spontaneously developed overt type 1 diabetes associated with heavy leukocytic infiltrations within the pancreatic islets (insulitis). Paradoxically, this female was not found in the line being selected for fasting hyperglycemia. Instead, the female with spontaneous type 1 diabetes was found in the line being inbred as a diabetes-free euglycemic control line. The progeny of this diabetic female were the founders of the NOD strain. Since the line originally selected for high fasting glucose levels never progressed to overt diabetes at the time that type 1 diabetes appeared in the euglycemic control (the latter now the NOD) line, the former strain was designated NON, for nonobese normal, and more recently, redesignated as nonobese nondiabetic (8,11). It was serendipitous not only that Makino coselected a euglycemic "control" line but also that his screening of this line was sufficiently rigorous to permit the discovery of that the "exceptional" female and the selection of her progeny to produce the NOD strain. Another serendipitous happenstance was that the husbandry environment in Makino's vivarium was sufficiently free of murine pathogenic agents such that the diabetic phenotype could develop (see the section "Critical Role of Environment"). It should be noted that while subsequent inbreeding of ICR mice in Japan produced other inbred strains, including the ILI (ICR-L line-Ishibe), NSY (Nagoya-Shibata-Yasuda), ALS (alloxan-induced diabetes susceptible), and ALR (alloxan-induced diabetes resistant), none of the latter have developed spontaneous, autoimmune type 1 diabetes (although some that will be described in sections to follow

have developed IGT, pre-type 2 diabetes, or overt type 2 diabetes) (12–14).

Distribution of NOD and its closely related strains was tightly restricted to Japan within the first 5 years of their development (15). However, NOD mice are now widely available from suppliers in Japan (NOD/Shi from Clea, Tokyo), the United States (NOD/LtJ from The Jackson Laboratory, Bar Harbor, ME; and NOD/MrkTac from Taconic, Germantown, NY), and Europe (NOD/HIBom, Bomholtgard, Ay, Denmark). Substrain differences have been reported, notably, the very low incidence of type 1 diabetes present in the NOD/Wehi substrain in Australia (16). To avoid substrain divergence resulting from accumulation of recessive mutations distinct from those being fixed in the source colony, new breeders from the source colony can be imported every 10 to 20 generations to maintain uniformity with the mice being studied by other investigators.

CRITICAL ROLE OF ENVIRONMENT

Investigators studying NOD mice must be aware of the critical role of a specific pathogen-free environment in allowing penetrance of the underlying genetic susceptibility (17). The investigator has to choose between two options: maintaining a NOD breeding colony on site or ordering the requisite number of mice necessary for specific studies. Whichever option is selected, the investigator must house the mice in a specific pathogen–free (SPF) vivarium maintained to high standards of cleanliness and good animal care practice to achieve the diabetes frequencies mentioned above [reviewed in reference (18)]. This is necessary because NOD mice are subject to protective immunomodulation when stimulated by a broad spectrum of extrinsic pathogens, including viruses, bacteria, or their products or when fed semipurified diets lacking diabetogenic catalysts (6).

CLINICAL COURSE OF TYPE 1 DIABETES

In marked contrast to the male gender–biased susceptibility observed in rodent models of type 2 diabetes to be discussed later, one of the mouse-specific characteristics of type 1 diabetes pathogenesis in NOD mice is that it is female gender–biased. This bias is presumably attributable to the development of larger lymphoid organs in females than in males and the stronger response of females to immunization. In high-incidence colonies of NOD mice, the incidence in females typically reaches 80% to 90% by 24 weeks of age, whereas the incidence in males is lower and much more variable, usually reaching more than 40% by 30 weeks of age in SPF colonies. In the author's (EHL) colony of NOD/Lt males at The Jackson Laboratory, the frequency of type 1 diabetes in males varies from

year to year, with a recorded low of 40% by 30 weeks of age and a high of 70% by 24 weeks of age. One of the unusual characteristics of the development of type 1 diabetes in NOD mice is that insulin therapy is not obligatory to sustain life over the first 2 to 4 weeks following the first diagnosis of hyperglycemia or glycosuria. This, in part, represents the ability of diabetic NOD mice to resist development of severe ketoacidosis (19). Diabetic NOD/Lt mice in the author's colony must exhibit chronically high blood glucose levels (>500 mg/dL) before severe ketonemia can be demonstrated. For example, a diabetic NOD/Lt female with a glucose level of 337 mg/dL had a β-hydroxybutyrate level of only 0.5 mg/dL, a nondiabetic background level. A dipstick test of this mouse's urine was also negative for ketones (acetoacetic acid). Two chronically diabetic NOD/Lt females (glucose levels of 913 and 954 mg/dL) also were negative for urine ketones but did exhibit blood levels of β-hydroxybutyrate of 10 and 20 mg/dL. Ketone bodies in urine appear only after the establishment of pronounced ketonemia. It should be noted that ketone bodies in the blood of chronically diabetic mice are considerably lower than those in humans, probably because mice can metabolize blood ketones to lactate (20). As hyperglycemia and glycosuria become more severe, mice exhibit polyuria, dehydration, and weight loss. Complete protocols for monitoring the diabetic state have been published elsewhere (18). In vivaria where high levels of NOD intra-islet insulitis develop, but unknown environmental factors suppress the transition to clinical type 1 diabetes, the onset of disease in both males and females can be precipitated by treatment with cyclophosphamide (21). Commonly, 200 mg/kg of body weight is administered intraperitoneally initially, with a second injection given 2 weeks later if required. Cyclophosphamide-accelerated type 1 diabetes is a particularly useful tool for synchronizing activation of diabetogenic effectors in young (7- to 10-week-old) NOD/Lt males.

CONTROL OF BLOOD GLUCOSE LEVELS WITH INSULIN IN DIABETIC MICE

It is exceedingly difficult to maintain stable normoglycemia in a diabetic mouse (NOD or otherwise) by insulin injection, although life span can be extended. A protocol used by Dr. M. Hattori (Joslin Diabetes Center, Boston, MA) (22) entails twice-daily subcutaneous insulin (a 1:1 mixture of regular and NPH insulin administered at 7:30 a.m. and 4:00 p.m.). The dose of insulin (between 0.5 and 1.0 units) is adjusted according to the severity of matinal and evening glycosuria. Table 18.2 shows random glucose and glycosylated hemoglobin (HbA₁) measurements in diabetic animals with and without insulin treatment.

TABLE 18.2. Hemoglobin A1 Levels in Diabetic Nonobese Diabetic Mice With and Without Insulin Treatment				
Mice (n)	Age at HbA ₁ assay (mo)	Duration of diabetes at HbA_1 assay (wk)	HbA ₁ (%)	Blood glucose (mg/dL)
Diabetic NOD				
Insulin (9)	7.0 ± 0.9	6.0 ± 1.5	6.4 ± 0.5^{a}	$370 \pm 2^{a,b}$
No insulin (6)	5.8 ± 0.7	4.7 ± 0.4	9.2 ± 0.5^{a}	$439 \pm 26^{a,b}$
Nondiabetic NOD (6)	3.9 ± 0.7	_	3.3 ± 0.2	73 ± 4
C57BL/6 (4)	6–7	—	3.6 ± 0.1	120 ± 2

NOD, nonobese diabetic.

CONTROL STRAINS FOR NONOBESE DIABETIC MICE

An important issue for investigators studying genes and phenotypes in the NOD mouse is that of an appropriate control. The literature shows that C57BL/6J (B6) or BALB/c are commonly used as "standard" strains against which to compare NOD immunophenotypes or gene sequences. However, since neither strain was Swiss-derived, the differences observed could represent normal variation expected for independently derived mouse strains. Selection of a control strain depends on the nature of the experiment and the hypotheses being tested. A partial listing of possible control strains and their potential uses is provided in Table 18.3. For an investigator interested in associating a particular genetic polymorphism with a phenotype associated with NOD diabetes, it is logical to compare the NOD genotype/phenotype with that found in NOD-related but type 1 diabetes-resistant inbred strains. These include mice with a common Swiss origin but with differences in their major histocompatiblity complex (MHC) haplotype and/or other non-MHC genes (designated Idd loci) conferring various degrees of resistance to type 1 diabetes. Figure 18.1 provides an illustration wherein Swiss-derived strains were surveyed for the phenotype of high percentages of T lymphocytes in the peripheral blood and spleen, an NOD strain characteristic very possibly associated with the resistance of these T lymphocytes to apop-

tosis (23). This complex phenotype is not unique to NOD; it also is characteristic of the SJL/J strain. SJL/J (H2s) mice are highly susceptible to experimental allergic encephalomyelitis (EAE). A genetic contribution to the SJL strain susceptibility to EAE colocalizes to a 0.15-cM region on chromosome (Chr) 3 that also confers susceptibility to type 1 diabetes (Idd3) in outcrosses of NOD with certain type 1 diabetes-resistant strains (24,25). The logical candidate within this interval is the *ll2* gene, with NOD and SJL showing identity for an Il2 gene polymorphism associated with a presumed hyperglycosylated interleukin-2 (IL-2) molecule (26,27). However, it is unknown whether the SJL trait of high numbers of peripheral T cells cosegregates with EAE susceptibility and the SJL Il2 allele. Indeed, SWR/J, another Swiss-derived strain, also shares the Il2 polymorphism with NOD but does not exhibit the T lymphoaccumulation phenotype (Fig. 18.1). This does not exclude the *ll2* polymorphism as a contributor to the phenotype but illustrates that genetic control of the trait is oligo- or multigenic. These examples also illustrate the value of comparing NOD to more than one control strain.

Because it is $H2^{g7}$ -identical, but diabetes- and insulitis-resistant, NOR/Lt is an NOD-related strain frequently used to evaluate the effect of changes in non-MHC genes. This is a recombinant congenic strain arising from outcross of NOD with

TABLE 18.3. Control Strains and Stocks for Nonobese Diabetic (NOD) Mice			
Strain/stock name	Characteristics and uses		
A. Related inbred strains			
ALR/LtJ	Genome scan shows close relation to NOD/Lt, including very similar <i>H2gx</i> haplotype; strongly resistant to free radical-mediated stress; diabetes- and insulitis-free. Available from JAX.		
NOR/LtJ	H2g ⁷ -identical recombinant congenic strain (~87.5% NOD/LtJ genome, 12.5% C57BLKS/J genome). Resistant to intraislet insulitis and diabetes-free; useful for immunopathologic comparisons since periinsulitis develops. Available from JAX.		
ILI/ShiJos	H2g ⁷ -identical Swiss-derived strain; diabetes- and insulitis-free. Little additional information because strain still not distributed by Japanese investigators.		
SWR/J	Common derivation from Swiss mice; immunocompetent; useful as control when studying immune defects in NOD/LtJ mice. <i>H2^q</i> haplotype; available from JAX.		
SJL/J	Common derivation from Swiss mice; like NOD, exhibit high % of CD4 ⁺ and CD8 ⁺ T lymphocytes in spleen (T-lymphoaccumulation phenotype). <i>H2^s</i> haplotype; available from JAX.		
NON/LtJ	Related to NOD/LtJ; IDDM-resistant MHC; males develop IGT, and NON mice become relatively CD8 ⁺ T cell–deficient with age; useful for genetic analysis of diabetes susceptibility genes. <i>H2^{nbl}</i> haplotype; available from JAX.		
B. MHC congenics			
NOD.B10- <i>H2^b</i> NOD.NON- <i>H2^{nbl}</i> NOD.SWR- <i>H2</i> ^q	Diabetes-resistant MHC on NOD genetic background; exhibit some but not all immune dysfunctions of NOD/LtJ mice; useful in dissecting the role of MHC vs. non-MHC gene in producing immunologic abnormalities. All available from JAX.		
NON.NOD- $H2^{g7}$ B6.NOD- $H2^{g7}$	Diabetogenic NOD MHC on type 1 diabetes-resistant backgrounds; exhibit some but not all immune dysfunctions of NOD mice; useful in dissecting the role of MHC vs. non-MHC gene in producing		
	immunologic abnormalities. Both available from JAX.		
C. NOD congenics with mutations affecting immunocompetence

C57BLKS/J (28). As discussed in detail below, the major genetic determinant of diabetes susceptibility in NOD mice is their H2g7 MHC haplotype (K^d , A^{g7} , E^{null} , D^b). If an investigator is interested in analyzing the diabetogenic functions of the NOD H2g7 MHC haplotype, stocks congenic for MHC haplotypes conferring resistance to type 1 diabetes are available for analysis of the selection of an autoimmune repertoire. Conversely, the diabetogenic NOD *H2g⁷* haplotype is available for study on the type 1 diabetes-resistant B6 background and in recombinant congenic strains (RCS) between CBA and NOD (29). During the initial period of NOD investigations in Japan, destruction of pancreatic β -cells was firmly established as a T lymphocyte–mediated process [reviewed in reference (10)]. For analysis of the diabetogenic potency of specific NOD T-cell clones or populations of immune effectors, NOD stocks congenic for immunodeficiencyproducing mutations blocking development of functional T lymphocytes and/or B lymphocytes are available for adoptivetransfer studies. It has recently been demonstrated that B lymphocytes are essential antigen-presenting cells (APCs) for initiation of type 1 diabetes (B lymphocyte-deficient NOD mice congenic for the $Ig\mu$ targeted mutation were protected from type 1 diabetes) (30). Therefore, T and B lymphocyte-deficient

NOD mice congenic for either the Prkdcscid (severe combined immunodeficiency mutation; henceforth denoted as scid) or targeted mutations in the recombinase-activating gene (Rag1, Rag2) provide useful diabetes- and insulitis-free mice for adoptive-transfer studies without a requirement for prior irradiation (31-34). The NOD-Rag1 and -Rag2 congenics do not exhibit the DNA repair defects associated with the scid mutation and hence can tolerate sublethal irradiation. Moreover, thymic lymphomagenesis, a strain characteristic of NOD-scid, is slower to develop in NOD-Rag mice (32). Further, these stocks provide an excellent source of NOD pancreatic islets free of insulitic infiltrates. Not included in Table 18.3 is a listing of a growing battery of congenic stocks with defined chromosomal regions bearing non-MHC Idd loci affecting diabetes-related immunophenotypes (35). Certain of these will be discussed below in the section on genetic control of type 1 diabetes.

INSULITIS AND DEVELOPMENT OF TYPE 1 DIABETES

Insulitis, the disruption of islet structure and function by infiltrating leukocytes, is the major pathognomonic feature of the development of type 1 diabetes in NOD mice (8). In these mice, the development of insulitis is not abrupt; rather, the first stages are detectable in females around the time of weaning (4 weeks), at least 2 to 3 months before development of overt diabetes. Islets develop in the perivascular/periductular areas of the pancreas. Insulitis initiates as "periinsulitis," a pervasive leukocytic infiltrate emanating from the pancreatic vasculature and secretory ducts. Periinsulitis is not unique to NOD/Lt mice; for example, it can be detected in older mice of the related, but diabetes-resistant, NON/Lt strain, as well as in the diabetes-resistant NOR/Lt strain (36,37). However, what distinguishes the histologic appearance of insulitis in NOD mice from that observed either in the T-lymphopenic BBDR (BB diabetesprone) rat or in humans is the unusually large numbers of leukocytes associated with all the pancreatic vascular spaces, including the lymphatics (lymphoaccumulation) (38). Lymphoaccumulation is not restricted to the pancreas; increased percentages of T lymphocytes are found in peripheral blood, in lymphoid organs, and in other endocrine tissues. Data in Figure 18.1 comparing NOD/Lt to other ICR (Swiss)-derived inbred strains illustrate this phenomenon. Perhaps reflective of this phenomenon, lymphoid tumors are common in aging NOD/Lt mice that remain free of type 1 diabetes (39). Accumulation of leukocytic infiltrates around the perivascular and periductular regions of the pancreas and subsequent development of progressively more severe insulitis (Fig. 18.2), usually initiates between 3 and 5 weeks in NOD females and several weeks later in males. These intrapancreatic lymphoaccumulations primarily, but not exclusively, comprise T lymphocytes ($CD4^+ > CD8^+$) (40-42). B lymphocytes and macrophage/dendritic cells also are found in the infiltrates (43). Although initially few in number, T lymphocytes capable of adoptively transferring type 1 diabetes into T and B lymphocyte-deficient NOD/LtSz-scid recipients can be isolated from islet donors as young as 3 weeks old (44).

Periinsular leukocytic aggregates around NOD islets usually initiate at one pole but eventually surround the entire islet perimeter (periinsulitis). After initiation of periinsulitis (usually in 3- to 5-week-old females and several weeks later in males), only a subset of islets observed in a microscopic field appears to be penetrated by leukocytes. However, as the mice transit through puberty, an increased prevalence of islet profiles showing intra-islet leukocytic infiltrates, coupled with erosion of between 25% and 90% of the insulin-stainable β -cell mass, is noted (18). The early insulitis, although leading to complete destruction of a percentage of islets in a given pancreas, appears

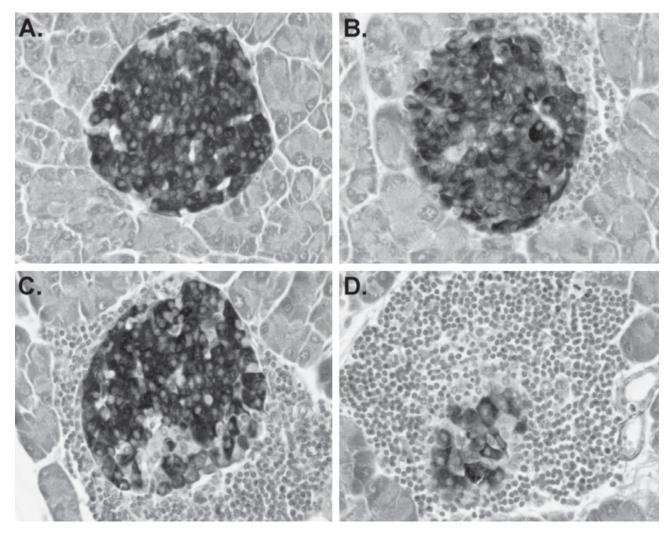

Figure 18.2. Illustration of the various stages of insulitis development in NOD/Lt mice. Islet profiles shown all were photographed in the same pancreas stained with aldehyde fuchsin to identify granulated β -cells. **A:** Unaffected islet at the level of section examined. **B:** Islet showing periinsulitis initiating at one pole. **C:** More extensive insulitis producing erosion of β -cell mass. **D:** Terminal stages of insulitis. Islet residua eventually comprise exclusively non- β endocrine cells.

to be partially compensated by a period of islet growth. During the period between 5 and 12 weeks, NOD/Lt islets are actually quite large in comparison to those of the closely related NON/Lt strain despite the heavy leukocytic aggregations surrounding or penetrating many of the islets in the former. Basal plasma insulin levels are significantly higher in NOD mice of both sexes between 4 and 6 weeks of age compared with levels in C57BL/6 (B6) mice bred in the same vivarium (45). Similarly, NOD fetal pancreas in organ culture secretes higher levels of insulin than does fetal BALB/c pancreas (46). Marked decreases in pancreatic insulin content are demonstrable in NOD/Lt females at around 12 weeks of age and several weeks later in males (47). At this time, increased numbers of atrophic "endstage" islet profiles are detected. Immunocytochemical staining of these islet residua detects primarily non-β-islet endocrine cells. When more than 90% of the β -cell mass of the pancreas is destroyed, clinical symptoms of diabetes (hyperglycemia, glycosuria, polydipsia, and polyuria) appear abruptly (48). Although intra-islet insulitis initiates early after weaning, some immunoregulatory mechanism apparently keeps many of the infiltrating T lymphocytes in a resting state until a later activation event allows more widespread destruction of the β -cell mass (47,49).

CELLULAR AND MOLECULAR ANALYSIS OF THE INSULITIC PROCESS: "MACROPHAGE INSULITIS"

In considering the insulitis process, the reader should be reminded that important substrain and environmental differences distinguish extant colonies of NOD mice around the world (39). Hence, a longitudinal analysis of cellular and molecular events descriptive of insulitic progression in one colony may not exactly match an analysis of the same parameters in a separate colony. This is especially true for reverse transcriptase–polymerase chain reaction (RT-PCR) estimations of cytokine messenger RNAs (mRNAs) expressed in longitudinal studies.

Islet-associated macrophages may mediate cytopathic events indirectly (through secretion of lymphocyte chemoattractants and through the presentation of autoantigens to them) or directly (via secretion of toxic monokines, prostanoids, nitric oxide, and other reactive oxygen species). An immunocytochemical study of NOD mice from a colony in Paris detected ER-MP23⁺ and MOMA-1⁺ macrophages/dendritic-like cells as

the first leukocytes to appear around swollen periinsular vessels in 3-week-old mice of both sexes (50); this was termed "macrophage insulitis." At 7 weeks, periinsular accumulations of leukocytes were reported that contained, in addition to the ER-MP23⁺ and MOMA-1⁺ cells, a BM8⁺ cell described as a phagocytotic macrophage. A shift in location from the periinsular space to the islet interior of BM8+ macrophages was associated with intra-islet insulitis and occurred earlier and at higher frequency in the pancreas of females than in the pancreas of males (50). In NOR/Lt mice, in which heavy periinsulitis develops with age, macrophages penetrate into the islet interior but T cells do not, possibly suggesting absence of a critical chemokine (36). Analysis by RT-PCR of spontaneously developing insulitis in NOD mice shows that, although individual islets within a single pancreas may exhibit a T-lymphocyte population expressing a relatively oligoclonal spectrum of T-cell receptor (TCR) genes, pooled islets exhibit a much more diverse spectrum of TCR clonotypes (51). The islet-reactive CD4+ T-cell clones now available from NOD spleens or islets show a diverse array of TCR α - and β -chain rearrangements (52,53). Interestingly, among the H2-K^d-restricted CD8⁺ islet-reactive clones isolated from NOD pancreatic islets, a more restricted TCR- α gene utilization has been noted, with up to 30% to 35% using an identical V α 17 to J α 42 TCR gene rearrangement (54,55).

As discussed in more detail below, CD4+ T lymphocytes of NOD mice are strongly biased to secrete a T-helper 1 (T_H1) spectrum of proinflammatory lymphokines, especially interferon-y (IFN-y). IL-12 and IL-18 are two cytokines associated with the deviation of T lymphocytes toward a T_H1 cytokine profile. Both are expressed at high levels in NOD splenic and islet-infiltrating macrophages (56,57). In the cyclophosphamide (CY)-accelerated model of diabetogenesis in NOD mice, a T_H1-insulitis in NOD/Bom was correlated with upregulation of IL-12 and IL-18 mRNA levels in both spleen and pancreas (56,57). The importance of these monokines is indicated by the observation that onset of type 1 diabetes was retarded by a T_H2 deviation achieved by chronic treatment of prediabetic NOD/Lt females with an IL-12 antagonist (58). An elegant quantitative RT-PCR analysis found I-A β^{g7} and Igµ transcript levels to be elevated by 20-fold in islets from 20-day-old NOD/Jsd mice compared with nondiabetic control strains (59). However, these markers for intra-islet APCs encompassing both macrophages and B lymphocytes failed to distinguish NOD/Jsd females that transited to overt type 1 diabetes at a high frequency (80% to 85% by 30 weeks) from NOD/Jsd males that were quite resistant to type 1 diabetes (10% to 15% diabetic by 30 weeks). Fox and Danska (36) subsequently used their quantitative RT-PCR techniques to compare a variety of APC-specific and T lymphocyte-specific transcript levels in NOD/Jsd versus the H2g7 identical, but insulitis- and diabetes-resistant NORLt strain. They reported independent genetic regulation of the macrophage insulitis (found in NOD and NOR) from the more advanced phase involving T-lymphocyte penetration (found primarily in NOD) (36). These findings support the concept that clear "checkpoints" in the development of insulitis exist. The swollen periinsular vasculature prior to lymphocyte penetration of islets described above is associated with increased expression of MHC class II and addressin on vascular endothelium. These changes probably facilitate the NOD strain-characteristic T-lymphocyte accumulation in the pancreatic lymphatics and the subsequent extravasation of $\alpha_4\beta_7$ -integrin—positive lymphocytes into the periinsular zones (60,61).

CELLULAR ANALYSIS OF THE INSULITIC PROCESS: THE ROLE OF T AND B LYMPHOCYTES

Small numbers of T lymphocytes (both CD4⁺ and CD8⁺), as well as B lymphocytes, are present in the early insulitic lesions

(41,62). Studies of adoptive transfer into NODLtSz-scid mice confirmed previous reports that pathogenic contributions from both CD4⁺ and CD8⁺ subsets are required in the natural progression of the disease (63,64). CD4+ splenic T lymphocytes preactivated in situ in overtly diabetic donors can adoptively transfer type 1 diabetes into NOD/LtSz-scid recipients in the absence of the CD8⁺ subset. In contrast, both CD4⁺ and CD8⁺ subsets are required to transfer type 1 diabetes if isolated from young, prediabetic donors (63). In NOD/LtSz-scid mice, CD8+ T lymphocytes adoptively transferred into NOD-scid recipients cannot home to islets in the absence of CD4⁺ cells (63). The mutual dependency of CD4⁺ and C8⁺ T lymphocytes for initiation of disease in adoptive transfers into NOD-scid is elegantly illustrated by using NOD-scid recipients also homozygous for a targeted β -2 microglobulin (B2m) gene. The islets in these recipients do not express MHC class I cell surface molecules and thus do not serve as CD8+ targets. When splenic T lymphocytes from NOD donors of various ages are transferred into this immunodeficient stock, only those from overtly diabetic donors transfer type 1 diabetes in the absence of class I-expressing islets (54, 65). Thus, the earliest initiation, and all but the final phases of autoimmune pancreatic β -cell destruction, require MHC class I-dependent T cells that are able to recognize cognate antigen on MHC class I–expressing β -cell targets. The contributions of CD4+ T cell-secreted cytokines to the development of insulitis through various checkpoints are discussed in the next section.

Adoptive-transfer studies have focused attention on the pathogenic contributions of T lymphocytes, which, when derived from diabetic donors, are able to transfer disease into young recipients without recruitment of host B lymphocytes (66). However, B lymphocytes serving as APCs to amplify Tlymphocyte responses to β-cell autoantigens are essential diabetogenic catalysts in NOD mice. This was established by the discovery that NOD/Lt mice rendered B lymphocyte-deficient either by congenic transfer of a disrupted immunoglobulin heavy-chain gene (Igµ "knockout") or by treatment with antibody to μ chain rarely developed type 1 diabetes (67–69). The absence of B lymphocytes rather than the potential presence of any diabetes resistance genes inadvertently transferred with the genetically disrupted Igµ locus on Chr 12 was demonstrated by abrogation of resistance to type 1 diabetes following repopulation of these mice with B lymphocytes. Autoantibodies, most likely maternal in origin, are found on β -cells from islets of 2- to 3-week-old donors (41). However, such autoantibodies are apparently not required for pathogenesis, since passive transfer of purified serum immunoglobulins from diabetic NOD/Lt donors into these NOD/Lt. $Ig\mu^{null}$ mice, in contrast to repopulation by B lymphocytes, failed to abrogate the resistance to type 1 diabetes of this stock. It is not known whether the B lymphocytes infiltrating the islet play essential roles in presentation to T lymphocytes of β -cell autoantigens released by T lymphocyte– and/or macrophage-catalyzed β -cell lysis.

MOLECULAR ANALYSIS OF THE INSULITIC PROCESS: THE CHANGING CYTOKINE PROFILE OF ISLET-INFILTRATING LYMPHOCYTES AND THE $\rm T_{H}1\text{-}T_{H}2$ PARADIGM

One of the most unusual aspects of the diabetogenic process in NOD mice is that the autoimmune destruction of β -cells can be drastically retarded by so many different manipulations (70). In essence, the immune dysregulation of NOD mice that predisposes the strain to type 1 diabetes, particularly impaired APC function, can be partially corrected by immunostimulation (71). In some instances, the damage mediated by the insulitic process can be halted or reversed at quite a late stage in disease progression (72). In almost all cases in which the consequences of a protective manipulation have been investigated at the level of

cytokine expression in the pancreas and, more germane, in the islet-infiltrating lymphocytes, a deviation in the spectrum of cytokine profiles expressed is indicated that suggests a $T_H1 \rightarrow T_H2$ shift has occurred (73,74). Whereas more than 140 manipulations can drastically retard the onset of hyperglycemia in NOD mice, a much smaller number (mostly entailing transgenic or gene targeting manipulations of genes associated with antigen presentation) are capable of completely suppressing the development of insulitis. This paradox of disease suppression, but not insulitis elimination, has given rise to the concept that a "benign" or "nondestructive" form of insulitis that is present in juvenile NOD mice (or NOD male mice in some colonies) can either be maintained or be elicited through maturity. It is widely held that T lymphocytes producing proinflammatory cytokines associated with the T_{H1} phenotype, especially IFN- γ , are more likely to effect tissue damage in either spontaneous or experimentally induced T lymphocyte-mediated diseases in mice. Although IL-2 is sometimes used as a paradigm T_H1 cytokine, NOD/Lt T lymphocytes are low producers of IL-2 on a per-cell basis, and the NOD's IL-2 allele may prove to be the susceptibility gene at the *Idd3* locus (75). T_{H2} functions [especially the production of IL-4, IL-10, and transforming growth factor- β $(TGF-\beta)$] are viewed as protective, or at least as neutral. The genomic makeup of NOD mice predisposes their CD4+ T lymphocytes to respond to antigenic stimulation in a T_H1-biased fashion. As noted previously, NOD macrophages express high levels of IL-12 and IL-18 mRNA (56,57,76,77). This would perhaps partially explain why IFN-y responses dominate over IL-4/IL-10 secretory responses in NOD mice.

A longitudinal analysis of cytokine gene expression in a colony of NOD/Jsd mice with a marked gender difference in the frequency of type 1 diabetes illustrates the changing cytokine profile that accompanies the progression of NOD mice toward frank hyperglycemia (59). Quantitative RT-PCR analysis showed that islet-infiltrating lymphocytes in males maintained a higher ratio of IL-4/IFN- γ transcripts through puberty than did females, with the increased likelihood of the development of type 1 diabetes in the latter associated with waning expression of T_{H2} transcripts (59). These types of data reinforce the concept that insulitic destruction of β -cells in NOD mice is represented neither by a continuous linear regression line nor by an abrupt, late-activating process but rather by a gradual and chaotic progression wherein both regulatory events (including the changing endocrine milieu imposed by puberty and reproduction) and stochastic events (the particular subpopulation of CD4⁺ and CD8⁺ T lymphocytes "resident" in any given islet) determine the rate at which the diabetes threshold of more than 90% β-cell destruction is reached. The finding that many immunomodulatory interventions that retard type 1 diabetes development in this model produce a $T_H1 \rightarrow T_H2$ deviation is generally assumed to be evidence that the deviation itself was the basis for the retarded destruction of β -cells by islet-infiltrating effectors. However, recent analysis of NOD stocks congenic for disrupted genes encoding IFN- γ , IFN- γ receptor β chain, IL-4, and IL-10 has forced a reevaluation of this rather simplistic, but attractive concept.

NOD mice congenic for either a disrupted IFN- γ or IFN- γ receptor β gene (e.g., unresponsive to IFN- γ signaling while producing high levels of T_H2 cytokines) develop type 1 diabetes, while NOD stocks homozygous for disrupted IL-4 and IL-10 genes do not become diabetic at an accelerated rate (35,78,79). Although NOD mice congenic for a disrupted IFN- γ receptor α subunit have been reported to be resistant to type 1 diabetes, a subsequent report indicates that the resistance is not the result of the targeted allele on Chr 10 but rather a contribution of strain 129 genome in tight linkage (80,81). Treatment of

standard prediabetic NOD mice with the nonspecific immunomodulator BCG (bacille Calmette-Guérin) induced resistance to type 1 diabetes resistance with a $T_H 1 \rightarrow T_H 2$ deviation. This treatment also protected NOD stocks congenic for disrupted IL-4 or IL-10 genes (35,82). Surprisingly, the IFNγ-deficient stock is not protected by BCG (35). Collectively, these observations suggest that the $T_H1 \rightarrow T_H2$ deviation so commonly associated with protective immunomodulatory protocols are consequences, rather than causes, of the deviation. A number of studies have shown that NOD APCs, particularly macrophages, are not fully mature and hence fail to provide normal costimulatory signals such as IL-1, while producing high levels of prostaglandin E₂ (83,84). The resistance of NOD peripheral T lymphocytes to activation-induced cell death (AICD) may explain the T_{H1} bias, since T_{H1} cells normally are more prone to AICD than are T_{H2} cells (85,86). Hence, if certain type 1 diabetes-preventative protocols differentially stimulate the AICD of β -cell autoreactive T lymphocytes in a way that preferentially spares those producing T_H2 cytokines, it would give the appearance of a $T_H 1 \rightarrow T_H 2$ cytokine shift (35).

MOLECULAR ANALYSIS OF THE INSULITIC PROCESS: THE ROLE OF THE β -CELL AND CANDIDATE β -CELL AUTOANTIGENS

A number of genetic and molecular genetic manipulations designed to limit the T-cell receptor repertoire available to CD4+ and/or CD8+ T cells in the NOD mouse generally fail to prevent type 1 diabetes (87). Hence, the NOD thymus is extremely flexible in its ability to generate a diabetogenic T-cell repertoire, even when rearranged TCR transgenes dictate a repertoire predominantly skewed to an "irrelevant" antigen [e.g., lymphocytic choriomeningitis virus (LCMV) peptide not expressed in NOD β -cells]. The broad spectrum of TCR clonotypes of both CD4⁺ and CD8⁺ T cell lines and clones reported to produce βcytotoxicity effects in the NOD mouse reinforce the diversity of antigens recognized. An unresolved issue is whether a single βcell autoantigen is targeted initially, followed by "downstream" immune reactivities as other antigens are processed and presented following the initial destruction of a few β -cells. The most commonly discussed candidate autoantigens in humans (based upon spontaneous autoantibody development) are insulin, glutamic acid decarboxylase (GAD), and IA-2, a putative tyrosine phosphatase localized in β -granules (88–91). Debate about NOD mice has focused on whether insulin or GAD represents the primary autoantigen. T-lymphocyte responses to GAD peptides appear earlier than to other candidate autoantigens, including carboxypeptidase E, peripherin, and heat-shock protein 60 (92). Administration of autoantigens in tolerogenic doses to prediabetic NOD mice can retard the development of type 1 diabetes (93,94). A rather controversial report that GAD67 is the primary autoantigen in NOD β -cells has not been replicated and is suspect because of the claims of easily detectable GAD67 protein in NOD β -cells by immunocytochemistry (95). Based on the plasticity of the T-cell repertoire capable of destroying NOD islets, the most conservative position regarding β -cell autoantigens in the NOD model is that a multiplicity must exist, each individually capable of serving as a target for autoimmune initiation. As noted above, CD8+ T lymphocytes are essential for such initiation, suggesting that the initiating event entails recognition of autoantigenic peptide presented by the β -cell target or vascular endothelium near the β-cells.

Most studies examining the interaction between NOD T lymphocytes and their β -cell targets assume that if the appropriate autoantigen(s) is present and there are T lymphocytes in the periphery with the appropriate TCR clonotype(s), then type

1 diabetes will ensue. This is not necessarily true. Both rodent and human β -cells have very weak defenses against oxidative stress (96). NOD β -cells appear typical of most mouse strains in being quite sensitive to cell death mediated by combinations of monokines and IFN- γ . Analysis of β -cells from ALR/Lt mice, a strain closely related to NOD and selected for resistance to type 1 diabetes induced by a low dose of alloxan, has demonstrated that genes expressed at the β -cell level, and presumably associated with dissipation of reactive oxygen species, can protect against both toxic combinations of cytokines and monokines, as well as against islet-reactive cytotoxic T cells isolated from NOD islets and capable of recognizing antigens presented by ALR/Lt islets (13,97–99).

GENETICS OF TYPE 1 DIABETES

"Idd" loci: What and How Many?

A provisional nomenclature exists to describe murine chromosomal regions carrying genes capable of modulating susceptibility of type 1 diabetes. Such loci, designated "Idd" loci are uncovered either by out-crossing NOD mice to type 1 diabetes-resistant strains of mice and then doing segregation analysis or by genetically disrupting specific genes and analyzing the consequences on the development of type 1 diabetes (100). Segregation analysis has shown that many strains harbor potential "Idd" susceptibility contributions but that the NOD strain is unfortunate in terms of the large numbers randomly inbred into them during the generation of the strain. If the large numbers of genes shown by gene-targeting experiments to be essential for mediation of the diabetogenic process are excluded and only "Idd" loci identified by out-crossing NOD to type 1 diabetes-resistant strains are considered, linkage of more than 19 loci on 10 chromosomes have been reported [reviewed in references (39,87)]. Although originally given sequential numbers as they were reported in the literature, segments of chromosomes now carrying genes capable of modifying the frequency of type 1 diabetes are simply being described by molecular markers physically delimiting the region (generally simple sequence repeat-containing alleles). As noted above, certain of the susceptibility linkages derive from the genomes of type 1 diabetes-free outcross partner strains, and in one case, admixture of a wild-derived strain's genome produced a male gender-biased type 2 diabetes (3,4). To further complicate matters, a chromosomal segment identified initially through segregation analysis as containing a single "Idd" generally yields multiple loci when subcongenic analysis is conducted. Classical genetic segregation analysis greatly underestimates the actual number of genes required for the development of type 1 diabetes since transgenic and gene-targeting technologies being applied to analyze the genetic control of the development of type 1 diabetes in NOD mice are providing an ever-expanding panoply of contributory "Idd" loci, only a few of which will be discussed. Although most genomic manipulation by transgenic or gene "knockout" technology has focused on genes expressed in the immune system, it is now clear that genes expressed systemically and within the pancreatic β -cell can also be important modifiers of susceptibility (101). A discussion of the MHClinked diabetogenic contributions ("Idd1") will suffice to underscore the complexity of "Idd" loci and their interactions.

Paramount Role of Major Histocompatibility Complex

The first genetic analysis of type 1 diabetes in the NOD mice reported a recessive susceptibility for clinical disease linked to MHC (102). Because the MHC complex contains genes essential for antigen processing and presentation, as well as for immune cell function, and given evidence indicative of broad-based immunotolerogenic defects in NOD mice, it is not surprising that H2g7, encompassing both common class I alleles, a rare class II Ag7 allele, and absence of class II E (the HLA-DR homologue), provides the major component of genetic susceptibility (103-105). Indeed, specific amino acid substitutions in the H2-Abg⁷ chain reflect similar residues present in the human HLA-DQ0302 allele linked to increased susceptibility to type 1 diabetes in whites. These include a histidine residue at position 56 and a serine residue at position 57 of the β chain. Recent radiographic crystallographic analysis helps to understand the diabetogenic properties of the I-Ag7 molecule. The NOD I-Ag7 molecule behaved very much like I-A^d, a MHC class II molecule that shares the same β chain with I-A^{g7} but contains proline and aspartic acid at residues 56–57 of the β chain and protects from diabetes. Binding affinities of a large collection of peptides are comparable for I-A^{g7} and I-A^d. Presence of negatively charged residues in the C-terminal region of the peptide increases binding affinity to I-A^{g7}. Exchange of the aspartic acid, as found in I-A^d, by a serine at position β 57, increases the size of the P9 pocket of I-A^{g7} and exposes positively charged residues. As a consequence, the I-A^{g7} P9 pocket can bind negatively charged residues and residues with larger side chains than does I-A^d. These two features expand the peptide repertoire of I-A^{g7} by several-fold in comparison to I-A^d. Immunoprecipitation studies suggested that I-Ag7-peptide complexes are more unstable than similar MHC class II complexes from B6 (106). This might imply that I-A^{g7} bound more peptides, but with lower affinities such that cytopathic T-effectors are not centrally or peripherally deleted.

Molecular Dissection of "Idd1"

The diabetogenic relevance of the nested set of five nucleotide substitutions between position 248-252 converting a conserved proline residue at amino acid position 56 to histidine and aspartic acid 57 to serine was confirmed separately by production of transgenic stocks of NOD mice expressing Abg7 alleles modified by site-specific mutagenesis to convert either the histidine 56 residue to proline or the serine 57 residue to aspartic acid (107-110). Further demonstration that "Idd1" comprised at least two linked, but separable susceptibility components was provided by the demonstration that the development of type 1 diabetes was also drastically suppressed or completely prevented in stocks of NOD mice expressing H2-Eatransgenes that restored H2-E expression on APC (107,109-111). It is not only the MHC class II region that contributes susceptibility in NOD mice but rather multiple loci in the extended haplotype. The requirement for MHC class I expression for cytopathic CD8+ Tlymphocyte targeting of islet β -cells has been detailed above. It is noteworthy that extended haplotype analysis of human genes in linkage disequilibrium with HLA-DR and -DQ alleles conferring susceptibility to type 1 diabetes indicates additional susceptibility components toward the class I region (112). Analysis of NOD stocks congenic for recombinant haplotypes generated by crossover between H2g7 and H2²⁰⁹ provide evidence of additional "Idd" contributors centromeric to a Lmp2 recombinatorial hotspot that both includes and extends proximal to the H2-K gene (113). One of these could represent "Idd16," initially mapped in linkage disequilibrium to Idd1 on Chr 17 (114). Because of this complexity, it is difficult to discuss whether the haplotype contributes susceptibility in a dominant or recessive fashion. Segregants heterozygous for H2g7 may develop subclinical levels of insulitis (suggesting dominant H2g7 contributions to this important diabetes subphenotype) and may even develop overt type 1 diabetes following cyclophosphamide treatment (115,116). However, type 1 diabetes rarely develops spontaneously in such heterozygotes, especially when an Ea product is expressed by the other H2 haplotype (116). In this regard, the NOD model diverges from the human situation, where certain HLA heterozygous haplotypes increase rather than suppress susceptibility to type 1 diabetes (117). In summary, *"Idd1"* is a collective descriptor for multiple disease-predisposing alleles within or linked to the MHC complex.

Diabetogenesis Entails Complex Major Histocompatibility

Complex-Non-major-Histocompatibility Complex Interactions Susceptibility to type 1 diabetes in segregating hybrids following outcross of NOD to other mouse strains is inherited as a polygenic threshold liability, requiring a complex interaction between the H2g7 haplotype and numerous other MHCunlinked genes (118). None of the non-MHC genes present in the NOD genome contributes the same risk as the extended MHC haplotype, but homozygosity for H2g7 in the absence of a diverse collection of the NOD strain's collection of non-MHC susceptibility modifiers is insufficient to trigger type 1 diabetes (119). Unraveling the genetic basis for the development of type 1 diabetes in the NOD mouse is complicated by interactions between the NOD mouse's diabetogenic H2g7 and the welter of non-MHC "Idd" loci, none of which alone is sufficient to elicit type 1 diabetes. This can be demonstrated by developing B6 stocks congenic for long "Idd" susceptibility intervals from NOD (120). Although some level of periinsulitis can be seen, severe insulitis does not develop, even when bicongenic stocks are analyzed that carry both the non-MHC interval and the NOD "Idd1" genes on Chr 17 (121). Genetic analysis is further complicated by the finding that the set of non-MHC genes segregated are not constant but vary depending upon the type 1 diabetes-resistant partner strain used in the outcross. An "Idd" exerting a strong effect in one cross may not be detectable at all in another outcross combination. The situation is made even more complex by the knowledge that strong environmental influences, as well as intergenic interactions, affect gene penetrances and ultimate presentation of clinical disease. The interested reader is referred to a recent review of current knowledge of the locations and potential functions of the most intensively studied of the known non-MHC loci (87). Several examples are provided below to illustrate the nature and complexity of the intergenic "cross-talk" required for diabetogenesis.

Illustrations of Diabetogenic Epistasis

Segregation analysis between H2g7-identical NOD/Lt and NOR/Lt mice permitted elucidation of a Chr 2/Chr 17 (MHC) interaction. Even though the MHC class I alleles of NOD and NOR mice $(H2K^d, H2D^{\bar{b}})$ are commonly expressed in non-autoimmune-prone strains, they acquire diabetogenic function in NOD mice (122). A relatively long segment of NOR/Lt-derived genome on Chr 2 containing at least two resistance genes (collectively described as "Idd13") provided partial protection from type 1 diabetes in a NOD congenic stock (123). Included in this congenic interval was an NOR-derived B2m^b allele, replacing the equally common $B2m^a$ allele expressed by NOD. This seemed an unlikely candidate gene for an "Idd13" component since these two MHC class I-binding proteins differed at only a single amino acid and did not alter total expression levels of MHC class I molecules. However, conformational analysis indeed showed that dimerization of NOD MHC class I K^d and D^b chains with the alternative $\beta 2m$ isoforms differentially altered their structural conformation (123). The type 1 diabetes-free NOD.B2m^{null} stock described above provided the means for a rigorous test of B2m candidacy by transgenic insertion directly into these zygotes of transgenes encoding either β_2 m isoform. A CD8⁺ T-cell repertoire was positively selected in both lines, but only the line with the reconstituted expression of the *B2m^a* (NOD-type) isoform developed type 1 diabetes (87). This represents the first empirical demonstration of the molecular nature of a non-MHC "*Idd*" candidate.

In addition to this Chr 2/Chr 17 (MHC) epistatic interaction, a recent genetic analysis of the markedly different course of insulitis progression in NOR versus NOD has suggested an epistatic interaction between the Chr 2 "*Idd13*" region containing the *B2m* candidate and Chr 1 ("*Idd5.2*" region) (124). Epistasis has also been reported among "*Idd*" loci on Chr 3, specifically the *Idd3* locus marked by the *Il2* allele and more distal loci denoted as "*Idd10/17/18*" (116).

Genetics of Mouse Type 1 Diabetes and the Identification of Human Type 1 Diabetes Genes

Although the H2g7 haplotype was originally thought to be unique to the NOD mouse, this haplotype is shared by the type 1 diabetes-free ILI strain (125). Several of its diabetogenic components (e.g., the class II alleles and the H2-K^d allele) also present in the related ALR and CTS strains (126,127). Since the ALR/Lt strain exhibits remarkable genetic resistance to autoimmune stress, it is clear that "diabetogenic" MHC alleles are not inherently diabetogenic but acquire diabetogenic potency only in the context of the non-MHC background (101). Moreover, not all of the susceptibility alleles will derive from the NOD genome, and some admixtures can produce type 2 rather than type 1 diabetes (4). What is the implication of this complexity for the inheritance of type 1 diabetes in humans? Will identification of mouse "Idd" loci identify possible homologous susceptibility regions in the human genome? There are a number of reasons why many of the known non-MHC mouse "Idd" loci are not matched by type 1 diabetes loci in the syntenic regions of the human genome. Important genus-specific differences distinguish mice from humans. The human IDDM2 locus has been identified in both association and linkage studies and is defined by polymorphisms in a VNTR (variable number of tandem repeats) upstream of the human insulin (INS) gene (128). Although proinsulin/insulin represents a major type 1 diabetes autoantigen in both humans and NOD mice, an NOD homologue of the human INS gene (mouse Ins2 on distal Chr 7) has not been detected in most segregation analyses (129,130). This lack of concordance might be expected because mice express two genes for insulin (the additional gene is Ins1 on Chr 19). The "Idd3" (Il2) linkage is one of the strongest and most commonly identified non-MHC loci segregating in NOD outcrosses; the IL2 gene in the homologous 4q26-q27 region in humans has not yet been implicated as a major type 1 diabetes-susceptibility locus (25). Of all the non-MHC loci identified in NOD outcrosses, the "Idd5.1" region containing the Cd152 (Ctla4) locus may be reflected by the IDDM12 linkage to the homologous region on human 2q33 (131,132). Despite the finding that non-MHC genes contributing to the development of type 1 diabetes in NOD mice often are not reflected by demonstration in humans of linkage to the syntenic region, the value of the mouse system is to elucidate specific immunologic or endocrinologic dysfunctions that are entrained when sufficient numbers of "Idd" genes are present. While the human IL2 structural gene has not been implicated as a gene for type 1 diabetes, it is certainly possible that an unlinked gene, acting in *trans*, could confer a higher risk for type 1 diabetes by affecting IL-2 glycosylation state, as is implicated in the NOD mouse. Even if the controlling genes are not transposable from mice to humans in a one-to-one ratio, many of the phenotypes diagnostic of high susceptibility may be common. Further discussion of the similarities and differences between humans and mice in this regard is found in Chapter 21.

CELLULAR BASIS FOR GENETIC SUSCEPTIBILITY

Defective Antigen-Presenting Cell Functions

Although T lymphocytes often are the focus of studies describing immunotolerogenic defects in the NOD mouse, studies using bone marrow chimeras have demonstrated that the origin of many of the defects can be traced to APC dysfunction (macrophage, dendritic cells, and B lymphocytes). Diminished levels of antigen presentation by MHC molecules represent one likely mechanism whereby immune tolerance is not fully acquired. Both intrathymic and peripheral tolerance induction also requires costimulatory signals delivered to T lymphocytes by APC. Considerable evidence indicates that the APC of NOD mice maintained in SPF environments are deficient in ability to provide sufficiently high levels of costimulation. NOD macrophages maturing from bone marrow precursors do not become as functionally mature as macrophages from control strains (83,133,134). This blunted functional development is indicated by subnormal lipopolysaccharide (LPS)-stimulated IL-1 secretion and by reduced CD86 (B7-2) gene expression (83, 133,135). D-galactosamine-sensitized NOD mice are resistant to doses of LPS and TNF- α that produce lethal hepatocellular injury and apoptosis in B6 mice (136). These hypofunctions are negatively reinforced by constitutive expression of the normally inducible prostaglandin E₂ synthase gene (Pgst2 on Chr 1) and hence secrete higher than normal levels of prostaglandin E2 (84). Defects in both the high-affinity Fcy1 receptor and Fcy2 receptor have been reported (84,137). Both defects might be expected to affect the ability of macrophages to phagocytose monomeric IgG2c and IgG2b antibodies, respectively (the NOD mouse expresses the IgG2c and not the IgG2a isotype as is commonly assumed) (138). Glutathione levels are lower in NOD macrophages than in the NOR/Lt control strain, possibly contributing both to reduced capacity to process and present MHC class II-restricted antigens to CD4+ T cells and to the T_H1 bias in response to antigen priming (139,140). Some anomalies in development of marrow-derived NOD dendritic cells have also been reported (141). Vitamin D metabolism is also disturbed in NOD macrophages (141a). The ability of many different microbial immunomodulators, such as CFA, BCG, and OK432, to upregulate APC function and to promote T-lymphocyte apoptosis links APC defects in costimulatory signaling to this major defect in the NOD T-lymphocyte compartment (e.g., their resistance to multiple forms of apoptosis) (35,142). Indeed, the high production of prostaglandin E2 from NOD macrophages could contribute to T-lymphocyte apoptosis resistance by antagonizing TCR-coupled protein kinase C (PKC) second-messenger activities.

Thymocyte/T-lymphocyte Anomalies

The T-lymphocyte accumulation characteristic of NOD mice, reflected at its most extreme by the formation of what appear to be lymphoid follicles in the perivascular spaces of the pancreas and submandibular salivary glands, is a secondary reflection of resistance to AICD. Both NOD thymocytes and peripheral T lymphocytes are relatively resistant to AICD, as well as to apoptosis induced by dexamethasone, irradiation, or stress (143-148). A less severe resistance of male thymocytes to AICD may explain the reduced male susceptibility to type 1 diabetes (149). As discussed above, elevated prostaglandin E₂ levels may account for the association between poor proliferation in response to TCR cross-linking agents and reduced ability of thymocytes/T lymphocytes to activate TCR-coupled PKC second-messenger pathways (150). The earliest thymic immigrants, especially in females, may be enriched for effector T lymphocytes versus regulatory cells, because thymectomy at 3

weeks of age accelerates the onset of type 1 diabetes in females, but interestingly, not in NOD males (151).

IL-2 is now recognized not only as a growth factor for T lymphocytes but also as a required factor for AICD. The *ll2^b* allele expressed by NOD is distinguished from the Il2^a allele expressed by NON, BALB/c, and C57BL strains by presence of a T \rightarrow C point mutation producing at residue 6 a Ser \rightarrow Pro substitution, a four-amino-acid insertion at residue 8 (Ser-Ser-Pro-Thr), and a deletion of four glutamine residues within a polyglutamine stretch between residues 19 and 30 (152,153). Il2 is an attractive candidate gene not only because IL-2 treatment of prediabetic NOD mice suppresses the development of type 1 diabetes but also because genetic disruption of the Il2 gene produces severe lymphoproliferative disease with widespread tissue infiltrates, including pancreatitis and insulitis (71,154). Production by NOD splenic T lymphocytes of bioactive IL-2 on a "per-cell" basis was less than that from SWR/Bm, another Swiss-derived strain that shares the $Il2^{b}$ allotype (155,156). The NOD-produced molecule is associated with a higher glycosylation state, and this may affect either half-life or ability to induce AICD (157).

Numerous defects in T-regulatory cell functions have been reported in NOD mice (158). Among the presumed regulatory cells are natural killer T (NKT) cells. Representing a small population (<3%) of peripheral lymphoid cells, they are CD3⁺, CD8⁻, and either CD4⁻ or CD4⁺. Their selection entails recognition of glycolipid antigens presented by the nonclassical MHC class I-like CD1 molecule (159). Deficiencies in both number and immunoregulatory function of NOD NKT cells have been reported (160,161). These deficiencies include a low level of IL-4 secretion, a defect that can be corrected either by IL-7 treatment or by congenic transfer of B6 genes regulating natural killer (NK) and NKT function (including their NK1.1 phenotypic marker) in the "Idd6" type 1 diabetes-resistance region (162-164). Enriched populations of cells with an NKT phenotype can protect NOD mice from type 1 diabetes, leading to the suggestion that T_H2 cytokine secretion by these cells mediates the protection (162). However, NKT cells stimulated in vitro and *in vivo* actually produce more IFN-γ than IL-4 (165,166). Indeed, type 1 diabetes-resistant NOD.B6-"Idd6" mice produce more serum IFN- γ upon stimulation with α -galactosyl ceramide than do standard NOD mice (164). Hence, the molecular basis for NKT-mediated protection may be more complicated than a simple T_H1 to T_H2 deviation.

POLYGLANDULAR AUTOIMMUNITY

Salivary and Lacrimal/Harderian Glands

The multiplicity of immunodeficiencies characteristic of NOD mice leads to leukocytic infiltrations into endocrine organs in addition to pancreatic islets. Particularly notable are heavy infiltrations of the submandibular salivary gland (sialoadenitis) and the lacrimal and harderian gland of the eye (dacryoadenitis). Both sialoadenitis and dacryoadenitis in NOD mice develop after puberty, considerably later than insulitis. Splenic T lymphocytes from both overtly diabetic and young prediabetic NOD mice adoptively transfer these lesions into NOD/LtSzscid mice (167). Although T lymphocytes are present, the infiltrates are not associated with a loss of glandular acinar cells as extensive as the progressive loss of β -cells in the pancreas (168,169). Since the sialoadenitis impairs salivary flow rates and protein content, and since NOD mice also develop leukocytic infiltrates in their lacrimal and harderian glands, NOD mice may serve as a model for Sjögren syndrome in humans (170). Although loss of salivary gland structural integrity is not as extensive as in Sjögren syndrome in humans, xerostomia ("dry

mouth"), a clinical condition often associated with both Sjögren syndrome and type 1 diabetes in humans, is reflected in NOD mice (170). The dacryoadenitis develops at fourfold higher frequency in postpubertal males than females and can be suppressed by male castration, while tamoxifen treatment significantly increased frequency of this lesion in males (171). Its autoimmune nature was documented by upregulation of inflammatory T_H1 cytokine genes in the infiltrating T lymphocytes (171). As is the case for insulitis, salivary gland infiltrates are composed primarily of CD4⁺ cells with smaller numbers of CD8⁺ cells and with a diversity of TCR clonotypes represented (172). Insulin and insulin-like growth factors I and II are found at low concentrations in mouse saliva, as well as in parotid and submandibular glands, and hence may represent a potential target antigen (173). TNF- α is apparently involved in lesion development, since treatment of NOD mice with a soluble TNFreceptor p55 subunit inhibits infiltration in both submandibular and lacrimal glands (174). NOD strain-specific anomalies in the development of the submandibular gland were found in NOD/LtSz-scid mice lacking functional T and B lymphocytes (175). Hence, these developmental anomalies may trigger sialoadenitis when a functional immune system is present. An interesting aspect of the sialoadenitis in NOD mice is the potential role of autoantibodies. B lymphocyte-deficient NOD/ Lt. $Ig\mu^{null}$ mice rarely develop type 1 diabetes, but they do develop sialoadenitis and dacryoadenitis in the absence of insulitis and type 1 diabetes (176). Passive transfer into these immunoglobulin-deficient mice of serum immunoglobulins either from standard NOD mice or from patients with primary Sjögren syndrome, but not from healthy controls, inhibited binding of ligands to muscarinic receptors on salivary membranes (176).

Thyroid Glands

Another common histopathologic lesion described in NOD mice is the presence of leukocytic infiltrates in the thyroid follicles (thyroiditis). This is of interest because autoimmune thyroid disease (Grave disease or Hashimoto thyroiditis) is frequently associated with type 1 diabetes in humans. However, the spontaneously developing lesions in NOD are not so severe that clinical manifestations of hypothyroidism appear. If goiters are induced and followed by iodine loading, severe lesions causing hypothyroidism are elicited (177,178).

Splenocytes from diabetic NOD/Lt donors also adoptively transferred thyroiditis into NOD/LtSz-scid recipients, albeit at a lower efficiency than insulitis (167). Spontaneous development of thyroiditis varies widely among different NOD colonies, with differences in environmental factors such as dietary iodine content representing possible explanations (179). Parathyroiditis has also been reported in one colony (180). Criteria for assessing thyroiditis may be partially responsible for the variability between colonies. A confounding factor in the diagnosis of both thyroiditis or parathyroiditis in NOD mice is the presence of a high frequency of thymic ectopies to the thyroid gland (181). Thymic ectopies are present at ~20% frequency in this author's (EHL) NOD/Lt colony, but significant leukocytic infiltration into thyroid interstitium or into follicles is relatively rare (~5% of mice sampled to 16 weeks of age). In a colony of NOD mice with a low incidence of diabetes accompanied by a high incidence (77%) of subclinical thyroiditis, as well as by antithyroid autoantibodies in older mice, thyroiditis was clearly independent from spontaneous development of type 1 diabetes (182). This was reinforced by the findings in a NOD colony in Paris with a high frequency of type 1 diabetes accompanied by a high incidence (20.5%) of thyroiditis in nondiabetic survivors (mostly males) aged to 90 weeks (183). When this incidence was

compared with that of a diabetes-resistant NOD stock congenic for the $H2^k$ haplotype (associated with high susceptibility of the CBA/J inbred strain to experimentally induced thyroiditis), a significantly higher (30.3%) frequency of thyroiditis was noted (183). An age-associated increase in MHC class II expression on macrophages and thyroid epithelial cells has been noted (184). Clinically significant lesions comparable to Hashimoto thyroiditis can be induced in NOD mice by administration of a diet high in sodium iodide following induction of goiters using a diet low in iodine in combination with treatment with phenylthiourea (178). NOD/Mrk congenic for an intra-MHC recombinant haplotype ($H2^{h4}$) expressing $H2-K^k$ and $H2-A^k$ alleles will develop thyroiditis following exposure to sodium iodide alone (116).

AGING-ASSOCIATED PATHOLOGIES

Cancer

In addition to these polyendocrinopathies, leukocytic infiltrates of varying intensity can be found in liver (mild focal hepatitis), kidney (focal nephritis), and muscle (myositis) (185). If development of type 1 diabetes in NOD mice is prevented such that life span is extended, this strain exhibits a virtual "Pandora's box" of pathologies (185). A spectrum of tumors has been identified in the research colony at The Jackson Laboratory. Of these, lymphomas are those diagnosed most frequently. This propensity for lymphomagenesis in the absence of diabetes is starkly illustrated by the near 100% frequency of thymic lymphomas in NOD/LtSz-scid mice and B (follicle center) cell lymphomas in NOD/LtSz-Rag^{mull} congenic mice (32,186). Osteosarcomas, a relatively rare tumor in mice, are also detected at a relatively high frequency in standard NOD/Lt mice in The Jackson Laboratory research colony (186).

Hearing Defects

NOD mice are severely hearing-impaired, developing a progressive hearing loss as assessed by auditory-evoked brainstem responses (187,188). In most NOD mice, hearing loss progresses to complete deafness by 3 months. CBA/J mice have normal hearing. Three recombinant congenic stocks have been produced by outcross of NOD mice to CBA/LtJ, followed by a backcross to CBA and then inbreeding of first backcross progeny (29). Testing of auditory-evoked brain-stem response of these three recombinant congenic lines carrying mixtures of *NODLt* and *CBALtJ* genes indicates that this trait is under polygenic control, since one line hears as well as CBA and two lines have moderately impaired hearing. Because all three lines share the *H2*^{g7} MHC haplotype with NOD, genes within this complex are excluded.

Hemolytic Anemia

Hemolytic anemia accompanied by development of Coombspositive autoantibodies, reticulocytosis, splenomegaly, and jaundice, has been observed in aging (older than 200 days) mice of both the NOD/Wehi and NOD/Lt substrains maintained in Australia (189). In the low-diabetes-incidence NOD/Wehi substrain, 14 of 17 nondiabetic mice were affected by 550 days.

EXPERIMENTALLY INDUCED LESIONS

NOD mice are susceptible to a variety of experimentally induced organ-specific immune diseases, including druginduced diabetes, lupus, colitis, encephalomyelitis, and thyroiditis. Not surprisingly, young NOD/Lt males, like outbred CD1 males, are susceptible to induction of type 1 diabetes by multiple low doses of the fungal antibiotic streptozotocin (190). This sensitivity is independent of autoimmune T-cell involve-

ment, since NOD/LtSz-scid males are even more sensitive to low doses of this diabetogen (190). Injection of a single dose of 2.6×10^7 heat-killed Mycobacterium tuberculosis (BCG) intravenously into 8-week-old NOD mice prevented diabetes but precipitated a syndrome similar to systemic lupus erythematosus (191). Exposure of NOD/Lt mice to 3.5% dextran sodium sulfate in the drinking water for 5 days elicits a severe colitis (192). Experimental allergic encephalomyelitis can be induced in NOD mice using a peptide fragment (residues 56-70) in adjuvant from proteolipid protein (193). The NOD allele at the "Idd3" locus (in the region of the gene encoding IL-2) has been shown to be a component of this strain's high susceptibility to encephalitis induction (24). A similar demyelinating disease can be induced by injection of the MOG peptide (residues 35-55) in adjuvant; this model is prevented by treatment with anti-IL-12 antibody. A single intravenous injection of pertussin without adjuvant into NOD mice induced a T-cell-mediated encephalitis (194).

The BioBreeding Rat

INSULITIS AND DEVELOPMENT OF TYPE 1 DIABETES: COMPARISONS WITH NONOBESE DIABETIC

BioBreeding (BB) rats are a diabetes-prone strain derived from outbred Wistar rats from a commercial colony in Canada (195). The interested reader is referred to comprehensive recent reviews (196-200). Spontaneous type 1 diabetes was discovered in 1974, and selective breeding for that phenotype ensued. As with NOD mice, multiple substrains of BB rats exist, and lymphoid infiltrates are not limited to the pancreatic islets (201). The best-characterized BB colonies are those developed at the University of Massachusetts Medical School and now commercially distributed by Biomedical Research Models (Worcester, MA). A diabetes-resistant substrain (BBDR/Wor) has been selected, as have several diabetes-prone (BBDP/Wor) lines. These BB rats are fully inbred and characterized. In the Worcester virus-antibody-free (VAF) barrier colony, the frequency of type 1 diabetes in both sexes of DP rats exceeds 90%, whereas no spontaneous type 1 diabetes develops in VAF BBDR/Wor rats. A major genetic and phenotypic difference distinguishing the DR from the various DP strains is the presence in the DP line of a recessive mutation, lymphopenia (*Lyp*), on Chr 4 (202–204). Although DP rats develop a thymus of normal size and cellularity, recent thymic T lymphocyte emigrants to the periphery

[phenotypically Thy-1⁺ and not yet expressing a cell-surface adenosine diphosphate (ADP)-ribosyltransferase (formerly designated RT6 and now designated ART2)] are very short-lived (205,206). The consequence is a profound T-lymphopenia/lymphocytopenia. Hence, these rats are severely immunocompromised, as reflected by impaired T-lymphocyte function in vitro, impaired ability to reject foreign tissue grafts, increased susceptibility to B-lymphomagenesis, and requirement for special husbandry procedures to protect against infections by opportunistic pathogens. This obviously contrasts sharply with NOD mice, whose T lymphocytes are long-lived in the periphery, present in large numbers, and express a functional ortholog of rat RT6 (now designated as ART2 in both genera) (207). Whereas BBDP rats are strongly immunocompromised, as evidenced by difficulty in rejecting non-islet allografted tissues and being susceptible to infectious pathogens, NOD T cells are capable of rapidly rejecting allografted tissues, and NOD mice are remarkably pathogen-resistant. There are many additional distinctions between BB rats and NOD mice in the diabetes syndrome itself, reviewed elsewhere, and some are summarized in Table 18.4 (6,197,198).

GENETICS OF TYPE 1 DIABETES

Superficially, the genetic basis for the spontaneous development of type 1 diabetes in rat models appears less complex than that in the NOD mouse or in humans. However, this may relate to the level of study of the process, since initially the genetics of type 1 diabetes in NOD mice was also inferred to be less complex, and possibly only oligogenic (100,102). As in humans and mice, the detection of "Idd" loci in the rat genome has been facilitated by the development of polymorphic microsatellite markers that can now be scored by automated methods (201). Segregation analysis between BBDP crossed with other type 1 diabetes-resistant strains have established that the MHC class II alleles encoded by the *RT1^u* haplotype of the BB rat are essential for diabetogenesis (201,208-211). This MHC susceptibility, designated "Iddm2," is permissive for insulitis in the heterozygous state; however, most diabetic segregants are MHC homozygotes. Analyses of insulitis and development of type 1 diabetes following outcross of diabetes-prone BB/Wor rats of the "NB" subline to RT1^u congenic stocks of PVG rats carrying recombinants in the class I versus class II region have established the requirement for the RT1-D^u/B^u alleles at the two class II loci (homologues of human DQ and DR, respectively) (210). Unlike

Phenotype/treatment	BBDP rat	BBDR rat ^a	NOD mouse
T-lymphopenic	Yes	No	No
Virus exposure	Not required	Kilham rat virus triggers type 1 diabetes	Virus exposure protects
High-dose poly I:C treatment	Accelerates type 1 diabetes	Accelerates type 1 diabetes in RT6 depletion model	Retards type 1 diabetes
Cyclophosphamide treatment	Inhibits type 1 diabetes	Induces type 1 diabetes	Induces type 1 diabetes
NK cell number and function	High	High	Virtually absent
NKT cell number and function	Low	Normal	Low
Hemolytic complement	Present	Present	Absent (C5)
Insulin required immediately after onset of type 1 diabetes	Yes	Yes	No
Ketoacidosis	Yes	Not diabetic	Very mild until late stages
Gender difference in susceptibility	F = M	F = M	F >> M

TABLE 18.4. Comparison of Differences Between Three Rodent Models of Type 1 Diabetes

F, female; M, male.

aReferences are to unmanipulated, nondiabetic rats.

the nonexpression of H2-E molecules on APC of the NOD mouse, APC of the BB rat do express the DR homologue (RT1-D^u). Sequence analysis of the BB rat DQ homologue (RT1-B^u) showed it differed from both the high diabetes risk–conferring human HLA-DQ β alleles and the NOD H2-Ab^{g7} molecule. In contrast to NOD mice and humans, the BB rat allele contains an aspartic acid at residue 57 of the β chain instead of exhibiting "diabetogenic" non-Asp substitutions (212,213). All RT1^u-expressing rat strains carry the requisite class II "*Iddm2*" alleles. Class I alleles from non-RT1^u–positive rat strains apparently will substitute for the RT1-A^u, E^u, and C^u class I alleles. Interestingly, although insulitis and thyroiditis were suppressed in class II heterozygous segregants in one outcross/backcross analysis, thyroiditis (another characteristic immune pathology of the BBDP-NB subline used in the outcross) was not (210).

"Iddm1" was initially assigned to the recessive Lyp (lymphopenia) mutation in BBDP rats on Chr 4, in tight linkage to the neuropeptide Y (Npy) locus (202). The gene mutation that yields the lymphopenia phenotype has been positional cloned to the immune associated nucleotide 5 (Ian5) locus by two groups (213a,213b). Although most diabetic probands in segregation analyses between BBDP stocks and nonlymphopenic stocks, including BBDR, have been homozygous for this mutation, the traits (lymphopenia versus type 1 diabetes) have occasionally been separated, leading to the speculation that another locus in tight linkage with the Lyp mutation was contributing (204,214). Such a locus, designated "Iddm4" and proposed to be involved in insulitis initiation, has been discovered in outcross between BBDR and an inbred WF stock followed by backcross to WF (215). As noted above, BBDR rats express a wild-type allele at the Lyp locus and therefore, like WF rats, are not T-lymphopenic. However, unlike WF rats, BBDR rats can be turned diabetic by the anti-RT6.1 antibody plus treatment with poly I:C. Since the backcross was made to the type 1 diabetes-resistant (but RT1^u-identical) WF strain, type 1 diabetes in susceptible genotypes had to be induced by transient T-cell depletion using an anti-RT6.1 monoclonal antibody together with treatment with poly I:C. The poly I:C presumably activates T-effector cells surviving the depletion. An ortholog for "Iddm4" in the NOD mouse, if it existed, would be the "Idd6" segment on mouse Chr 6. Suggestive evidence for another diabetogenic locus on Chr 3, this time contributed by the WF parent and designated "Iddm6," also was noted, as was another locus on Chr X designated "Iddm5." The existence of "Iddm3" was originally inferred based on outcross of BBDP to Fisher 344 rats (202). This designation was subsequently used to describe suggestive evidence for a locus on Chr 18 contributing to development of spontaneous type 1 diabetes in outcross of BBDP/OK (a distinct line of BB rats in Germany) to the DA strain (216-219). Additional evidence for weak linkages following outcross to other nondiabetic strains was suggested in certain of these latter studies.

CELLULAR ANALYSIS OF THE INSULITIC PROCESS

In marked contrast to the periweaning onset of lymphoaccumulation and periinsulitis in NOD mice, the development of insulitis in BB rats does not occur around weaning, but rather focuses around and into the islets after the development of puberty and within 2 to 3 weeks of the (abrupt) onset of clinical symptoms. Indeed, the abrupt onset of hyperglycemia and the requirement for immediate insulin therapy are other factors distinguishing BB rats from NOD mice (Table 18.4); the latter often can survive for 3 to 4 weeks after first detection of hyperglycemia such that when diabetic splenocyte donors are used for adoptive transfer experiments these donors generally have not been maintained by daily insulin injections. As is true for NOD mice, most BBDP rats develop insulitis whether or not they develop diabetes and, as in NOD females, peak onset occurs after puberty, with more than 90% of diabetic animals identified between 8 and 16 weeks of age. Interestingly, this same time frame corresponds to the period of peak development of type 1 diabetes in NOD/Lt females. In common with NOD mice, the earliest phase of the insulitis process in BBDP rats also seems to be a phase in which both permeability changes in the pancreatic vascular endothelium and "macrophage insulitis" are noted (201).

Perhaps because of the paucity in BBDP rats of mature peripheral T lymphocytes, especially those expressing the OX8⁺/OX19⁺ Τ cytotoxic/suppressor phenotype, OX8⁺/OX19⁻ asialoGM1⁺ NK cell was initially implicated as a primary effector of β -cell destruction (200). Cells with this NKlike phenotype appeared to be the most prevalent of the isletinfiltrating leukocytes, but an NK cell-specific monoclonal antibody to the NKR-P1 receptor failed to reduce the frequency of diabetes in BBDP rats (220). Pathogenic roles for rat CD4+ (W3/25⁺) and CD8⁺ (OX8⁺/OX19⁺) T lymphocytes were indicated by the finding that concanavalin A (con A)-activated splenocytes from acutely diabetic BBDP donors would adoptively transfer type 1 diabetes into young prediabetic BB or athymic nude recipients. Treatment of prediabetic BBDP rats with the nondepleting anti-CD4 monoclonal antibody, W3/25, reduced the frequency of type 1 diabetes, but not insulitis, whereas treatment with pan-T (OX19) monoclonal antibody completely prevented insulitis and type 1 diabetes without a reduction in the NK population (200). That both CD4+ and CD8+ T lymphocyte subsets synergistically contributed to insulitis was shown using manipulated T lymphocytes from the nonlymphopenic BBDR strain. Treatment of these nominally diabetes-resistant rats with a depleting monoclonal antibody to ART2/RT6 (the cell-surface ADP ribosyltransferase marking ~70% of mature peripheral T lymphocytes) could rapidly elicit insulitis and type 1 diabetes within a 2-week period if the rats were conventionally housed (see next section) (221). The availability of MHC-identical WAG-athymic nude rats allowed adoptive transfer experiments showing that transfer of both CD4⁺ and CD8⁺ subsets from BBDR donors treated with anti-RT6DR were required for rapid and efficient transfer of type 1 diabetes (222). Cotransfer of RT6+ T lymphocytes from untreated BBDR donors with the RT6-depleted population blocked this pathogenesis, confirming the presence of a regulatory population of RT6⁺ suppressor cells in the BBDR rat. Presumably, the absence of this regulatory population due to the T lymphopenia produced by the Lyp gene accounts for the high spontaneous incidence in the BBDP strain. It has since been shown that other inbred rat strains without spontaneous development of type 1 diabetes nevertheless contain potential diabetogenic T-cell clones in the periphery whose autoreactivities are suppressed by thymus-derived regulatory cells (223). It is interesting that the BBDP, but not the BBDR, rat, resembles the NOD mouse in exhibiting a deficiency in a NKP-R1⁺ NKT subset (224). NKT cells from Wistar rats expressing RT6 conferred protection against recurrent pancreatic transplant rejection in BBDP recipients, suggesting that these cells were regulatory and capable of deviating autoaggressive cells to a T_H2 phenotype (225).

THE BB DIABETES-PRONE RAT AS A MODEL OF ENVIRONMENTALLY TRIGGERED TYPE 1 DIABETES

Environmental triggers may exist that are capable of unleashing autoreactive function in T lymphocytes that escape thymic deletion and are normally held under immunoregulatory control in the periphery. In the case of type 1 diabetes, human pathogenic viruses often are discussed as potential diabetogenic catalysts, but this has been exceedingly difficult to prove (226). Diabetogenesis in the BB/Wor rat was initially assumed to be relatively unaffected by its physical environment (227). However, this view has altered radically with the discovery that the rare sporadic breakout of type 1 diabetes in a nonbarrier colony of BBDR/Wor rats correlated with seropositivity to Kilham rat virus (KRV). Subsequent study showed that experimental infection of BBDR rats with this parvovirus rapidly led to insulitis and the development of type 1 diabetes (228). KRV infects lymphoid tissues, but not islet cells, so the catalytic effect on diabetogenesis was assumed to entail immunomodulation (229). Even rat strains not prone to diabetes that have the appropriate RT1 class I A^u and class II B/D^u restriction elements can be rendered diabetic by KRV exposure in combination with either anti-ART2/RT6 monoclonal antibody or administration of poly I:C (230). This effect is dependent on both CD4⁺ and CD8⁺ T lymphocytes, macrophages, and/or macrophage-secreted monokines and is virus-specific, because exposure of BBDP rats to LCMV virus reduces the incidence of type 1 diabetes (230,231). The ability of a virus to act as a diabetogenic trigger in rats makes this murine genus much more suitable for analysis of the role of viruses in type 1 diabetes than is the NOD mouse, in which viral exposure stimulates protective immunoregulatory mechanisms (Table 18.4).

MOLECULAR ANALYSIS OF THE INSULITIC PROCESS

Studies performed on the cytokine genes expressed by isletinfiltrating leukocytes in the BB rat are supportive of comparable studies done in NOD mice, indicating that pathogenesis is driven by a T_H1 cytokine spectrum. Consistent with the early "macrophage insulitis" described in the DP model, increased expression of IL-12p40 mRNA has been reported (232,233). Upregulated IFN-y transcripts, with minimal or undetectable IL-4 and IL-10 transcripts, were found in islet-infiltrating leukocytes (233,234). The advantage of the RT6-depleted BBDR model is that insulitis development is rapid and synchronous, with macrophages and a few T lymphocytes present within 10 days of treatment and a progressively more florid insulitis developing between days 10 and 18 (235). A T_H1 cytokine profile similar to that developing in BBDP rats was observed in BBDR rats following RT6⁺ T-cell depletion (233). Feeding BBDP rats a semipurified diet that reduces the incidence of type 1 diabetes is associated with reduced IFN-y transcript levels and increased IL-10 and TGF- β transcript levels (236). Activation of macrophages by poly I:C correlates with induction of IFN- α/β gene transcription, translation, and secretion. Whereas poly I:C, which mimics a double-stranded RNA viral genome, like most viral infections, prevents type 1 diabetes in NOD mice, only a low dose can inhibit the development of type 1 diabetes in DP-BB rats (71,237). When administered at a dose of 10 μ g per g of weight, poly I:C accelerates the development of type 1 diabetes in both DP and DR rats (238). Islets of unmanipulated DP, but not DR, rats showed increasing IFN- α transcript levels with age, and poly I:C-induced type 1 diabetes in DR rats was similarly correlated with induced expression of this cytokine (238). Unlike prediabetic NOD mice and BBDR/Wor rats in which cyclophosphamide treatment promotes a rapidly destructive insulitis, in BB rats this treatment inhibits the development of type 1 diabetes (239).

OTHER ENDOCRINOPATHIES: THYROIDITIS

The BBDP rat shares with the NOD mice the susceptibility to subclinical thyroiditis and sialitis development (196). The thyroiditis can be exacerbated by environmental manipulation to produce clinically significant lesions and hypothyroidism (177,178). Spontaneous lesions are more commonly encoun-

tered in diabetic (59%) versus nondiabetic (11%) BBDP/Wor rats (240). The University of Massachusetts, Worcester, developed six substrains of lymphopenic BB rats. Although the incidence of type 1 diabetes among these substrains was relatively constant, major differences (ranging between 4.9% and 100%) in incidences of spontaneous or excess iodine-elicited thyroiditis were observed (241). The immunoregulatory defects induced by the lymphopenia (Lyp) mutation are critical in this pathology, since it is rare in genetic segregation analysis between BB rats and nonlymphopenic strains to identify nonlymphopenic rats with thyroiditis (242). In a genetic analysis in which all diabetics were homozygous for RT1.B^u class II genes, thyroiditis was distributed equally between RT1.B^u homozygotes and heterozygotes (242). Thyroiditis can be transferred into athymic rats by the same population of con A-activated BB splenocytes that transfer type 1 diabetes (243). However, the antigens recognized between β -cells and thyrocytes are presumably not common, since insulin prophylactic therapy can retard insulitis but not the severity of thyroiditis (244).

AVAILABILITY

Information on the status of BB rat colonies can be obtained from the *International Index of Laboratory Animals* and the Institute for Laboratory Animal Research (ILAR) Web site (http://dels.nas.edu/ilar/). The major American supplier of BB rats is Biomedical Research Models (http://www.biomere.com); the major European vendor is M&B, A/S, Ry, Denmark (http://www.m-b.dk/).

Komeda Diabetes-Prone Rats

ORIGINS AND FREQUENCY OF TYPE 1 DIABETES

Spontaneous development of autoimmune type 1 diabetes with histopathologic characteristics (insulitis) very similar to those observed in BB rats was first reported in the Long-Evans-Tokushima lean (LETL) strain in 1991 (245). Although sharing the RT1^u MHC haplotype with BBDP rats, LETL rats were not Tlymphopenic or T-lymphocytopenic. Probably because these rats are not T-lymphopenic, the extent of insulitic infiltrates around islets appears more extensive than that observed in BBDP rats (246). As in the NOD and BB rat models, polyglandular infiltrates were observed in salivary and lacrimal glands (245). After 20 generations of inbreeding, the frequency of type 1 diabetes was 21.1% in males and 15% in females. Seven cycles of further selected breeding of diabetic versus nondiabetic parents from the original LETL strain by Komeda and colleagues (246) has led to the isolation of a nonlymphopenic diabetes-free control substrain (LETL-KND) and a nonlymphopenic line with a high incidence of type 1 diabetes (LETL-KDP). In the latter, type 1 diabetes was first detected at 60 days. A cumulative frequency of type 1 diabetes of ~70% for both sexes was attained by 120 days of age and one of 82% was obtained by 220 days, whereas KND rats remained free of type 1 diabetes. Onset of type 1 diabetes in KDP rats, as in BB rats, was abrupt, and diabetic rats exhibited reduced pancreatic insulin content (246). Severe insulitis was observed in all KDP rats by 220 days of age, yet only periinsulitis was observed in KND rats.

GENETICS

A search for genetic polymorphisms among 165 microsatellites tested found no differences among the KDP, KND, and the original LETL strains (246). Three mapping crosses have been reported wherein the LETL-KDP substrain has been out-crossed to the related LETO (Long-Evans Tokushima obese) strain, as well as to the Tester Moriyama (TM) strain and the unrelated

Brown Norway (BN/Sea) strain. LETO and TM strains were *RT1^u* identical with LETL-KDP, whereas BN rats express the *RT1ⁿ* MHC haplotype. All F1 hybrids were type 1 diabetes-free, such that backcrosses to KDP were performed. All three backcrosses confirmed the presence of a diabetogenic recessive locus on Chr 11, designated *Iddm/kdp1* (247). In outcross to TM, weak evidence linked *Iddm/kdp1* to insulitis severity and overt type 1 diabetes development. Positional cloning has identified a C to T transition mutation in Casitas B-lineage lymphoma b (*Cblb*) as the major susceptibility gene in KDP rat diabetes (247a). In the mapping cross with BN, eight of nine backcross mice were homozygous for the *RT1^u* haplotype of LETL, indicating linkage to *Iddm2* (MHC).

AVAILABILITY

At the time of this writing, these strains have not been made available for distribution outside of Japan.

Single Gene Mutations Producing Insulin-Responsive Diabetes

C57BL/6NJCL-INSULIN2AKITA

Strain Origin and Diabetic Phenotype

An autosomal dominant mutation producing juvenile-onset hyperglycemia in the absence of obesity was discovered in C57BL/6N mice in Akita, Japan (248). The mutation was initially named Mody4 and mapped to distal Chr 7. The initial gene symbol assigned was Mody (for maturity-onset diabetes of the young). This choice was based on the autosomal dominant mode of inheritance and the findings that the β -cells in the pancreatic islets failed to develop a normal mass and that β -cell secretory responses to glucose were subnormal (248,249). Heterozygous males in the source colony developed severe hyperglycemia at weaning (4 weeks), whereas heterozygous mutant females developed a less severe hyperglycemia. Histologic analysis showed a dearth of islets; those detected were extremely atrophic and devoid of granulated β-cells. This histopathology was similar to that observed in mice rendered insulin-dependent diabetic by treatment with chemical diabetogens. Despite the juvenile onset of hyperglycemia, heterozygous diabetic males were both viable and fertile. In Japan, the mutation is maintained by breeding diabetic male heterozygotes to wild-type females. The C57BL/6NJcl-Ins2Akita mouse has features observed in certain human MODY families. Indeed, the model was initially described as a model for earlyonset type 2 diabetes. The initial linkage marker, D7Mit189, maps within 3 cM of Ins2, the ortholog of the human INS gene and one of the two insulin genes in the mouse (the other, Ins1, is on Chr 19). Sequencing of the Ins2 gene in these mutant mice indeed confirmed the presence of a missense mutation at residue 96 that converted a cysteine (TGC) to a tyrosine (TAC) at amino acid residue 7 of the A chain (7). This is a critical substitution, since the A7 cysteine is required to form the interchain disulfide bond with the corresponding cysteine at the seventh amino acid residue on the B chain. In heterozygous Ins2+Ins2Akita mice, the conformational change leading to defective proinsulin chain folding of the mutant insulin triggers massive compensatory "quality-control" mechanisms in the endoplasmic reticulum (suggesting an influx of chaperonins). These responses are so massive that not only is proinsulin processing from the mutant allele blocked but folding and processing of Ins1 gene products are also strongly inhibited. This disruption in normal processing in the regulated secretory pathway leads to the failure of β -cells to secrete normal levels of mature insulin and,

hence, to early development of hyperinsulinemia. The failure of the islet β -cell mass to develop normally further suggests a role for insulin as an autonomous β -cell growth factor. The knowledge of the molecular basis for the syndrome led to the mutant symbol change from *Mody4* to *Ins2*^{Akita}.

The mutant stock was imported to The Jackson Laboratory in 1999, where the mutation has been maintained by backcrossing heterozygous males to normal C57BL/6J females. Comparison of the development of hyperglycemia and of survival of heterozygotes versus that of mutant homozygotes maintained on a 6% fat diet (PMI, NIH-31) showed that homozygotes rarely survived beyond 12 weeks of age. As was noted in Japan, heterozygous mutants remained viable for relatively long periods in the face of chronic hyperglycemia, with the development of hyperglycemia progressing more slowly in females than in males. Groups of four heterozygous males and females sampled for plasma glucose levels at 6 weeks of age exhibited comparable initial mean hyperglycemia ($325 \pm 57 \text{ mg/dL}$ for males vs. $325 \pm 57 \text{ mg/dL}$ for females). The mean plasma glucose levels in the same mice at 12 and 18 weeks were 12 and 18 weeks, mean plasma glucose in males was 645 ± 109 (12 weeks) and \pm 101 (18 weeks), whereas the averages in females were 341 ± 78 (12 weeks) and 398 ± 61 (18 weeks). Sensitivity of hyperglycemic Ins2^{Akita} mice to exogenously administered insulin had not previously been tested in Japan. A pair of hyperglycemic males tested at The Jackson Laboratory was insulin-responsive. This observation has important implications for the use of this model for testing insulin replacement therapies.

Potential Research Uses

Islets from $Ins2^{Akita}$ mice are β -cell–depleted, and residual β -cells release very little mature insulin. This fact, coupled with the finding that the mutant mice respond to exogenously administered insulin, indicates that this model would serve as an excellent substitute for mice made insulin-dependent diabetic by treatment with diabetogens such as alloxan or streptozotocin. Chemically diabetic mice are widely used for the study of the effects of chronic hyperglycemia and diabetic complications. The difficulty has been that these chemical diabetogens may produce unwanted toxic side effects on multiple organ systems in addition to the pancreatic β-cells, thus complicating interpretations of damage produced by hyperglycemia versus direct toxin-induced damage. The observation that Ins2^{Akita} mice spontaneously develop an insulin-responsive hyperglycemia but will survive with chronic hyperglycemia without insulin therapy further suggests that they will be an excellent source of diabetic recipients for allogeneic or xenogeneic islets in studies designed to investigate induction of transplantation tolerance. Indeed, preliminary studies at The Jackson Laboratory indicate that intrarenal transplantation of 400 syngeneic C57BL/6 wildtype islets can correct the hyperglycemia.

Availability

C57BL/6J-*Ins2*^{Akita} mice are available as heterozygotes from The Jackson Laboratory (stock number 003548). Controls are B6-^{+/+} segregants.

C57BL MICE CARRYING THE *FAT* MUTATION AT THE CARBOXYPEPTIDASE E LOCUS

Origin and Diabetic Phenotype

The autosomal recessive *fat* mutation arose spontaneously in 1972 in the HRS/J inbred strain (250). Obesity manifesting by 8 weeks of age was preceded by marked increases in immunologically detectable insulins (both proinsulins I and II and insulins I and II) in serum. Blood glucose levels were modestly elevated

above normal such that insulin resistance was presumed. The phenotype elicited by the fat mutation proved to be heavily influenced by the inbred strain background. When the fat mutation was transferred from the HRS/J background to C57BLKS/J (BKS), a male gender-biased diabetes developed (250). Since hyperinsulinemia was accompanied by obesity, the model was originally considered to represent an insulin-resistant model of type 2 diabetes. However, on the BKS background, the diabetes syndrome produced by this mutation differs markedly from that produced by either the Lep^{ob} (leptin-deficient ob/ob) or Lepr^{db} (leptin receptor-deficient db/db) mutations on the same background. Unlike the latter two mutations, neither hypercorticism nor the glucocorticoid-induced shifts in hepatic sex steroid metabolism were elicited by the fat mutation (250). Another major distinction was the absence of hyperphagia in the BKS-fat homozygous mice (250). Finally, the hyperglycemic BKS-fat homozygotes were markedly sensitive to exogenously administered insulin, a finding that indicated that the molecular basis for the diabetes syndrome was a defect in proinsulin processing, a defect that could easily be explained by a defective carboxypeptidase E gene (250).

Genetics

The *fat* mutation had been mapped to Chr 8 within the vicinity of the carboxypeptidase E (*Cpe*) locus (251). CPE was initially identified as the carboxypeptidase involved with the biosynthesis of the enkephalins (252). Based on the broad neuroendocrine distribution and substrate specificity of CPE, this enzyme was thought to be involved with the processing of all neuroendocrine peptides that are produced from precursors by selective cleavage at sites containing basic amino acids (253). Following endopeptidase action, most peptides require removal of the C-terminal basic amino acids to generate the bioactive form of the peptide. In some cases, further processing to generate a C-terminal amide moiety also is required for bioactivity; this step is mediated by the enzyme peptidylglycine- α -amidating monooxygenase (254).

CPE is an important component of proinsulin processing in the β -cell. The unexpected discovery that *fat* mice were sensitive to exogenously administered insulin despite high serum levels of endogenous insulins, coupled with colocalization of the *Cpe* and *fat* genes to Chr 8, prompted an evaluation of the levels of CPE activity in *fat/fat* mice. Mutant mice were indeed found to have extremely low levels of CPE-like activity. Analysis of the *Cpe^{fat}* gene revealed a point mutation within the coding region, which substituted a proline for a serine (251). When the mutant form of CPE was expressed in a variety of cell culture systems, the resulting protein was inactive and was rapidly degraded within the cell prior to secretion, suggesting that the *Cpe^{fat}* is a null allele (281,255).

Potential Research Uses

The pleiotropic actions of the Cpe^{fat} mutation leading to obesity development are not resolved. The working hypothesis is that the defective CPE leads to loss of a peptide or peptides that function to control nutrient partitioning rather than caloric intake. Although the specific peptide or peptides has not been identified, a large number of peptides are detected with C-terminally extended basic residues in Cpe^{fat}/Cpe^{fat} mouse brain; none of these peptide precursors are found in control mouse brains, since CPE activity rapidly removes the C-terminal basic residues as soon as the endopeptidase has cleaved the precursor. Further studies are needed to determine the pleiotropic imbalances that underlie excess fat accumulation in Cpe^{fat}/Cpe^{fat} mice. The Cpe^{fat} mutation has led to discovery of several new members of the carboxypeptidase family and to novel neuroendocrine peptides. In the absence of CPE, the Cpe^{fat}/Cpe^{fat} mice presumably survive due to the ability of additional carboxypeptidases, such as carboxypeptidase D, to partially compensate in the processing of neuroendocrine peptides. The function of the other novel members of the carboxypeptidase family remains elusive, but it is unlikely that these other proteins participate in peptide processing. Further studies are needed to investigate the proposal that several of the novel members of the carboxypeptidase family function as binding proteins rather than active enzymes.

Availability

The BKS-*Cpe^{fat}* stock at N11 is available from The Jackson Laboratory. More recently, the mutation has been transferred onto the C57BL/6J inbred strain background, and this stock is available from The Jackson Laboratory. This latter congenic stock offers the advantages that the B6 background is free of the malocclusion and polycystic kidney lesions that are strain characteristic pathologies resident in the BKS inbred strain background. Homozygous mutants do not reproduce such that the stocks are maintained by heterozygous matings or by mating heterozygous males to females (e.g., NOD-*Prkdc^{scid}*) carrying ovarian transplants of mutant female ovaries.

ANIMAL MODELS OF TYPE 2 (NON–INSULIN-DEPENDENT) DIABETES MELLITUS

The onset of hyperglycemia, the hallmark symptom of all forms of diabetes, is the result of the breakdown either in insulin production or in insulin action or a combination of the two. Either can be primary and, if severe enough, either alone can be sufficient to produce hyperglycemia. In many cases, onset of type 2 (or non-insulin-dependent) diabetes occurs when compensatory mechanisms for insulin resistance drive β -cell failure. A host of errors, both genetic and environmental, is thought to be able to initiate insulin insufficiency and/or insulin resistance in humans. These phenotypes, which are checkpoints in the development of diabetes, also are present in rodents. A large array of rodent models exist for the study of type 2 diabetes, and although these models manifest hyperglycemia, the stresses needed for onset of diabetes, as well as the associated phenotypes, are, as in humans, drastically different.

Mouse Models of Type 2 Diabetes

SINGLE GENE MUTATIONS THAT PREDISPOSE MOUSE STRAINS TO TYPE 2 DIABETES

Spontaneous mutations in the mouse gene for leptin (Lep) and its receptor (Lepr), as well as "yellow" mutations at the agouti (A) locus, have been intensively studied because of their ability to produce diabetogenic obesity syndromes. The mutation formerly named *obese*, *ob*, is now designated *Lep*^{ob}; the mutation formerly named *diabetes*, *db*, is now designated *Lepr*^{*db*}. There is a plethora of reviews on the roles of mutations in these three genes (256-258); therefore, only a cursory review of the mutations and the phenotypes they elicit will appear in this chapter. The discovery that these monogenic obesity mutations are potentially diabetogenic, with their potential wholly dependent on genetic modifiers in the inbred strain background, provides major insight as to the complexity of type 2 diabetes etiopathogenesis in humans. Human morbid obesity syndromes elicited by mutations in the orthologous LEP and LEPR loci are rare and not reflective of the "garden variety" diet-influenced obesities contributing to the prevalent forms of human type 2 diabetes (259-261). Nevertheless, the diabetes syndromes elicited by

interactions between a monogenic obesity mutation, background genetic modifiers, and environmental factors provide model systems for analysis of how an obesity-associated type 2 diabetes syndrome develops.

Mutations in Leptin (Lep^{ob})

The *ob* mutation (*Lep^{ob}*) was first described in 1950 and mapped to Chr 6 (262). In 1994 the ob mutation was found to be in the gene for leptin (263). Currently, there are two known obesity-producing mutations at the Lep locus; these have been designated Lep^{ob} (also known as Lep^{ob-1J}) and Lep^{ob-2J}. Mice carrying these mutations do not produce leptin, a hormone produced by adipose tissue that provides information on the level of fat stores to the hypothalamus and acts as a satiety factor, regulating appetite and energy expenditure in mammals. Hence, leptin-deficient ob/ob mice are always highly sensitive to the weight-reducing effects of leptin. Leptin decreases food intake and increases the basal metabolic rate (264–266). Lep^{ob} mice are also infertile, and administration of recombinant leptin to Lepob mutants restores reproductive function, indicating that leptin is involved in more than energy balance and food intake (267). Administration of leptin to these mice corrects most of the pleiotropic metabolic anomalies associated with this mutation (268).

B6-Lep^{ob} mice begin to develop obesity at weaning that becomes progressively more severe with age, and they exhibit hyperphagia throughout life. Insulin resistance is a key phenotype of the B6-Lep^{ob} mouse. It has been shown that, in both muscle and liver, multiple deleterious alterations in the insulin signaling contribute to the peripheral insulin insensitivity (269). Hyperinsulinemia is detectable at 15 days of age in *Lep^{ob}* mice and increases with age, reaching 10 to 50 times the level of ageand sex-matched, identical strain controls. Yet, hyperinsulinemic B6-Lep^{ob} mice develop only mild hyperglycemia (270,271). The highest plasma insulin levels are at ~7 months of age; afterwards, the levels decline but are highly variable (272). This increase in circulating insulin is witnessed in the pancreas as an increase in β -cell mass, with islet hypertrophy and hyperplasia. Islet volume of old B6-Lep^{ob} can be increased 10-fold compared with that of controls. Due to the increase in circulating insulin and a lower β cell mass in young as compared with old B6-Lep^{ob} mice, younger mice have islets that are degranulated and stain poorly for insulin, whereas old mice have well-granulated islets (273).

As noted above, the diabetogenicity of the *Lep^{ob}* mutation is dependent on strain background. Whereas the B6 background can compensate for the diabetogenic effects of the mutation by sustained β-cell hypertrophy and hyperplasia, such compensation was not observed when the Lep^{ob2J} mutation occurred spontaneously on the SM/J background, with severe diabetes resulting (EHL, unpublished data, 1991). When transferred onto the closely related C57BLKS/J (BKS) by intercross followed by five cycles of backcross to BKS, the phenotype of BKS-Lep^{ob} homozygotes was similar in most respects to the chronic and severe diabetes syndrome produced by the Lepr^{db} mutation on the same background. The major difference would be that the BKS-Lep^{ob} diabetes syndrome would be treatable with leptin, whereas the BKS-Lepr^{db}-induced syndrome would not (see below). B6 mice with the Lep^{ob} have been used for years for therapeutic interventions to prevent the obesity and mild hyperglycemia. The appropriate controls would be the +/+ littermate because heterozygous mice have been reported to have some intermediate phenotypes.

Mutations in the Leptin Receptor (db)

The recessive autosomal diabetes (db) mutation, which maps to Chr 4, spontaneously arose on the C57BLKS/J (BKS) stock at The Jackson Laboratory (274,275). The cloning of this mutation

revealed that, as originally proposed based on parabiosis experiments between normal mice and *ob* and *db* mutants, the *db* mutation encoded a loss-of-function mutation at the leptin receptor (Lepr) locus. Including the Lepr^{db}, more than nine mutations in Lepr have been identified, including db^{2j}, db^{3j}, db^{5j}, db^{ad}, *db*^{pas1}, *db*^{pas2} *db*^{ad}, *db*^{dmpg}, and *db*^{rtnd} (256). For the purpose of this review, we will focus on BKS-Leprdb. In this mutant stock, hyperinsulinemia is present as early as 10 days of age (274). As is the case with mice carrying the *ob* mutation, mice with the Lepr^{db} weigh less than littermate controls before weaning, but the postweaning phenotype is hyperphagia and a continued increase in adiposity. Hyperglycemia establishes between 4 and 8 weeks of age. By 12 weeks of age, insulin levels are elevated up to ten times that of the +/+ controls (274,276). Unlike the massive obesity in mice carrying the *ob* mutation, BKS-*Lepr*^{*db*} only reach 60 g. When mice reach 4 to 6 months of age, the blood insulin levels diminish and the mice enter the phase of insulin insufficiency in the face of severe insulin resistance. Pancreatic morphology follows the demand for insulin. In young Lepr^{db} mice, the islets are of normal size and well granulated. As the demand for insulin increases, so too does the β -cell mass. This stage is followed by β -cell failure, driven by necrosis and islet atrophy (277).

The demand for increased insulin production is due to insulin insensitivity at the level of the target organ in obese *Lepr*^{*db*} mice. Hepatic production of glucose is hyperactive in mice with defective leptin receptors, adding to the hyperglycemic state. Treatment with exogenous insulin is not effective, and *in vitro* studies show a highly suppressed ability of muscle and adipose cell to transport glucose in response to insulin (278). While GLUT4 expression is not affected, cell-surface expression of insulin receptor is decreased and is inversely correlated with the insulin levels (279). Further, receptor kinase activity is also diminished when compared with that in controls (280).

Mice with mutations in the leptin receptor have been used for years for therapeutic interventions to prevent the obesity and mild hyperglycemia. The appropriate controls would be the +/+ littermates or mice from the identical strain.

"Yellow" Mutations at the Agouti Locus

Like the autosomal recessive mutations at the Lep and Lepr loci that are associated with diabesity (diabetes and obesity), dominant "yellow" mutations at the agouti (A) locus (Chr 2) produce obesity, with the development of hyperglycemia dependent on inbred strain background and gender. This obese phenotype is in direct correlation to the amount of yellow in the coat color [for reviews see references (281,282)]. The Agene product is a secreted paracrine factor that regulates pigment in hair-follicle melanocytes. The mutations at the A locus (A^y, A^{vy}, A^{iy}, A^{sy}, A^{hvy}, A^{iapy}) produce systemic expression of a protein of 131 amino acids that is normally only expressed at high levels in the dermal layer of the skin. Most of the cloned mutations at A are due to the insertion of an intracisternal A particle (IAP) retrotransposon upstream of the gene. This insertion disrupts the endogenous promoter's control of expression (283–287). The impact of these mutations is detected on both insulin secretion and action. Peripherally, agouti promotes lipogenesis by increasing fatty acid synthase (FAS) expression and activity in a Ca2+-dependent manner (288,289). Insulin and agouti act in an additive manner to induce FAS expression and activity in adipocytes, as the FAS promoter contains both an insulin and agouti response element (288). Insulin treatment of mice that have agouti mutations increases adiposity. β -Cell phenotypes also are affected by the A gene product, as expression of the agouti protein in β -cells causes the hypersecretion of insulin (290-292).

The ectopic expression of agouti protein results in yellow fur, obesity, insulin resistance, hyperinsulinemia, and hyper-

glycemia. Further phenotypes include increased linear growth and skeletal mass, as well as increased susceptibility to tumors. The severity of these phenotypes varies among mouse strains. Mouse strains such as KK or ALS are very sensitive, with males and females affected and presenting hyperglycemia; strains such as ALR are almost completely resistant to the onset of hyperglycemia, while still manifesting the obesity syndrome (293). In mice with severe phenotypes, the onset of hyperinsulinemia begins at 6 weeks of age and insulin levels continue to increase with age (294,295). The increase in circulating insulin is proceeded by β -cell hyperplasia and hypertrophy (296). The type 2 diabetes syndrome that is driven by mutations the A locus is very complex, with important contributions from multiple endocrine glands. Removal of the adrenal glands prevents hyperglycemia and reduces obesity, and hypophysectomy ablates the diabetes and the hyperinsulinemia but has only a small effect on the level of obesity (297-300).

Appropriate controls for use in experiments with mice carrying mutations at the *A* locus would be mice of the identical strain that are A/A at the agouti locus. Mice carrying A^{y} , A^{vy} , A^{iy} , A^{sy} , A^{hvy} , A^{hvy} , A^{iapy} are available from The Jackson Laboratory.

ALLOXAN-SUSCEPTIBLE MICE: A MODEL OF NUTRITIONALLY EVOKED TYPE 2 DIABETES

Strain Origin and Diabetic Phenotype

ALS (alloxan-susceptible) mice were derived from outbred CD-1 mice by selection for sensitivity to alloxan-induced diabetes concomitant with selection for an alloxan-resistant line now designated ALR. Alloxan is a potent generator of free radicals. The basis for the differential alloxan sensitivity of the ALS/Lt and ALR/Lt strains was correlated with differential ability to dissipate free-radical stress (97). ALS mice respond to a relatively low concentration of alloxan (47 to 49 mg/kg) with development of insulin-dependent diabetes within 24 hours after administration. One of the unusual features of this chemically induced diabetes is the relationship between plasma insulin and glucose. In most strains, alloxan induces massive β -cell necrosis and release of insulin stores within hours after administration, producing an immediate hyperinsulinemia that, in turn, elicits an initial drop in blood glucose levels before hyperglycemia is detected. In alloxan-treated ALS/Lt mice, the expected immediate hyperinsulinemia is not accompanied by transient hypoglycemia, but rather by hyperglycemia. Indeed, unlike other strains rendered insulin dependent by alloxan treatment, ALS/Lt males made diabetic at 10 weeks of age by an alloxan dose of 52 mg/kg (intravenous) failed to respond to insulin therapy. This was suggestive of an underlying insulin resistance. Longitudinal measurements of plasma insulin and glucose levels in completely untreated ALS/Lt males maintained on a chow diet containing 4%, 6%, or 11% fat confirmed underlying defects in glucose homeostasis associated with a progressively more severe insulin resistance (301). Males exhibited marked glucose intolerance as early as 6 weeks of age. At this age, plasma insulin levels were moderately increased (4.7 \pm 0.7 ng/mL) and increased progressively with age (14.5 ± 1.4) ng/mL by 12 weeks; 40 ± 15 ng/mL by 20 weeks). Mice of either sex are large and exhibit moderate obesity as they age [male ALS have 8.5% body fat as measured by dual energy xray absorptiometry (DEXA)]. Histologic examination of pancreatic sections of unmanipulated ALS males shows increased islet volume and islet-cell hypertrophy and hyperplasia. Females of this strain on a chow diet containing 6% fat are neither glucoseintolerant nor hyperinsulinemic. ALS/Lt females do exhibit increased islet numbers compared with closely related control strains, which include ALR/Lt, NON/Lt, and NOD/Lt.

Although ALS males present these pre-type 2 diabetes phenotypes, the incidence of overt hyperglycemia is sporadic and very low, even when mice are fed a diet containing 11% fat by weight. However, type 2 diabetes can be induced in 100% of ALS males if they are placed on a chow diet containing 11% fat and are singly housed. Under these conditions, these mice have a significantly increased plasma glucose level 2 weeks after the onset of the treatment and 100% will become hyperglycemic by 6 weeks after the onset of the stress. Plasma insulin levels under this stress attain exceedingly high levels, attaining an average of 212 ± 131 ng/mL after 8 weeks of stress (301). Histologic examination reveals severe degranulation of the pancreatic islets. The volume of islets of ALS/Lt males subjected to dietary stress is increased over that of the already large islets of ALS/Lt males, apparently due to an increase in the number of islet cells rather than to cell hypertrophy.

The ALS/Lt strain should prove especially valuable for analyzing the relationship between reactive oxygen species and the development of type 2 diabetes and its complications, because many of the pathologic changes associated with diabetic hyperglycemia entail increased production of reactive oxygen species. ALS/Lt males, when compared with ALR/Lt males, show significantly lower ratios of reduced-to-oxidized glutathione, as well as an increase in circulating lipid peroxides (97,98). These ratios decrease with age in ALS and correlate with onset of hyperinsulinemia and impaired glucose intolerance. That progressive free-radical damage is associated with dietary fat-induced development of type 2 diabetes in ALS/Lt males was shown by inclusion of the antioxidant lipoic acid in the diabetogenic diet. This manipulation markedly reduced hyperinsulinemia, led to improved glucose tolerance, and prevented the dietary induction of type 2 diabetes. These indications of a reduction in the ability of ALS mice to dissipate freeradical stress suggest that ALS males will serve as interesting models for the study the effects of oxidative stress on type 2 diabetes and its complications (301).

PHENOTYPES WITH MUTATIONS PREDISPOSING TO OBESITY OR TYPE 2 DIABETES

The yellow mutation (A^y) at the agouti locus on Chr 2 has been moved onto both the ALS and ALR backgrounds for comparison (293). The incidence of diabetes at 24 weeks of age in ALS males and females heterozygous for A^y was 100% and 60%, respectively. Only 50% of ALS. A^y males survived to 50 weeks. Pancreatic β -cell function in males was virtually abolished by 24 weeks, as evidenced by absence of circulating insulin. ALS. A^y females hypersecreted insulin as early as 16 weeks of age, even when fasting.

Potential Research Uses

The progressive development of pre–type 2 diabetes metabolic anomalies in the ALS male, coupled with the ability of dietary and behavioral stress to push the male across a threshold into clinical type 2 diabetes, provides investigators with an unusual opportunity to study the contributions of reactive oxygen species to the development of these phenotypes, and especially the progressively more severe peripheral insulin resistance. Since the genome of this strain is being characterized, it may also provide important new genetic insights into the genetics of type 2 diabetes.

Availability

ALS/Lt mice are available from The Jackson Laboratory. Control strains for research with the ALS include the co-selected ALR/Lt strain (systemically high free-radical dissipation and

mild obesity without impaired glucose tolerance and hyperinsulinemia). ALS/Lt mice exhibit considerable genome sharing with the related NON/Lt strain, including *H2* haplotype ($H2^{nb1}$) and *Thy1* allele (*Thy1*^a). Although NON/Lt males share the phenotype of impaired glucose tolerance with ALS/Lt males, the former are differentiated by impaired insulin secretory responses (302). SWR/J, another Swiss-derived strain with normal glucose tolerance and plasma insulin levels, can be used as a lean control strain.

C57BL/6J MICE (A MODEL OF NUTRITIONALLY EVOKED TYPE 2 DIABETES)

Diabetic Phenotype

While used as a control strain for many studies of type 2 diabetes, the C57BL/6 (B6) male is a model for diet-induced type 2 diabetes. The studies and phenotypes described in this section may call into question the validity of the C57Bl/6J as a control strain for studies of type 2 diabetes. Males fed a diet high in fat and simple carbohydrate (58% fat by kcal) develop hyperglycemia, hyperinsulinemia, hyperlipidemia, and increased adiposity (303). The type 2 diabetes phenotypes are associated with insulin resistance and poor insulin secretion. Insulin secretory responses from islets isolated from B6 mice fed a highfat/high-simple carbohydrate (HFHSC) diet were blunted compared with those in controls (304,305). Plasma levels of leptin in B6 mice remain significantly lower than those in controls. HFHSC feeding of B6 mice increased body weight in the absence of hyperphagia (306,307). This suggests that the B6 strain exhibits an increased feed efficiency when compared with that in the control nondiabetic A/J strain, and this was shown, as B6 mice gain more weight per calories consumed (306). This increase in feed efficiency drives the increase in adiposity via increased fat cell number (303). The increase in specific fat-pad size, particularly the mesenteric fat depot, is important for the onset of type 2 diabetes in this model. It is interesting that the BKS males, which are susceptible to severe diabetes induced by the Lep^{ob} and Lepr^{db} mutations, are much more resistant to obesity induced by a HFHSC diet (308).

Complications

HFHSC feeding has been shown to cause diabetes-like symptoms during pregnancy (309).

Potential Research Uses

Since many humans with type 2 diabetes can control their diabetic conditions with dietary changes and exercise, the model of diet-induced type 2 diabetes is important for studying the diabetogenic changes induced by diet and the interventions that can reverse the phenotypes. This should be an excellent model of dietary, exercise, and pharmaceutical interventions. Gestational IGT can also be induced in this strain.

Availability

Young C57BL/6J males can be obtained from The Jackson Laboratory. See (310) for the control and diabetogenic diets. In addition to B6 males maintained on standard chow, the type 2 diabetes–resistant A/J male fed HFHSC diet has been used for metabolic comparison in most of the published work.

NAGOYA-SHIBATA-YASUDA MICE

Strain Origin and Diabetic Phenotype

The Nagoya-Shibata-Yasuda (NSY) mouse strain was inbred from outbred Jcl:ICR stock by selecting for impaired glucose tolerance (311). Impaired glucose tolerance was shown to be malespecific and to develop by 12 weeks of age (14). The cumulative incidence of IGT is 98% in males and 31% in females at 48 weeks of age, with increased adiposity and mild hyperinsulinemia. Fasting plasma insulin level was higher in male NSY mice than in male C3H/He control mice (545 ± 73 vs. $350 \pm 40 \text{ pmol/L}$, p < 0.05, at 36 weeks, respectively). Decrease of glucose-stimulated insulin secretion *in vitro* can be detected by 12 weeks of age. Blunted insulin secretion in response to a glucose challenge was seen in all males by 24 weeks of age. The diminished β -cell function drives the impaired glucose tolerance. Pancreatic insulin content was higher in male NSY mice than in male C3H/He mice (76 ± 8 vs. 52 ± 5 ng/mg wet weight, p < 0.05, at 36 weeks of age). No abnormal morphologic findings exist such as hypertrophy or inflammatory changes in the pancreatic islets at any age tested.

Genetics

The cumulative incidence of impaired glucose tolerance and fatty liver in reciprocal F1 hybrid males was 100% (25 of 25) in (C3H \times NSY) F1 and 97% (29 of 30) in (NSY \times C3H) F1 at 48 weeks of age (312). Insulin resistance also was inherited dominantly but was more severe in F1 hybrid males in both directions than measured in parental NSY males, suggesting that the combined interaction of the C3H and NSY genomes produced a more severe pre-type 2 diabetes phenotype. Adiposity and impaired glucose-stimulated insulin secretion were both inherited in a recessive autosomal fashion, while body mass index was inherited as a codominant trait. Genetic dissection of the F2 generation using microsatellite markers throughout the genome mapped three major loci involved in IGT (313). Nidd1^{nsy} (Chr 11) and Nidd4^{nsy} (unmapped) influenced insulin secretion, and Nidd2^{nsy} (Chr 14) and Nidd3^{nsy} (Chr 6) appeared to affect insulin sensitivity. The Nidd3nsy locus also affected epididymal fat weight. Positional cloning of susceptibility genes for type 2 diabetes in NSY mice has not been completed. Currently, a candidate susceptibility gene for Nidd1^{nsy} is Tcf2 (encoding the HNF1 β transcription factor) because NSY has a rare sequence variant in the DNA-binding domain (314).

Complications

The life span of NSY mice was found to be 618.7 ± 72.5 days (315), considerably shorter than that of C57BL/6 mice. Amyloid deposition was present in the tongue, esophagus, stomach, small intestine, large intestine, rectum, lung, heart, and adrenal glands and to a slight degree in the liver and the spleen. The most dominant amyloid deposition in NSY mice was seen in the glomerulus of the kidneys. NSY mice that lived for more than 400 days showed rising levels of blood urea nitrogen and large amounts of amyloid deposits in the glomerulus of the kidneys. NSY mice die of renal amyloidosis. Immunologic methods revealed evidence of ApoA_{II} in the amyloid deposits of NSY mice (315). In NSY males glomerular basement membrane thickens with the progression of the type 2 diabetes and lesions can be inhibited by lysozyme treatment (316).

Potential Research Uses

The polygenic nature of type 2 diabetes in the NSY mouse coupled with its the kidney complications make this strain a unique and useful tool for gene discovery and evaluating new agents for the improvement of kidney function in diabetic patients (314).

Availability

Possible controls for the NSY are the closely related SWR/J (lean control), NON/LtK (IGT, impaired insulin secretion control), ALS/LtJ (IGT, hyperinsulinemic mildly obese control), or

the ALR/LtJ (mild obesity, no impaired glucose tolerance). The NSY strain is available from Japan SLC, Shizuoka, Japan.

TALLYHO MICE

Strain Origin and Diabetic Phenotype

The TallyHo (TH) strain was derived from two male ancestors of an outbred Theiler Original colony that had late-onset (~26 weeks of age) polyuria and glucosuria. The TH strain has been selected based on breeding only hyperglycemic males from the original deviant stock. This strain is now maintained as inbred at The Jackson Laboratory. The progenitor population from which this strain was derived is unknown, but this albino strain appears to be of Swiss origin on the basis of its H2^s MHC haplotype (shared with Swiss-derived SJL/J mice).

As with many mouse strains predisposed to type 2 diabetes, in the TH strain type 2 diabetes is sexually dimorphic, with only males of the strain exhibiting all phenotypes of type 2 diabetes. TH mice grow quickly, with males and females reaching 45 g by 26 weeks. At 26 weeks of age, TH males and females are obese [adiposity index, defined as weight of five fat pads (g)/body weight minus five fat pads = $\overline{0.18} \pm 0.12$ males; 0.39 ± 0.01 females], hyperlipidemic (TG = 652 ± 35 males; 349 ± 24 females) (total cholesterol = 213 ± 6 males; 132 ± 10 females) (FFA = 0.32 ± 0.02 males; 0.33 ± 0.03 females), hyperinsulinemic $(16 \pm 2.1 \text{ males}; 7 \pm 1.9 \text{ females})$, yet only males are hyperglycemic (544 \pm 24 males; 162 \pm 9 females). By 14 weeks of age, all males have nonfasting plasma glucose levels higher than 300 mg/dL and insulin levels higher than 3 ng/mL. Pancreatic islets of 20-week-old TH males are hypertrophied, and β -cells are degranulated (317).

Genetics

For the genetic dissection of the diabetes-associated traits from TH, outcrosses and first backcrosses to the nondiabetic and unrelated B6 and CAST/Ei (CAST) strains were used. Because of the male-specific susceptibility to diabetes, only males were used for both sets of genetic experiments. No F1 mice in either cross became diabetic. Quantitative-trait loci (QTL) mapping was performed for the phenotypes of plasma glucose (PG), BW, and fat pad weight. In the crosses with the B6 mice, two significant linkages were detected for PG. These were Tanidd1 (Chr 19) and Tanidd2 (Chr 13). The Tanidd1 locus also was found to be associated with increased body weight. These QTL exhibited a recessive mode of inheritance. Further, for the traits of body weight and fat-pad weights alone, two separate QTL were discovered. Chr 7 was significantly linked to increased body weight. Unlike the loci for PG, this body weight-associated QTL showed that, even though the TH was the strain susceptible to obesity, the heterozygotes at this locus showed the greater body weights. A QTL controlling fat-pad weight only was located on Chr 4. Again, heterozygotes showed significantly higher values than the TH homozygotes.

Potential Research Uses

The TallyHo male provides a new model for the study of polygenic type 2 diabetes. Like the TSOD strain described below, complete disease penetrance in males makes this strain a unique and very useful tool for gene discovery and the evaluation of new antidiabetic agents.

Availability

TallyHo mice are available from The Jackson Laboratory. Although B6 has been used as a control strain for TallyHo, Swiss-derived strains such as the lean SJL/J or SWR/J strains with normal glucose tolerance and plasma insulin levels may provide a more closely related backgrounds for comparison.

TSUMURA, SUZUKI, OBESE DIABETES MICE

Strain Origin and Diabetic Phenotype

The Tsumura, Suzuki, obese diabetes (TSOD) inbred strain was established in 1992 following selective breeding of outbred Slc:ddY progenitors exhibiting high body weight and glycosuria in males (318). Type 2 diabetes in this strain is male gender-specific, with 100% exhibiting diabetes by 20 weeks of age. Hyperinsulinemia is demonstrable at 13 weeks of age and probably develops earlier. Male TSOD mice are hyperphagic throughout life and exhibit rapid weight gain during the peripubertal period (319). Blood lipid profiles of TSOD males are also abnormal, with cholesterol and triglycerides increasing with age. Histologic examination of the pancreas reveals hypertrophy of the pancreatic islets. Immunostaining of pancreatic sections for insulin and glucagon at 52 weeks of age demonstrates a significant decrease in insulin-positive staining of pancreatic islets, suggesting either partially or completely βdegranulated islets compared with insulin-positive control, nondiabetic TSNO (Tsumura, Suzuki, non-obesity) or to Slc:ddy males. Glucagon staining of islet α -cells is equivalent in TSOD and TSNO controls.

Genetics

Genetic outcrosses of TSOD with BALB/cA showed that the genetics of the development of type 2 diabetes in the TSOD parental males is recessive and under polygenic control, as no type 2 diabetes developed in either F1 or F2 males (319). A genome-wide screen for loci linked to glucose intolerance, insulin secretion, and body weight allowed mapping of three QTL controlling these diabetes-related phenotypes. The major genetic determinant of glucose intolerance was identified on Chr 11 and designated *Nidd4*. While *Nidd4* is located near the *Nidd3* locus reported in the NZO genome, the phenotypic effects and QTL peaks presumably distinguish these QTL (320). Two separate body-weight QTL were found on Chr 1 (*Nidd6*) and Chr 2 (*Nidd5*). *Nidd5* on Chr 2 also significantly affected insulin secretion in response to a glucose challenge. *Nidd5* is located in the region that contains Obesity QTL 3 (*Obq3*) (321).

Potential Research Uses

The polygenic nature of type 2 diabetes in the TSOD mouse coupled with complete disease penetrance in males make this strain a unique and very useful tool for gene discovery and for evaluating new antidiabetic agents (319).

Availability

The TSOD and the concomitantly derived TSNO control are not distributed.

NEW ZEALAND OBESE MICE

Strain Origin and Diabetic Phenotype

New Zealand Obese (NZO) is an inbred strain derived in New Zealand from outbred stock from the Imperial Cancer Research Fund Laboratories in London (322). Selection was initially for agouti coat color and later for polygenic obesity (both increased abdominal and subcutaneous adiposity) when this phenotype developed at F10. NZO neonates have high birth weights, and mice of both sexes are large and at weaning, have an elevated amount of carcass fat (323). The adiposity is more reflective of adipocyte hypertrophy than of hyperplasia (324). The related (but nonobese) New Zealand Chocolate (NZC) strain is some-

times used as a control strain for metabolic studies conducted using NZO/Wehi mice from the colony in Melbourne, Australia (325-327). NZO mice have not been as extensively studied as their well-studied sister strains, the autoimmune-prone New Zealand Black (NZB) and New Zealand White (NZW) strains, or the monogenic obesity mutants described above, because they are difficult to breed and, until recently, have not been available from commercial suppliers. Certain earlier studies in the literature describing the metabolic, endocrinologic, and pathophysiologic characteristics of NZO mice may not accurately describe the current generations of NZO substrains available for research [reviewed in reference (328)]. More recent generations of NZO/ Wehi mice develop juvenile-onset obesity associated with hyperphagia, IGT, insulin resistance, and leptin resistance but do not develop overt diabetes under the current animal husbandry conditions at the Walter and Eliza Hall Institute in Melbourne (329). NZO/Hl is another currently studied substrain maintained for over 30 years by Dr. Lieselotte Herberg at the Diabetes Research Institute, Düsseldorf, and now distributed by Bomholtgard/ Denmark. Approximately 40% to 50% of group-caged virgin NZO/Hl males, but not females, will transit from IGT into overt type 2 diabetes between 12 and 20 weeks of age when maintained on a chow diet containing 4.5% fat (320). This "cluster" comprised those males showing the greatest rate of body weight gain between 4 and 8 weeks of age. Genetic backcross analysis between NZO/Hl and either NON/Lt or SJL/J has confirmed that obesity-induced diabetes (diabesity) in this polygenic obesity model represents a complex threshold phenomenon whereby the rate of early adiposity development establishes a diabetogenic level of insulin and leptin resistance (330,331).

Hepatic insulin resistance and excessive glucose output have been documented as early abnormalities in NZO males (332), yet the mechanism of this hepatic resistance is quite different from the insulin resistance developing in the more intensively studied Lep^{ob} and Lepr^{db} mice. In the latter, genes encoding glycolytic (glucokinase, pyruvate kinase) and gluconeogenic [phosphoenolpyruvate carboxykinase (PEPCK), glucose 6phosphatase] enzymes that should be suppressed in chronically hyperinsulinemic mutant mice are not. In contrast, these same genes respond normally to insulin in NZO mice (325). This difference may relate to absence in NZO/Lt mice of the severe hypercorticism characteristic of Lep^{ob} and Lepr^{db} mice (our unpublished observations). Hence, alternative mechanisms must be considered. Indeed, metabolic analysis of NZO mice suggests that hepatic insulin resistance is the consequence of increased lipid availability, particularly from glycerol gluconeogenesis, due to early postpartum increases in the hepatic activity of fructose 1,6-bisphosphatase (326,327). In the NZO/HILt colony at The Jackson Laboratory, hepatic glycogen depletion and lipidosis is a consistent histopathologic feature and is particularly severe in those males crossing the threshold into overt type 2 diabetes. Although the unusually high body weights are evident by 2 weeks of age in NZO/HILt males, plasma levels of insulin and leptin are not elevated until a later maturational stage (9 to 12 weeks of age). A drawback limiting widespread study is the difficulty in identifying an appropriate control, since obesity is polygenic in etiology. Obesity in NZO mice is characterized by widespread accumulation of subcutaneous as well as visceral fat. The obesity in these mice is accompanied by glucose intolerance in males associated with increased hepatic and peripheral insulin resistance (332). In marked contrast to genetically obese *Lep^{ob}* and *Lepr^{db}* mice, in these mice the genes encoding certain gluconeogenic and glycolytic enzymes in the liver retain normal responsiveness to insulin, although evidence for an inappropriately active fructose 1,6-biphosphatase has been obtained (325).

Defects in glucose stimulated insulin secretion in the β -cells of NZO mice both in vitro and in vivo have been reported (332, 333). The defect appears to be in the early part of the glycolytic pathway between glucose transport and the triose isomerase step, since normal levels of insulin secretion are stimulated by glyceraldehyde but not by glucose (333). A defect in pancreatic polypeptide (PP) secretion has also been suggested, although numbers of PP cells immunocytochemically detectable in NZO/Hl and NZO/HlLt islets increase as the mice age [reference (334) and EHL, unpublished observation]. A previous report that transplantation of either allogeneic islets into NZO mice or treatment with avian or bovine PP reversed diabetes, hyperinsulinemia, and weight gain led to the proposal that a genetic deficiency in PP was responsible for the diabetes syndrome in NZO (335,336). However, this seems unlikely given more recent unpublished immunocytochemical evidence that PP is present in abundance in islets of NZO/Hl and NZO/HlLt mice.

With regard to the diabetogenic subphenotypes of plasma/ serum glucose and insulin, data provided are from the author's (EHL) colony of NZO/HILt mice maintained at The Jackson Laboratory on a low-fat (6%) chow diet. As noted above, obesity is juvenile-onset; mean body weight for a group of 10 weanling 4week-old males was 25.8 g. By 8 weeks, mean weight had increased to 42.7 g. At this age, plasma insulin and leptin levels are not yet markedly increased above a normal range (2 to 3 ng/mL) and the mice are normoglycemic. By 16 weeks of age, when body weights are ≥ 50 g (total carcass fat = 20 g or higher by DEXA measurement), a range of plasma insulin levels between 4 and 16 ng/mL is observed. Those mice with the highest body weights and plasma insulin values at 16 weeks generally exhibit plasma glucose values higher than 250 mg/dL and develop a more pronounced hyperglycemia by 20 to 24 weeks (plasma glucose ranges increasing to between 300 and 400 mg/dL). Untreated diabetic males maintain chronic hyperglycemia at these levels for many months without loss of weight. Hence, hyperglycemia is late-onset and chronic once it is established.

Genetics

Genetic segregation analysis has confirmed that a large number of NZO-derived codominant polygenes capable of additive or epistatic interactions underlie the development of obesity (321, 330,337). QTL for both obesity and diabetes subphenotypes (plasma glucose and insulin) are distributed over a large number of chromosomes. When NZO is out-crossed to the unrelated Swiss-derived NON/Lt strain, which is a model for IGT, the two parental genomes "synergize" to produce a frequency of type 2 diabetes of 90% to 100% in F1 males (320). Among the numerous obesity QTL contributing to obesity ("Obq" or "Nob""), only a subset are required for the development of diabesity when NON/Lt is the outcross partner strain (330,337,338). Complex epistatic interactions between genotype and factors in the postparturition environment (e.g., in milk from obese dams) have been further shown to be important contributors to the early development of obesity in NZO × NON out-cross (330). In contrast, outcross of NZO to SJL, another unrelated Swiss-derived strain without IGT, prevents the development of type 2 diabetes in F1 males (338). Both NON/Lt and SJL/J outcross partners contribute a diabetogenic locus on Chr 4 near the leptin receptor locus that interacts synergistically with obesity contributions from NZO (320,331). NZO mice express the same leptin receptor variant (LeprA720T/T1044I) as the related NZB strain, which is neither hyperphagic nor markedly obese (339). This variant appears to signal normally following activation by ligand (338). However, the NZO allele at this locus or another gene in tight linkage enhances the weight-increasing effects of the NZO allele at Nob1 (Chr 5) and the serum insulin-increasing effects of

the NZO allele at *Nob2* (Chr 19) (338). One of the authors (EHL) has used NZO/HILt as the donor strain and NON/Lt as the recipient background to produce recombinant congenic strains fixed for different combinations of NZO-derived "*Obq*"; certain of these combinations are capable of triggering diabesity spontaneously, while other combinations are diabetogenic if appropriate environmental stress (increased dietary fat) is applied.

Immunologic Anomalies
